Attempting to relate activation of coagulation, platelets or fibrinolysis with the risk for thromboembolism remains difficult for VAD patients. Although thromboembolic events are uncomfortably common, most centers do not have the numbers of patients to collect the number of observations necessary to statistically relate specific hemostatic alterations to thromboembolic events. As a result, markers of thromboembolism that do not result in an obvious clinical event (e.g., stroke) have been utilized to relate to measurable thrombotic markers in the blood (as discussed in Chapter II.2.6 – Hanson & Tucker). Microembolic signals detected in the cerebral arteries of VAD patients using ultrasound techniques have been explored as a potential indicator of stroke risk in VAD patients. Some reports have suggested that microembolic signals increase on days when patients experience a clinically obvious thromboembolic event (Schmid et al., 1998). Others have shown that thrombin generation increases on days when large numbers of microemboli are detected in the cerebral arteries (Wilhelm et al., 1999).

As with all cardiovascular devices, anticoagulation and antiplatelet therapy are options to control the reactions at the device–blood interface. A variety of specific anticoagulation and antiplatelet drug and monitoring regimens have been developed for VAD patients. Most commonly patients are managed acutely with heparin, and chronically with oral anticoagulants (i.e., warfarin) and antiplatelet agents (i.e., aspirin, clopidogrel). Anticoagulation is monitored with measurement of the activated partial thromboplastin time during heparin therapy and with the prothrombin time or international normalized ratio during oral anticoagulation. Antiplatelet therapy effectiveness can be monitored with thromboelastography. For the HeartMate, patients generally are not given chronic anticoagulation due to the unique lining of this device, and in only a fraction of the patient population are antiplatelet agents administered.

The fact that HeartMate VAD patients do not require chronic anticoagulation, yet still appear to have a markedly lower rate for thrombembolic complications, merits discussion and has important ramifications for our definition of material biocompatibility in this setting. In much of the clinical literature the lower rate

for thromboembolic complications in HeartMate VAD patients is attributed to the textured surfaces discussed above which lead to the formation of a biological pseudointima. This concept of encouraging well-anchored clot formation as a means of ultimately encouraging a biological lining goes back to the mid-1960s and earlier when Sharp, Hall, and other investigators researched this concept (Sharp et al., 1964; Hall et al., 1967).

There are few reports to date regarding the mechanisms through which the HeartMate pseudointima might act to reduce thromboembolism. Investigators have shown the mature surface to be dominated by inflammatory and fibroblastic cell lineages expressing tissue factor, inflammatory cytokines, and laying down matrices that include type I collagen (Menconi et al., 1995; Spanier et al., 1999). Such a surface would not appear to have anti-thrombotic properties. Indeed, Spanier et al. (1999) suggested that such a surface may work by creating a sustained prothrombotic and potentially proinflammatory environment that triggers ongoing coagulation through the tissue factor pathway. The body's extended fibrinolytic response to the ongoing coagulation on this surface may serve as auto-anticoagulation to prevent large potential thromboemboli from developing. Alternative explanations for the HeartMate VADs impressive clinical results should also be considered. The development of small thrombi on the surface of the pump may occur with regularity throughout the implant period, but these thrombi may have a much lower likelihood of embolizing due to stronger adhesion to the extracellular matrix present on the surface. Deposition of the pseudointima may also act to "smooth" discontinuities in pump surfaces that otherwise would serve as a nidus for thrombi formation. The macroscopic flow patterns within the pumping chamber should also be considered. This VAD has been designed to have a "wandering vortex" which may act to minimize the size of thromboemboli generated from pumping chamber surfaces (Slater et al., 1996). Unfortunately, this surface design has not been able to be successfully translated to smaller volume, continuous flow pumps, and likely the smaller blood-contacting surface areas of these pumps offsets any potential increased risk. In fact, it has been reported that the HeartMate II has a stroke rate of 8.9% (plus an additional 2% with transient ischemic attacks), with the event rate dropping to 0.05 events per patient year (Pagani et al., 2009).

Infection

Infection is considered by many physicians and investigators to be the most serious complication facing VAD patients and a major obstacle to the implementation of current VAD designs as permanent implants to treat end-stage heart failure. As implant periods for bridge to transplant patients increase, the primary cause of death becomes infection (El-Banayosy et al.,

1999a). Historically, the reported infection rates in VAD patients has varied widely between centers due to the criteria selected to classify this complication, as well as patient selection and medical management differences. Infection rates can be reported in a very general sense to include all patient infections, usually defined as clinical evidence of infection reflected by elevated leukocyte count, fever or both in the presence of a positive culture. With this general definition, infection rates generally fall near 50% for all three aforementioned types of VADs (El-Banayosy et al., 1999a; McBride et al. 1999; Sun et al., 1999). Alternatively, only device-related infections may be reported. These infections can be classified as positive cultures from percutaneous drivelines and cannulae, and from the VAD pocket or mediastinum (Figure D.8). With this definition the infection rates tend to fall in the 20–30% range. As noted above, interest in standardizing definitions and reported outcomes has resulted in the formation of the Interagency Registry for Mechanically Assisted Circulatory Support (INTERMACS). Reporting information on implantations of FDA-approved devices is mandatory in the US in order to receive reimbursement from the Centers for Medicare and Medicaid Services. INTERMACS has defined major infection as an event requiring antimicrobial treatment that occurs in the setting of pain, fever, drainage, and/or leukocytosis, preferably with positive culture results. Infection is subdivided into localized non-device infection (no systemic involvement), percutaneous site and/or pocket infection (positive culture from the skin and/or tissue surrounding the drive line or from the tissue surrounding the external housing of a pump implanted within the body), internal pump infection (involving the blood-contacting surfaces of the VAD documented by positive culture), and sepsis (positive blood cultures and/or hypotension). INTERMACS recently reported 479 episodes of infection in 193 out of 483 patients (Holman et al., 2009).

FIGURE D.8 *Candida albicans* vegetations partially obstructing the inflow valve of a Novacor VAD patient at the time of valve replacement. (Kindly provided by R. L. Kormos, M.D, Director, and S. Winowich of the University of Pittsburgh Medical Center Mechanical Circulatory Support Program.).

Infection is responsible for the death of 4.3% bridge to transplant VAD patients in recent INTERMACS data (Holman et al., 2009). The seriousness of an infection is largely related to its location. Infections of the blood-contacting interior surfaces of the VAD, confirmed at device explant, are associated with high rates of mortality (~50%). Infection may also contribute to embolic damage and death by the generation of septic emboli or through enhancement of the thromboembolic process. Patient infections not directly related to the device are not as serious, with the exception of positive blood cultures, which may indicate interior VAD surface vegetations. As discussed in Chapter II.2.8, there are distinct bacterial and fungal species which tend to infect biomaterial surfaces and often these infections include multiple organisms. In Figure D.9 the composition of infections in a multi-center study are presented in terms of the infected site. Common skin bacteria that are traditionally associated with biomaterial infections dominate the VAD-infecting strains.

Management of infection in patients can be accomplished to a reasonable degree with antibiotics and antifungal agents. It is fortunate that the patient population remains dominated by individuals awaiting device removal at the time of transplantation. Surprisingly, a history of infection during VAD support is not a counter-indication for heart transplantation and studies have shown that, despite the use of anti-rejection drugs in the post-transplant period, these patients do well (Argenziano et al., 1997). For those patients with suspected infection of the interior VAD surfaces, it has been suggested that device replacement may be an effective method of treatment if transplant is not a short-term option (Argenziano et al., 1997).

Prevention of infection is a primary goal during device implantation and later patient medical management. Prophylactic antibiotics and, in some instances, antifungal agents are utilized in the perioperative period. Careful cleaning and attention to the percutaneous driveline and cannulae sites are also of primary importance. From a biomaterials perspective two important design issues arise. First, it is critical for the exterior surfaces of the drivelines and cannulae to rapidly encourage tissue healing and to discourage bacterial colonization. Second, the mechanical properties of the percutaneous lines are of relevance, in that large mismatches in stiffness between the skin and lines places stress at the biomaterial–tissue interface. The resulting abrasion may prevent or retard adequate wound healing. While the elimination of percutaneous lines altogether through the introduction of transcutaneous power transmission and control systems has been extensively studied (Weiss et al., 1999), this technology has not been perfected to the point where it would be attractive for widespread adoption.

Bleeding

Bleeding remains a potentially lethal complication associated with VAD implantation, but one that generally occurs in the early postoperative period, when numerous wound sites exist. Reported bleeding rates range from 30–35% (El-Banayosy et al., 1999b; McBride et al., 1999) to about 40% of patients (537 events in 201 out of 483 patients, with the majority occurring in the first 30 days) in the recent INTERMACS report (Holman et al., 2009). Bleeding can be defined in terms of the administration of blood products, chest tube drainage after surgery or surgical interventions to treat hemorrhage. Subsequent trips to the operating room to address bleeding place patients at risk for bacterial and fungal colonization, linking this complication to infection risk. Also of concern in this patient population is the exposure and sensitization of transplant candidates to human antigens associated with blood products which can limit organ matching (Massad et al., 1997). The use of leukocyte-filtered products has been utilized to address this latter concern.

A number of mechanisms contribute to hemorrhage in VAD patients. As mentioned previously, VAD
FIGURE D.9 Incidence of infectious organisms grouped by site. Cultures were performed of driveline exit site infection, pump pocket infection, and blood (septicemia) in a group of 118 Novacor VAD patients. The number of patients with infection for each site are presented above each pie chart as is the percentage of total patients experiencing infection at this site. (Reprinted from A. El-Banayosy, M. Deng, D. Y. Loisance, H. Vetter, E. Gronda, M. Loebe, and M. Vigano, *Eur J Cardiothorac Surg* **15**:835–841, 1999.).

implantation surgery is associated with consumption and activation of patients' platelets and coagulation system, as well as activation of the fibrinolytic pathway (Livingston et al., 1996). End-stage heart failure patients undergoing VAD implantation have deficiencies in coagulation factors, even in the absence of obvious liver dysfunction (Wang et al., 1995). After post-operative stabilization, patients are placed on chronic anticoagulation therapy which carries an ongoing risk for over-anticoagulation (and possible bleeding). Of particular concern in the extended support setting are cerebral bleeds leading to neurologic complications. Anticoagulation in these VAD patients is thus carefully monitored throughout the implant period.

Mechanical Failure

In the extensive clinical experience with VADs over the past several decades there have been very few reported incidents of mechanical failure related to material issues. This is likely due to the long development phases through which all three aforementioned FDA-approved devices have passed. The pulsatile VAD systems subject internal diaphragms, cams, bearings, and springs to cyclic loads that would likely lead to more wear-associated failure were these devices asked to perform beyond their design specifications. In bridge to transplant implantations bearing wear has been reported, but has not lead to catastrophic failure (Sun et al., 1999). Other complications reported involve tearing of Dacron inflow conduits in the HeartMate device (Scheld et al., 1997) (Figure D.10). This complication was likely due to wear from the metal support cage rubbing on the graft surface, and the design has since been altered to constrain cage motion. Other complications can involve the external drive units, electric power supply, batteries, controller or cables. Second and third generation pumps are expected to have significantly improved pump longevity, which is needed for patients being permanently supported. INTERMACS has recently reported a total of 81 device malfunctions in 62 out of 483 patients (Holman et al., 2009).

A variety of diagnostic techniques have been suggested to non-invasively assess the wear process in implanted VAD electrical and mechanical components short of pumping failure that would result in clinical symptoms. Acoustic and power consumption monitoring have been reported as innovative methods for evaluating wear (Dohmen et al., 1999). Durability and reliability testing *in vitro* will continue to be essential for discovering the typical time course of electromechanical failure modes, and to provide the opportunity to develop such diagnostic methods. This failure can be readily detected and may thus prevent unnecessary replacement of devices at fixed implant periods, while allowing detection of failure and remediation in those devices that may develop early signs of this wear (Lee
FIGURE D.10 Ruptured Dacron inflow conduit of a HeartMate VAD that lead to sudden blood loss after 22 days of pump implantation. (Reprinted from H. H. Scheld, R. Soeparwata, C. Schmid, M. Loick, M. Weyand, and D. Hammel, *J Thorac Cardiovasc Surg* **114**: 287–289, 1997.).

et al., 1999). With knowledge of the failure mode engineers are provided a focal point to work on redesign of the device, leading to further improvements in long-term durability and reliability.

CONCLUSIONS

Major advances have occurred in mechanical circulatory support technology over the past several decades. Bridging patients to cardiac transplantation has now become routine, with seven devices currently approved by the FDA to fill this role in the United States. This success has set the stage for the application of VADs as alternatives to cardiac transplantation in the transplant-ineligible population, and one device is already approved by the FDA for this indication. As one would expect with an extensive blood-contacting biomaterial implantation accompanied by percutaneous drivelines, thromboembolism, infection, and bleeding remain complications of primary concern in VAD patients. Rotary blood pumps and perhaps completely implantable VADs may serve to reduce these complications, and improve device durability and reliability. In the next decade the challenges associated with supporting patients for years, as opposed to months, will be faced. Biomaterial and biocompatibility issues will

likely be central to the problems and solutions that arise as mechanical circulatory support devices continue to evolve.

CHAPTER II.5.4 ARTIFICIAL CELLS

Thomas Ming Swi Chang
Director, Artificial Cells and Organs Research Centre, Departments of Physiology, Medicine and Biomedical Engineering, Faculty of Medicine, McGill University, Montreal, QC, Canada

BASIC FEATURES OF ARTIFICIAL CELLS

The initial research on artificial cells (Chang, 1964) forms the basic principle that has been extended for use in many areas by many groups (Chang, 2005a, 2007, 2010; Liu and Chang, 2010). Very brief examples of some of these basic features include (Figure II.5.4.1):

1. Artificial cells can contain the same biological material as biological cells. In addition, they are more versatile since adsorbents, magnetic materials, drugs, cells, stem cells, enzymes, multienzyme systems, hemoglobin, microorganisms, vaccines, gene-for-gene therapy, genetically engineered cells, hormones, peptides, and many other materials can also be included separately or in combination (Figure II.5.4.1).

2. The membrane of an artificial cell separates its content from the outside, but at the same time the membrane can be prepared to selectively allow different types of molecules to cross (Figure II.5.4.1). For example, one can prepare artificial cell membranes that selectively allow the movement of molecules according to molecular size, lipid solubility, affinity to carrier mechanisms, etc. By selecting the proper membrane material, the permeability can range from a membrane that does not allow any molecules to cross, to those that allow even very large molecules such as proteins to cross. The membrane material includes polymer, biodegradable polymer, lipid, cross-linked protein, lipid–polymer complex, lipid–protein complex, and membrane with transport carriers.

3. Surface properties of artificial cell membrane can be varied by: (1) incorporation of negative or positive charge; (2) incorporation of albumin to increase blood compatibility; (3) incorporation of antigens to bind antibodies or antibodies to bind antigen; (4) incorporation of polysaccharide such as heparin or polyethylene glycol (PEG) to increase compatibility or retention time in circulation.

4. In addition to being of cellular dimensions in the micron range, they can also be in the macro range, in the nano range or in the nanobiotechnological range (Figure II.5.4.1).

5. The artificial cell membranes can be ultrathin and yet strong. There is a large surface area to volume relationship. For example, 10 ml of 20 μm diameter artificial cells has a total surface area of 2500 cm^2, which is the same as that in an artificial kidney machine. Since the artificial cell membrane is also 100 times thinner, permeant molecules can potentially move across 10 ml of 20 μm diameter artificial cells 100 times faster than across the artificial kidney machine (Chang, 1966). In addition, the microscopic size of artificial cells allows material to diffuse rapidly inside the artificial cells.

RESEARCH INTO THE APPLICATIONS OF ARTIFICIAL CELLS

This includes hemoperfusion, immunosorbents, drug delivery, blood substitutes, enzyme therapy, cell and stem cell therapy, biotechnology and nanobiotechnology, nanomedicine, regenerative medicine, agriculture, industry, aquatic culture, nanocomputers, nanorobotics, nanosensors, and other areas (Table II.5.4.1). The following is a brief overview of some examples of artificial cells.

ARTIFICIAL CELLS IN HEMOPERFUSION

This is the first large-scale US Food and Drug Administration (FDA) approved routine clinical application in patients based on artificial cells. As mentioned above, the microscopic dimensions of artificial cells result in a large surface-to-volume relationship. This, together with the ultrathin membranes, allows artificial cells containing bioadsorbents to be much more effective when compared to standard hemodialysis in removing toxins and drugs from the blood of patients (Chang, 1966, 1969, 1972a, 1975, 2007; Chang et al., 1973). In this method, thousands of 90 micron diameter artificial cells containing adsorbents are retained by screens at either end, inside a column the size of a tea cup (Figure II.5.4.2). Blood from the patients containing toxins or drug can perfuse through the screens to come into contact with the

artificial cells. Toxins or drugs diffusing into the artificial cells are removed by the adsorbents inside artificial cells. This cleanses the blood that returns to the patient.

Routine Clinical Uses in Patients with Suicidal Drug Overdose

The most common routine use of this approach is the use of microscopic polymeric artificial cells encapsulating activated charcoal (Chang, 1969, 1975, 2007; Chang et al., 1973) (Figure II.5.4.2). This solves the major

problems of release of embolizing particles and damage to blood cells when bioadsorbents are used without artificial cell membranes. This was first successfully used in suicidal overdose patients (Chang et al., 1973) (Figure II.5.4.3). Since then, this has been become a routine treatment worldwide for acute poisoning in adults and children, especially in suicidal overdose (Chang, 1975; Chang et al., 1973; Winchester, 1996; Kawasaki et al., 2000; Lopez Lago et al., 2002; Lin et al., 2002, 2004; Singh et al., 2004; Peng et al., 2004). This is particularly useful in places where dialysis machines are not

easily available, and the hemoperfusion devices are less costly, especially outside North America. Hemoperfusion has saved the lives of thousands of suicidal drug overdose patients in some countries outside North America.

Immunosorbents

The success in the clinical uses of artificial cells containing bioadsorbents for detoxification has led to increasing interest in research and development in many other
FIGURE II.5.4.3 Clinical and laboratory results of hemoperfusion in a patient with severe suicidal methyprylon overdose. (Figure from Chang (2007), with copyright permission from World Scientific Publisher.)

areas. One of these is in artificial cells containing immunoadsorbents (Chang, 1980).

Albumin can bind tightly to the ultrathin collodion membrane of adsorbent artificial cells (Chang, 1969). This was initially used to increase the blood compatibility of the adsorbent artificial cells for hemoperfusion (Chang, 1969). We also applied this albumin coating to synthetic immunosorbents resulting in blood compatible synthetic blood group immunoadsorbents (Chang, 1980). This albumin-coated synthetic adsorbent has been applied clinically for removing blood group antibodies from plasma for bone marrow transplantation (Bensinger et al., 1981). In addition, albumin-coated collodion activated charcoal (ACAC) was found to effectively remove antibodies to albumin in animal studies (Terman et al., 1977). This has become the basis of one line of research in which other types of antigens or antibodies are applied to the collodion coating of the activated charcoal to form immunoadsorbents. Other immunoadsorbents based on this principle have also been developed for the treatment of human systemic lupus erythematosus, removal of antiHLA antibodies in transplant candidates, treatment of familial hypercholesterolemia with monoclonal antibodies to low-density lipoproteins, and other conditions (Terman et al., 1979; Hakim et al., 1990; Wingard et al., 1991; Yang et al., 2004).

NANOBIOTECHNOLOGY FOR PARTIAL ARTIFICIAL RED BLOOD CELLS

There is much recent interest in nanobiotechnology and nanomedicine. This is a large and complex area that embraces many diverse approaches. One of these is to make the original artificial cells smaller, using the same basic principle and methods. This includes biodegradable nanoparticles, nanosphere, and nanocapsules. Examples include nano-artificial red blood cells with lipid membrane or biodegradable polymeric membranes. A later section will summarize other examples used in drug delivery systems. Much smaller nanobiotechnological

complexes can be prepared by the assembling of biological molecules. Examples include the assembling of hemoglobin molecules into soluble polyhemoglobin, and the assembling of hemoglobin molecules and enzymes into soluble polyhemoglobin–enzyme complexes.

Nanobiotechnology and Artificial Cells

Nanobiotechnology is the assembling of biological molecules into nanodimension complexes of different configurations. These include nanostructures with nano-range diameters, membranes with nanodimension thickness or nanotubules with nanodimension diameters.

The first nanobiotechnology approach reported is the cross-linking of hemoglobin into an ultrathin polyhemoglobin (PolyHb) membrane with nanodimension thickness (Chang, 1964, 1965) (Figure II.5.4.4). This is used to form the membrane of artificial red blood cells (Chang, 1964, 1965, 1972a). If the emulsion is made very small, then the whole submicron artificial cells can be cross-linked into PolyHb of nanodimension. Glutaraldehyde can cross-link hemoglobin into soluble PolyHb of nanodimension, each consisting of an assembly of 4–5 hemoglobin molecules (Chang 1972b; Keipert and Chang, 1985, 1987) (Figure II.5.4.4).

Two groups have independently developed this 1971 (Chang, 1971b) basic method of glutaraldehyde cross-linking for clinical use. One is glutaraldehyde human PolyHb (PolyHb) (Gould et al., 1998, 2002). Their phase III clinical trial shows that this can replace blood lost in trauma surgery by keeping the blood hemoglobin at an acceptable level. More recently they have carried out clinical trials in prehospital ambulance patients (Moore et al., 2009). The second PolyHb is glutaraldehyde-crosslinked bovine PolyHb which has been tested in phase III clinical trials (Pearce and Gawryl, 1998; Sprung et al., 2002; Pearce et al., 2006; Jahr et al., 2008). South Africa has approved this for routine clinical use in patients. Unlike red blood cells, there is no blood group in PolyHb, and thus PolyHb can be given on the spot, without waiting for typing and cross-matching in the hospital. PolyHb is also free from infective agents such as HIV, hepatitis C, bacteria, parasites, and so on. Furthermore, whereas donor blood has to be stored at 4°C and is only good for 42 days, PolyHb can be stored at room temperature for more than one year. Thus, PolyHb can have important uses in a number of clinical conditions, notably for surgery when there is no potential for ischemia-reperfusion, as will be discussed below (Chang, 2006a, 2009).

Nanobiotechnology and the Assembling of Hemoglobin with Antioxidant Enzyme

As PolyHb can be kept at room temperature and used immediately, it can have potential for treating severe bleeding (hemorrhagic shock). However, this has to be done as soon as possible, since if there is much delay PolyHb alone might result in the production of oxygen radicals that cause tissue injury (ischemia-reperfusion injuries). Antioxidant enzymes normally present in red blood cells are insufficient to prevent this problem. We use glutaraldehyde cross-linking to assemble a soluble nanobiotechnology complex by cross-linking hemoglobin, superoxide dismutase, and catalase into PolyHb-SOD-CAT (D'Agnillo and Chang, 1998; Chang 2006b, 2007, 2008) (Figure II.5.4.4). This way, one can increase the antioxidant enzymes to much higher levels than those in red blood cells.

Obstruction of arteries due to clots or other causes can result in stroke (cerebral ischemia) or heart attack (myocardial infarction). As it is a solution, PolyHb can more easily perfuse partially obstructed vessels. However, if there is prolonged lack of oxygen, reperfusion with PolyHb alone may result in damaging oxygen radicals resulting in ischemia-reperfusion injuries. Thus, in patients with coronary heart disease and myocardial ischemia, infusion with polyhemoglobin can result in ischemia-reperfusion injury that can be severe enough to result in heart attack (myocardial infarction). In severe trauma, one is often faced with hemorrhagic shock from severe bleeding, in addition to cerebral ischemia due to head injuries. In a hemorrhagic shock and stroke rat model, after 60 minutes of ischemia, reperfusion with PolyHb resulted in significant increase in the breakdown of the blood–brain barrier, and an increase in brain water (brain edema) (Powanda and Chang, 2002). On the other hand, PolyHb-SOD-CAT did not result in these adverse changes (Powanda and Chang, 2002). In sustained hemorrhagic shock due to severe loss of blood, ischemia-reperfusion can result in irreversible shock due to leakage of bacteria and endotoxins from the intestine into the circulating blood. Our study shows that in an ischemia-reperfusion rat inestinal model, polyhemoglobin resulted in significant increases in oxygen radicals. On the other hand, the use of PolyHb-SOD-CAT did not result in any significant increases in oxygen radicals (Razack et al., 1997; Chang, 2007).

Nanobiotechnology for the Assembling of Hemoglobin with Other Enzymes

The microcirculation structure in tumors is abnormal, and as a result there is a decrease in perfusion by oxygen carrying red blood cells. This results in a lower oxygen tension in the tissue of many types of tumors (Pearce and Gawryl, 1998). It is known that radiation therapy and some chemotherapy can work better when the tissue oxygen tension is higher. PolyHb can more easily perfuse the abnormal microcirculation of tumors to supply oxygen needed for chemotherapy or radiation therapy. With a circulation half-time of 24 hours, the effect is not long-term and can be adjusted to the duration of chemotherapy or radiation therapy. When used together with chemotherapy, PolyHb decreases tumor growth and increases the lifespan in a rat model of gliosarcoma brain tumor

(Pearce and Gawryl, 1998). We have recently cross-linked tyrosinase with hemoglobin to form a soluble PolyHb-tyrosinase complex (Yu and Chang, 2004) (Figure II.5.4.4). This has the dual function of supplying the needed oxygen, and at the same time lowering the systemic levels of tyrosine needed for the growth of melanoma. Intravenous injections delayed the growth of the melanoma without causing adverse effects in the treated animals (Yu and Chang, 2004).

Polyhemoglobin-Fibrinogen

Blood is a multifunctional fluid. As a blood substitute, PolyHb is limited by its lack of platelets and/or coagulation properties. In situations of high blood volume loss, large volumes of PolyHb have to be infused to replace the lost blood. Replacing the loss of red blood cells without replacing the lost platelets and coagulation factors can result in the inability of the blood at the injured sites to clot, resulting in continued severe bleeding. As a result, platelets and coagulation factors have to be infused in these situations. Unfortunately, donor platelets are very hard to obtain. There has been development in platelet substitutes to combat thrombocytopenia, but with limited success. We therefore prepared a novel blood substitute that is an oxygen carrier with platelet-like activity. This is formed by cross-linking fibrinogen to hemoglobin to form polyhemoglobin-fibrinogen (PolyHb-Fg) (Wong and Chang, 2007). This was studied and compared to PolyHb for its effect on coagulation, both *in vitro* and *in vivo*. In the *in vitro* experiments PolyHb-Fg showed similar clotting times as whole blood, whereas PolyHb showed significantly higher clotting times. This result was confirmed in *in vivo* experiments using an exchange transfusion rat model. Using PolyHb, exchange transfusion of 80% or more increased the normal clotting time (1–2 mins) to >10 minutes. Partial clots formed with PolyHb did not adhere to the tubing wall. With PolyHb-Fg, a normal clotting time (1–2 mins) is maintained even with 98% exchange transfusion.

NANOBIOTECHNOLOGY FOR COMPLETE ARTIFICIAL RED BLOOD CELLS

Original Micron Dimension Complete Artificial Red Blood Cells

The first artificial red blood cells (RBCs) prepared in 1957 (Chang, 1957) have an oxygen dissociation curve similar to red blood cells. We continued to study a number of artificial cell membranes including cellulose, silicone rubber, 1,6-hexamethylenediamine, cross-linked protein, phospholipid–cholesterol complexes on cross-linked protein membrane or polymer (Chang, 1964, 1965, 1972a). However, these artificial RBCs, even with a diameter down to one micron, survived for a short time in the circulation after intravenous injection. Our study showed that the long circulation time of RBCs is due to the presence of neuraminic acid on the membrane (Chang, 1965, 1972a). This led us to study the effects of changing surface properties of the artificial RBCs (Chang, 1964, 1965, 1972a). This has resulted in significant increases in circulation time, but is still insufficient for clinical use.

Submicron Hemoglobin Lipid Vesicles as Artificial Red Blood Cells

We prepared larger artificial cells with lipid membrane by supporting the lipid in the form of lipid–protein membrane and lipid–polymer membrane (Chang, 1972a). Others later reported the preparation of submicron (0.2 micron) diameter artificial RBCs using lipid membrane vesicles to encapsulate Hb (Djordjevich and Miller, 1980). This increased the circulation time significantly, although it was still rather short. Many investigators have since carried out research to improve the preparation and circulation time. The most successful approach to improve the circulation time is to incorporate polyethylene glycol (PEG) into the lipid membrane of artificial RBCs, resulting in a circulation half-time of more than 30 hours (Philips et al., 1999). Another group in Japan has for many years carried out extensive research and development, commercial development, and preclinical animal studies. Their extensive studies are available in many publications and reviews (Kobayashi et al., 1997; Sakai et al., 2004; Tsuchida, 1998).

Biodegradable Polymeric Nanodimension Completely Artificial Red Blood Cells

We have used a biodegradable polymer, polylactic acid (PLA), for the microencapsulation of Hb, enzymes, and other biologically active material since 1976 (Chang, 1976). More recently, we started to prepare artificial RBCs of 100 nanometer mean diameter using PLA, PEG–PLA membrane, and other biodegradable polymers (Yu and Chang, 1994, 1996; Chang, 1997a, 2006c, 2007; Chang et al., 2003). A typical electron micrograph for the biodegradable polymer Hb nanocapsules prepared with d,l-PLA shows that they are spherical and homogeneous. Their diameter ranges from 40–120 nm, with a mean diameter of 80 nm. The membrane thickness is 5–15 nm. We have replaced most of the 6 g/dl of lipid membrane in Hb lipid vesicles with 1.6 g/dl of biodegradable polymeric membrane material (Figures II.5.4.5 and II.5.4.6). This marked decrease in the lipid component would lessen the effects on the reticuloendothelial system (RES), and lessen lipid peroxidation in ischemia-reperfusion.

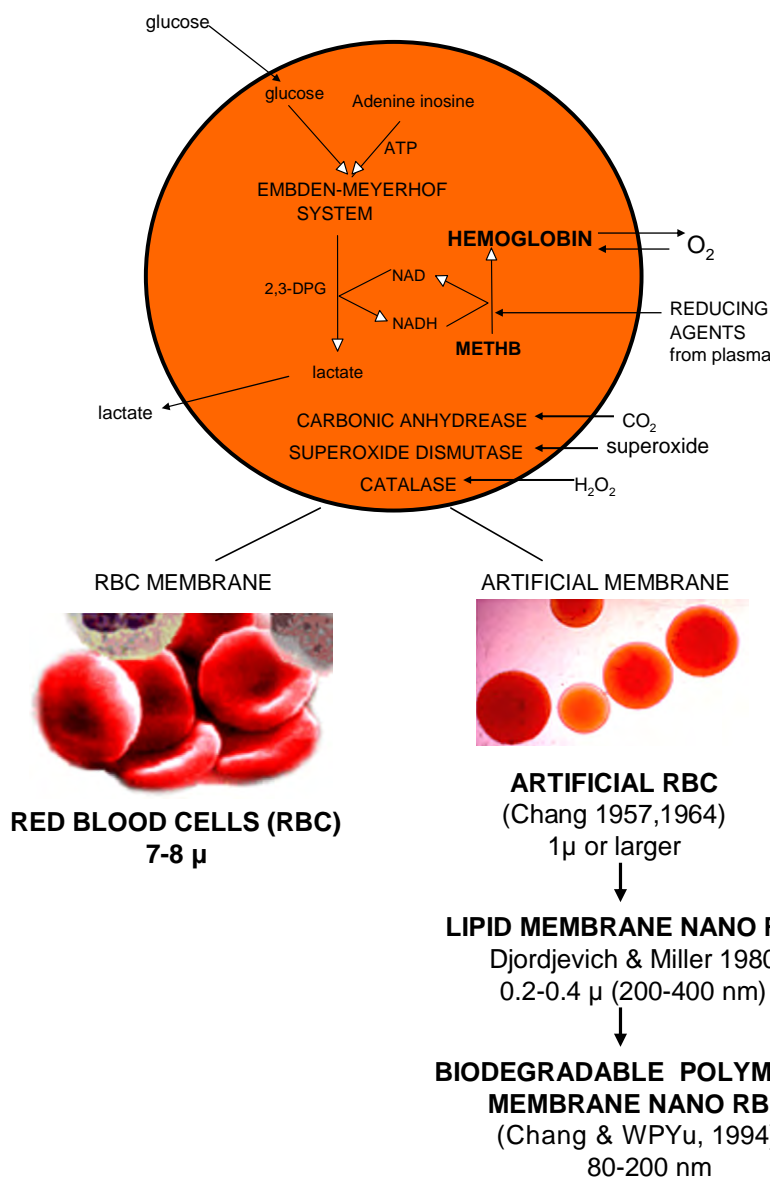
We can increase the Hb content in the PLA nano-artificial cell suspension from 3 g/dl to 15 g/dl (the same as whole blood). This has normal P_{50}, Hill's coefficient, and Bohr coefficient. Nanocapsules can be prepared


FIGURE II.5.4.5 Upper: Composition of red blood cell and artificial red blood cells. Lower Left: Red blood cells. Lower Right: First artificial RBC of 1 micron or larger diameter, first lipid membrane nanodimension artificial RBC, first nanodimension biodegradable polymeric membrane artificial RBC. (Figure from Chang (2007), with copyright permissions from World Scientific Publisher.)

with up to 15 g/dl Hb concentration. The preparation of PLA nano-artificial RBCs does not have adverse effects on the Hb molecules. This is shown by the following experimental results. There is no significant difference in the oxygen affinity (P_{50}) of Hb nano-artificial RBC and the original Hb used for the preparation, the Hill coefficient is 2.4 to 2.9 and the Bohr effect is –0.22 to –0.24 (Yu and Chang, 1994, 1996; Chang, 1997a, 2006c, 2007; Chang et al., 2003).

We have earlier carried out basic research on artificial cells containing multienzyme systems with cofactor recycling (Chang, 1987). A number of enzymes such as carbonic anhydrase, catalase, superoxide dismutase and the MetHb reductase system, normally present in RBC have been encapsulated within nano-artificial RBC and

retain their activities (Figure II.5.4.5) (Chang et al., 2003; Chang, 2007). Unlike lipid membrane, biodegradable polymeric membrane is permeable to glucose. Thus, the inclusion of an RBC MetHb reductase enzyme system prevents MetHb formation even at 37°C, and we can also convert MetHb to Hb at 37°C. In addition, unlike lipid membrane, the nanocapsule membrane allows plasma factors such as ascorbic acid to enter the nanocapsules to prevent MetHb formation (Figure II.5.4.5).

In order to increase the circulation time, we synthesized a new PEG–PLA copolymer for the artificial RBC membrane (Chang et al., 2003). After a 30% blood volume toploading using PolyHb (10 g/dl), the best PolyHb can only attain a maximal Hb concentration of 3.35 g/dl. The best PEG–PLA nano-artificial RBC,
FIGURE II.5.4.6 Top: Amount of membrane material in hemoglobin lipid vesicles compared to polylactide membrane nano RBC. Bottom: Fate of polylactide membrane in PLA nano RBC compared to PLA metabolism in the body. (Figure from Chang (2007), with copyright permission from World Scientific Publisher.)

on the other hand, can reach a maximal Hb concentration of 3.60 g/dl. After extensive research, we now have a circulation time in rats that is double that of glutaraldehye cross-linked PolyHb. Since the RES in rat is much more efficient in removing particulate matter compared to humans, it is likely that the half-time would be longer in humans. Recent long-term studies in rats show no adverse effects in the kidney and the reticuloendothelial systems (liver and spleen) (Liu and Chang, 2008).

CELLS, ISLETS, STEM CELLS, GENETICALLY ENGINEERED CELLS, AND MICROORGANISMS

Introduction

The first artificial cells containing intact biological cells were reported in 1964 based on a drop method (Chang, 1964), and it was proposed that: "protected from immunological process, encapsulated endocrine cells might survive and maintain an effective supply of hormone" (Chang et al., 1966) (Figure II.5.4.1).

Artificial Cells Containing Islets, Hepatocytes, and Other Cells

With Chang's encouragement and initial consultation, Sun from Conaught Laboratory and his collaborator developed Chang's original drop method (Chang, 1964,

1965, 1972a; Chang et al., 1966) by changing to alginate-polylysine-alginate (APA) as the artificial cell membrane (Lim and Sun, 1980). They showed that after implantation, the insulin secreting islets inside artificial cells indeed remained viable and continued to secrete insulin to control the glucose levels of diabetic rats (Lim and Sun, 1980; Sun et al., 1996). Extensive research has been carried out by many laboratories around the world since that time and is available in reviews (Calafiore, 1999; De Vos et al., 2002; Orive et al., 2003, 2004; Hunkeler, 2003; Chang, 2005a,b, 2007). The major hurdle is the need for long-term function after implantation.

We have been studying the use of artificial cells containing liver cells (hepatocytes) for liver support. Implanting these increases the survival of acute liver failure rats (Wong and Chang, 1986); lowers the high bilirubin level in congenital Gunn rats (Bruni and Chang, 1989); and prevents xenograft rejection (Wong and Chang, 1988). We developed a two-step cell encapsulation method to improve the APA method, resulting in improved survival of implanted cells (Wong and Chang, 1991). Artificial cells containing hepatocytes effectively lower the systemic bilirubin in hyperbilirubinemia Gunn rats (Bruni and Chang, 1989, 1995). We used the two-step method plus the co-encapsulation of stem cells and hepatocytes into artificial cells (Liu and Chang, 2000). This results in further increases in the viability of encapsulated hepatocytes, both in culture and after implantation (Liu and Chang, 2002). One implantation of artificial cells containing both hepatocytes and stem cells into Gunn rats

lowers the systemic bilirubin levels and maintains this low level for two months (Liu and Chang, 2003). Without stem cells, implanted hepatocytes in artificial cells can only maintain a low level for one month.

Genetically Engineered Cells and Microorganisms

Many groups have carried out extensive research on artificial cells containing genetically engineered cells. This is a very important area which includes potential applications in amyotrophic lateral sclerosis, Dwarfism, pain treatment, IgG$_1$ plasmacytosis, Hemophilia B, Parkinsonism and axotomized septal cholinergic neurons, tumor suppression, and other areas (Winn et al., 1994; Saitoh et al., 1995; Aebischer et al., 1996; Al-Hendy et al., 1996; Basic et al., 1996; Tan et al., 1996; Hagihara et al., 1997; Dalle et al., 1999; Bachoud-Lévi et al., 2000; Lorh et al., 2001; Xu et al., 2002; Cirone et al., 2002; Bloch et al., 2004). To avoid the need for implantation, we studied the oral use of artificial cells containing microorganisms for the removal of cholesterol (Garofalo and Chang, 1991) or conversion of phenol to tyrosine (Lloyd-George and Chang, 1995). We have also studied the use of genetically engineered nonpathogenic *E. coli* DH5 cells to lower systemic urea in renal failure rats (Prakash and Chang, 1993, 1996; Chang, 1997b, 2005a,b). Genetically engineered *E. coli* allows for proof of principle. For safe use, we have studied the use of a modified *Lactobacillus*, similar to those used in yoghurt, for enclosure in artificial cells to remove urea (Chow et al., 2003).

General

Cell bioencapsulation for cell therapy has been extensively developed by many groups, especially using artificial cells containing endocrine tissues, hepatocytes, genetically engineered cells, and stem cells (Chang, 1972a; Orive et al., 2003; Chang, 2005a,b, 2007). The major hurdle is the need to develop systems that can function on a long-term basis after implantation.

ARTIFICIAL CELLS CONTAINING STEM CELLS IN REGENERATIVE MEDICINE

The above examples of artificial cells containing islets, cells, genetically engineered cells, and other cells require long-term treatment. Developments are needed before artificial cells are ready for long-term implantation use. To allow for more immediate use, one area of research in this laboratory is to look at the use of artificial cells in regenerative medicine. For this we have been studying the use of artificial cells containing bone marrow stem cells for liver regeneration. Marked decrease in liver function due to fulminant hepatic failure or extensive liver resection for metastatic cancer or severe injury can result in the death of the patient. Since liver can

regenerate if given the required time and conditions, we therefore studied whether artificial cells containing bone marrow stem cells can maintain the experimental animal alive long enough to allow the liver to regenerate and the animal to recover (Figure II.5.4.7).

Artificial Cells Containing Bone Marrow Stem Cells in 90% Hepatectomized Rats

In the present study we injected intraperitoneally artificial cells containing bone marrow stem cells into 90% hepatectomized rats (Liu and Chang, 2005, 2006) (Figure II.5.4.7). In the hepatectomized groups that received no treatment, only 20% of the animals survived by the second day. In the hepatectomized animals receiving free bone marrow stem cells, only 20% of the animals survived on the seventh day. There was no significant difference in survival rate between the normal control group (with no hepatectomy) and the group receiving artificial cells containing bone marrow stem cells. The survival for both groups was 100% when followed for 14 days. Thus it would appear that in rats, artificial cells containing bone marrow stem cells are effective in improving the survival rates of 90% hepatectomized rats. For those rats that survived at week 2 post hepatectomy, the remnant livers were removed and the weights were measured. In the 90% hepatectomized rats that received artificial cells containing bone marrow stem cells, the liver wet weights had recovered to the same size as that of the normal control group (Liu and Chang, 2006). On the other hand, those few animals in the other groups that survived had very low liver weights.
FIGURE II.5.4.7 Survival rates of rats with 90% of liver surgically removed, hepatectomy, compared to those without removal of liver tissues, no hepatectomy. One peritoneal injection of artificial cells containing bone marrow stem cells resulted in the survival of the 90% hepatectomized rats. On the other hand, free bone marrow stem cells did not significantly increase the survival rates (Liu and Chang, 2006). (Figure from Chang (2007), with permission from World Scienctific Publisher.)

Plasma Hepatic Growth Factor (HGF) Levels

In the hepatectomized groups that received artificial cells containing bone marrow stem cells, the blood levels of HGF peaked at day 2 and 3 post-surgery, and were significantly higher than the other groups (Liu and Chang, 2006). After this, the levels decreased and returned to pre-surgery levels on day 14. In the hepatectomized groups that received: (1) no treatment; or (2) free bone marrow stem cells, the blood HGF levels were much lower.

Laparotomy, Histology, and Immunocytochemistry

Two weeks after implantation, laparotomy shows that in the group that received artificial cells containing bone marrow stem cells, the artificial cells remained in the peritoneal cavity. They were found freely disseminated throughout the peritoneal cavity, aggregated behind the liver or under the spleen, or attached to the large omentum. Histological examination of bone marrow stem cells in the artificial cells showed that before transplantation most cells were polygonal, star-like, some with tail shaped cytoplasm. When they were retrieved two weeks after transplantation, most cell morphology transformed to round or oval (Liu and Chang, 2006).

Before implantation, the bone marrow stem cells recovered from artificial cells did not show positive immunochemistry stain. However, when bone marrow stem cells were recovered from artificial cells at week 2 after implantation, there were scattered cells positively stained with hepatocyte markers CK8 and CK18, and also albumin production. There were also cells that stained positively with AFP (Liu and Chang, 2006). In the bone marrow stem cells recovered from artificial cells retrieved 2 weeks post-transplantation, there were cells stained positive for PAS, indicating that there were also cells capable of glycogen production.

Possible Mechanisms Responsible for the Recovery of 90% Hepatectomized Rat Model

What are the mechanisms responsible for the survival and recovery of the 90% hepatectomized rat model in our present study? Most likely this is due to two combined mechanisms (Chang, 2007).

1. Transdifferentiation of bone marrow stem cells in the artificial cells into hepatocytes. This is supported by our immunochemistry stain studies which show that some of the bone marrow stem cells recovered from artificial cells transdifferentiated into hepatocyte-like cells that expressed ALB, CK8, CK18, and AFP, which are typical markers of hepatocytes. They also produced albumin and glycogen. However, this is a slow process that takes time, and is most likely only responsible for the later phases of the recovery of the animals.

2. Hepatic growth factor (HGF) is an important factor in liver regeneration (Rokstad et al., 2002) and also in stimulating the transdifferentiation of bone marrow cells into hepatocytes (Spangrude et al., 1988). There are two subgroups of HGF, one >100,000 Da the other <10,000 Da (Michalopoulos et al., 1984). Alginate-polylysine-alginate membrane artificial cells allow the passage of molecules of 64,000 Da or less, and retain those >64,000 Da (Ito and Chang, 1992). HGF of >100,000 mw secreted by hepatocytes are retained and accumulated in the artificial cells, thus helping to increase the regeneration of hepatocytes in the artificial cells (Kashani and Chang, 1988, 1991) and also the transdifferentiation of BMCs. The smaller molecule weight HGF of <10,000 can diffuse out of the artificial cells to stimulate the regeneration of the remaining 10% liver mass in the 90% hepatectomized rats. Thus, the 90% hepatectomized rats that received artificial cells containing bone marrow stem cells had significantly higher blood HGF levels than the other groups. Our result shows that artificial cells containing bone marrow stem cells stayed in the peritoneal cavity throughout the 14 days of the study. This way, HGF secreted can be drained into the portal circulation to reach the 10% remaining liver mass to stimulate its regeneration. On the other hand, intraperitoneal injection of free bone marrow stem cells did not increase survival rates. Most likely this is because the free bone marrow stem cells are rapidly removed from the peritoneal cavity through the lymphatic drainage, and any HGF released does not drain into the portal circulation to have the most effective stimulating effect on the remnant liver.

Artificial Cells Containing Stem Cells in Regenerative Medicine

It would appear from the above study that implantation of artificial cells containing bone marrow stem cells results in the regeneration of the 90% hepatectomized liver, and the survival of the animal. These observations could stimulate further investigation of the potential for the treatment of acute liver failure or extensive liver resection to allow the liver to regenerate. The use of artificial cells containing stem cells could also be investigated in other areas of regeneration medicine.

GENE AND ENZYME THERAPY

Artificial cells have been studied for use in gene and enzyme therapy (Chang, 1964, 1972a, 2005a, 2007). The enclosed enzyme would not leak out, but could act on external permeant substrates. This would avoid protein sensitization, anaphylactic reaction or antibody production with repeated

injection (Figure II.5.4.1). Implanted urease artificial cells convert systemic urea into ammonia (Chang, 1964, 1965). Implanting artificial cells containing catalase replaces the defective enzyme in mice with a congenital defect in catalase – acatalasemia (Chang and Poznansky, 1968). The artificial cells protect the enclosed enzyme from immunological reactions (Poznansky and Chang, 1974). Artificial cells containing asparaginase implanted into mice delay the onset and growth of lymphosarcoma (Chang, 1971b).

Giving enzyme artificial cells by mouth avoids the need for repeated injection. For example, artificial cells containing urease and ammonia adsorbent can lower the systemic urea level (Chang, 1972a). In Lesch-Nyhan disease, enzyme defect results in the elevation of hypoxanthine to toxic levels. Given by mouth, artificial cells containing xanthine oxidase lower the toxic systemic hypoxanthine levels in an infant with this disease (Chang, 1989; Palmour et al., 1989). Phenylketonuria is a more common congenital enzyme defect. Artificial cells containing phenylalanine ammonia lyase given by mouth lower the systemic phenylalanine levels in phenylketonuria (PKU) rats (Bourget and Chang, 1985, 1986). This has led to investigation into recombinant sources of this enzyme (Safos and Chang, 1995; Sarkissian et al., 1999; Liu et al., 2002) that are now being tested in clinical trials.

Multienzyme Systems with Cofactor Recycling

Most enzymes in the body function as multienzyme systems with cofactor recycling. After basic research on artificial cells containing multienzyme systems (Campbell and Chang, 1976; Cousineau and Chang, 1977; Yu and Chang, 1982; Chang 1985; Ilan and Chang, 1986) we looked into their possible use. Thus, artificial cells containing three different enzymes can convert metabolic waste such as urea and ammonia into essential amino acids (Gu and Chang, 1988, 1990). The needed cofactor, NADH, can be recycled and retained inside the artificial cell by cross-linking to dextran or by the use of a lipid–polymer membrane. As discussed earlier, under artificial red blood cells, all the multienzyme system in red blood cells can be incuded inside nanodimensional artificial red blood cells (Chang, 2007; Chang et al., 2003) (Figure II.5.4.5).

DRUG DELIVERY

Gene and enzyme therapy is a form of drug delivery using artificial cells. However, the genes and enzymes are retained inside the artificial cells at all times, and act on substrates diffusing into the artificial cells. Artificial cells in different modified forms have also been used in drug delivery. However, these are used to separate the drug from the external environment, and to release the drug at a specific site and a specific rate when and where it is needed. Drug delivery is an extremely large and wide area, and many excellent reviews and books are available. In this chapter, only artificial cell-related systems will be very briefly summarized.

Polymeric Membrane Artificial Cells of Microscopic Dimensions

Luzzi (1970) used nylon membrane artificial cells, microcapsules, prepared as reported (Chang, 1964), to microencapsulate drugs for slow release for oral administration. Others have also extended this approach. However, the modern approaches in drug delivery systems are based on injectable biodegradable systems.

Biodegradable Polymeric Artificial Cells (Microparticles, Nanoparticles, Microcapsules, Nanocapsules)

Biodegradable polylactide membrane artificial cells have been prepared to contain enzymes, hormones, vaccines, and other biologicals (Chang, 1976). The polylactide polymer can degrade in the body into lactic acid, and finally into water and carbon dioxide. Variations in preparation can result in artificial cells that release insulin at different rates (Chang, 1976) (Figure II.5.4.8).

We have also used these for the slow release of prostaglandin E2 (Zhou and Chang, 1988) and ciprofloxacin (Yu et al., 1998, 2000). Biodegradable drug delivery systems are now used widely in different forms, ranging from microscopic to nanodimensions. They are also known as nanoparticles, nanocapsules, polymersomes, nanotubules, etc. Langer's group has written an excellent review on this topic (LaVan et al., 2002). Copolymers of polyethylene glycol (PEG) and polylactic acid (PLA) have been used to increase the circulation time of nanodimensional artificial cells. As described earlier in this chapter, this also forms the basis for preparing nanodimension PEG–PLA membrane artificial red blood cells (Yu and Chang, 1996; Chang et al., 2003; Chang, 2005a, 2006a).

Liposomes Evolved into Lipid Membrane Artificial Cells and Then Back into Polymeric Membrane Artificial Cells

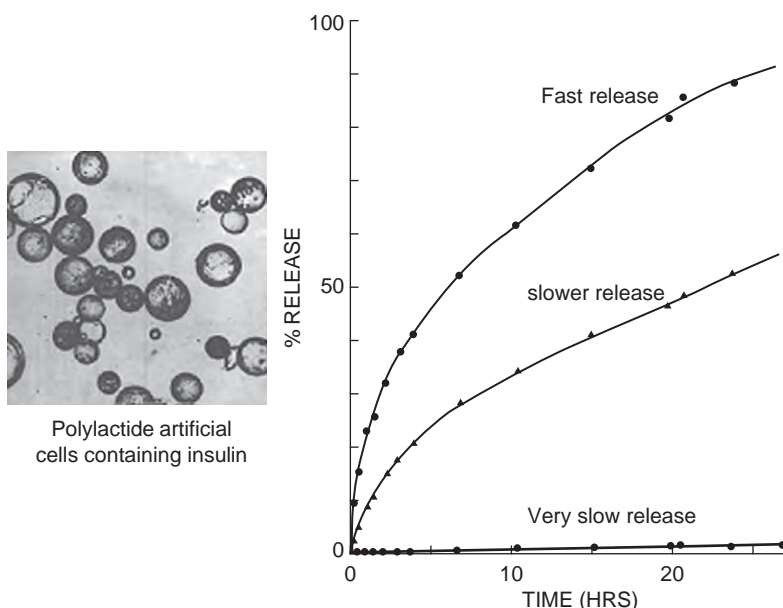
Bangham (1965) reported the preparation of liposomes each consisting of microspheres of hundreds of concentric lipid bilayers – multi-lamellar. This was initially used as membrane models in basic research. Gregoriadis (1976) first reported the use of liposomes as drug delivery systems. However, the large amount of lipid in the multi-lamellar liposome limits the amount of water-soluble drugs that can be enclosed. Thus, the basic principle and method of preparing artificial cells using ether as the dispersing phase (Chang, 1957, 1964) was extended by researchers into what they call an "ether evaporation method" to form single bilayer (unilamellar) lipid membrane liposomes (Deamer and Bangham, 1976). These lipid membrane artificial cells have since


FIGURE II.5.4.8 Biodegradable membrane artificial cells have been prepared to contain enzymes, hormones, vaccines, and other biologicals (Chang, 1976). This figure summarizes the result of polylactide artificial cells prepared by double emulsion method. Variations in the molecular weight of polylactide and the thickness of the membrane can result in artificial cells that release insulin at different rates. Faster release comes from the encapsulation of insulin solution at high concentration. Very slow release comes from the encapsulation of insulin crystals (Chang, 1976). (Figure from Chang (2007), with copyright permission of World Scientific Publisher.)

been extensively studied for use as drug delivery systems (Torchilin, 2005). Surface charges have also been incorporated into liposomes for possible targeting of drug, and more recently the use of positively charged lipid to complex with DNA. Polyethylene glycol (PEG) has also been incorporated to the liposome surface to result in longer circulation time. Thus, lipid vesicles are becoming more like the lipid–polymer membrane artificial cells (Chang, 1972a), and are no longer pure lipid vesicles. Further development led to the incorporation of antibodies into the lipid membrane, to allow for targeting to cells with the corresponding antigens. The principle of loading magnetic particles into artificial cells (Chang, 1966) has also been used for loading into liposome, allowing for magnetic targeting. One major advantage of lipid vesicles is in their ability to fuse with cellular membrane or membranes of intracellular organelles. This allows for much versatility in their ability to deliver drugs to different sites of the cells. A number of drugs in PEG–lipid vesicles have already been approved for clinical use or are in clinical trial (Torchilin, 2005). Discher's group (Discher et al., 1999; Photos et al., 2003) tried to increase the strength of the PEG–lipid membrane artificial cells by using self-assembling of copolymer to form a membrane of PEG polymer. This significantly increased the circulation time and strength when compared to PEG–lipid membrane artificial cells Thus, multilamellar liposome has evolved into lipid membrane artificial cells, then polymer(PEG)–lipid membrane artificial cells, and finally back to the original polymeric membrane artificial cells (Chang, 1964) now called polymersomes.

OTHER AREAS OF ARTIFICIAL CELLS

Artificial Cells Containing Magnetic Materials

When magnetic material is included in artificial cells (ACs) containing bioactive materials, one can use an external magnetic field to direct the artificial cells (Chang, 1966). This way, the magnetic field can: (1) direct the movement of the AC; (2) remove the AC after reaction; (3) retain the AC at specific site of action; (4) stir or agitate the AC as in bioreactors. This principle is now being used very extensively in bioreactors, in removing specific materials from a mixture as in diagnositcs kits, in drug delivery systems, and in other areas of application.

Nanobiosensors

Nanobiosensors is an area that is of increasing interest, and different approaches are being investigated. One of the many approaches is to use a biosensor where a lipid bilayer is "tethered" on ultrathin polymeric support to form a lipid–polymer complex. In this form, different "channels" can be inserted into the membrane to allow for selective movement of specific solute for detection, somewhat similar to the principle reported earlier (Chang, 1969, 1972a; Rosenthal and Chang, 1971, 1980). Another approach that is also possible is to encapsulate enzymes inside artificial cells of microscopic or nanodimension. This way, the product of enzymatic reaction can be followed by fluorescence or

other methods. The ability to prepare artificial cells with intracellular compartmentation (Chang, 1965, 1972a; Chang et al., 1966) would allow multi-step enzyme reaction to occur and be detected separately. Depending on the type of reaction being followed, one can use either polymeric membrane artificial cells, lipid membrane artificial cells or lipid–polymer membrane artificial cells.

Artificial Cells Containing Radioisotopes or Radio-Opaque Material

The general principle of artificial cells could be explored in many other areas. Thus, artificial cells containing radioactive isotopes or antimetabolites might be used for intra-arterial injection into tumors. In this case, some of the microcapsules might lodge at the tumor site, while others would be carried by lymphatic channels to metastases in regional lymph nodes. Artificial cells containing radio-opaque material would provide a contrast medium. Provided they can circulate readily in the bloodstream, they might be used as vehicles for contrast materials in angiography.

Nonmedical Uses of Artificial Cells

There are many developments and uses of the principle of artificial cells for agriculture, bioreactors, cosmetics, food production, aquatic culture, nanocomputers, and nanorobotics. However, these are not within the scope of this chapter.

THE FUTURE OF ARTIFICIAL CELLS

The 1972 monograph *Artificial Cells* (Chang, 1972a) predicted that: "Artificial Cell is not a specific physical entity. It is an idea involving the preparation of artificial structures of cellular dimensions for possible replacement or supplement of deficient cell functions. It is clear that different approaches can be used to demonstrate this idea." This prediction is already out of date since, in the last 50 years (Chang, 1957), artificial cells have progressed way beyond this 1972 prediction. Artificial cells can now be of macro-, micro-, nano-, and molecular dimensions. There are also unlimited possibilities in variations for artificial cell membranes and contents (Figure II.5.4.1). We have just touched the surface of the potential of artificial cells.

CHAPTER II.5.5 EXTRACORPOREAL ARTIFICIAL ORGANS

Alastair Campbell Ritchie
Department of Mechanical, Materials and Manufacturing Engineering, University of Nottingham, Nottingham, UK

INTRODUCTION

Extracorporeal circulation is, by definition, any procedure in which blood is taken from a patient, treated, and then returned. The vast majority of these procedures are performed intermittently, or as a temporary partial or total replacement. In this chapter, we will consider only those artificial organs which undertake mass transfer to and from the blood. This includes devices used for dialysis in renal replacement therapy, plasma separation (plasmapheresis), and extracorporeal oxygenation.

All these procedures involve the contact of blood with biomaterials, mechanical pumping of the blood, and mass transfer to and from the blood. The issues of biocompatibility are essential to the success or failure of a procedure; readers are advised to refer to the previous chapter on blood–biomaterials interaction for a full discussion of the effects of blood–biomaterial contact, as in this chapter only those aspects specific to extracorporeal therapy will be discussed.

Renal Replacement Therapy

Renal replacement therapy describes treatments such as peritoneal dialysis, hemodialysis, and hemofiltration, used to detoxify blood in cases of renal insufficiency. Renal insufficiency may be caused by acute renal failure, typically of rapid onset and due to external causes or by chronic renal failure, usually due to damage to the tissues of the kidneys. Chronic renal failure may be caused by infection, toxins or hypertension, and may also arise as a complication in diabetes mellitus. The number of prevalent (i.e., alive and receiving treatment) patients with end-stage renal disease in the USA between 1980 and 2007 is given in Figure II.5.5.1 (USRDS, 2009). As can be seen from the graph, the incidence of chronic renal failure has risen steadily since 1980, and diabetes has become the prominent cause of renal failure, accounting for some 37.4% of all cases in 2007, followed by glomerulonephritis, and renal vascular disease. Of the 527,283 surviving end-stage renal disease (ESRD) patients listed by the United States Renal Data System in that year,[1] 158,739 (30.1% of the total) had received a transplant that was still functioning. The other patients were dependent upon renal replacement therapy.

In 2007, there were 368,544 patients receiving renal replacement therapy in the United States, of whom 92.5% received hemodialysis treatment (USRDS, 2009). Blood may be treated by extracorporeal hemodialysis (familiarly known as dialysis), peritoneal dialysis, and extracorporeal hemofiltration (a form of plasmapheresis) (Coles and El Nahas, 2000). Figure II.5.5.2 shows the numbers of patients treated by blood purification therapies in the USA between 1980 and 2007 (USRDS, 2009). As can be seen, as the patient population has increased,

---

[1]Data from US Renal Data System, USRDS, 2009, *Annual Data Report: Atlas of End-Stage Renal Disease in the United States*, National Institutes of Health, National Institute of Diabetes and Digestive and Kidney Diseases, Bethesda, MD, 2009. The data reported here have been supplied by the United States Renal Data System (USRDS). The interpretation and reporting of these data are the responsibility of the author, and in no way should be seen as an official policy or interpretation of the US government.
FIGURE II.5.5.1 Prevalence and causes of chronic renal failure in the USA, 1980–2007 (Source: United States Renal Data System (USRDS) Annual Data Report, 2009. Data is as at December 31st of stated year.)
FIGURE II.5.5.2 Number of patients receiving regular dialysis (hemodialysis and peritoneal dialysis) in the USA, 1980–2007 (Source: United States Renal Data System (USRDS) Annual Data Report, 2009.)

the number and proportion of patients treated by hemo-dialysis has increased similarly. The number of patients treated by peritoneal dialysis has actually decreased, from 9580 in 1995 to 6734 in 2007. The proportion of patients treated by hemofiltration is very small, as this is predominantly used in intensive care medicine, par-ticularly in the treatment of multiple organ failure (Coles and El Nahas, 2000).

Function of the Kidney. The kidney is responsible for maintaining the osmotic and water balance of the body; for detoxification and the removal of metabolic waste; and for endocrine functions. It operates by a combination of filtration, selective reabsorption, and active secretion. The functional unit of the kidney is the nephron, of which there are approximately 1 mil-lion in each kidney. Figure II.5.5.3 shows a schematic

representation of a nephron, and its associated special-ized blood vessels.

In the glomerulus, the whole blood is filtered. The fil-trate contains water and solutes with a molecular weight below 60,000 (small proteins, amino acids, glucose, urea, and ionic solutes), of similar composition to blood plasma. Approximately 10% of the blood volume enter-ing the glomerulus is filtered here. The remaining blood passes into the peritubular capillaries and vasa recta, while the filtrate enters the proximal convoluted tubule. Within the remaining structures of the kidneys, water, small proteins, and solutes are reabsorbed by active and passive processes, while certain metabolites are secreted directly into the tubular fluid. These processes result in a net reabsorption of approximately 98–99% of the water filtered, and total reabsorption of glucose, proteins,
FIGURE II.5.5.3 Structure of a renal nephron.

FIGURE II.5.5.4 Positioning of catheter in peritoneal cavity for peritoneal dialysis.

and amino acids from the filtrate. A healthy individual will excrete 1–2 liters of concentrated urine per day, on average.

In addition to its excretory function, the kidney also has regulatory and endocrine functions. It controls the acid–base balance of the blood, and the water balance of the body, through selective secretion of H^+ into the urine to control pH, and the action of antidiuretic hormone, which controls the urine concentration. The kidney plays a role in the regulation of blood pressure through secretion of renin and tissue hormones (prostaglandins). The kidney also secretes erythropoietin, which promotes red blood cell formation in the bone marrow.

Treatment of Renal Failure. In its initial stages, chronic renal failure (end-stage renal disease or ESRD) is treated conservatively. As the disease progresses, blood purification is needed to remove toxins from the blood (Wing and Jones, 2000). The severity of chronic renal failure may be reduced by restricting a patient's protein, potassium (K^+), and water intake through carefully managed diets, and the administration of bicarbonate supplements to maintain a healthy blood pH. Erythropoietin supplements are given to maintain the patient's haematocrit (Coles and El Nahas, 2000). As the disease progresses, some form of renal replacement therapy becomes necessary.

Peritoneal Dialysis. Peritoneal dialysis (PD) uses the peritoneum, the membrane lining the walls of the abdominal cavity, and the abdominal organs for mass exchange. Dialysate is introduced into the peritoneal cavity through a catheter, as shown in Figure II.5.5.4. While in the peritoneal cavity, metabolic wastes such as urea and creatinine, toxins, and excess solutes (K^+, for example) are transferred from the blood into the dialysate by dialysis,
while water is removed by osmosis (Sargent and Gotch, 1996). Used dialysate is then removed.

Peritoneal dialysis is dependent on a number of factors. The rate of solute removal is dependent on the blood flow in the capillaries of the peritoneum and its permeability, as well as on concentration gradients between the blood and the dialysate. In addition, the suitability of a patient for treatment by peritoneal dialysis is often dependent on the amount of residual renal function.

There are two principal forms of peritoneal dialysis therapy. *Continuous Ambulatory Peritoneal Dialysis* (CAPD) is the most commonly used form, particularly in younger patients who can manage their own therapy. In this treatment method, the dialysate is infused into the peritoneal cavity, allowed to dwell for a set length of time, then drained and replaced with fresh dialysate. Typically, a patient would perform between five and six exchanges per day (Malchesky, 2004). It has the advantage that it offers patients a certain amount of independence, as they are not tied to any equipment for the majority of the time.

In *Automated Peritoneal Dialysis* (APD), also known as continuous cycler-assisted peritoneal dialysis (CCPD), a machine (cycler) performs the exchanges, usually at night while the patient is sleeping. APD can increase the clearance of metabolites considerably, particularly in patients with rapid rates of exchange between the peritoneum and the dialysate (high or fast transporters). In APD treatment, the cycler will perform several complete exchanges in a night, with a complete cycle of infusion, dwell, and drainage being completed in 30 minutes or less, and treatment for 8–12 hours in total. APD is sometimes referred to as *intermittent peritoneal dialysis*, if the APD is only performed at night. Many patients use a combination of CAPD during the day and APD at night.

Toxin removal in peritoneal dialysis is the sum of the patient's residual renal function and the toxin removal by hemodialysis. The overall removal of toxins, metabolites, and water must be sufficient to keep the patient healthy.

As water removal is dependent on the osmotic pressure of the dialysate, dialysate is supplied in three different strengths: 3.86% glucose; 2.27% glucose; and 1.36% glucose. All three strengths are hypertonic, and will result in water transfer to the dialysate; the rate of transfer is dependent on the osmotic gradient. A more concentrated dialysate will increase the ultrafiltration rate, and hence the removal of solutes as well as water will be enhanced; however, the stronger dialysate concentrations are only used when necessary, and most transfers are performed using the standard (1.36%) dialysate strength.

Peritoneal dialysis has the advantage that the patient's blood does not come into contact with any artificial surfaces; hence there is no need for anticoagulation. It has the disadvantage that the dialysate has to be infused into a body cavity, with the attendant risk of infection (Malchesky, 2004). It is vital to ensure the sterility of the dialyzing solutions, and to prevent infections at the access site. The most common complication of peritoneal dialysis is peritonitis, and this is also the most common reason for the discontinuation of PD. In most cases where peritoneal dialysis has to be discontinued, patients will begin treatment by hemodialysis.

Hemodialysis. Dialysis is the process of solute transfer across a semi-permeable membrane, and is similar in principle to diffusion. It is a passive process, with solute molecules that are small enough to pass through the membrane traveling from an area of high solute concentration to an area of low solute concentration. Typical hemodialysers use membranes with a molecular weight cut-off between 5000 (low-flux membranes) and 20,000 (high-flux membranes) (Boure and Vanholder, 2004), and a surface area of between 0.5 and 2.1 m^2.

In the hemodialyser, blood flows through membrane hollow fibers, with dialysate flowing in counter-current fashion, as shown in Figure II.5.5.5. Metabolic wastes such as urea and creatinine are transferred from the blood into the dialysate, due to the concentration gradient. The dialysate must be carefully formulated to ensure that normal concentrations of glucose and blood solutes are maintained. The blood and dialysate are osmotically balanced; hence any solute removal is by ultrafiltration, due to the differential pressure ($P_B - P_D$) between the blood and dialysate compartments.

Hemodialysis is an intermittent therapy, and is typically administered every 48 hours, with sessions lasting up to six hours at a time (Malchesky, 2004). The limiting factor for hemodialysis session duration is the rate of water removal, as water can only be drawn out of the blood plasma, and rates of fluid transfer from the intracellular fluid and interstitial fluid pools to the plasma (plasma refilling) must be sufficient to maintain normal blood pressure. A rare complication of hemodialysis, dialysis disequilibrium syndrome, should not be confused with the maintenance of blood pressure by plasma refilling.

Figure II.5.5.6(a) shows a typical hemodialysis circuit, incorporating a blood pump, dialyser, and arterial line filter. Blood is drawn from a dialysis access (Figure II.5.5.6b), usually located in the arm, and pumped through the dialyser (Figure II.5.5.7) at rates varying between 50 and 400 ml/min, depending on the condition of the patient, particularly the blood flow and blood pressure within the access vessel, and the required solute clearance and ultrafiltration rates. The dialysate is either
FIGURE II.5.5.5 Principle of dialysis.

FIGURE II.5.5.6 (a) Circuit for hemodialysis. (b) Hemodialysis access from arteriovenous fistula (top) and from a graft (bottom). Arteriovenous fistula is most commonly used outside the USA (Wing and Jones, 2000).

FIGURE II.5.5.7 Modern hollow fiber dialyser (Terumo Clirans C061) with end cap removed to show arrangement of hollow fibers.

TABLE II.5.5.1	Types of Hemodialysis Membranes (Boure and Vanholder, 2004)	
Unmodified Cellulose	**Modified Cellulose**	**Synthetic**
Low-flux	Low-flux	Low-flux
Cuprophan®	Hemophan®	Polysulfone
Cellulose diacetate		Polycarbonate
Cuprammonium rayon		
	High-flux	High-flux
	Cellulose triacetate	Polysulfone
		Polyamide
		Polyethersulfone
		Polyacrylonitrile
		Polymethylmethacrylate

Synthetic membranes such as polysulfone and polyamide have also been developed. These membranes have better biocompatibility than unmodified cellulosic membranes, but poorer than modified cellulose. They can be produced in both low flux and high flux membrane types. Table II.5.5.1 gives some examples of the polymers used in hemodialysis membranes.

The principal advantage of synthetic membranes over modified cellulosic membranes is the range of pore sizes available. A further advantage of these synthetic membranes is their adsorption capability, particularly for the adsorption of bacterial by-products which may enter the dialysate circuit. However, due to the low membrane areas present, this adsorption capability is limited (Boure and Vanholder, 2004).

As with all blood-contacting biomaterials, the following compatibility issues are present: complement activation; platelet adhesion; and thrombus formation. In artificial organs, complement activation normally takes place through the alternate pathway, leading to systemic inflammation in the patient and a post-procedural drop in leukocyte count (leukopenia) (Kay and Raij, 1987; Tayama et al., 1999). Contact with artificial materials will initiate coagulation via the intrinsic pathway, through activation of factor XII and the release of platelet phospholipids (Mackay and Arrowsmith, 2004; Hanson, 2004). Thrombus formation is prevented by the use of heparin, which accelerates the action of antithrombin III in blocking the coagulation pathway, preventing the formation of a fibrin clot. It should be noted that heparin will not prevent platelet adhesion to the membrane and platelet activation. Platelet activation and aggregation can lead to the formation of thrombi, and can also lead indirectly to leukocyte activation. All blood returning to the patient is filtered to ensure that thrombi cannot enter the patient's bloodstream.

In addition to the membranes of the hemodialyser, the blood will also come into contact with the tubing and connectors used in the extracorporeal circuit. Commonly used materials for blood tubing include polyvinyl chloride

prepared in batches or continuously, typically by mixing concentrate and processed mains water. Dialysate flow rates vary within the range of 300–800 ml/min, with most procedures performed at 500 ml/min. A higher dialysate flow rate will increase the clearance of solutes from the blood, but this increase in performance has to be balanced against the increased cost of the dialysate used.

The intermittent nature of treatment means that there is a build-up of metabolites and fluids between treatments, in comparison to the normal continuous function of the kidney. At the time of writing, the standard frequency of treatment is once every 48 hours for most patients, with sessions lasting up to six hours, although it has been shown that more frequent treatment gives better clinical outcomes. Frequency of hemodialysis treatments is therefore a balance between efficacy of treatment, cost, and convenience.

Membrane Materials. The first membranes to be used for hemodialysis were sausage skins made of regenerated cellulose (cellophane), as this was the only suitable membrane material available to Willem Kolff at the time (Broers, 2006). Regenerated cellulose thus became the standard hemodialysis membrane, and remains in clinical use. Although mass transport through these membranes is satisfactory, the molecular weight cut-off is only 5000 (low flux), and there are a number of biocompatibility issues, particularly complement activation (Boure and Vanholder, 2004; Kay and Raij, 1987). These membranes are normally referred to as unmodified cellulosic membranes. In order to improve the biocompatibility of cellulosic membranes, chemical processes are used to mask hydroxyl groups on the surface of the membrane – these membranes are known as modified cellulose.

FIGURE II.5.5.8 Schematic showing access and extracorporeal circuit for hemofiltration.

(PVC), polyurethane, and silicone rubber (PDMS, poly-dimethyl siloxane). However, the area of these materials, and the exposure time, is much lower than for the functional membrane surface.

Extracorporeal Hemofiltration. Extracorporeal hemofiltration is mostly used in the treatment of acute renal failure, particularly where renal failure is accompanied by fluid overload. The toxins and excess water are removed by ultrafiltration, and fluid balance is maintained by addition of an isotonic substitution fluid "downstream" of the filter (see Figure II.5.5.8). This method is particularly effective in the removal of toxins, although as the substitution fluid is mixed directly with the blood, and hence enters the body directly, it is very expensive to prepare. Its principal advantage over dialysis is the enhanced removal of solutes from the blood, of particular importance in cases of poisoning and multiple organ failure.

The most modern hemofiltration techniques use pure hemofiltration (convective transfer) in combination with dialysis (diffusive transfer) to achieve the desired blood purification. This technique is usually referred to as hemodiafiltration or high flux dialysis; the set-up is similar to that for conventional dialysis, although the vascular access is still artero-venous (Malchesky, 2004).

Hemoperfusion

The term hemoperfusion applies to the direct perfusion of whole blood over a sorbent bed or reactor. The sorbent used may be activated charcoal, non-ionic or ionic resins, or immunosorbents, while reactors may contain enzymes, cells or tissues. The purpose of the treatment is either to remove specific toxins or metabilites, or to carry out specific biochemical reactions. Issues with biocompatibility, safety, and immunological isolation have limited the application of hemoperfusion to the use of charcoal and resins as sorbents (Kambic and Nose, 1993).

Sorption of the solute into the sorbent is based on chemical affinity, rather than molecular size. Due to the nature of the sorbent granules, the surface area for sorption is very high, but it also makes it possible for particulates (fines) to be released from the reactor into the blood. The nonspecific nature of charcoal sorption can also lead to the removal of beneficial compounds from the blood. For these reasons, hemoperfusion has largely been superceded by plasma treatment (plasma perfusion) and sorbent dialysis, which have a similar therapeutic effect with fewer potential hazards.

The very large surface area of sorbents also leads to extensive blood–biomaterial contact, resulting in complement activation and initiation of the coagulation cascade. These events will cause a reduction in leukocyte and platelet levels in the blood.

Therapeutic Apheresis

"Apheresis" describes any technique in which a fraction of the blood (platelets, plasma, red blood cells, leukocytes) is removed, and the remaining blood is returned to the donor. This can be divided into "donor apheresis," in which volunteers give blood fractions for the treatment of others, and "therapeutic apheresis," where blood fractions are selectively removed to achieve a therapeutic result (Zydney, 2006).

Therapeutic apheresis can be used to treat diseases where abnormal blood proteins or cells are present in the bloodstream, and these proteins or cells are implicated in the condition's progression. In plasmapheresis, the plasma is separated and either replaced (plasma exchange) or treated prior to recombination with the blood (plasma treatment). In cytapheresis, one or more of the cellular components of the blood is selectively removed. Cytapheresis is overwhelmingly used as a donation procedure, for collection of blood proteins, platelets, and immune cells, with only 0.8% of the 1562 patient cases (13 cases) studied in the 2007 International Apheresis Registry[2] treated with therapeutic cytapheresis.

Plasmapheresis. Plasmapheresis has been used with considerable success in the treatment of a number of conditions, notably myasthenia gravis, leukemia, multiple myeloma, non-Hodgkins lymphoma, and other disorders affecting the blood and blood-forming organs (Zydney, 2006; Kambic and Nose, 1993). Plasmapheresis is also

---

[2]The 2007 International Apheresis Registry is drawn from 20 participating centers offering apheresis treatment; these numbers should not be taken as estimates of the total number of patients worldwide.
FIGURE II.5.5.9 Modes of treatment and conditions treated by apheresis, from the 2007 International Apheresis Registry (Malchesky et al., 2009). ASCT = Autologous Stem Cell Therapy; GBS = Guillan-Barre Syndrome; HUS = Hemolytic Uremic Syndrome; MG = Myasthenia Gravis; MM = Multiple Myeloma; NHL = Non-Hodgkins lymphoma; PE & PT = Plasma Exchange and Plasma Treatment; SLE = Systemic Lupus erythematosus; TTP = Thrombotic thrombocytopenic purpura.

used in the management of possible rejection of transplanted tissue due to ABO mismatch. Figure II.5.5.9 gives a breakdown of the number of treatments, number of patients treated by therapeutic apheresis, and the type of treatment used in the 2007 International Apheresis Registry (Malchesky et al., 2009). Note that stem cell infusion was recorded in the survey, although it is not an apheresis technique. Myasthenia gravis was the most common condition treated, both in terms of the number of patients and the number of treatments (it is a chronic condition, hence repeated treatments would be necessary), followed by leukemia (this figure does not

include Hodgkins disease and non-Hodgkins lymphoma), multiple myeloma, and non-Hodgkins lymphoma.

Plasma Separation

Plasma separation can be achieved by centrifugal or membrane methods. Centrifugal methods can be batch or continuous. In a batch method, anticoagulated blood is removed from the patient, and then centrifuged to separate the plasma, red blood cells, and buffy coat (lymphocytes and platelets). In a continuous process, shown schematically in Figure II.5.5.10, blood is fed
FIGURE II.5.5.10 Centrifugal separation of blood into plasma, buffy coat, and red cells (adapted from Malchesky, 2004).

TABLE II.5.5.2	Cell Properties in Plasmapheresis			
	Normal Concentration in Blood (per Liter)	Cell Diameter (μm)	Mean Density (g/ml)	Sedimentation Coefficient (×10⁷)
Red blood cell	$4.2–6.2 \times 10^{12}$	8	1.098	12.0
White blood cells	$4.0–11.0 \times 10^{9}$	–	–	1.2
Lymphocyte	$1.5–3.5 \times 10^{9}$	7–18	1.072	–
Granulocyte	$2.5–8.0 \times 10^{9}$	10–15	1.082	–
Monocyte	$0.2–0.8 \times 10^{9}$	12–20	1.062	–
Platelet	$150–400 \times 10^{9}$	2–4	1.058	0.032
Plasma	–	–	1.027	–

Membrane separation is dependent on cell diameter, while centrifugal separation is dependent on sedimentation coefficients.

into the center of a rotating bowl, and centrifugal forces (in the order of 100 G) cause separation into three distinct streams of red blood cells, buffy coat, and plasma (Malchesky, 2004; Zydney, 2006). Table II.5.5.2 gives the concentration, cell diameter, density, and sedimentation coefficient for the constituents of whole blood. The most dense element of the blood is the red blood cells, and hence these will be most affected by the centrifugal forces, followed by the white blood cells, and then the platelets. One stage separation can isolate the red blood cells, buffy coat, and the plasma, but two or more stages are required if concentration of specific white blood cell types is to be achieved. As the velocities used in the separation must not be too high to prevent damage to the cells, it is usual for the plasma fraction to contain some cells – usually platelets.

Membrane plasma separation is dependent on the pore size of the membrane, and it is usual to use pore sizes much smaller than the cells to prevent sieving. Figure II.5.5.11 shows the principle of membrane separation. If the pressure on the blood side is higher than the pressure on the plasma side, then there will be ultrafiltration of water and solutes with a molecular weight lower than the membrane cut-off. Due to the nature of the process, the separated plasma will not contain any cells, and the concentration of macromolecular solutes in the filtrate will be almost identical to the concentration in the plasma.

The production of particulate-free filtrate by membrane plasma separation is considered to be a key advantage of this process over centrifugal plasma separation. The absence of these particulates is particularly important if the plasma is to be treated and then returned to the patient, as the particulates may interfere with the treatment process.

Plasma Exchange. Plasma exchange has already been introduced in the section on hemofiltration. It is the most
FIGURE II.5.5.11 Membrane plasma separation (adapted from Malchesky, 2004).

used form of plasmapheresis, and is very effective in the removal of toxins from the bloodstream. However, it has the disadvantage that it is indiscriminate – in addition to the toxins and metabolites removed, large quantities of beneficial or physiological proteins including albumins, immunoglobulins, and clotting factors will be removed as well. This limits the volume of plasma that can be removed in a single session, and the infusion of substitution fluids carries the risk of allergic reactions or viral infections. Plasma exchange would usually be used when the specific pathogenic factors in the plasma are unknown or where a specific technique to remove these factors is not available (Malchesky, 2004). It could also be used if a combination of factors is to be removed, and plasma exchange is the simplest and most effective method to achieve this. The substitution fluid typically contains ionic solutes and albumin, but in some cases donated whole plasma or reconstituted plasma containing plasma fractions such as immunoglobulins can be used.

Plasma Treatment. Plasma may be treated by dialysis, membrane filtration, sorption, and processing by enzyme or biological reactions. Dialysis of fractionated plasma is similar to the dialysis of whole blood, and achieves the same result – removal of small solutes with a molecular weight below the membrane's cut-off. In membrane filtration, the plasma is filtered through one or more membranes following separation from the blood. The membrane cut-off of these membranes would be larger than a dialysis membrane, but smaller than the cut-off

of the membrane plasma separator, so that larger molecules in the plasma would be filtered out. It is also possible to perform membrane filtration at temperatures below physiological levels (cryofiltration) and above physiological levels (thermofiltration). Cyrofiltration is used to remove serum solutes which aggregate at lower temperatures, while thermofiltration is used to selectively remove low density lipoproteins (LDL) in the treatment of hyperlipidemia.

The principle of plasma treatment by sorption is similar to hemoperfusion over a sorbent column. The plasma is perfused through a sorbent column to remove the targeted solutes, then recombined with the concentrated cell fraction and returned to the patient. Sorption has been used to treat poisoning, drug overdose, uremia, liver insufficiency, autoimmune disorders, and familial hypercholesterolemia.

Cytapheresis. Although, as noted earlier, cytapheresis is usually a donation procedure, it has been used clinically to treat leukemia by leukocytapheresis (selective removal of the white blood cells). Leukocytapheresis is normally performed by centrifugation of the whole blood, rather than a membrane method, due to the similar cell diameters of white and red blood cells. Lymphocytapheresis has been investigated as a means to treat autoimmune diseases, including rheumatoid arthritis, and to prevent rejection in renal transplantation. Erthyrocytapheresis (red blood cell removal) has been used to treat sickle cell anaemia and malaria. In addition, thrombocytapheresis has been used to reduce very high levels of platelets in the blood (normally over 10^{12}/liter) (Malchesky, 2004).

While cytapheresis can be performed by centrifugation, it is also possible to use filters for therapeutic cytapheresis, particularly those with an affinity for certain types of blood cell – for example, lymphocytes will adhere preferentially to acrylic and polyester fibers, while granulocytes will adhere to cotton. In these cases, whole blood is perfused through the device and the cells are removed.

Photophoresis can be used to remove white blood cells in the treatment of T-cell lymphoma. The patient is given oral methoxsalen, which binds to the DNA in the nucleus of white blood cells. Blood is taken from the patient and centrifuged to separate the plasma and buffy coat, which are irradiated with UVA light. The UVA radiation activates the drug, which blocks replication of the white blood cells. After treatment, the blood is recombined and returned to the patient (Malchesky, 2004).

Sorbent Dialysis

The main area of application for sorbent dialysis is the treatment of acute liver failure, a condition for which the medical prognosis is usually poor (Bosch, 2005; Galletti and Jauregui, 2006). There has been considerable research into the development of a bioartificial liver

(extra-corporeal liver assist device or ELAD); however, at the time of writing (January 2012), clinical trials of ELADs have not shown significant improvement in patient outcome over conventional intensive care medicine.

Improvement in patient condition has been shown as a result of treatment by albumin dialysis (molecular adsorbent recirculating system or MARS), and by fractionated plasma separation and adsorption (Prometheus), a form of plasmapheresis, discussed above.

The MARS system passes the patient's blood through a high flux dialyser, and albumin-bound toxins in the patient's blood diffuse through the membrane to bind with albumin recirculating in the primary dialysate compartment. The dialysate coming out of the dialyser is regenerated in a series of sorbent columns (typically activated charcoal and anion exchange resin) which will remove toxins from the albumin, and a low-flux dialyser which removes water-soluble toxins. Prospective randomized controlled trials of MARS treatment in acute-on-chronic hepatic failure have shown significantly improved patient survival compared to the control group (patients receiving conventional ICU care). A meta-analysis of MARS trials has shown that further studies are needed before a final judgment can be made regarding the superiority of the MARS treatment (Bosch, 2005).

Blood Oxygenation

Applications of Extracorporeal Oxygenation. Extracorporeal oxygenation is required if respiratory gas exchange in the lungs is insufficient, usually due to acute respiratory distress syndrome or ARDS. If used to treat ARDS over a prolonged period, this is termed extracorporeal life support or ECLS. It is also used to maintain vital function during isolation of the heart and lungs for surgery, termed cardiopulmonary bypass or CPB, with a duration of a few hours (Murphy and Bryan, 2004; Mulholland, 2008; Lim, 2006).

Extracorporeal life support is often subdivided into extracorporeal membrane oxygenation or ECMO, and extracorporeal CO_2 removal, $ECCO_2R$. In ECMO, the oxygenator supplies all of the patient's metabolic oxygen demand and removes CO_2. $ECCO_2R$ is a partial bypass technique in which the oxygenator is used to remove the metabolically generated CO_2 from the blood. Only 20–30% of the cardiac output is treated in the oxygenator, which is sufficient to remove all the CO_2 generated metabolically. The lungs are kept filled with oxygen by low-frequency positive-pressure ventilation, and uptake of oxygen from the lungs supplies the remainder of the patient's oxygen demand. In all cases of ECLS, whether treating neonates or adults, the aim of treatment is to promote the recovery of function in the patient's lungs.

In cardiopulmonary bypass, the heart and pulmonary circulation are isolated and vital function is maintained by a pump and oxygenator. Blood is taken from the venous return to the heart in the vena cava, and returned to the arterial tree in the aorta. Blood scavenged from the operation site is also oxygenated and returned to the patient (Murphy and Bryan, 2004; Mulholland, 2008; Lim, 2006; Galletti and Colton, 2006). Cardiopulmonary bypass procedures are typically used during coronary artery bypass grafting procedures, although they are also used for heart or lung transplantation.

As surgical techniques have advanced, the number of procedures requiring the maintenance of vital function by an oxygenator has reduced. In 1995, there were an estimated 573,000 coronary artery bypass graft (CABG) procedures in the USA, whereas in 2003 there were only 466,369 (source: OECD Indicators, 2005). In addition to the reduced number of procedures, there are also a growing number of CABG procedures done on a beating heart, without the extracorporeal circuit (usually termed off-pump CABG). The reduction in numbers of CABG procedures can also be attributed in part to better monitoring of patients at risk, and a rise in coronary angioplasty procedures, from an estimated 433,000 in 1995 to 1,237,000 in 2003 (OECD, 2005). Membrane oxygenators can also be used to maintain vital function during procedures to correct congenital defects in neonates. Numbers of ECLS procedures are much smaller, as this is an acute therapy used in the treatment of adult and neonatal respiratory failure.

Equipment Used in Extracorporeal Oxygenation. The circuit for extracorporeal oxygenation includes a pump, reservoir, heat exchanger, and oxygenator, as shown schematically in Figure II.5.5.12. Additional pumps used for scavenging of blood from the operation site and venous return are not shown. Most of the oxygenators available at the time of writing (January 2012) combine a reservoir, heat exchanger, and oxygenator compartment, as shown in Figure II.5.5.13. The heat exchanger is used to control the patient's temperature. While ECLS is usually carried out in normothermic conditions, deep core hypothermia is induced in CPB procedures to reduce the patient's metabolic oxygen demand. In addition to the advantages of reducing oxygen demand, reducing blood temperature will also increase the volume of oxygen that can be transported by the blood for a given O_2 partial pressure.

Within the oxygenator, the blood and gas are separated by a membrane which is permeable only to gas. The membrane may be either microporous or homogeneous. The microporous membranes rely on the surface tension of the blood and the hydrophobic nature of the membrane material to prevent liquid intrusion into the pores. Homogeneous membranes operate on the principle of solution-diffusion driven by concentration gradients, and although mass flux through these membranes is lower, they can be used for sustained periods. A third class of membranes, composite or hybrid membranes, incorporates a thin homogeneous layer on a microporous support.

The gas transfer processes in microporous and homogeneous membranes are shown schematically in
FIGURE II.5.5.12 Circuit for cardiopulmonary bypass.

FIGURE II.5.5.13 The Medtronic Affinity® oxygenator with integral heat exchanger and attached hard shell blood reservoir. Note the mesh filter within the reservoir to prevent passage of macroemboli through the heat exchanger and oxygenator. (Image courtesy of Medtronic, Inc., Minneapolis, MN.)

Figure II.5.5.14. In the microporous membrane, gas transport through the pores is by diffusion, driven by concentration gradients. At the gas–blood interface, oxygen must first dissolve into the blood before diffusing
FIGURE II.5.5.14 Principle of gas exchange in microporous and homogeneous membranes (Campbell Ritchie et al., 1996).

through the blood plasma and binding to hemoglobin within the red blood cells. Similarly, CO_2 is released from the bound state (bound to plasma proteins and hemoglobin) into the plasma, and then from the plasma into the gas within the pore. The limiting factors on the gas transfer are the solubility and mobility of the gas molecules in blood plasma. CO_2 is both more soluble and more mobile, and hence the limiting factor in microporous membrane oxygenators is the oxygenation rate. The pore diameter and void fraction of the membrane are also factors that influence the performance of the oxygenator.

The porous nature of the membrane gives rise to the phenomenon of "pore wetting," where the blood plasma intrudes into the pores, eventually causing plasma to leak through the pore into the gas compartment. It has been shown that this phenomenon occurs more rapidly if there is a high concentration of polar phospholipids in the blood, and it has been ascribed to a loss of hydrophobicity of the membrane as phospholipids coat the membrane surface, and particularly the pores of the

membrane. As microporous membranes are run in conditions of overpressure, where the blood is at a higher pressure than the gas, the blood pressure will drive liquid through the pores if the hydrophobic repulsion is overcome. Overpressure ensures that in the event of membrane rupture or leakage, blood will leak out rather than gas leaking in, with the attendant risk of gaseous emboli entering the systemic circulation.

For this reason, membrane oxygenators incorporating microporous membranes are only approved for short-term procedures such as cardiopulmonary bypass. For extracorporeal life support, homogeneous membranes are required. The most commonly used homogeneous membranes are made from polydimethylsiloxane or PDMS, usually reinforced by a fabric mesh support. In homogeneous membranes, gas molecules dissolve into the solid matrix before diffusing through the material. Composite membranes, with a very thin homogeneous layer on top of a microporous support, have also been developed (Karichev and Muler, 2001; Nogawa, 2002).

The permeability coefficients of a number of materials of importance in membrane oxygenators are given in Table II.5.5.3. As can be seen from the table, PDMS is the most permeable membrane material, and has completely displaced polyethylene and PTFE (polytetrafluoroethylene), which were used in early membrane oxygenators (Lim, 2006; Galletti and Colton, 2006). Microporous membranes rely on diffusion through the air in the pores, a much faster process than solution-diffusion through PDMS, (Campbell Ritchie et al., 1996) and it can be seen from Table II.5.5.3 that a microporous membrane with a typical porosity of 30–40% and thickness of 30 μm will have a much higher gas flux than a homogeneous membrane of similar thickness, and hence the membrane areas of homogeneous oxygenators are much larger (most adult oxygenators using microporous membranes have a membrane area of approximately 2.0 m^2, compared to 3.5 m^2 for homogeneous membranes). There is therefore a balance between the intrinsically more biocompatible nature of homogeneous membranes, where there is no direct air–blood contact, and the effect of exposure to a larger area of a non-biological material.

Biocompatibility. Extracorporeal oxygenation is the most challenging of the extracorporeal procedures in clinical use, due to the high blood flow rates required, extent of biomaterial exposure, and the tissue trauma inherent in the surgical procedure. During a cardiopulmonary bypass procedure, performed on an open heart, there will be extensive trauma to skin, bone, and cardiovascular tissues, resulting in the release of tissue factor and activation of the extrinsic pathway of coagulation. Exposure of the blood to the biomaterials of the extracorporeal circuit will result in platelet activation, activation of the intrinsic pathway of coagulation, and complement activation via the alternate pathway (Tayama et al., 1999; Hanson, 2004). In addition to these issues, there will also be mechanical damage to the formed elements of the blood due to the high flow rates required (Lever, 2005) and the action of the blood pump, which is discussed in more detail below.

As with hemodialysis, heparin is used to prevent thrombus formation (Murphy and Bryan, 2004; Mulholland, 2008). As heparin blocks the activation of fibrinogen at a late point in the coagulation cascade, there will be platelet reduction and depletion of blood factors. This can result in postoperative bleeding or coagulopathy. The action of heparin is reversed by protamine once the procedure is completed (Mulholland, 2008).

Complement and platelet activation will result in a systemic inflammatory response: cytokine release; activation of endothelial cells; and migration of activated macrophages into peripheral tissues. Activation of lymphocytes and lymphocyte destruction or sequestration in the extracorporeal circuit results in a post-procedural drop in circulating lymphocytes to below 50% of the preoperative level. This challenge to the immune system can make patients more vulnerable to postoperative infection.

In cardiopulmonary bypass, some thrombus formation is inevitable, and although the arterial line filter will

TABLE II.5.5.3	O_2 and CO_2 Permeability Coefficients for Materials Important to Blood Oxygenation		
Material	**Common Name**	**O_2 Permeability (ml mm min^{-1} m^{-2} atm^{-1})**	**$\dfrac{P_m(CO_2)}{P_m(O_2)}$**
Air	–	1.27×10^6	0.8
Polydimethylsiloxane	Silicone rubber	27.94	5
Water	–	3.810	18
Polystyrene	–	1.397	5
Polyisopropene	Natural rubber	1.270	6
Polybutadiene	Butyl rubber	1.016	7
Polyethylene	–	0.3048	5
Polytetrafluoroethylene	Teflon (PTFE)	0.2032	3
Polyvinylidene chloride	–	2.540×10^{-4}	6

The permeability coefficient is defined as the product of the diffusion coefficient, D, and the Henry's law solubility coefficient, α. (Adapted from Galletti and Colton, 2006).

remove emboli >40 μm, other emboli can pass through and lodge in smaller blood vessels, resulting in widespread low level cell necrosis.

Blood Pumps in Extracorporeal Circulation

The common factor in all the extracorporeal circuits described in this chapter is the need for a pump to move the blood through the circuit. In apheresis and hemodialysis, roller pumps are used as blood flow rates are relatively small and the flexible tubing required for pumping can be easily incorporated into a single-use tubing kit. In extracorporeal oxygenation, much higher blood flow rates are needed, and a variety of pumps are used.

While a full discussion of the operating principles and efficiency of the pumps used in extracorporeal circulation lies beyond the scope of this chapter, mechanical pumping of the blood will have an effect on its condition, and may add to the complications of the procedure.

Roller Pumps. In a roller pump, a section of flexible tubing is mounted against a rigid outer support, as shown in Figure II.5.5.15. The rollers compress a section of tubing, preventing backflow, and pushing the blood forwards. The flow from a roller pump is pulsatile, which can have a beneficial effect on mass transfer, and if the rollers occlude the tubing completely the flow rate is dependent on the speed of rotation of the roller head, and relatively independent of the back-pressure due to the flow resistance of the extracorporeal circuit.

The roller pump is very versatile, and flow can be reversed if this is desired. It has the disadvantage that it can damage the blood, due to high shear rates induced in the vicinity of the rollers during occlusion, and particularly during the reopening of the tubing once the roller has passed. During reopening, there may be momentary

backflows with very high velocities. High shear on the cell membranes can lead to premature aging of the red blood cells, which leads to clumping, and in extreme cases, to hemolysis of the red blood cells, releasing hemoglobin into the plasma.

Platelets and leukocytes are more susceptible to shear damage than red blood cells, and hence the mechanical trauma of pumping will add to the effects of blood–biomaterial contact, particularly platelet activation and leukopenia. The degree of trauma is considerably increased when high flow rates are needed – hence the roller pump is most often used in applications where flow rates are low, such as dialysis and apheresis.

Centrifugal Pumps. The earliest type of centrifugal pump used in cardiopulmonary bypass was the conventional vaned type, where vanes on the rotating impeller accelerate the blood, pushing it out into the volute, where it decelerates. The kinetic energy is converted to potential energy, providing the driving pressure (pressure head) to push the blood through the extracorporeal circuit. The effect of the whirling vanes on the flow patterns and static pressure of the blood can be seen from the velocity and pressure plots in Figure II.5.5.16.

The centrifugal pump is more efficient and less damaging than the rotary pump (Nishinaka et al., 1996), but has the disadvantage that it is designed to operate over a smaller range of operating conditions (usually termed the design point, a specified combination of pressure head and flow rate). Operating a turbine type pump under conditions away from the design point can lead to an increase in the shear imparted to the blood, and in extreme conditions to cavitation, the formation of vapor bubbles in areas of very low pressure. Cavitation will cause severe hemolysis. In addition, the high velocity of the rotor tips will add to the shear-induced damage to the blood.

FIGURE II.5.5.17 The Bio-Pump® Plus vaneless centrifugal pump. (Image courtesy of Medtronic, Inc., Minneapolis, MN.)

To address these shortcomings the vaneless centrifugal pump which uses a spinning cone, rather than a vaned impeller, was developed to accelerate the fluid. The Medtronic Bio-Pump®, shown in Figure II.5.5.17, is one example of a vaneless centrifugal pump. As the blood flows through the pump, the cone diameter increases, and the surface velocity increases accordingly. The viscosity of the blood is key to the operation of the Bio-Pump, as it relies on the friction between the spinning cone and the blood. The Bio-Pump is much less damaging to the blood than a conventional vaned pump, at the cost of reduced pumping efficiency.

Most centrifugal pumps use magnetic coupling between the drive motor and the rotating impeller, which allows the pumping head to be a disposable sealed unit, suitable for single use only.

CHAPTER II.5.6 ORTHOPEDIC APPLICATIONS

Nadim James Hallab and Joshua James Jacobs
Department of Orthopedic Surgery, Rush University Medical Center, Chicago, IL, USA

INTRODUCTION

Orthopedic biomaterials are enormously successful in restoring mobility and quality of life to millions of individuals each year. Orthopedic implants include reconstructive implants, fracture management products, spinal products, rehabilitation products, arthroscopy products, electrical stimulation products, and casting products. These products are generally used for fracture fixation enhancement, joint replacement or dynamic stabilization. More specific orthopedic applications within these categories are listed here.

Fracture fixation devices:
- Spinal fixation devices
- Fracture plates
- Wires, pins, and screws
- Intramedullary devices
- Artificial ligaments

Joint replacement (Figure II.5.6.1):
- Hip arthroplasty
- Knee arthroplasty
- Spine arthoplasty
- Ankle arthroplasty
- Shoulder arthroplasty
- Elbow arthroplasty
- Wrist arthroplasty
- Finger arthroplasty

Dynamic stabilization devices (new):
- Spine stabilization devices.

Orthopedic Biomaterials Market

The overwhelming success of orthopedic biomaterials is exemplified by their worldwide market, dominating biomaterial sales at approximately $24 billion in 2007, with an expected growth rate of 7–9% annually. Global sales of trauma fracture management products only totaled approximately $3.7 billion in 2007, whereas $10 billion was spent on knee and hip joint replacements (Figure II.5.6.1). Global sales of knee implant products equaled approximately $5.8 billion in 2007, representing approximately 1.5 million knee replacement surgeries which include first-time joint replacement procedures and revision procedures for replacement, repair or enhancement of an implant product or component from a previous procedure. Revision procedures are growing at an accelerated rate of approximately 60% in the United States.

Orthopedic Biomaterials

Orthopedic biomaterials are generally limited to those materials that withstand cyclic loadbearing applications. While metals, polymers, and ceramics are used in orthopedics, it remains metals, which have over the years uniquely provided appropriate material properties such as high strength, ductility, fracture toughness, hardness, corrosion resistance, formability, and biocompatibility necessary for most loadbearing roles required in fracture fixation and total joint arthroplasty (TJA). The use of orthopedic biomaterials generally falls into one of three surgical specialty categories: upper extremity; spine; or lower extremity; and each specialty is typically divided into three general categories: pediatric; trauma; and reconstruction. Despite these numerous specialties and the hundreds of orthopedic applications, there are only a few orthopedic

FIGURE II.5.6.1 Total joint arthroplasties (TJA) are currently used to replace hip, knee, shoulder, etc. (Courtesy of BioEngineering Solutions Inc.)

TABLE II.5.6.1	Most Common Orthopedic Biomaterials
Material	**Primary Use(s)**
Metals	
Ti alloy (Ti-6%Al-4%V)	Plates, screws, TJA components (non-bearing surface)
Co–Cr–Mo alloy	TJA components
Stainless Steel	TJA components, screws, plates, cabling
Polymers	
Polymethylmethacrylate (PMMA)	Bone cement
Ultra-high molecular weight polyethylene (UHMWPE)	Low friction inserts for bearing surfaces in TJA
Ceramics	
Alumina (Al_2O_3)	Bearing surface TJA components
Zirconia (ZrO_2)	Bearing surface TJA components

STRUCTURE AND PROPERTIES OF CALCIFIED TISSUES

There are several different calcified tissues in the human body, and several different ways of categorizing them. All calcified tissues have one thing in common: in addition to the principal protein component, collagen, and small amounts of other organic phases, they all have an inorganic component hydroxyapatite (abbreviated OHAp, HA or $Ca_{10}(PO4)_6(OH)_2$). In the case of long bones, such as the tibia or femur, an understanding of the organization of these two principal components is central to characterization. It has been convenient to treat the structure of compact cortical bone (e.g., the dense bone tissue found in the shafts of long bones) using four levels of organization.

The first, or molecular, level of organization is the collagen triple helical structure (tropocollagen) and OHAp crystallography. It forms a hexagonal unit cell with space group symmetry $P6_3/m$ and lattice constants $a = 9.880$ Å and $c = 6.418$ Å, containing two molecular units, $Ca_5(PO4)_3OH$, per unit cell. How cells produce this mineral phase, and whether it is the first calcium phosphate laid down, are subjects of considerable research at present. Because of its small crystallite size in bone (approximately $2 \times 20 \times 40$ nm), the X-ray diffraction pattern of bone exhibits considerable line broadening, compounding the difficulty of identifying additional phases. A Ca-bearing inorganic compound in one of the components of calcified tissues has led to the development of a whole class of ceramic and glass–ceramic materials that are osteophilic within the body (i.e., they present surfaces that bone chemically attaches to). As yet, we do not know fully how the two components, collagen and OHAp, are arranged and held together at this molecular level. Whatever the arrangement, when it is interfered with (as is apparently the case in certain bone pathologies in which

metals, ceramics, and polymers which dominate all implants. Knowing the general properties, uses, and limitations of the "primary" orthopedic biomaterials is requisite to understanding what is required to improve the performance of current implant materials, and why only a few dominate the industry. A summary of seven more prevalent orthopedic biomaterials and their primary use(s) are listed in Table II.5.6.1.

Orthopedic Biomaterials Design

New biomaterials for orthopedic purposes face the same concerns present in current implants: (1) the material must not adversely affect its biological environment; (2) in return the material must not be adversely affected by the surrounding host tissues and fluids; and (3) new materials must exceed the performance of present materials. Thus, understanding the interrelationship between the structure and properties of the natural tissues that are being replaced is important. An appreciation of the "form–function" relationship in calcified tissues will help provide insight into critical factors determining implant design, as well as deciding which materials best meet a specific orthopedic need.

the collagen structure is altered during formation), the result is a bone that is formed or remodeled with seriously compromised physical properties.

The second or ultrastructural level may be loosely defined as the structural level observed with transmission electron microscopy (TEM) or high magnification scanning electron microscopy (SEM). Here, too, we have not yet achieved a full understanding of the collagen–OHAp organization. It appears that the OHAp can be found both inter- and intrafibrillarly within the collagen. At this level, we can model the elastic properties of this essentially two-component system by resorting to some sort of linear superposition of the elastic moduli of each component, weighted by the percent volume concentration of each.

The third or microstructural level of organization is where these fibrillar composites form larger structures, fibers, and fiber bundles, which then pack into lamellar-type units that can be observed with both SEM and optical microscopy. The straight lamellar units forming the plexiform (lamellar) bone are found generally in young quadruped animals, the size of cats and larger. This is the structural level that is described when the term "bone tissue" is used or when histology is generally being discussed. At this level, composite analysis can also be used to model the elastic properties of the tissue, thus providing an understanding of the macroscopic properties of bone. Unfortunately, this modeling is very complex and a complete description lies beyond the scope of this chapter (and the authors). Interested readers are referred to some of the original sources (Katz, 1980a,b).

The fourth level is that of each of the macroscopic levels of each bone sample or large section of bone. Since a significant portion of bone is composed of collagen, it is not surprising to find that, in addition to being anisotropic and inhomogeneous, bone is also viscoelastic like all other biological tissues. Duplicating such properties with long-lasting synthetic biomaterials remains an unrealized goal of orthopedic biomaterials, where the history of implant development has been characterized by the elimination of available candidate materials based on their poor performance, rather than production of biocompatible synthetic bone-mimetic materials.

Perhaps the best example of how orthopedic biomaterials have undergone implant design improvements over the past 100 years resulting in widespread success is total hip replacement (THR) or total hip arthroplasty (THA). Newer types of total joint arthroplasties, such as those currently used for disc replacements (total disc arthroplasty, TDA), have benefitted from the arduous history of the total joint arthroplasty. Many, if not all, of the biomaterial-related issues (both mechanical and biological) that impact the performance of the THR's are applicable to other orthopedic implants. Therefore, this chapter will detail where we have come from, using the total hip arthroplasty, and where we are now, using the example of current total disc arthroplasty designs, general current orthopedic materials technology, and future developments

as a proxy of clinical concerns of orthopedic biomaterial development and current technology. The history of total hip arthroplasty is particularly pertinent to biomaterials science, because it is one of the best illustrations of how an implant first used over a century ago has evolved to the highly successful status it has, primarily because of advances in biomaterials.

BIOMATERIALS DEVELOPMENT: A HISTORY OF TOTAL HIP ARTHROPLASTY

The earliest attempts to restore mobility to painful and deformed hip joints took place in the 1820s (White in 1822 and Barton in 1827), and centered on simply removing the affected femoral and acetabular bone involved. This evolved in the 1830–1880s into ghastly attempts to restore mobility using interpositional membranes between the femoral head and acetabulum, where such materials as wooden blocks and animal (e.g., pig) soft tissue were tried. The first prosthetic hip replacement is dated to 1890, when Gluck published a description of a carved ivory femoral head replacement using bone cement-like materials such as pumice and plaster of paris to secure the implants in place (Walker, 1978; Stillwell, 1987).

The interpositional membrane strategy continued from the 19th into the 20th century, where the use of new implant materials in the early 1900s (1900–1920) included organic materials (e.g., pig bladders and peri-implant soft tissues), and inorganic materials such as gold foil. The use of the individual's own soft tissues was the most popular method of interpositional membrane hip surgery. The limited success of this procedure prevented widespread use, and thus the treatment (rather than surgery) of painful, disfigured, and "frozen" (ankylosed) hip joints remained commonplace into the 1920s.

Mold Arthroplasty

It was not until 1923 when Marius Smith-Peterson was credited with ushering in the modern era of total joint replacement with his development of the "mold" arthroplasty (Figure II.5.6.2), made of glass, inspired by a shard of glass found in a patient's back with a benign synovial-like membrane around it. This mold or cup arthroplasty was designed as a cup that fitted in between the femoral head and the acetabular cup, and articulated on both surfaces prompting a "tissue-engineered" synovial/cartilage-like layer. This was the first widespread attempt to develop a better interpositional membrane, a technique that had been in practice for the previous 100 years. The efforts of Smith-Peterson and his colleagues over the years from 1923–1938 were spent improving the fracture resistance of the glass mold arthroplasty cup design, using materials such as early polymers (e.g., celluloid or phenol-formeldehyde Bakelite® or Formica®) and improved glass, e.g., Pyrex®. But it was not until
FIGURE II.5.6.2 The history of total hip arthroplasty is particularly pertinent to biomaterials science because it is one of the best illustrations of how an implant first used over a century ago has evolved to the highly successful status it has, primarily because of advances in biomaterials.

1939 when the first metal implant, a cobalt alloy termed Vitallium®, became available and, as used by Venable, Stuck, and Beach, showed that the corrosion resistance of the hip arthroplasty provided sufficient biocompatibility and performance to be incorporated into future popular implants such as the Judet, Moore and Thompson hip arthroplasties.

In 1937 Venable, Stuck, and Beach published a landmark article that was the first to analyze in a systematic fashion the electrolytic effects of various metals and alloys on bone and tissues (e.g., aluminum, copper, iron, nickel, lead, gold, magnesium, silver, stainless steel, and other alloys). They arrived at the conclusion that Vitallium® (a cobalt–chromium alloy) was superior to the other metals in corrosion resistance and in the mechanical properties required for implants (Venable et al., 1937; Charnley, 1979). By observing the effects of corrosion, and proposing guidelines for performance Venable, Stuck, and Beach set the standard by which future metallic alloys were selected for use in hip and other types of implants.

The superior material properties of the Vitallium® alloy facilitated further design modifications of the mold

arthroplasty by Otto E. Aufranc (Figure II.5.6.2), where the rim of the Smith-Peterson mold was removed (which was often the cause of adhesions and cup "freezing," with subsequent pain and immobility), and matching curves on the inner and outer surface were machined to meet at the rounded outer edge. Despite the high short-term success rates (<4 years) reported by Aufranc (>82%), the overall failure rate remained high (>50%). Another design modification of the mold arthroplasty in the 1940–1950s was the fixation of the mold to the acetabulum rim with screws by such physicians as Albee-Pearson and Gaenslen. Although used in only four cases, Gaeslen reported using a cobalt alloy mold fixed to the acetabulum and another fixed to the femoral head, creating a metal-on-metal total hip replacement. The popularity of mold arthroplasties endured into the 1970s, when they remained touted as the treatment of choice for traumatic arthritis of the hip by leading orthopedic surgeons (Harris, 1969). However, back in the 1930s the natural progress in THA development was the progression from mold arthroplasty to short-stem prosthesis.

Femoral Head Prostheses/Short-Stem Prostheses

Femoral head prosthetics were first made of such materials as ivory (Gluck in 1890) and rubber (Delbet in 1919), and were cemented (using a plaster-like cement) for stability (Walker, 1978; Stillwell, 1987). At about the same time these replacement heads were first fitted with a short-stem by Earnest Hey Groves, who used an ivory nail to replace the articular surface of the femur. These types of implants were rare and remained unpopular compared to mold arthroplasties until 1937, when Harold Bohlman, using the work of Venable and Stuck, designed a corrosion-resistant cobalt–chrome alloy femoral head replacement with a short-stem. This design was popularized by the Judet brothers in Paris in 1946; they used polymethylmethacrylate (PMMA), which was presumed biologically inert *in vivo*, to manufacture short-stemmed prostheses (Figure II.5.6.2). Initial good results were soon replaced with problems of implant fracture and excessive wear debris, and by the early 1950s these implants were losing favor and being removed by surgeons. Vitallium® (cobalt–chrome alloy) eventually replaced acrylic in several other short-stem designs. However, there were sound short-stem designs as early as 1938, when Wiles introduced the cobalt alloy femoral shell attached to the femur with a central nail. This design was later popularized by Peterson in 1950, where he used a similar Vitallium® shell design with a central nail and a plate attached to the nail for added stability. Others adopted and adapted the Judet brothers design using Vitallium®, such as J. Thompson (1951) and Rossignal (1950). Rossignal designed large threads onto the stem to aid in fixation. These short-stem designs were subject to what was deemed high shear stress, and

resulted in early loosening and failure in some patients. Short-stem designs were gradually replaced by longer-stem designs that provided less stress concentration.

Long-Stem Prostheses

Long-stem prostheses continued the trend established by short-stemmed prostheses, that is, more and more weight-bearing forces were transferred to the femur though an intramedullary stem. The pattern for a long-stem prosthesis was established in 1940 by Bohlman in collaboration with Austin T. Moore, in which they implanted a 12 inch Vitallium® prosthesis that replaced the femoral head and had long supports that were screwed into the outside of the femoral shaft (Moore, 1943). And while there were innovations in long-stem design in the 1940s, such as the door knob design of Earl McBride where a threaded stem was screwed into the intramedullary canal of the femur for fixation and load transferal, these designs were not popular. It was not until 1950 with the designs of Frederick R. Thompson and Austin T. Moore that long-stemmed prostheses became popular (Figure II.5.6.2). These designs were cast in Vitallium® (cobalt–chrome alloy), and required the removal of the femoral head but only part of the neck. The design of Moore differed from that of Thompson in that it had fenestrations through the implant to allow bone growth, and it had a rear vane to enhance rotational stability. Initially, these implants were used without bone cement. Evidence for the successful designs of the Thompson and Moore prostheses is proved by their continued use today, with only slight variations from the original. Despite the excellent design of these early long-stemmed prostheses they were primarily successful when used in place of diseased femoral heads, and did not work well when acetabular reaming was required. Therefore, this inadequacy prompted the development of the total hip replacement arthroplasty.

Total Hip Replacement Arthroplasty

Philip Wiles is credited with first total hip arthroplasty in 1938, when he used a stainless steel ball secured to the femur with a bolt and a stainless acetabular liner secured with screws (Wiles, 1953). The results of this design were disappointing, because of the poor corrosion resistance of early stainless steel *in vivo*, and the high stress concentrations of short-stemmed prostheses. An adaptation of this design that proved successful was developed by G. K. McKee and J. Watson-Farrar in 1951. They used a stain-less steel cup and long-stemmed prosthesis (Thompson stem) which failed rapidly due to the poor corrosion resistance of the stainless steel, and was then replaced by cobalt–chrome alloy with greater success. The McKee–Farrar prosthesis evolved quickly to incorporate a true spherical femoral head that was undercut at the neck to reduce the impingement of the head on the rim of the acetabular prosthesis to provide a greater

range of mobility (Figure II.5.6.2) (McKee and Watson-Farrar, 1943).

The next milestone in the evolution of modern total hip arthroplasty was the advent/popularization of acrylic dental bone cement, first used by Sven Kiar in 1950 to attach a plastic prosthesis to bone (Charnley, 1964). Later that year the Hospital for Joint Diseases in New York used polymethylmethacrylate (acrylic) bone cement as a means of fixation in total hip arthroplasties (Wilson and Scales, 1970). The development of acrylic bone cement dramatically reduced the rates of loosening associated with metal–metal total hip arthroplasty. The Stanmore metal–metal design which used a horseshoe-shaped cup was popular, but it led to excessive wear and was replaced by a complete cup. McKee and Watson-Farrar adapted their design to facilitate bone cement with a land-mine-like studded acetabular cup intended to maximize mechanical fixation.

The 1950s marked the introduction and populariza-tion of the total hip arthroplasty where it became simple and reliable enough to be practiced on a wide scale by the average orthopedic surgeon. However, the squeaking reported to occur in Judet and some later metal pros-theses was identified by Charnley to be a result of the relatively high frictional forces in the joint. These high torque and frictional forces resulted in the generation of significant metallic debris, which purportedly resulted in early loosening. In 1960 Charnley developed a "low fric-tion arthroplasty" device using shells of polytetrafluo-roethylene, PTFE (commonly called Teflon® in related publications) on the femoral and acetabular sides, which resulted in early/immediate failures because of massive debonding and wear debris. This was quickly followed by a thick-walled PTFE acetabular component articulat-ing on a small head designed to reduce the shearing forces and torque. However, this design also generated exces-sive wear debris, which produced immediate and severe inflammation and failure of the prosthesis. Charnley then replaced the PTFE with high density polyethyl-ene which was not as friction-free as Teflon®, but was 1000-times more wear resistant. This prototype of total hip arthroplasty developed in 1962 was the basis for future designs which remain the most popular form of total hip arthroplasty performed today (Figure II.5.6.2).

The basic design of Charnley was modified by Muller with variable neck sizes and larger heads. At the same period metal-on-metal designs by Smith, Ring, and oth-ers (Ring, 1968) were unsuccessful challengers to the basic Charnley metal-on-polymer design. Other currently adopted design modifications were developed by Ling, Aufranc, Turner, Amstutz, Harris, and Galante, which include such innovations as femoral prosthesis geomet-rical modification for increases in stability and mobil-ity, modular components for increased customization, porous coatings, surface texturing/coating to increase fixation and bone ingrowth, etc. Charnley is often dei-fied in orthopedic literature as the metaphorical spark that lit the flames of innovation in prosthetic design. This is a typical surgeon-centered over-glorification. For one thing, other implant designs which predate Charnley, such as the all metal McKee-Farrar THA implant, have enjoyed similar success rates to those reported by Charn-ley. More importantly, total hip arthroplasty is, per-haps, the best example of how orthopedic biomaterials and implant success have evolved over the last century through the innovation and hard work of many scien-tists and physicians, and advances in areas of materials technology, biomechanics, biochemistry, immunology, infectious diseases, thrombosis, and pharmacology, to name a few.

NEW DEVELOPMENTS: TOTAL DISC ARTHROPLASTY

In contrast to THA, total disc arthroplasty (TDA) is a relatively recent development which has yet to become a mainstream option for treating disc degeneration when compared with fusion. Spinal fixation device usage is steadily increasing, where the number of cervical and lumber fusions increased 111% from the years 1993 to 2003, to roughly 105 fusions per 100,000 people in the US which is about 305,000 fusions per year (Cowan et al., 2006). The ultimate goal of intervertebral disc replacement technology is to replace spine fusion, elimi-nate pain, and restore structure and mobility. The first disc arthroplasties were cobalt alloy spheres, implanted as early as 1957 in between vertebrae without any method of fixation (Harmon, 1963). A decade later, stainless steel metal spheres termed Fernström balls were used in 103 patients (Figure II.5.6.3) starting in 1969 (Fernstrom, 1966; McKenzie, 1995). Other clinicians around the same time tried using polymer balls made of polymethylmethacrylate, but the results were disas-trous (Hamby Wallace, 1959). The era of modern disc arthroplasty began in 1982 with the first functional arti-ficial intervertebral disc, the SB Charité™, at the Charité Hospital in Berlin (Figure II.5.6.4) (Büttner-Janz, 1992). This design used the low-friction arthroplasty principle of John Charnley, which by that time had been success-fully used in total hip replacement for over 20 years. The Charité TDA consisted of a UHMWPE sliding core, which articulated between two metal endplates with multiple teeth-like projections for fixation to the verte-bral endplates (Figure II.5.6.4). The following sections detail the different kinds of material selection used in dif-ferent modern total disc replacement (TDR) designs in the bourgeoning world of both lumbar and cervical total disc replacements.

In addition to what is termed total disc arthro-plasty, there are several disc sparing and motion pres-ervation devices that, while not technically TDAs, are a new type of implant called "dynamic stabilization" implants. However, none of these dynamic stabilization implants are approved for general use. The following
FIGURE II.5.6.3 Fernström Ball implants (stainless steel metal spheres) were the first disc arthroplasties. (Courtesy of BioEngineering Solutions Inc.)

FIGURE II.5.6.4 In 1982, Schellnack and Büttner-Janz developed the SB Charité™ artificial disc, which consisted of a UHMWPE sliding core articulating unconstrained between two highly polished stainless steel metal endplates. (Courtesy of Depuy Spine, Inc.)

list summarizes three central types of motion preserving spine implants, their articulation couple, and primary material constituents:

1. Lumbar Posterior Motion Sparing Technology (Figure II.5.6.5)

    Stabilimax NZ®, Applied Spine Technologies, Inc. (metal-on-metal: articulation: cobalt alloy-on-cobalt alloy, titanium)

    TOPS®, Impliant, Inc. (metal-polymer-metal with elastic core: cobalt alloy-polyurethane-cobalt alloy)

    Dynesis®, Zimmer, Inc. (metal-polymer-metal with elastic core-like structures: cobalt alloy-polyurethane-cobalt alloy)

    DIAM™, Medtronic (all polymer, polyester, silicone)

2. Cervical Disc Arthroplasty (Figure II.5.6.6)

    Bryan® Cervical Disc, Medtronic (metal-polymer-metal: elastic core: cobalt alloy-polyurethane-cobalt alloy)

    PCM®, Cervitech (metal-on-polymer: articulation: cobalt alloy-on-UWMWPE)

    PRESTIGE® Cervical Disc, Medtronic (metal-on-metal: articulation: stainless steel-on-stainless steel)

    PRODISC-C®, Synthes, Inc. (metal-on-polymer: articulation: cobalt alloy-on-UWMWPE)

    Secure®-C, Globus Medical (metal-on-polymer: articulation: cobalt alloy-on-UWMWPE)

3. Lumbar Disc Arthroplasty (Figure II.5.6.7)

    NUBAC™, Pioneeer Surgical, Inc. (polymer-on-polymer: articulation: PEEK on PEEK)

    SB Charité®, DePuy Spine, Inc. (metal-on-polymer: articulation: cobalt alloy-on-UWMWPE)

    Prodisc™ II, Synthes, Inc. (metal-on-polymer: articulation: cobalt alloy-on-UWMWPE)

    Maverick®, Medtronic (metal-on-metal: articulation: cobalt alloy-on-cobalt alloy)

    eDisc™, Theken (metal-polymer-metal: elastic core: cobalt alloy-polyurethane-cobalt alloy)

    Freedom™ Lumbar Disc, Axiomed, (metal-polymer-metal: elastic core: cobalt alloy-polyurethane-cobalt alloy)

    Activ L, Asculap (metal-on-polymer: articulation: cobalt alloy-on-UWMWPE)
FIGURE II.5.6.5 Dynamic Spine Stabilization Implants: A new class of motion preservation implants are under investigational use in the lumbar spine: (a) Stabilimax NZ® (Applied Spine Technologies, Inc.); (b) TOPS® (Impliant, Inc.); (c) Dynesis® (Zimmer, Inc.); all of these use a combination of articulation and spring or elastomeric interior components to provide both articulation and resistance force back a neutral position. (Courtesy of BioEngineering Solutions, Inc.)

FIGURE II.5.6.6 Cervical IDRs (Intervertebral Disc Replacement): There are a number of cervical total disc replacements in use which employ the three primary types of disc joint articulation. 1. Metal-on-Polymer Articulation: (a) The PRODISC-C® (Synthes, Inc.); and (b) PCM® (Cervitech); use Co-alloy endplates that articulate on a polymeric (UHMWPE) core that is mechanically fixed to one of the endplates and articulates in a ball-and-socket type manner. 2. Metal-on-Metal Articulation: (c) The PRESTIGE® Disc (Medtronic) has metal-on-metal articulation where the end plates are constructed of stainless steel. 3. Elastic Core Articulation: (d) The Bryan® Cervical Disc System (Medtronic) is axially symmetric and incorporates cobalt-chrome alloy clamshell-shaped endplates, which flex upon a loadbearing polymeric (polyurethane-based) nucleus core. A novel feature in the design of this component is the polyurethane flexible membrane that surrounds the entire articulation and forms a sealed space containing a saline lubricant to reduce friction and prevent migration of any wear and corrosion debris. (Pictures provided courtesy of DePuy Spine, Inc., Medtronic, Spine Solutions, Inc., and BioEngineering Solutions, Inc.)
FIGURE II.5.6.7 Lumbar total disc replacements include metal-on-polymer, metal-on-metal, polymer-on-polymer, and flexible core technologies. (a) Metal-on-Polymer Articulation: *The LINK® SB Charité III* (DePuy Spine, Inc.) cobalt–chrome alloy endplates articulate on a mobile bearing ultra-high molecular weight polyethylene core. The endplates are covered with an osteoconductive surface of titanium/calcium-phosphate double coating under the trade name "TiCaP®." (b) Metal-on-Polymer Articulation: The Prodisc (Synthes, Inc.) lumbar TDR is composed of cobalt–chrome–molybdenum alloy and covered with a porous titanium alloy and articulates on a central core of UHMWPE. (c) Metal-on-Polymer Articulation: ActivL (Aesculap) uses a polymeric center core intended to allow both translation and rotation and to more closely approximate physiological motion. (d) Metal-on-Polymer Articulation: Dynardi (Zimmer, Inc.) is a disc replacement implant with two opposing cobalt alloy (Co–Cr–Mo) endplates coated with porous pure titanium for bone ingrowth, that articulate on a semi-constrained UHMWPE core. (e) Polymer-on-Polymer Articulation: NUBAC™ (Pioneer Surgical, Inc.) is a polymer-on-polymer disc arthroplasty device and the first polyetheretherketone (PEEK)-on-PEEK articulated disc arthroplasty device. (f) Metal-on-Metal articulation: The Maverick Disc (Medtronic) uses metal-on-metal articulation where the end plates are constructed of Co-alloy. (g) Elastic Core Articulation: The Theken eDisc™ (Theken Disc) represents another step in the evolution orthopedic implant devices in that as well as containing an elastic polyurethane based core it provides measured *in vivo* load information to the surgeon and patient via electronic sensors and transmitters. (h) Elastic Core Articulation: The Freedom™ Lumbar Disc (Axiomed) uses a viscoelastic polymer (like polyurethane) to replicate the native function of a natural disc. The elastic core in combination with the implant design provides a three-dimensional motion that functions within the natural biomechanics of the spine. (Pictures provided courtesy of DePuy Spine, Inc., Medtronic, Spine Solutions, Inc., and courtesy of BioEngineering Solutions, Inc.)

In general, current TDA designs have a THA-like primary articulation (or motion) using polymer-on-metal, polymer-on-polymer, metal-on-metal or some form of an all elastic core technology. However, because the emerging area of motion preservation in spine orthopedics facilitates the use of a wide array of implant designs and materials, the following sections will detail some of these designs and the materials they are comprised of.

Metal-on-Polymer Articulation. Examples of metal-on-polymer articulating TDA implants are as follows:

- *SB Charité III Artificial Disc* (Depuy Spine, Inc.). The Charité III includes thick cobalt chrome endplates (Figure II.5.6.7). The metal endplates are coated with an osteoconductive surface of porous titanium beads and calcium-phosphate double coating under the trade name "TiCaP®." This coating is also used in non-cemented total joint arthroplasty such as femoral stems, acetabular cups, ankle joint prostheses, and dental implants (Liefeith et al., 2003).
- *Prodisc* (Synthes, Inc.). The lumbar TDA Prodisc reflects how hip and knee designs have shaped TDA designs (Figure II.5.6.7). The two cobalt-chrome-molybdenum alloy endplates are covered with a porous titanium alloy, and articulate on a UHMWPE core. The locking polyethylene core provides ball and socket movement which is different from other "mobile" bearing designs, e.g., the Charité. The cobalt-chrome alloy endplates are also coated with pure titanium (Plasmapore), in similar fashion to the Charité.

Metal-on-Metal Articulation. Examples of metal-on-metal articulating TDA are currently used in both lumbar and cervical disc replacement applications, and dynamic stabilization devices of the lumbar spine.

- *Dynamic Stabilization*: *Stabilimax NZ®* (Applied Spine Technologies, Inc.). The Stabilimax NZ® dynamic spine system is an implant that provides stabilization of the lumbar spine for patients with spine surgery that results in less superstructure for stability (e.g., bone removal for spinal stenosis; Figure II.5.6.5). It is composed of two ball-and-socket joints with cobalt alloy on cobalt alloy (ASTM F-75) articulation, two titanium alloy (Ti-6Al-4V) screws, and an interposed spring of cobalt alloy in between the two ball-and-socket joints (Figure II.5.6.5a). This type of device attempts to offer a less invasive surgical procedure than fusion or disc replacement.
- *Total Disc Arthroplasty*: *Prestige Disc*. The Prestige Disc (Medtronic) uses metal-on-metal articulation where the end plates are currently constructed of stainless steel (and in the near future cobalt alloy) (Figure II.5.6.6). The articulation mimics that of a ball-and-socket construct with a more constrained center of rotation, i.e., not the joint kinematics of mobile bearing. Because the wear resistance of stainless steel

exceeds that of polyethylene, the amount of total particulate debris generated by metal-on-metal couples is an order of magnitude less than that produced by metal-on-polymer couples. The location of this implant next to vital tissues raises concerns associated with the release of metallic debris. However, the importance of metal debris will be resolved primarily through careful clinical follow-up and peer reviewed analysis.

Polymer-on-Polymer Articulation. The lower loads of the spine when compared to hip and knee replacements has enabled the use of polymer-on-polymer articulation designs of total disc arthroplasty devices, which if successful will be a new phenomena in the world of total joint arthroplasty.

NUBAC™ (Pioneer Surgical, Inc.) is a polymer-on-polymer disc arthroplasty device made of polyetheretherketone (PEEK). This implant aims to maintain or restore the disc height and mechanical function by replacing only the nucleus of a spine disc, theoretically using a less invasive procedure than other total disc arthroplasty implants, i.e., it is inserted into a partially resected disc, and has partial structural support of part of the remaining disc (the annulus around the outside of the implant). It does not restrict any physiological rotational motions, leaving constraint and stability to the retained surrounding annulus of the disc and ligaments. The risk of implant extrusion is low, because biomechanics of motion tend to push it in the opposite direction (Figure II.5.6.7).

Elastic Intervertebral Replacement Devices. The advent of elastic core total disc replacement implants represents another pioneering effort in the world of total joint implants. Elastic core total joint replacement (TJR) technology is feasible because there are relatively small motions associated with disc arthroplasty implants when compared to a hip or knee. There are generally two different kinds of total disc arthroplasty designs with elastic "core "components: (1) elastic cores interposed between two endplates; and (2) all elastic devices for nucleus replacement.

Total Disc Arthroplasty: Bryan® Cervical Disc Prosthesis (Medtronic). The Bryan® Cervical Disc System was approved by the United States FDA for distribution on May 12, 2009, and incorporates cobalt-chrome alloy endplates, which sandwich and flex on a load-bearing polymeric (polyurethane-based) nucleus core. The endplates have a porous coating of 250 micron titanium beads sintered to the cobalt alloy endplates. There is also a polyurethane flexible membrane that surrounds the entire articulation, which forms a sealed space to prevent migration of any wear and corrosion debris. This sheath also aims to prevent the intrusion of connective tissue or the creation of a pseudo-capsule over time. The inclusion of a sheath component to address the clinical concern of wear and corrosion debris (discussed later) is a significant development in the design of orthopedic joint arthroplasty components.

All these spinal implants seek to replace fusion as the operative solution for disc degeneration or injury. Many of these designs are new to orthopedics in terms of materials and/or design, and have not withstood the test of time; it is likely that only a few of these designs will dominate and become more popular over time. However, these disc replacement implants represent how imaginative new designs and materials are being used to address age-old orthopedic problems that remain unresolved in this new 21st century.

CURRENT BIOMATERIALS IN TOTAL ARTHROPLASTY

Today, the archetype of the total hip implant remains much as it was in the 1970s, albeit with a wider variety of implant materials and geometries (Figure II.5.6.8). Current THA is typically constructed of a titanium or cobalt–chromium alloy femoral stem (cemented with polymethylmethacrylate, PMMA, or press fit into place; Figure II.5.6.9), connected to a "modular" cobalt–chrome alloy or ceramic head that articulates on a ultra-high molecular weight polyethylene (UHMWPE) or ceramic acetabular cup fitted into a titanium or cobalt–chromium cup liner which is cemented, screwed or press fitted into place (Figure II.5.6.9). Despite this simple archetype of the total hip replacement, there are hundreds of variations on this theme offered to today's orthopedic surgeons, with little in terms of absolute guidelines as to which type of implant is (or which of the over 10 major manufacturers has) the best for well-defined orthopedic disease states. However, there are some general guidelines. Typically, implants in older individuals (>80 years of age) are cemented into place with PMMA bone cement, because the chance for revision is minimal when compared to younger individuals (<60 years), and removing bone cement is both technically challenging and may compromise the availability of bone stock. Generally, there are choices of surface roughness, coatings, geometry, material composition, etc., and each manufacturer claims that its product is superior to the rest. This, in combination with little or no publicly available information tracking the performance of each type of implant in patients, precludes accurate scientific analysis of which implant materials and designs perform best. Additionally, competition between manufacturers, and the requisite attention to marketing required to compete in the marketplace, has resulted in a dizzying array of new implants released each year claiming to be an improvement over last year's model. These claims are suspect, because the typical total hip replacement enjoys a success rate of over 90% at seven years, therefore in most cases a minimum of seven to ten years must pass

FIGURE II.5.6.8 Examples of typical current total hip arthroplasty (THA) components available from a single manufacturer: titanium alloy stem, with a cobalt-base alloy (ASTM F-75) modular head bearing on an ultra-high molecular weight polyethylene (UHMWPE) liner within a titanium alloy cup. Also shown are a ceramic head and three acetabular sockets with various surfaces for both cemented and cementless fixation. From left to right the stems are all components of the VerSys® Hip System (Zimmer, Inc, Warsaw, IN, USA), and from left to right are designated Beaded Fullcoat, Beaded Fullcoat with distal flutes, Cemented, Fiber Metal Taper, and Fiber Metal Midcoat. (Photographs courtesy of Zimmer, Inc.)

before such claims can be substantiated, and even then proof of superior performance is compromised by a myriad of external factors, such as the surgeon, region of the country, average activity of patient populations, etc. This conflict between science, marketing, and market share may (in the opinion of this author) represent the single biggest obstacle to the scientific determination of superior implant design and progress. The unenviable responsibility rests with the FDA to prevent the zeal of

economic pressure from undermining implant design in a regressive fashion. Today, optimal implant selection is primarily based on which material couple may best suit the individual (Figure II.5.6.10).

Polymers

Polymers are most commonly used in orthopedics as articulating bearing surfaces of joint replacements

FIGURE II.5.6.9 Examples of cemented and non-cemented stems showing the plug and centralizer used with a cemented stem. (Picture courtesy of Zimmer, Inc.)

FIGURE II.5.6.10 Examples of the three types of bearing couples used in modern TJA. From top to bottom: metal-on-polymer, ceramic-on-ceramic, and metal-on-metal (Lineage™ line from Wright Medical Technology, Inc. Arlington, TN, USA).

(Figure II.5.6.8), and as an interpositional cementing material between the implant surface and bone (Figure II.5.6.8). Polymers used as articulating surfaces must have a low coefficient of friction, and low wear rates when in articulating contact with the opposing surface, which is usually made of metal. Initially, John Charnley used polytetrafluoroethylene (PTFE) for the acetabular component of his total hip arthroplasty (Figure II.5.6.2). However, its accelerated creep and poor stress degradation (for the material he used) caused it to fail *in vivo*, requiring replacement with his ultimate choice, ultra-high molecular weight polyethylene (UHMWPE).

Polymers used for fixation as a structural interface between the implant component and bone tissue require the appropriate mechanical properties of a polymer, which can be molded into shape and cured *in vivo*. The first type to be used, polymethylmethacrylate (PMMA), was again popularized by Charnley, who borrowed it from the field of dentistry. He adapted dental PMMA as a "grouting" material to fix both the stem of the femoral component and the acetabular component in place, and thus distributed the loads more uniformly from the implant to the bone. Since high interfacial stresses result from the accommodation of a high modulus prosthesis within the much lower modulus bone, the use of a lower modulus interpositional material has been a goal of those seeking to improve upon PMMA fixation. Thus, polymers such as polysulfone have been tried as porous coatings on the implant's metallic core to permit mechanical interlocking through bone and/or soft tissue ingrowth into the pores. However, to date PMMA remains the substance of choice for orthopedic surgeons. This requires polymers that have surfaces that resist creep under the stresses found in clinical situations, and that have high enough yield strengths to minimize plastic deformation. As indicated earlier, the important mechanical properties of orthopedic polymers are yield stress, creep resistance, and wear rate. These factors are controlled by such parameters as molecular chain structure, molecular weight, and degree of branching or (conversely) of chain linearity.

One of the more prevalent polymerics used in orthopedics today is a highly cross-linked ultra-high molecular weight polyethylene (UHMWPE), which is typically used in total joint arthroplasty as a loadbearing articulating surface, designed to provide low friction loadbearing articulation. Polyethylene is available commercially in three different grades: low density; high density; and UHMWPE. The better packing of linear chains within UHMWPE results in increased crystallinity, and provides improved mechanical properties required for orthopedic use even though there is a decrease in both ductility and fracture toughness. In total hip arthroplasty applications, an acetabular cup of UHMWPE typically articulates against a femoral ball of cobalt–chromium alloy. The predominant problem presented by these metal–polymer articulating surfaces is the production of wear

particles, i.e., polymer debris. The resultant wear of the polyethylene bearing purportedly produces billions of sub-micron sized wear particles annually, in the <1–10 micron range. Producing greater cross-linking of polyethylene, using chemical and radiation techniques, has only recently improved its wear resistance in orthopedic applications. Wear tests have shown that the wear resistance of UHMWPE is improved by cross-linking with gamma irradiation at 2.5–5.0 Mrad and below, as evidenced by simulator studies; however, this can negatively affect such physical properties as tensile strength (McKellop et al., 2000). Therefore, care must be taken to minimize any negative oxidative effects, while preserving high wear resistance characteristics. Although newer more highly cross-linked polyethylene has generally been accepted as superior to previous implant UHMWPE, there remains incomplete data regarding its ultimate long-term performance. In order to maximize the performance characteristics of polyethylene, it is cross-linked prior to fabrication into its final form, e.g., an acetabular cup. Typically, an extruded bar of polyethylene is cross-linked using conventional gamma irradiation, and then heat treated to reduce residual free radicals.

Ceramics

In recent years, ceramics and glass ceramics have played an increasingly important role in implants. Although used in Europe for over a quarter century, the FDA has only recently (3 February, 2003) approved the first ceramic-on-ceramic bearing hip implant to be used in total hip replacement procedures (Figure II.5.6.10). The primary reason for the introduction of this alternative bearing surface is the superior wear resistance of ceramics when compared to metal–metal or metal–polymer bearing surfaces. This, and other improved properties such as resistance to further oxidation (implying inertness within the body), high stiffness, and low friction require the use of full-density, controlled, small, uniform grain size (usually less than 5 μm) ceramic materials. The small grain size and full density are important, since these are the two principal bulk parameters controlling the ceramic's mechanical properties. Any voids within the ceramic's body will increase stress, degrading the mechanical properties. Grain size controls the magnitude of the internal stresses produced by thermal contractions during cooling. In ceramics, such thermal contraction stresses are critical, because they cannot be dissipated as they can in ductile materials via plastic deformation.

Alumina (Al_2O_3) and zirconia (ZrO_2) ceramics have been used in orthopedic THA for the past 30 years. The first ceramic couple (alumina–alumina) was implanted in 1970 by Pierre Boutin. Since the outset, the theoretical advantage of hard-on-hard articulating surfaces was low wear. Ceramics, because of their ionic bonds and chemical stability, are also relatively biocompatible. Initial concerns about fracture toughness and wear have

been addressed by reducing grain size, increasing purity, lowering porosity, and improving manufacturing techniques (e.g., hot isostatic pressing, HIP). Early failures of these couples were plagued with both material-related and surgical errors. The very low wear rates combined with steadily decreasing rates of fracture (now estimated to occur 1 in 2000 over 10 years) have resulted in the growing popularity of all ceramic bearings.

Zirconia was introduced in 1985 as a material alternative to Al_2O_3 for ceramic femoral heads, and was gaining market share because of its demonstrably enhanced mechanical properties in the laboratory when compared to alumina. Femoral heads of zirconia can typically withstand 250 kN (or 25 tons), a value generally exceeding that possible with alumina or metal femoral heads. However, mechanical integrity of all ceramic components are extremely dependent on manufacturing quality controls, as evidenced in the recall of thousands of zirconia ceramic femoral heads by their manufacturer, St. Gobain Desmarquest, in 2001. This was because of *in vivo* fracture of some components due to a slight unintended variation in the manufacturing sintering process, caused when the company bought a newer high-throughput assembly line type oven. In general, ceramic particulate debris is chemically stable and biocompatible, and causes no untoward biologic responses at high concentrations.

There have been recent attempts to take advantage of the osteophilic surface of certain ceramics and glass ceramics. These materials provide an interface of such biological compatibility with osteoblasts (bone-forming cells) that these cells lay down bone in direct apposition to the material in some form of direct chemicophysical bond. Special compositions of glass ceramics, termed bioglasses, have been used for implant applications in orthopedics. The model proposed for the "chemical" bond formed between glass and bone is that the former undergoes a controlled surface degradation, producing an SiO-rich layer, and a Ca, P-rich layer at the interface. Originally amorphous, the Ca, P-rich layer eventually crystallizes as a mixed hydroxycarbonate apatite structurally integrated with collagen, which permits subsequent bonding by newly-formed mineralized tissues. There is still an entirely different series of inorganic compounds that have also been shown to be osteophilic. These include OHAp, which is the form of the naturally occurring inorganic component of calcified tissues, and calcite, $CaCO$, and its Mg analog, dolomite, among others being studied. The most extensive applications in both orthopedics and dentistry have involved OHAp. This has been used as a cladding for metal prostheses for the former, and in dense, particulate form for the latter. The elastic properties (modulus) of OHAp and related compounds are compared with those of bone, dentin, and enamel in Table II.5.6.2. The use of both OHAp and glass ceramics as cladding on the metallic stems of hip prostheses is still another method of providing fixation instead of using PMMA.

TABLE II.5.6.2	Mechanical Properties of Dominant Orthopedic Biomaterials							
Orthopedic Biomaterial	ASTM Designation	Trade Name and Company	Elastic Modulus (Young's Modulus)	Yield Strength (Elastic limit)	Ultimate Strength	Fatigue Strength (Endurance Limit)	Hardness	Elongation at Fracture

RC: Rockwell Hardness Scale.

In these cases, the fixation is via the direct bonding of bone to the cladding surface.

Metals

Since the principal function of the long bones of the lower body is to act as loadbearing members, it was reasonable that the initial materials introduced to replace joints, such as artificial hips, were metals. Both stainless steel, such as 316L, and cobalt–chromium alloys became the early materials of choice, because of their relatively good corrosion resistance and reasonable fatigue life within the human body. Of course, their stiffness, rigidity, and strength exceeded those of bone considerably. However, in certain applications, owing to size restrictions and design limitations (e.g., in rods used to straighten the spine in scoliosis), fatigue failures did occur. Metals remain the central material component of state-of-the-art total hip arthroplasties. Metals provide appropriate material properties, such as high strength, ductility, fracture toughness, hardness, corrosion resistance, formability, and biocompatibility necessary for use in loadbearing roles required in fracture fixation and total joint arthroplasty (TJA). Implant alloys were originally developed for maritime and aviation uses, where mechanical properties such as high strength and corrosion resistance are paramount. There are three principal metal alloys used in orthopedics and particularly in total joint replacement: (1) titanium-based alloys; (2) cobalt-based alloys; and (3) iron-(stainless steel) based alloys. The alloy's specific differences in strength, ductility, and hardness generally determine which of these three alloys is used for a particular application or implant component. However, it is the high corrosion resistance of all three alloys, more than anything, which has led to their widespread use as loadbearing implant materials. These material properties of metals (Table II.5.6.2) are due to the miraculous nature of the metallic bond, atomic microstructure, and elemental composition of alloys.

Stainless Steel Alloys

Stainless steels were the first metals to be used in orthopedics in 1926. However, it was not until 1943, when ASTM 304 was recommended as a standard implant alloy material, that steels were reliable as an implant alloy. All steels are comprised of iron and carbon, and may typically contain chromium, nickel, and molybdenum. Trace elements such as manganese, phosphorous, sulfur, and silicon are also present. Carbon and the other alloy elements affect the mechanical properties of steel through alteration of its microstructure.

The form of stainless steel most commonly used in orthopedic practice is designated 316LV (American Society for Testing and Materials F138, ASTM F138; others include F139, F899, F1586, F621, etc). "316" classifies the material as austenitic, the "L" denotes the low carbon content, and "V" defines the vacuum under which it is formed. The carbon content must be kept at a low level to prevent carbide (chromium–carbon) accumulation at the grain boundaries.

Although the mechanical properties of stainless steels are generally less desirable than those of the other implant alloys (lower strength and corrosion resistance), stainless steels do possess greater ductility, indicated quantitatively by a three-fold greater "percentage of elongation at fracture" when compared to other implant metals (Table II.5.6.2). This aspect of stainless steel has allowed it to remain popular as a material for cable fixation components in total knee arthroplasty, and a low cost alternative to titanium and cobalt alloys.

Cobalt–Chromium Alloys

Of the many Co–Cr alloys available, there are currently only two predominantly used as implant alloys (Table II.5.6.3). These two are: (1) cobalt–chromium–molybdenum (CoCrMo), which is designated ASTM F75 and F76; and (2) cobalt–nickel–chromium–molybdenum (CoNiCrMo) designated as ASTM F562. Other cobalt alloys approved for implant use include one which incorporates tungsten (W) (CoCrNiW, ASTM F90), and another with iron (CoNiCrMoWFe, ASTM F563). Co–Ni–Cr–Mo alloys which contain large percentages of nickel (25–37%) promise increased corrosion resistance, yet raise concerns of possible toxicity and/or immunogenic reactivity (discussed later) from released nickel. The biologic reactivity of released nickel from Co–Ni–Cr alloys is a cause for concern under static conditions, and due to their poor frictional (wear) properties Co–Ni–Cr alloys are also inappropriate for use in articulating components. Therefore the dominant implant alloy used for total joint components is CoCrMo (ASTM F75).

Cobalt alloys are generally cast into their final shape, because they are susceptible to work-hardening at room temperatures. The improvements in strength and hardness gained by cold-working are not worth the loss in fracture toughness. Thus, Co–Cr–Mo alloy hip implant components are predominantly manufactured using lost wax (investment) casting methods.

Although Co–Cr–Mo alloys are the strongest, hardest, and most fatigue resistant of the alloys used for joint replacement components, care must be taken to maintain these properties, because the use of finishing treatments can also reduce these same properties (Table II.5.6.2). For example, sintering of porous coatings onto femoral or tibal TJA Co–Cr–Mo stems can decrease the fatigue strength of the alloy from 200–250 MPa to 150 MPa after heating (annealing) the implant at 1225°C.

Titanium Alloys

Titanium alloys were developed in the mid-1940s for the aviation industry, and were first used in orthopedics

TABLE II.5.6.3	Approximate Weight Percent of Different Metals Within Popular Orthopaedic Alloys													
Alloy	Ni	N	Co	Cr	Ti	Mo	Al	Fe	Mn	Cu	W	C	Si	V
Stainless steel (ASTM F138)	10–15.5	<0.5	*	17–19	*	2–4	*	61–68	*	<0.5	<2.0	<0.06	<1.0	*

TABLE II.5.6.4	Electrochemical Properties of Implant Metals (Corrosion Resistance) in 0.1 M NaCl at pH=7				
Alloy	ASTM Designation	Density	Corrosion Potential (vs Calomel)	Passive Current Density	Breakdown Potential
		(g/cm³)	(mVolts)	(mAmps/cm²)	(mVolts)
Stainless steel	ASTM F138	8.0	−400	0.56	200–770
Co–Cr–Mo Alloys					
	ASTM F75	8.3	−390	1.36	420
Ti Alloys					
CPTi	ASTM F67	4.5	−90 to −630	0.72–9.0	>2000
Ti-6Al-4V	ASTM 136	4.43	−180 to −510	0.9–2.0	>1500
Ti5Al2.5Fe	**	4.45	−530	0.68	>1500
Ni45Ti	**	6.4–6.5	−430	0.44	890

** No current ASTM standard.
The Corrosion Potential represents the open circuit potential (OCP) between the metal and a calomel electrode. The more negative the OCP, the more chemically reactive and thus the less corrosion resistance. Generally low current density indicates greater corrosion resistance. The higher the breakdown potential the better, (i.e. the more elevated the breakdown potential, the more stable the protective layer).

around the same time. Two post-World War II alloys, commercially pure titanium (CPTi) and Ti-6Al-4V, remain the two dominant titanium alloys used in implants. Commercially pure titanium (CPTi, ASTM F67) is 98–99.6% pure titanium. While CPTi is most commonly used in dental applications, the stability of the oxide layer formed on CPTi, and consequently its high corrosion resistance (Table II.5.6.4), and its relatively higher ductility (i.e., the ability to be cold-worked) compared to Ti-6Al-4V, has led to the use of CPTi in porous coatings (e.g., fiber metal) of TJA components. Generally, joint replacement components (i.e., TJA stems) are made of Ti-6Al-4V (ASTM F136) Nb rather than CPTi, because of its superior mechanical properties (Table II.5.6.2).

Titanium alloys are particularly good for THA components because of their high corrosion resistance compared with stainless steel and Co–Cr–Mo alloys. A passive oxide film (primarily of TiO_2) protects both Ti-6Al-4V and CPTi alloys. Generally, Ti-6Al-4V has mechanical properties that exceed those of stainless steel, with a flexural rigidity less than stainless steel and Co–Cr–Mo alloys. The torsional and axial stiffness (moduli) of Ti alloys are closer to those of bone, and theoretically provide less stress shielding than cobalt alloys and stainless steel. However, titanium alloys are particularly sensitive to geometrical factors, in particular notch sensitivity. This reduces the effective strength of a component by increasing the material's susceptibility to crack initiation and propagation through the component. Therefore, care is taken both in the design geometry and in the fabrication of titanium alloy components. Perhaps the greatest drawback of titanium alloys is their relative softness compared with Co–Cr–Mo alloys (Table II.5.6.2), and their relatively poor wear and frictional properties. Ti-6Al-4V is >15% softer than Co–Cr–Mo alloy, and also results in significantly more wear than Co–Cr–Mo when used

in applications requiring articulation, e.g., total knee arthroplasty (TKA) or THA femoral heads. Thus, titanium alloys are seldom used as materials where hardness or resistance to wear is the primary concern.

NEW ALLOYS AND SURFACE COATINGS

The quest for new THA metal alloys with improved biocompatibility and mechanical properties remains an ongoing one. The use of Ti alloys, Co–Cr–Mo alloys or stainless steels in a specific application generally involves trade-offs of one desirable property for another. Some examples of this are the sacrifice of chemical inertness for hardness (wear resistance), as is the case with titanium alloy for Co–Cr–Mo in TJA bearing surfaces, and the compromise of strength for ductility when using stainless steel instead of titanium and Co–Cr–Mo alloys for bone fixation cables. Although new alloys claim to be just that, "new," they are often merely variations of the three categories of implant metals previously described (which are already approved for use). These improved alloys usually contain only the minor addition of new elements to protect assertions of substantial equivalence to existing ASTM and FDA approved alloys, therefore easing the burden of regulatory approval. These new alloys generally fall under one of four categories, i.e.: (1) titanium alloys; (2) cobalt alloys; (3) stainless steels; and less approved (4) refractory group metals and alloys.

New Zirconium and Tantalum Alloys

Zirconium (Zr) and tantalum (Ta) are characterized as refractory metals (others include molybdenum and tungsten) because of their relative chemical stability (passive oxide layer) and high melting points. Because of its high strength, chemical stability, and resistance to wear, alloys such as zirconium (e.g., Oxinium™) are likely to gain popularity as orthopedic biomaterials. Because of their surface oxide layer's stability, zirconium and tantalum are highly corrosion resistant. Corrosion resistance generally correlates with biocompatibility (although not always), because more stable metal oxides tend to be less chemically active and/or biologically available and are thus less participatory in biologic processes. This enhanced biocompatibility is produced by the relatively thick surface oxide layer (approximately 5 micrometers), and the ability to extend ceramic-like material properties (i.e., hardness) into the material through techniques such as oxygen enrichment. This has resulted in the production of new implant components using these alloys (see Figure II.5.6.11) (e.g., oxidized zirconium TKA femoral components, Smith and Nephew, Inc.). Although, new zirconium alloys such as Oxinium™ generally possess high levels of hardness (12 GPa) and wear resistance (approximately 10-fold that of cobalt and titanium alloys, using abrasion testing), which makes them well-suited for bearing surface applications, they are costly

FIGURE II.5.6.11 Examples of new THA and TKA oxidized zirconium components currently gaining opopularity because of enhanced mechanical and biocompatibility properties (Oxinium™, Smith and Nephew, Inc., Memphis, TN, USA). (Photographs courtesy of Smith and Nephew, Inc.)

to manufacture and currently are sought after in special circumstances where issues such as a metal allergy (or more accurately metal hypersensitivity) require particular attention to biocompatibility. As difficulties associated with the cost of forming and machining these metals are overcome, the use of these materials is expected to grow (Black, 1992).

New Titanium Alloys

One new group of titanium alloys put forward for orthopedic component uses molybdenum at concentrations greater than 10%. The addition of molybdenum acts to stabilize the BCC (Body Centered Cubic) (beta) phase at room temperature; thus these alloys are referred to as beta titanium alloys. These beta titanium alloys promise 20% lower moduli, which are closer to bone and thus provide better formability with maintenance of other mechanical properties typical of Ti-6-4.

Other attempts at improving traditional Ti-6Al-4V alloys seek to improve biocompatibility and mechanical properties by the substitution of vanadium (a relatively toxic metal) with other less toxic metals. Two such titanium alloys include Ti5Al2.5Fe and Ti6Al7Nb, which substitute iron and niobium for vanadium, respectively. These alloys have similar properties to traditional Ti-6-4, yet they claim higher fatigue strength and a lower modulus, thus enhancing bone to implant load transfer.

New Cobalt Alloys

Some "newer" cobalt alloys are identical in composition to traditional alloys, but use novel processing techniques to manipulate the microstructure of the implant materials to improve their mechanical properties. One such example recently patented, TJA-1537, although compositionally identical to ASTM F75, claims enhanced wear resistance and fatigue strength through elimination of carbide, nitride, and second phase particles (Allegheny Technologies). These particles normally form at the grain boundaries within a standard F75 CoCrMo alloy, and act to decrease wear and fatigue resistance. Other new cobalt alloys under development for use in orthopedics seek to improve biocompatibility by eliminating nickel, and improve mechanical properties by reducing the carbon content, thus avoiding carbide precipitation at grain boundaries.

New Stainless Steels

Because of the desirable cost, machinability, and ductility of stainless steels, there are still efforts to improve its mechanical properties to compete with cobalt and titanium alloys. The relatively poor corrosion resistance and biocompatibility of stainless steels when compared to titanium and Co–Cr–Mo alloys provide
FIGURE II.5.6.12 Examples of currently used surface coatings on stems of THA to enhance both short- and long-term fixation.

incentives for development of improved stainless steels. New alloys such as BioDur® 108 (Carpenter Technology Corp.) attempt to solve the problem of corrosion with an essentially nickel-free austenitic stainless alloy. This steel contains a high nitrogen content to maintain its austenitic structure, and boasts improved levels of tensile yield strength, fatigue strength, and improved resistance to pitting corrosion and crevice corrosion, as compared to nickel-containing alloys such as Type 316L (ASTM F138).

Surfaces and Coatings

A variety of surface coatings are currently used to enhance the short- and long-term performance of implants by encouraging bone ingrowth and providing enhanced fixation. These different surfaces include roughened titanium, porous coatings made of cobalt chromium or titanium beads, titanium wire mesh (fiber mesh), plasma-sprayed titanium, and bioactive non-metallic materials such as hydroxyapatite or other calcium phosphate compositions (Figure II.5.6.12). Currently osteoconductive and osteoinductive growth factors such as transforming growth factor beta (TGF beta) are being developed for use as osteogenic surface coating treatments to enhance orthopedic implant fixation.

ORTHOPEDIC BIOMATERIALS: CLINICAL CONCERNS

Implant biocompatibility/performance is dependent on the type and amount of degradation produced by wear and electrochemical corrosion. Host response to orthopedic implant debris is central to clinical performance (Willert and Semlitsch, 1977). Implant loosening due

to aseptic osteolysis accounts for over 75% of TJA implant failure, and is the predominant factor limiting the longevity of current total joint arthroplasties; other reasons include infection (7%), recurrent dislocation (6%), periprosthetic fracture (5%), and surgical error (3%) (Holt et al., 2007). Properly positioned implants tend to wear at predictable rates. However, there are variable amounts of debris-induced bone loss around implants in patients with similar rates of implant wear (i.e., debris generation). It is commonly noted that some individuals with severely worn components can demonstrate little periprosthetic bone loss, while others with modest amounts of wear can demonstrate extensive osteolysis and implant loosening (Willert et al., 1990; Huo et al., 1992; Jacobs et al., 1992; Jasty et al., 1994; Huk et al., 1994; Schmalzried et al., 1994; Harris, 1995; Thompson and Puleo, 1995; Yao et al., 1995; Goodman et al., 1998; Granchi et al., 1998; Jones et al., 1999; von Knoch et al., 2000). Debris-induced immune reactivity, aseptic inflammation, and subsequent early failure can be as high as 4–5% at 6–7 years post-operatively in current generation metal-on-metal total hip arthroplasties (Jacobs and Hallab, 2006; Korovessis et al., 2006; Milosev et al., 2006). The benefits provided to patients by orthopedic implants in terms of pain, mobility, and quality of life, are immeasurable. Therefore, the following sections which focus on the problems associated with implants, seek to provide the student of biomaterials with a foundation for understanding the relevant issues for orthopedic research and are not intended to serve as an indictment of orthopedic materials.

Despite their overwhelming success over the long term (>7 years), orthopedic biomaterials have been associated with adverse local and remote tissue responses. It is generally the degradation products of orthopedic biomaterials (generated by wear and electrochemical corrosion) which mediate these adverse effects. This debris may be present as particulate wear, colloidal nanometer size complexes (specifically or non-specifically bound by protein), free metallic ions, inorganic metal salts/oxides or in an organic storage form such as hemosiderin. Clinical aspects of biocompatibility regarding polymer and metal release from orthopedic prosthetic devices have taken on an increasing sense of urgency, due to the escalating rates of people receiving implants and the recognition of extensive implant debris within local and remote tissues. Particulate debris has enormous specific surface areas available for interaction with the surroundings and chronic elevations in serum metal content. Clinical issues associated with biomaterial degradation can be broken down into four basic questions: (l) how much material is released from the implant; (2) where is the material transported to and in what quantity; (3) what is the chemical form of the released degradation products (e.g., inorganic precipitate versus soluble organometallic complex); and (4) what are the pathophysiological interactions and consequences

of such degradation? The answers to these questions, over the long term, remain largely unknown. There is a growing body of literature addressing the issues associated with the first two questions. However, little is currently known with regard to the latter two questions. The remainder of this chapter will focus on that which is known (and of orthopedic clinical concern) regarding biomaterial degradation (through wear and electrochemical corrosion), dissemination of debris, and consequent local/systemic effects.

Orthopedic Biomaterial Wear

The generation of wear debris, and the subsequent tissue reaction to such debris, is central to the longevity of total joint replacements. In fact, particulate debris is currently extolled as the primary factor affecting the long-term performance of joint replacement prostheses, and the primary source of orthopedic biomaterial degradation (based on overall implant mass or volume lost). Particulate debris generated by wear, fretting or fragmentation induces the formation of an inflammatory reaction, which at a certain point promotes a foreign–body granulation tissue response that has the ability to invade the bone–implant interface. This commonly results in progressive local bone loss that threatens the fixation of both cemented and cementless devices (Jacobs et al., 1994b; Jacobs, 1995; Jacobs et al., 2001).

Mechanisms of Wear Debris Generation

Wear involves the loss of material in particulate form as a consequence of relative motion between two surfaces. Two materials placed together under load will only contact over a small area of the higher peaks or asperities. Electro-repulsive and atomic binding interactions occur at the individual contacts and, when the two surfaces slide relative to one another, these interactions are disrupted; this results in the release of material in the form of particles (wear debris). The particles may be lost from the system, transferred to the counterface or remain between the sliding surfaces. There are primarily three processes which can cause wear: (1) abrasion – by which a harder surface "plows" grooves in the softer material; (2) adhesion – by which a softer material is smeared onto a harder counter surface forming a transfer film; and (3) fatigue – by which alternating episodes of loading and unloading result in the formation of subsurface cracks which propagate to form particles that are shed from the surface.

Wear Rates. During an initial "wearing in" period, the relative motion of surfaces causes a large number of asperities to break, resulting in a high wear rate. After this initial period, the actual contact area increases and the two surfaces can be said to have adapted to one other. Over time, the wear rates decrease and eventually become linearly dependent on the contact force and

sliding distance represented by the steady-state wear equation:

$$V = KFx$$

where V is volumetric wear (mm³/year), K is a material constant of the material couple, F is the contact force (N) and x is the distance of relative travel (mm).

Different types of orthopedic materials and couples produce different amounts and kinds of wear debris. Hard-on-hard material couples such as metal-on-metal articulations generally produce less wear (weight loss) than metal-on-polymer (see Figure II.5.6.13). There is a great deal of variability associated with *in vivo* wear rates of orthopedic biomaterials, which are generally measured by radiographic follow-up studies. Radiographic wear measurements are expressed as linear wear rates, whereas *in vitro* studies generally report volumetric wear. Volumetric wear can be directly related to the number of wear particles released into periprosthetic fluids (typically in the order of 1×10^9 of particles per

year). The most common wear couple for hip and knee arthroplasty currently in use in the US is a cobalt-based alloy head (most commonly a Co–Cr–Mo alloy ASTM F75) bearing on an ultra-high molecular weight polyethylene (UHMWPE) cup or liner. The linear wear rates of this couple are generally in the order of 0.1 mm/year, with particulate generation as high as 1×10^6 particles per step or per cycle. Clinically, implant wear rates have been found to increase with the following: (1) physical activity; (2) weight of the patient; (3) size of the femoral head (32 versus 28 millimeters); (4) roughness of the metallic counterface; and (5) oxidation of the polyethylene (Jacobs et al., 1994a; Jacobs, 1995; Jacobs et al., 2001).

Although well established in the hip and knee, newer spinal implants are now undergoing the same types of analyses to try to assess which type of implant works best. The following two basic types of articulating bearing designs are available in spine, knee, and hip arthroplasties.
FIGURE II.5.6.13 A comparison of the amount of wear debris generated from different types of total joint arthroplasties. There is relatively less (10×) polymeric debris generated by a total disc arthroplasty with a metal-on-polymer articulation. Note: Figure References: Metal-Poly (Holt et al., 2007); Ceramic-Poly (Jacobs et al., 1994c); Metal-X-linked Poly (Martinon et al., 2006); Metal-X-linked Poly (Jacobs et al., 1994c); Metal-X-linked Poly (Hallab, 2009); Metal-X-linked Poly (Hallab, 2009); Metal-Metal (Huk et al., 1994); Ceramic-Ceramic (Hallab, 2009); Metal-UHMWPE TDA (Hallab, 2009); Metal-Metal TDA (Hallab, 2009).

Metal-on-polymer spine arthroplasty wear. *In vitro* analysis of wear has demonstrated wear rates of metal-on-polymer bearing lumbar total disc arthroplasty devices range from 2 to 20.8 mm^3 per million cycles (Pare et al., 2007; Popoola et al., 2007), where the size of the wear debris generally ranges from 0.1 μm to 100 microns in diameter UHMWPE (Anderson et al., 2003; Popoola et al., 2007; van Ooij et al., 2007; Hallab et al., 2008). This amount of debris is 10-fold less wear than THAs and TKAs that are composed of metal on highly cross-linked polyethylene (x-UHMWPE) bearing surfaces (Greenwald and Garino, 2001; Kurtz et al., 2005).

Metal-on-metal spinal arthroplasty wear. In general the wear of metal-on-metal TJA is well below that of metal-on-polymer (Figure II.5.6.13) (Wroblewski et al., 1996; Saikko et al., 2002; Tipper et al., 2002; Catelas et al., 2004; Heisel et al., 2004; Kurtz et al., 2005; Minoda et al., 2005; Callaghan et al., 2007). The few published reports on the volumetric wear rates of metal-on-metal disc arthroplasty prostheses indicate a wear rate of 0.93–1.26 mm^3 per million cycles (cobalt alloy) (Firkins et al., 2001; Pare et al., 2007). Another study of an all titanium-6%Al-4%V alloy disc arthroplasty found wear rates to be as high as 3 mm^3 per million cycles (Hellier et al., 1992). These values are similar to those reported for metal-on-metal hip replacements, which have been shown to range from approximately 0.05 to 6 mm^3 per million cycles (cobalt alloy) (McKellop et al., 1996; Clarke et al., 2000; Catelas et al., 2004). Long-term follow-up of patients undergoing total disc arthroplasty is required to assess how intimately wear will correlate with inflammation and poor implant performance.

Orthopedic Biomaterial Corrosion

Electrochemical corrosion occurs to some extent on all metallic surfaces including implants. This is undesirable for two primary reasons: (1) the degradative process may reduce structural integrity of the implant; and (2) the release of products of degradation is potentially toxic to the host. Metallic biomaterial degradation may result from electrochemical dissolution phenomena or wear, but most commonly occurs through a synergistic combination of the two. Electrochemical processes include generalized corrosion uniformly affecting an entire surface, and localized corrosion affecting either areas of a device relatively shielded from the environment (crevice corrosion) or seemingly random sites on the surface (pitting corrosion). Additionally, these electrochemical and other mechanical processes interact, potentially causing premature structural failure and/or accelerated metal release (e.g., stress corrosion cracking, corrosion fatigue, and fretting corrosion) (Brown and Merritt, 1981; Cook et al., 1983; Bundy et al., 1991; Brown et al., 1992; Collier et al., 1992b; Gilbert and Jacobs, 1997).

Corrosion Mechanisms

Corrosion of orthopedic biomaterials is a multifactorial phenomenon, and is dependent on five primary factors: (1) geometric variables (e.g., taper crevices in modular component hip prostheses); (2) metallurgical variables (e.g., surface microstructure, oxide structure and composition); (3) mechanical variables (e.g., stress and/or relative motion); (4) solution variables (e.g., pH, solution proteins, enzymes); and (5) the mechanical loading environment (e.g., degree of movement, contact forces, etc.). Current investigational efforts to minimize the corrosion of orthopedic biomaterials deal directly with the complex interactions of these factors.

There are two essential features associated with how and why a metal corrodes. The first has to do with thermodynamic driving forces, which cause corrosion (oxidation/reduction) reactions. In general, whether or not corrosion will take place under the conditions of interest depends on the chemical driving force (ΔG), and the charge separation. This separation contributes to what is known as the electrical double layer (Figure II.5.6.14) which creates an electrical potential across the metal–solution interface (much like a capacitor):

$$\Delta G = -nF\Delta E$$

where *n* is the valence of the ion, *F* is the Faraday constant (95,000 coulombs/mole electrons), and *E* is the voltage across the metal solution interface. This potential is a measure of the reactivity of the metals or the driving force for metal oxidation. Therefore, the more negative the potential of a metal in solution, the more reactive it will tend to be (i.e., the greater is ΔG for reduction).

The second factor governing the corrosion process of metallic biomaterials is the kinetic barrier to corrosion (e.g., surface oxide layer). Kinetic barriers prevent corrosion not by energetic considerations, but by physically limiting the rate at which oxidation or reduction processes can take place. The well-known process of passivation or the formation of a metal–oxide passive film on a metal surface is one example of a kinetic limitation to corrosion. In general, kinetic barriers to corrosion prevent either the migration of metallic ions from the metal to the solution, the migration of anions from solution to metal, or the migration of electrons across the metal–solution interface. Passive oxide films are the most well-known forms of kinetic barriers in corrosion, but other kinetic barriers exist, including polymeric coatings (Gilbert and Jacobs, 1997; Jacobs et al., 1998a).

Passivating Oxide Films

Most alloys used in orthopedic appliances rely on the formation of passive films to prevent significant oxidation from taking place. These films consist of metal oxides, which form spontaneously on the surface of the
FIGURE II.5.6.14 Schematic of the interface of a passivating alloy surface in contact with a biological environment.

metal in such a way that they prevent further transport of metallic ions and/or electrons across the film. Passive films must have certain characteristics to be able to limit further oxidation. The films must be compact and fully cover the metal surface, they must have an atomic structure which limits the migration of ions and/or electrons across the metal–oxide–solution interface, and they must be able to remain on the surface of these alloys even with the mechanical stress and abrasion which can be expected with orthopedic devices.

Passivating oxide films, which spontaneously grow on the surface of many metals and alloys, have five primary structural and physical characteristics, which are particularly relevant to implant degradation processes:

1. First, these oxide films are very thin, typically in the order of 5–70 Å which depends on the potential across the interface as well as solution variables

(e.g., pH). Furthermore, the oxide structure may be amorphous or crystalline. Since the potentials across the metal solution interface for these reactive metals are typically 1–2 volts, the electric field across the oxide is very high, in the order of 10^6–10^7 V/cm. One of the more widely accepted models is based on the theory of Mott and Cabrera, which states that oxide film growth depends on the electric field across the oxide. If the potential across the metal–oxide–solution interface is decreased (i.e., made closer to the electrochemical series potential), then the film thickness will decrease by reductive dissolution processes at the oxide. If the interfacial potential is made sufficiently negative or the pH of the solution is made low enough, then these oxide films will no longer be thermodynamically stable, and will undergo reductive dissolution without which corrosion will increase (Gilbert and Jacobs, 1997; Jacobs et al., 1998a).

2. Second, oxide films have the characteristics of semi-conductors with an atomic defect structure, which determines the ability for ionic and electronic transport across films. Metal cations and oxygen anions require the presence of cationic or anionic vacancies (respectively) in the oxide for transport of these species across the film. If there is a deficit of metal ions in the oxide film (i.e., there are cationic vacancies), for example, then metal ion transport is possible and these oxides are known as p-type semiconductors. Chromium oxide (Cr_2O_3) is such a metal-deficit oxide. On the other hand, if there is an excess of metal ions in the oxide (or a deficit of anions) then cation transport is limited, but anion transport can occur. These oxides will also have excess electrons and are known as n-type semiconductors. TiO_2 spontaneously formed on titanium alloy implant (Ti-6Al-4V) surfaces is one such n-type semiconductor. The greater the number of defects (vacancies or other valence species), the less able is the oxide film to prevent migration of ionic species, and the lower is the kinetic barrier to corrosion. TiO_2 is very close to being stoichiometric (chemically homogeneous) and hence does not have many ionic defects, resulting in an increased resistance to ionic transport. Other defects may be present in these passive oxide films which may alter their ability to limit corrosion. For instance, the addition of other metal ions with valence states which are different from the native metal ions can alter both the electronic and ionic transport of charge across the interface. These additions may enhance or degrade the ability of the oxide to prevent corrosion, depending on the nature of the oxide. One example of improved corrosion resistance from mixed oxides comes from what is known as a spinel. Spinels are typically mixed oxides of the form (A_2O_3)BO, where A and B are +3 and +2 valence metal ions. In Co–Cr alloys, for instance, a spinel of (Cr_2O_3)CoO can form on the surface. Spinels are typically known to have higher strengths and better resistance to diffusion of ions compared to single metal ion oxides. Therefore, a high concentration of spinels in the oxide layer will act to resist dissolution of a metal implant (Gilbert and Jacobs, 1997; Jacobs et al., 1998a).

3. Third, the ratio of the "oxide specific volume" to metal alloy specific volume (i.e., Pilling Bedworth ratio) will determine if the oxide will adhere to the metal or not. If there is too great a mismatch between the metal and oxide lattice parameters, then consequential stresses will be generated between the two. The magnitude of the internal stress will vary with the thickness of the oxide. Too great an oxide thickness will thus result in spontaneous fracture or spalling of the oxide, lowering the kinetic barrier effect of the oxide to corrosion (Gilbert and Jacobs, 1997; Jacobs et al., 1998a).

4. Fourth, the morphology of these oxide films is not one of a smooth, flat, continuous sheet of adherent oxide covering the metal. Transmission electron microscopy (TEM) and atomic force microscopy (AFM) techniques have shown that oxides of titanium, for instance, consist of needle or dome shapes. The size and shape of these oxide domes change with applied potential when immersed in oxalic and other acids (Gilbert and Jacobs, 1997; Jacobs et al., 1998a).

5. Finally, mechanical factors such as fretting, micro-motion or applied stresses may abrade or fracture oxide films. When an oxide film is ruptured from the metal substrate, fresh unoxidized metal is exposed to solution. When these films reform or repassivate, the magnitude of the repassivation currents which are subsequently generated may be large. This is because large driving forces exist for oxidation, and when the kinetic barrier is removed these large driving forces can operate to cause oxidation. However, the extent and duration of the oxidation currents will depend on the repassivation kinetics for oxide film formation. Hence, the mechanical stability of the oxide films, as well as the nature of their repassivation process, are central to the performance of oxide films in orthopedic applications (Gilbert and Jacobs, 1997; Jacobs et al., 1998a).

Corrosion at Modular Interfaces of Joint Replacements

One issue associated with orthopedic alloys is the corrosion observed in the taper connections of retrieved modular joint replacement components (Figure II.5.6.15). With the growing number of total joint designs which use metal-on-metal conical tapers as modular connectors between components, the effects of crevices, stress, and motion take on increasing importance. Severe corrosion attack can take place in the crevices formed by these tapers *in vivo*. Gilbert et al. (1993) have shown that, of 148 retrieved implants, approximately 35% showed signs of moderate to severe corrosion attack in the head–neck taper connections of total hip prostheses. This attack was observed in components which consisted of Ti-6Al-4V alloy stems and Co–Cr heads, as well as Co–Cr stems on Co–Cr heads. This corrosion process is the result of a combination of stress and motion at the taper connection, and the crevice geometry of the taper; the stresses resulting from use cause fracturing and abrasion of the oxide film covering these passive metal surfaces. This, in turn, causes significant changes in the metal surface potential (makes it more negative) and in the crevice solution chemistry as the oxides continuously fracture and repassivate. These changes may result in deaeration (loss of O_2) of the crevice solution, and a lowering of the pH in the crevice as is expected in crevice corrosion attack. The ultimate result of this process is a loss of the oxide film and its kinetic barrier effect, and an increase in

FIGURE II.5.6.15 Modular junction taper connection of a total hip arthroplasty showing corrosion of the taper connections. Macrograph of deposits of $CrPO_4$ corrosion particles on the rim of a modular cobalt–chrome femoral head.

the rate of corrosive attack in the taper region. The corrosion processes in the Co–Cr alloys have been observed to consist of intergranular corrosion, etching, selective dissolution of cobalt, and the formation of Cr-rich particles. In isolated cases, this occurs to such an extent that intergranular corrosion caused fatigue failure in the neck of a Co–Cr stem. Corrosion attack of titanium alloy stems has also been observed in some cases.

Very little is known about the mechanical stability of passive oxide films and the electrochemical reactions (e.g., ion and particle release) which occur when the oxide film is fractured. What is known is that when the oxide films of these orthopedic alloys are abraded or removed from the surface by rubbing, the open circuit potential can decrease to as low as –500 mV (versus Standard Calomel Electrode). These voltage potentials may be significant and prolonged enough to cause changes in the oxide structure and stability by bringing the interface potential into the active corrosion range of the alloy, thereby dramatically accelerating the corrosion rate and decreasing implant performance (Brown et al., 1992; Collier et al., 1992a; Gilbert et al., 1993; Bobyn et al., 1994; Brown et al., 1995).

Implant Debris Types: Particles and Ions

The degradation products of all orthopedic implants are one of two basic types: particles or soluble debris (metal ions). While there is a large distinction between the two (ions versus particles), the difference between them blurs as the size of particles decreases into the nanometer range and becomes essentially "in solution." Typically, particulate wear debris (metal, ceramic or polymer) exists from the submicron size up to thousands of microns (mm), while so-called "soluble debris" is limited to metal ions (or nanoparticles that are too small to be distinguished from ions) that are bound to plasma proteins.
Particulate Debris. Different types of joint arthroplasty designs not only produce different amounts and kinds of wear debris, but also different sizes and shapes of debris that are specific to the type of implant materials used for the bearing interfaces. For instance, hard-on-hard material couples such as metal-on-metal articulations generally produce smaller-sized (submicron), fairly round

debris, whereas traditional metal-on-polymer bearings produce larger (micron-sized) debris that is more elongated in shape (see Figure II.5.6.16).

As is evident in Figure II.5.6.16, hard-on-hard material couples (e.g., metal-on-metal) produce smaller debris than do hard-on-soft material couples (e.g., metal on polyethylene). The particles produced from articulating bearing in any metal-on-polymer bearing implants are dominated by polymer particles, with little metallic debris unless there are other sources of metal release, such as corrosion at metal–metal connections. Polymeric particles produced from implants generally fall into the range from 0.23 to 1 μm (Figure II.5.6.16). Past investigations, primarily of UHMWPE wear debris in peri-implant tissues, have shown that 70–90% of recovered particulates were submicron, with the mean size being approximately 0.5 μm (Maloney et al., 1993; Jacobs et al., 1994a; Campbell et al., 1995). Metal and ceramic particles have generally been characterized as an order of magnitude smaller than polymer particles (at approximately 0.05 μm in diameter).

Histological Identification of Particles *In Vivo*

The tissues surrounding modern implants may include areas of osseointegration, fibrous encapsulation, and a variable presence of the foreign-body response to polyethylene and cement debris in joint replacement devices. Absent is any specific histologic evidence of the slow release of metallic species that is known to occur with all metallic implants. However, accelerated corrosion and a tissue response that can be directly related to identifiable corrosion products can be demonstrated in the tissues surrounding multi-part devices (Urban et al., 2000).

1. **Stainless steels:** Histological sections of the tissues surrounding stainless steel internal fixation devices generally show encapsulation by a fibrous membrane, with little or no inflammation over most of the device. At screw plate junctions, however, the membranes often contain macrophages, foreign-body giant cells, and a variable number of lymphocytes in association
FIGURE II.5.6.16 Implant debris from four types of materials are shown where the metal (cobalt alloy and titanium) and ceramic (alumina) debris are more rounded versus the polymeric (UHMWPE) debris which is more elongated in shape. Note: Bar = 5 μm.

with two types of corrosion products. The first consists of iron-containing granules. The second, termed microplates, consists of relatively larger particles of a chromium compound. Microplates are found within the tissues as closely packed, plate-like particle aggregates ranging in size from 0.5 mm to 5.0 mm.

Hemosiderin–like granules often surround the collections of microplates, but the granules are also found alone. The granules are yellow–brown, mainly spherical, and 0.1–3 or more micrometers in diameter. They are predominantly intracellular, most often in macrophages, but may also be found in other periprosthetic cells (e.g., fibroblasts). X–ray diffraction has indicated that the granules consist of a mixture of two or more of the iron oxides, αFe_2O_3 and σFe_2O_3, and the hydrated iron oxides, $\alpha Fe_2O_3 \cdot H_2O$ and $\sigma Fe_2O_3 \cdot H_2O$.

2. **Cobalt–based alloys:** The nature of corrosion at modular connections are similar, whether modular heads are mated with cobalt–chromium alloy or Ti–6Al–4V alloy femoral stems. The principal corrosion product identified by electron microprobe energy-dispersive X–ray analysis and Fourier transform infrared microprobe spectroscopy is a chromium-phosphate

$(Cr(PO_4)4H_2O)$ hydrate-rich material termed "orthophosphate." This corrosion product can be found at the modular head–neck junction and as particles within the joint capsules, at the bone–implant interfacial membranes, and at sites of femoral osteolytic lesions. Particles of the orthophosphate material have been found at the bearing surface of the UHMWPE acetabular liners, suggesting their participation in three-body wear and an increased production of polyethylene debris. Particles of the chromium orthophosphate hydrate-rich corrosion product found in the tissues ranged in size from submicron to aggregates of particles up to 500 micrometers.

3. **Titanium-based alloys:** The degradation products observed in histologic sections of tissues adjacent to titanium-based alloys are of a different nature than the precipitates associated with stainless steel and cobalt-based alloys. Despite the remarkable corrosion resistance of titanium-based alloys, there have been persistent reports of tissue discoloration due to metallic debris in the periprosthetic tissues. These particulates observed in local tissues surrounding titanium alloy implants have the same elemental composition
FIGURE II.5.6.17 Transmission Electron Photomicrographs: (a) Macrophage containing phagocytized titanium particles. (b) Endothelial cell lining with embedded titanium debris. These specimens were obtained from a tissue sample overlying the posterolateral fusion mass (sixteen-week autograft + titanium) (TEM magnification = 20,000 ×).

as the parent alloy, as opposed to precipitated corrosion products which occur with stainless steel and cobalt–chromium alloys (Figure II.5.6.17). However, wear debris presents an enormous surface area for electrochemical dissolution, which, in all likelihood, is a major factor contributing to observed systemic elevations in titanium of patients with titanium implants (Urban et al., 1996a, 1997).

Particle Characterization

Traditionally particle characterization uses methods such as Scanning Electron Microscopy (SEM) or Transmission Electron Microscopy (TEM), both of which are

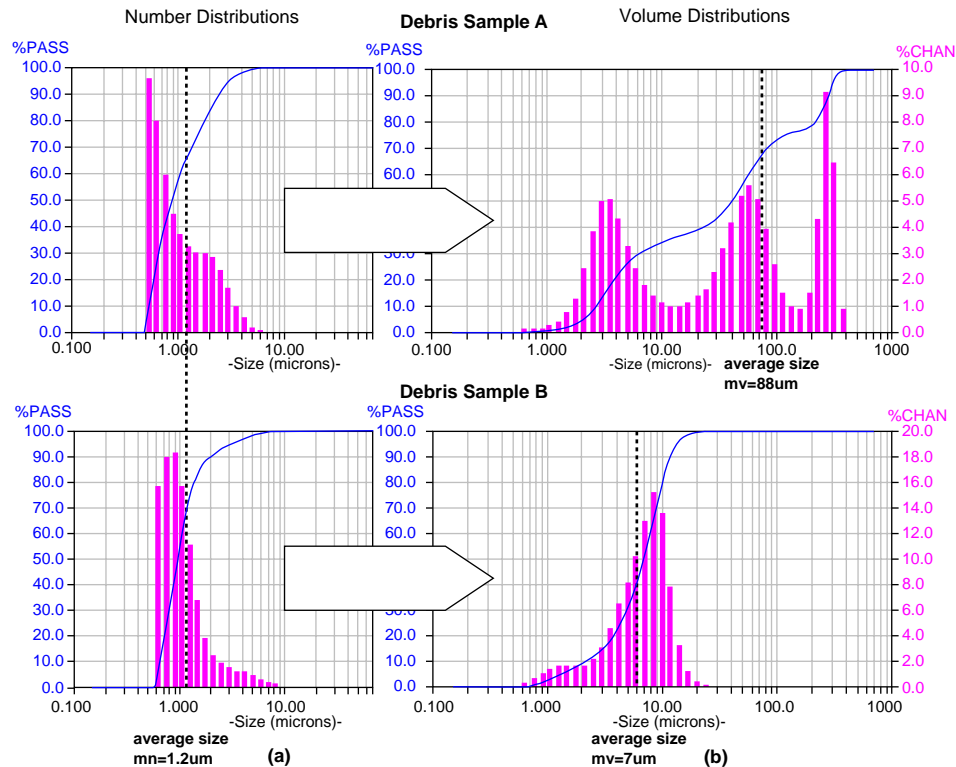
number-based counting methods. These methods have indicated that the majority of the wear (mass loss) from an implant is comprised of particles in the nanometer-to-submicron range. This understanding stems from the relatively low numbers of particles, (e.g., 100s–1000s) that are counted using image-based analysis techniques such as SEM. Newer analytical techniques, such as low angle laser diffraction (LALLS) have the capability of sampling millions to billions of particles, counted as they pass in front of and scatter a laser light beam proportionally to their size. Thus, as millions of particles flow by, LALLS analysis can detect the one-in-a-million large particle that comprises a significant portion of the total mass loss (i.e., total debris). This brings up the confusing concept that particle size of


FIGURE II.5.6.18 Analyses of: (a) volume; and (b) number distributions of two debris samples demonstrate that similar number distributions can result from very different actual size distributions. Note: The *x*-axis is particle diameter and the *y*-axis is (i) percentage of total number of particles in each size range; and (ii) the percentage of total mass in each size range. (Courtesy of BioEngineering Solutions, Inc.)

any given distribution depends on the method of evaluation. There is no one particle size. For example, the average size of 500 marbles and 5 basketballs is approximately the size of the marbles on a number basis, and approximately the size of the basketball on a volume basis. Thus, the question "what is the average size of particles that comprises approximately 50% of the total volume of particles?" is another way of asking what is the mean size (or average size) on a volume basis. Asking "what is the average size of the particles that comprises 50% of the total number of particles?" is the average size based on number basis. The stark differences between a volume and number-based analysis of implant debris are shown in Figure II.5.6.18. When comparing the volume and number distributions in this figure, the dominant contribution of larger particles to the total debris mass (volume) is evident, yet it is insignificant compared to the total number of particles (Figure II.5.6.18). Thus, as can be seen in both the simple example of marbles and basketballs and in the LALLS analysis of implant debris particles in Figure II.5.6.18, volume-based analysis tends to represent the largest (most massive) particles, and number analysis tends to depict the size characteristics of the most numerous.

The ability to comprehensively characterize implant debris is important to the new designs and bearing surfaces used in new spinal implants. This multi-analysis approach is necessary because a given amount of wear debris (weight loss from the implant) after a year of use could

be attributed to the loss of a relatively few large particles or hundreds of millions of small particles (e.g., approx 0.2 mm^3 volume loss after a million cycles of use could be from approx 400 particles of 100 microns diameter or 400 million particles only 1 micron in diameter). The bias of techniques limited to number analysis is that very similar number-based distributions can look very different from a volume perspective. This phenomenon is illustrated in Figure II.5.6.18 when comparing samples A and B, where different samples of particles look like very different volume-based distributions, however they look like very similar number-based distributions. This shows how important it is to have both number- and volume-based distributions of the same particles to fully characterize the types of particles in the mix, if there is enough particulate mass (>0.05 mg of particles) for a LALLS-type analysis. Unfortunately, in implant debris analysis there is usually less than the 0.05 mg of debris required for obtaining an accurate volume distribution, and thus historically SEM and TEM analyses have been used to characterize debris.

Particulate Debris Reactivity Characterization

Macrophages are immune cells that are involved in the phagocytosis of implant debris and the resulting inflammatory responses. Once debris is ingested by macrophages a host of biologic reactions can occur, such

as activation of T-cells through antigen presentation (Hallab et al., 2001a), release of pro-inflammatory mediators (Glant and Jacobs, 1994; Shanbhag et al., 1994; Ingham et al., 2000; Matthews et al., 2000; Cunningham et al., 2002), cytotoxicity (Hallab et al., 2005), DNA damage (Nagaya et al., 1989; Savarino et al., 2000; Hallab et al., 2005), and oxidative stress (Soloviev et al., 2005). Macrophage reactions to debris are responsible for mediating debris-induced inflammation that is the leading cause of implant loosening over time.

Despite the large number of studies on metallic, polymeric, and ceramic particles' effects on peri-implant cells (e.g., macrophages, fibroblasts, osteoblasts, and osteoclasts), there are surprisingly few guidelines on what type of debris is most deleterious or bioreactive. However, there are a few general particle characteristics on which local inflammation has been shown to depend: (1) particle load (which depends on both particle size and total volume); (2) aspect ratio (the shape of the particles); and (3) chemical reactivity (the chemical composition). Thus, theoretically, a bioreactivity index of particulate would take the mathematical form:

$$\text{Particle Pro} - \text{inflammatory Index} \approx K_{\text{Load}}(\text{particle load})$$
$$\times K_{\text{Shape}}(\text{aspect ratio}) \times K_{\text{Material}}(\text{material type}) \quad (1)$$

where K's are constants that depend on the testing environment, and particle load is a function of both particle size and total debris volume.

1. **Greater particle load: (size and volume) increases inflammation**. An inflammatory response *in vivo* is proportional to the particle load (the concentration of phagocytosable particles per tissue volume, which is characterized by both the size and total volume) (González et al., 1996; Matthews et al., 2000). While this seems obvious, the ramifications and the conditions under which this remains true are important and not so obvious. If a given amount of debris (mass loss from an implant) is comprised of small diameter particles, there will be far greater numbers than if that same mass of debris was composed of larger diameter particles (Matthews et al., 2000). The degree to which equal numbers (doses) of large particles (e.g., 10 micron diameter) and smaller particles (1 micron diameter) induce a proinflammatory response has not been thoroughly investigated, and remains unknown.
2. **Aspect ratio: elongated (fibers) particles are more proinflammatory than round particles** (Laquerriere et al., 2003; Sieving et al., 2003). That fibers are more reactive than round debris was well-established over 30 years ago, with studies of asbestos fibers (Bruch, 1974). However, it remains unknown at what aspect ratio (aspect ratio: length/width) in the transition from round particles to fibers that elevated inflammation is generally initiated, and thus to date there is no "guideline" aspect ratio for implant debris particles to remain below.

3. **More chemically reactive particles are more proinflammatory**. There is a growing consensus that metal particles are more proinflammatory when compared to other materials such as polymers (Ramachandran et al., 2006). However, this is not a unanimous opinion; others have concluded polymers are more proinflammatory than metals (von Knoch et al., 2000), and other reports have shown no differences between similar metal and polymer particles (Baumann et al., 2004, 2005, 2006). Despite these reports to the contrary, there is a growing consensus that metallic particles are more proinflammatory because they are capable of corroding and releasing ions that have been associated with hypersensitivity responses, cytotoxicity, and DNA damage (Hallab et al., 2001a, 2005; Caicedo et al., 2007).

Controversial Particle Characteristics

Does particle size matter? Absolutely. *In vitro* inflammatory responses generally require particles <10 microns in diameter to be phagocytosed. Thus, to produce an *in vitro* inflammatory response, particles need to be less than 10 μm, that is, within a phagocytosable range. Purportedly, particles with a mean size of 0.2–10 μm are the most proinflammatory. Within this range there is no consensus as to which specific size(s) and/or dose of particles (particles/cell or particles/tissue volume) are maximally inflammatory (Shanbhag et al., 1995; Rader et al., 1999; Matthews et al., 2000; Ingram et al., 2002).

The effects of bacteria products (or endotoxin) on implant debris particles is presumably important because it has been found in periprosthetic tissue of failed implants, even in the absence of clinical signs of infection (Nalepka et al., 2006). Furthermore, the bacteria that are present at below clinically detectable levels have been shown to affect implant performance, because antibiotic-eluting bone cement and systemically administered antibiotics reportedly reduce the frequency of long-term failure, i.e., aseptic loosening (Espehaug et al., 1997).

Metal Ions (Soluble Debris)

There is continuing concern regarding the release of chemically active metal ions which bind to proteins and remain in solution from which they can then disseminate into the surrounding tissues, bloodstream, and remote organs. Particulate metallic wear debris presents an enormous surface area for electrochemical dissolution, which, in all likelihood, is a major factor contributing to observed systemic elevations in metals of patients with titanium implants (Urban et al., 1996b, 1997, 1998; Jacobs et al., 1998b; Urban et al., 2000). Normal human serum levels of prominent implant metals are approximately 1–10 ng/ml Al, 0.15 ng/ml Cr, <0.01 ng/ml V, 0.1–0.2 ng/ml Co, and <4.1 ng/ml Ti. Following total joint arthroplasty, levels of circulating metal have been

shown to increase (Table II.5.6.5). The values in this table show that following successful primary total joint replacement there are measurable elevations in serum and urine cobalt, chromium, and titanium. The clinical ramifications of metal ion release are discussed in the next few sections.

Local Tissue Effects of Wear and Corrosion

Implant debris limits the long-term performance of total joint replacement by causing a local inflammatory response that leads to bone erosion and implant loosening. Normal bone maintenance relies in the balance of bone formation and bone resorption, which mainly involves the coordinated function of osteoblasts and osteoclasts. Thus, either a decrease in osteoblastic bone formation or an increase in osteoclastic bone resorption can result in net bone loss and osteolysis. Bone loss (i.e., osteolysis) around an implant is the primary concern associated with the local effects of orthopedic implant degradation. This osteolysis causing implant debris occurs through both wear and corrosion mechanisms. Osteolysis is observed either as diffuse cortical thinning or as a focal cyst-like lesion. It was initially thought that reaction to particulate polymethylmethacrylate (PMMA) bone cement produced osteolytic lesions based on histological studies demonstrating cement debris associated with macrophages, giant cells, and a vascular granulation tissue. Recently, however, osteolysis has been recognized in association with loose and well-fixed uncemented implants, demonstrating that the absence of acrylic cement does not preclude the occurrence of osteolysis (Jacobs et al., 2001; Vermes et al., 2001a,b).

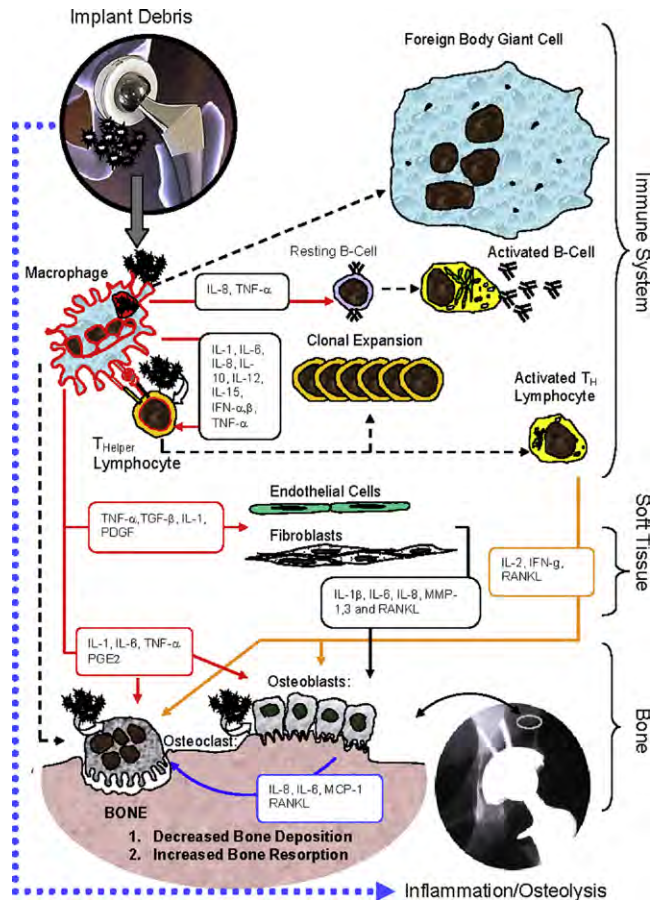
Implant debris causes low grade inflammation that ultimately leads to implant failure. Exactly how this happens remains unclear. Over the past 40 years implant debris-induced inflammation has been characterized *ad nauseam*, where debris-induced localized inflammation is caused in large part by macrophages which upregulate NFκβ and secrete inflammatory cytokines like IL-1β, TNFα, IL-6, and IL-8 (Jacobs et al., 2001) (Figure II.5.6.19). Other anti-inflammatory cytokines such as IL-10 modulate the inflammatory process. Other factors involved with bone resorption include the enzymes responsible for catabolism of the organic component of bone. These include matrix metalloproteinases collagenase and stromelysin. Prostaglandins, in particular PGE_2, are also known to be important intercellular messengers in the osteolytic cascade produced by implant debris. More recently, several mediators known to be involved in stimulation or inhibition of osteoclast differentiation and maturation, such as RANKL (also referred to as osteoclast differentiation factor) and osteoprotegerin, respectively, have been suggested as key factors in the development and progression of bone loss (osteolytic lesions) produced from implant debris. Over the past


FIGURE II.5.6.19 This schematic shows the numerous pro-inflammatory mediators produced by peri-implant tissue and immune cells reacting to implant debris, which can negatively affect bone turnover. The proinflammatory cytokines IL-1, IL-6, and TNF-α are thought to be some of the most potent cytokines in this cascade of signaling. These cytokines produced by cells react to implant debris acting through a variety of pathways to negatively affect bone turnover.

FIGURE II.5.6.20 The inflammasome pathway within cells such as macrophages has recently been reported to be central to implant debris-mediated proinflammatory reactivity. (Picture courtesy of BioEngineering Solutions, Inc.)

30 years we have understood that these mediators act to promote inflammation that decreases bone remodeling and is associated with the pathogenesis of osteolysis. However, we are only beginning to understand how implant debris could actually induce this immune system response at the cellular level.

Implant debris is typically sterile, relatively inert, and does not "look" like a pathogen in any molecularly recognizable way. How then can implant debris provoke an inflammatory response? That is, how do intracellular mechanisms sense and respond to sterile nonbiological challenge agents such as implant debris? This question has remained unanswered for the past 40 years, but recently progress has implicated the "inflammasome," a danger signaling pathway (Figure II.5.6.20) (Caicedo et al., 2009).

In 1996 the discovery of specific pattern recognition receptors (PRRs) in the membrane and cytosol of human immune cells, such as macrophages, identified toll-like receptors (Taguchi et al., 1996) and their role in recognizing specific bacterial glycoproteins, now called

"pathogen-associated molecular patterns" or PAMPs. We now understand that these receptors to highly conserved pathogen-associated molecular patterns (Mariathasan and Monack, 2007) include toll-like receptors (TLRs), mannose receptors (MR), and NOD-like receptors (NLRs) (Mariathasan and Monack, 2007). Upon pathogen/cell contact these PRRs initiate a downstream cascade of events that activate the cell and induce the secretion of proinflammatory cytokines, leading to a broader inflammatory response.

In 2005 danger signal pathways were discovered where nonpathogenic-derived stimuli were found to activate immune cells, similarly to PAMPs. Key components in this pathway were named the "inflammasome," and the activating stimuli were termed "danger-associated molecular patterns," or DAMPs (Martinon et al., 2006). The paradigm for immune system activation now includes reliance on specific receptors that recognize

both pathogen-associated molecular patterns (PAMPs) and danger-associated molecular patterns (DAMPs) (Medzhitov, 2008; Ting et al., 2008). The inflammasome complex of proteins were the first pathway to explain how cells transduce sterile, nonpathogen-derived stimuli (e.g., cell stress and cell necrosis), into an inflammatory response (Mariathasan et al., 2004; Mariathasan and Monack, 2007). Nonpathogen-derived danger includes such nonbiological stimuli as UV light, particulate adjuvants present in modern vaccines (Dostert et al., 2008; Hornung et al., 2008), and, as it turns out, implant debris (Caicedo et al., 2010).

When the inflammasome pathway is activated it causes the release of IL-1β, IL-18, IL-33 and other cytokines. How this happens is as follows:

Debris → Phagocytosis → Lysosome damage →
ROS(reactive oxygen species) → Inflammasome(NALP3/ASC)
→ Caspase1 → IL-1ß (and other IL-1-family) cytokines
(Figure II.5.6.20).

Once ingested by immune cells, DAMPs, such as asbestos and implant debris, etc., (i.e., macrophages) induce some degree of lysosomal destabilization. This causes an increase in NADPH (nicotinamide adenine dinucleotide phosphate oxidase), and an increase in reactive oxygen species (ROS). This is not surprising, given the protease and acid rich extreme environment inside lysosomes used to digest and breakdown ingested particles/bacteria, etc. The release of these intracellular contents are sensed by the intracellular multi-protein inflammasome complex which is composed of NALP3 protein (NACHT-, LRR- and pyrin domain-containing protein 3), in association with ASC (apoptosis-associated speck-like protein containing a CARD domain) (Mariathasan and Monack, 2007; Petrilli et al., 2007). Activation of the inflammasome (NALPs-ASC complex) leads to the cleavage of pro-caspase-1 into active caspase-1. Active caspase-1 is required for the processing and subsequent release of active proinflammatory cytokines such as IL-1β and IL-18 (and others) by cleaving intracellular

pro-IL-1β, pro-IL-18, etc., into their mature forms, IL-1β and IL-18, etc.

How different implant debris can cause different immune responses through specific mechanisms, such as the inflammasome, remains unknown and is currently under study. These new understandings facilitate both direct targeting for drugs and can enhance diagnostic measurement for improving, measuring, and predicting when implant debris will result in loose total joint arthroplasties.

Goldring et al. (1983) were among the first to describe the synovial-like character of the bone implant interface in patients with loose total hip replacements, and determine that the cells within the membrane have the capacity to produce large amounts of bone resorbing factors PGE$_2$ and collagenase. However, since studies typically can only document the end stage of the loosening process, rather than the initiating processes, pharmacologic interventions have been limited.

Osteolysis associated with total knee arthroplasty has been reported less frequently than that associated with total hip arthroplasty. It is unclear why. However, in addition to obvious factors such as implant/bone mechanical loading environments, other more subtle differential mechanisms of hip and knee wear, and differences in interfacial barriers to migration of debris have been postulated to account for this apparent disparity.

Although polyethylene particles are generally recognized as the most prevalent particles in the periprosthetic milieu, metallic and ceramic particulate species are also present in variable amounts, and may have important repercussions. The bulk of this debris originates from the articular surface and has easy access to local bone. When present in sufficient amounts, particulates generated by wear, corrosion or a combination of these processes can induce the formation of an inflammatory, foreign-body granulation tissue with the ability to invade the bone–implant interface (Figure II.5.6.21). Localized osteolytic lesions in these areas are common, but their clinical significance is limited unless large granulomatous lesions develop.
FIGURE II.5.6.21 Photomicrograph (5 ×) of a section through an acetabular section of a femoral stem retrieved at autopsy, 89 months after implantation. Note the periprosthetic cavity surrounded development of a granuloma emanating from an unfilled screw hole.

The common observance of particle-induced osteolysis remote from the articulation surfaces has shown there is substantial particle migration between the joint space and the distal regions of the THA implant space. Autopsy specimens of retrieved implants have demonstrated the presence of connective tissue macrophages (histiocytes) in cavities surrounding regions of the femoral component. While the overall incidence of femoral osteolysis associated with THA tends to be proximal in the initial stages, over time it tends to progress distally. The volume of debris generated from THA polyethylene is related to a number of variables, including the smoothness of the concave metallic surface of the acetabular component, the tolerance between polyethylene and metal shell, and the relative stability of the insert (LaBerge et al., 1998; Shanbhag et al., 1998; Wimmer et al., 1998).

Remote and Systemic Effects of Wear and Corrosion

Implant surfaces and wear debris generated from the implant may release chemically active metal ions into the surrounding tissues. While these ions may stay bound to local tissues, there is an increasing recognition that released metal products bind to specific protein moieties, and are transported in the bloodstream and/or lymphatics to remote organs. The concern about the release and distribution of metallic degradation products is justified by the known potential toxicities of the elements used in modern orthopedic implant alloys: titanium; aluminum; vanadium; cobalt; chromium; and nickel. In general terms, metal toxicity may occur through: (1) metabolic alterations; (2) alterations in host/parasite interactions; (3) immunologic interactions of metal moieties by virtue of their ability to act as haptens (specific immunological activation) or anti-chemotactic agents (non-specific immunological suppression); and (4) by chemical carcinogenesis (Luckey and Venugopal, 1979; Beyersmann, 1994; Goering and Klaasen, 1995; Britton, 1996; Hartwig, 1998).

Cobalt, chromium, and possibly nickel and vanadium, are essential trace metals in that they are required for certain enzymatic reactions. In excessive amounts, however, these elements may be toxic. Excessive cobalt may lead to polycythemia, hypothyroidism, cardiomyopathy, and carcinogenesis. Excessive chromium can lead to nephropathy, hypersensitivity, and carcinogenesis. Nickel can lead to eczematous dermatitis, hypersensitivity, and carcinogenesis. Vanadium can lead to cardiac and renal dysfunction, and has been associated with hypertension and depressive psychosis.

Biologically non-essential metallic elements also possess specific toxicities. Titanium, although generally regarded as inert, has been associated with pulmonary disease in patients with occupational exposure, and with platelet suppression in animal models. Aluminum toxicity is well-documented in renal failure, and has been associated with anemia, osteomalacia, and neurological dysfunction, possibly including Alzheimer's disease. However, when considering the variety of documented toxicities of these elements, it is important to keep in mind that the toxicities generally apply to soluble forms of these elements, and may not apply to the chemical species that result from prosthetic implant degradation.

At this time, the association of metal release from orthopedic implants with any metabolic, bacteriologic, immunologic or carcinogenic toxicity is conjectural, since cause and effect have not been well-established in human subjects. However, this is due in large part to the difficulty of observation, in that most symptoms attributable to systemic and remote toxicity can be expected to occur in any population of orthopedic patients (Jacobs et al., 1999b).

Metal Ion Release

In the long clinical experience of permanent and temporary metallic implants there has always been concern with local tissue reactions. There is a considerable literature concerning serum and urine chromium (Cr), cobalt (Co), and nickel (Ni) levels following total joint replacement, but relatively fewer studies examining titanium (Ti), aluminum (Al), and vanadium (V) levels. Many investigations have been hampered by technical limitations of the analytical instrumentation. Normal human serum levels of prominent implant metals are approximately: 1–10 ng/ml Al; 0.15 ng/ml Cr; <0.01 ng/ml V; 0.1–0.2 ng/ml Co; and <4.1 ng/ml Ti. Following total joint arthroplasty, levels of circulating metal (Al, Cr, Co, Ni, Ti, and V) have been shown to increase (Table II.5.6.5).

Multiple studies have demonstrated chronic elevations in serum and urine cobalt and chromium following successful primary total joint replacement. In addition, transient elevations of urine and serum nickel have been noted immediately following surgery. This hypernickelemia/hypernickeluria may be unrelated to the implant itself, since there is such a small percentage of nickel used in these implant alloys. Rather, this may be related to the use of stainless steel surgical instruments or the metabolic changes associated with the surgery itself.

Chronic elevations in serum titanium and chromium concentrations are found in subjects with well-functioning titanium and/or chromium containing THR components without measurable differences in urine and serum aluminum concentrations. Vanadium concentrations have not been found greatly elevated in patients with TJA (Table II.5.6.5) (Michel et al., 1984; Dorr et al., 1990; Jacobs et al., 1994c; Stulberg et al., 1994; Jacobs et al., 1998b).

Metal ion levels within serum and urine of TJA patients can be affected by a variety of factors. For example, patients with total knee replacement components containing titanium-based alloy and carbon fiber reinforced polyethylene wear couples demonstrated

a 10-fold elevation in serum titanium concentrations at an average of four years after implantation. Up to a hundred times higher than normal control values of serum titanium elevations have also been reported in patients with failed metal-backed patellar components where unintended metal/metal articulation was possible. However, even among these TJA patients there was no elevation in serum or urine aluminum, serum or urine vanadium levels, or urine titanium levels. Mechanically assisted crevice corrosion in patients with modular femoral stems from total hip arthroplasty has been associated with elevations in serum cobalt and urine chromium. It has been previously assumed that extensively porous coated cementless stems would give rise to higher serum and urine chromium concentrations, due to the larger surface area available for passive dissolution. Recent studies suggest that disseminated chromium can predominantly come from fretting corrosion of the modular head–neck junction. However, wear of the articulating surface remains the purported predominant source of metallic implant debris (Jacobs et al., 1998a,b, 1999b).

Homogenates of remote organs and tissue obtained postmortem from subjects with cobalt-based alloy total joint replacement components have indicated that significant increases in cobalt and chromium concentrations occur in the heart, liver, kidney, spleen, and lymphatic tissue (Table II.5.6.6). Similarly, patients with titanium-based alloy implants demonstrated elevated titanium, aluminum, and vanadium levels in joint pseudocapsules (with up to 200 ppm of titanium six orders of magnitude greater than that of controls, 880 ppb of aluminum, and 250 ppb of vanadium). Spleen aluminum levels and liver titanium concentrations can also be markedly elevated in patients with failed titanium-alloy implants (Jacobs et al., 1994c).

Systemic Particle Distribution

Variables influencing accumulation of wear debris in remote organs are not clearly identified. When the magnitude of particulate debris generated by a prosthetic device is increased, it seems likely that a corresponding elevation in both the local and systemic burden of particles may be expected. Thus, component loosening, duration of implantation, and the modular designs of contemporary hip and knee replacement prostheses provide the potential for increased generation of metallic and polymeric debris (Figure II.5.6.22). Wear particles found disseminated beyond the periprosthetic tissue are primarily in the submicron size range. Numerous case reports document the presence of metallic, ceramic, or polymeric wear debris from hip and knee prostheses in regional and pelvic lymph nodes (Figure II.5.6.23), along with the findings of lymphadenopathy, gross pigmentation due to metallic debris, fibrosis (build-up of fibrous tissue), lymph node necrosis, and histiocytosis (abnormal function of tissue macrophages), including complete effacement of nodal architecture. The inflammatory response to metallic and polymeric debris in lymph nodes has been demonstrated to include immune activation of macrophages and associated production of cytokines. Metallic wear particles have been detected in the para-aortic lymph nodes in up to 70% of patients with total joint replacement components.

Lymphatic transport is thought to be a major route for dissemination of wear debris. Wear particles may migrate via perivascular lymph channels as free or phagocytosed particles within macrophages. Within the abdominal para-aortic lymph nodes, the majority of disseminated particles are submicron in size; however, metallic particles as large as 50 micrometers, and polyethylene particles as large as 30 micrometers, have also been identified. These particles may further disseminate to the liver or spleen where they are found within
FIGURE II.5.6.22 Polarized light micrograph (190 ×) of para-aortic lymph node demonstrates the abundance and morphology of bire-fringent particles within macrophages. The larger filamentous particles were identified by infrared spectroscopy to be polyethylene.

macrophages or, in some cases, as epithelioid granulomas throughout the organs. Within liver and spleen, the maximum size of metallic wear particles are nearly an order of magnitude less than that in lymph nodes, indicating there may be additional stages of filtration preceding the lymphatic system or alternate routes of particle migration. In the liver and spleen, as in the lymph nodes, cells of the mononuclear–phagocyte system may accumulate small amounts of a variety of foreign materials without apparent clinical significance. However, accumulation of exogenous particles can induce granulomas or granulomatoid lesions in the liver and spleen (Figure II.5.6.23). It is likely that the inflammatory reaction to particles in the liver, spleen, and lymph nodes is modulated, as it is in other tissues by: (1) material composition; (2) the number of particles; (3) their rate of accumulation; (4) the duration that they are present; and (5) the biologic reactivity of cells to these particles. Metallic particles in the liver or spleen have been more prevalent in subjects with previously failed arthroplasties when compared with cases of well-functioning primary joint replacements. Metal particles, unlike polyethylene debris, can be characterized using an electron microprobe, which allows identification of individual, submicron metallic wear particles against a background of particulates from environmental or sources other than the prosthetic components. Overall, the smallest identifiable disseminated particles using the microprobe are approximately 0.1 micrometers in diameter. However, metallic wear debris may extend into the nanometer range, suggesting that additional methods of specimen preparation and analytic instrumentation may be required to more fully define the high burden of metallic wear particles in remote tissues (Urban et al., 2000).
FIGURE II.5.6.23 Epithelioid granulomas: (a) within the portal tract of the liver (40 ×); and (b) within the splenic parenchyma (15 ×) in a patient with a failed titanium-alloy total hip replacement and symptomatic hepatitis. (c) Backscattered SEM of a granuloma in the spleen (3000 ×) demonstrating titanium alloy particles.

Polyethylene particles comprise a substantial fraction of the disseminated wear particles both in subjects with revision and primary TJAs. While the presence of these polyethylene particles in lymph nodes can be confirmed by Fourier Transform Infrared Spectroscopy microanalyses, polyethylene particulates in liver and spleen have so far precluded unequivocal identification. In these sites, the size of wear particles may be much smaller than 0.1 micrometers, making differentiation impossible by polarized light microscopy or infrared spectroscopy.

Diseases which cause obstruction of lymph flow through lymph nodes, such as metastatic tumor, or which cause generalized disturbances of circulation, such as chronic heart disease or diabetes, may be expected to decrease particle migration to remote organs. Other diseases, such as acute or chronic-active inflammation in the periprosthetic tissues may increase particle migration (Urban et al., 1995; Jacobs et al., 1999b, 2001).

Hypersensitivity

Some adverse responses to orthopedic biomaterials are subtle, and continue to foster debate and investigation. One of these responses is "metal allergy" or hypersensitivity to metallic biomaterials. Released ions, while not sensitizers on their own, can activate the immune system by forming complexes with native proteins. These metal–protein complexes are considered to be candidate antigens (or allergens) in human clinical applications. Polymeric wear debris is not easily chemically degraded *in vivo* and has not been implicated as sources of allergic type immune responses. This is presumably due to the relatively large degradation products associated with the mechanical wear of polymers *in vivo*, which may be large enough to prevent the formation of polymer–protein haptenic complexes with human antibodies (Hallab et al., 2000a,b, 2001a,b).

Metal hypersensitivity is a well-established phenomenon. Moreover, dermal hypersensitivity to metal is common, affecting about 10–15% of the population. Dermal contact and ingestion of metals have been reported to cause immune reactions which most typically manifest as skin hives, eczema, redness, and itching. Although little is known about the short- and long-term pharmacodynamics and bioavailability of circulating metal degradation products *in vivo*, there have been many reports of immunologic type responses temporally associated with implantation of metal components. Individual case reports link hypersensitivity immune reactions with adverse performance of metallic clinical cardiovascular, orthopedic, plastic surgical, and dental implants.

Metals accepted as sensitizers (haptenic moieties in antigens) include beryllium, nickel, cobalt, and chromium, while occasional responses have been reported to tantalum, titanium, and vanadium. Nickel is the most common metal sensitizer in humans, followed by cobalt and chromium. Cross-sensitivity reactions between metals are common. Nickel and cobalt are, reportedly, the most frequently cross-reactive.

Type IV Delayed Type Hypersensitivity (DTH) is a cell mediated type of response with which orthopedic implant associated hypersensitivity reactions (metal sensitivity or metal allergy) are generally associated. Metal-antigen sensitized T-DTH lymphocytes release various cytokines which result in the accumulation and activation of macrophages. The majority of DTH participating cells are macrophages. Only 5% of the participating cells are antigen specific T lymphocytes (T-DTH cells), with a fully developed DTH response. The effector phase of a DTH response is initiated by contact of sensitized T cells with antigen. In this phase T cells, which are antigen-activated, are termed T-DTH cells and secrete a variety of cytokines that recruit and activate macrophages, monocytes, neutrophils, and other inflammatory cells. These released cytokines include IL-3 and GM-CF, which promote hematopoesis of granulocytes; monocyte chemotactic activating factor (MCAF) which promotes chemotaxis of monocytes toward areas of DTH activation; INF-γ and TNF-β which produce a number of effects on local endothelial cells facilitating infiltration; and migration inhibitory factor (MIF), which inhibits the migration of macrophages away from the site of a DTH reaction. Activation, infiltration, and eventual migration inhibition of macrophages is the final phase of the DTH response. Activated macrophages, because of their increased ability to present class II MHC (Major Histocompatibility Complex) and IL-2, can trigger the activation of more T-DTH cells, which in turn activates more macrophages, which activates more T-DTH cells, and so on. This DTH self-perpetuating response can create extensive tissue damage.

The first apparent correlation of eczematous dermatitis to metallic orthopedic implants was reported in 1966 by Foussereau and Laugier (1966), where nickel was associated with hypersensitivity responses. Over the past 20 years, growing numbers of case reports link immunogenic reactions with adverse performance of metallic cardiovascular orthopedic, plastic surgical, and dental implants. In some instances clinical immunological symptoms have led directly to device removal. In these cases reactions of severe dermatitis (inflammation of the skin), urticaria (intensely sensitive and itching red round wheels on the skin), and/or vasculitis (patch inflammation of the walls of small blood vessels) have been linked with the relatively more general phenomena of metallosis (metallic staining of the surrounding tissue), excessive periprosthetic fibrosis, and muscular necrosis. The temporal and physical evidence leaves little doubt that the phenomenon of hypersensitivity to metal released from orthopedic implants does occur in some patients. These cases of severe metal sensitivity raise the greatest concern.

Incidence of Hypersensitivity Responses Among Patients With Metal Implants

The incidence of metal sensitivity among patients with both well- and poorly-functioning implants is roughly twice as high as that of the general population, approximately 25% (Figure II.5.6.24). Furthermore, the average incidence of metal sensitivity among patients with a "failed" implant (in need of revision surgery) is approximately 50–60% (Figure II.5.6.24). This is greater than five times the incidence of metal sensitivity found in the general population, and two to three times that of patients with metal implants. This increased prevalence of metal sensitivity among patients with a loose prosthesis has prompted the speculation that immunological processes may be a factor in implant loosening.

Specific types of implants with greater propensity to release metal *in vivo* may be more prone to induce metal sensitivity. Failures of total hip prostheses with metal-on-metal bearing surfaces were associated with greater incidence of metal allergy than similar designs with metal-on-ultra-high molecular weight polyethylene bearing surfaces. Alternatively, several published reports have indicated that after total joint replacement with metallic components some patients show an induction of metal tolerance; that is, previously diagnosed metal sensitivity abated after implantation of a metallic prosthetic.

Additionally confounding to any clear connection between metal sensitivity and implant failure is the lack of any reported correlation between incidence of metal sensitivity and implant residence time, infection, reason for removal or pain. This lack of causal evidence implicating cell-mediated immune responses has prompted some to conclude that implantation of cemented metal-to-plastic joint prosthesis is safe, even in the case of a pre-existing metal allergy. However, this is not a consensus opinion. At this time, however, it is unclear whether metal sensitivity causes implant loosening or whether implant loosening results in the development of metal sensitivity.

The majority of investigations conclude that metal sensitivity can be a contributing factor to implant failure. Such cases include instances in which clinical immunological symptoms lead directly to the need for device removal. In these or similar cases there have been reported reactions of severe dermatitis, urticaria, and/or vasculitis, all presumably linked to what has been reported as metallosis, excessive periprosthetic fibrosis, and muscular necrosis. The clinical observation of apparent immune sensitivity to metallic implants is not limited to orthopedic surgery. Some case reports suggest metal sensitivity to pacemakers, heart valves, reconstructive, dental, and general surgical devices. The temporal and physical evidence associated with such cases leaves little doubt that the phenomenon of metal-induced hypersensitivity does occur in some cases, currently accepted within the orthopedic community to be <1% of patients. However, it is currently unclear whether metal sensitivity exists only as an unusual complication in a few susceptible patients or
FIGURE II.5.6.24 A compilation of investigations show the averaged percentages of metal sensitivity among the general population for nickel, cobalt, and chromium, among patients after receiving a metal-containing implant, and among patient populations with failed implants. All subjects were tested by means of a patch or metal-LTT (lymphocyte transformation test).

is a more subtle and common phenomenon, which over time plays a significant role in implant failure. It is likely that cases involving implant-related metal sensitivity have been under-reported, because alternate causes were attributed to the failure of the implant. Mechanisms by which *in vivo* metal sensitivity occurs have not been well-characterized. Thus, the degree to which a precondition of metal hypersensitivity may elicit an over-aggressive immune response in a patient receiving an implant remains unpredictable. Continuing improvements in immunologic testing methods will likely enhance future assessment of patients susceptible to hypersensitivity responses (Hallab et al., 2000a,b, 2001a,b).

Carcinogenesis

The carcinogenic potential of the metallic elements used in TJA remains an area of concern. Animal studies have documented the carcinogenic potential of orthopedic implant materials. Small increases in rat sarcomas were noted to correlate with high serum cobalt, chromium or nickel content from metal implants. Furthermore, lymphomas with bone involvement were also more common in rats with metallic implants. Implant site tumors in dogs and cats – primarily osteosarcoma and fibrosarcoma – have been associated with stainless steel internal fixation devices.

Initially, epidemiological studies implicated cancer incidence in the first and second decades following total hip replacement. However, larger more recent studies have found no significant increase in leukemia or lymphoma; although these studies did not include as large a proportion of subjects with a metal-on-metal prosthesis. There are constituitive differences in the populations with and without implants that are independent of the implant itself, which confound the interpretation of epidemiological investigations.

The association of metal release from orthopedic implants with carcinogenesis remains conjectural, since causality has not been definitely established in human subjects. The identification of such an association depends both on the availability of comparative epidemiology, and on the ability to perform tests on the patient before and after device removal. The actual number of cases of tumors associated with orthopedic implants is likely under-reported. However, with respect to the number of devices implanted on a yearly basis, the incidence of cancer at the site of implantation is relatively rare. Continued surveillance and longer-term epidemiological studies are required to fully address these issues (Gillespie et al., 1988; Visuri and Koskenvuo, 1991; Matheisen et al., 1995; Nyren et al., 1995).

Preventive Strategies and Future Directions

Current strategies designed to address the problem of biomaterial-related implant failure are primarily aimed at decreasing the amount of periprosthetic particulate burden and any subsequent effects. Recently there has been a great deal of innovation regarding stronger, more wear-resistant polyethylene. These more highly cross-linked UHMWPE polymers are currently in various phases of clinical trials. However, initial results show demonstrable decrease in polyethylene wear, with potential for less particulate-induced bioreactivity/osteolysis, and therefore greater implant performance. In the same vein, femoral heads with diameters of 32 mm have been associated with increased volumetric polyethylene wear; to combat this smaller 28 mm heads are currently extolled as more biocompatible. Manufacturing flaws, such as fusion defects and foreign-body inclusions, have also been suggested to contribute to adverse polyethylene wear properties. The elimination of polyethylene is another approach being investigated clinically in various centers. With the realization that early problems may have been related to the design and not the articulation, there has been a renewed interest in the application of metal–metal and ceramic–ceramic bearings. Future designs which attempt to reduce wear include: improved tolerances between polyethylene inserts and their metal backing; improved surface finish on the metallic concave surfaces; secure locking mechanisms; and the avoidance of holes on the convex portion of the acetabular prosthesis.

Metallic wear is also being addressed through techniques such as nitriding and nitrogen ion implantation to decrease the potential for abrasive wear and fretting in titanium alloy and cobalt alloy stems. Fabrication of metallic bearing surfaces with extremely low roughness can be expected to decrease articular wear rates. A polished metal head can be made as smooth as a ceramic head. Polishing of the stem will remove surface asperities and decrease particle generation from stem/bone fretting. In addition, polishing will minimize silicate contamination.

New metallic biomaterials are being proposed which attempt to improve load transfer to the bone and reduce the incidence of loosening and thigh pain. Currently used alloys (Co–Cr–Mo alloy, E = 227 GPa and Ti-6Al-4V alloy, E = 115 GPa) have relatively high elastic moduli which limit smooth transfer of load to the surrounding bone in THA. Designs to improve load transfer can use a reduced cross-sectional area to increase flexibility, but at the expense of adequate stability of the implant within the bone. Additionally, the stresses may exceed the relatively low fatigue strength of Co–Cr–Mo implant alloy. Lower modulus, more corrosion-resistant implant alloys are being developed. A Ti-13Nb-13Zr (E = 79 GPa) alloy is one such alloy which contains fewer elements of questionable cell response (i.e., Co, Cr, Mo, Ni, Fe, Al, V), and which possesses comparable strength and toughness to existing Ti-6Al-4V implant alloy. The niobium and zirconiun constituents seek to improve bone biocompatibility and corrosion resistance.

Additionally, novel surface treatments on implant alloys (such as the diffusion hardening (DH) treatment proposed for the Ti-13Nb-13Zr alloy), can produce a hardened surface with wear resistance superior to that of Co–Cr–Mo alloy, currently the industry leader. These enhanced surface properties may lead to an improvement in the resistance to micro-fretting occurring within femoral head–neck taper regions and modular interfaces of current implant designs.

Electrochemical corrosion of orthopedic implants remains a significant clinical concern. Although the freely corroding implants used in the past have been replaced with modern corrosion resistant "superalloys," deleterious corrosion processes have been observed in certain clinical settings. Attention to metallurgical processing variables, tolerances of modular connections, surface processing modalities, and appropriate material selection can diminish corrosion rates and minimize the potential for adverse clinical outcomes. For example, nitriding can reportedly significantly reduce the magnitude of fretting corrosion of Ti-6Al-4V devices. A need to further investigate the mechanical–electrochemical interactions of metal oxide surfaces in implants persists. Characterization of the stresses and motion needed to fracture passivating oxide films, as well as the effects of repeated oxide abrasion on the electrochemical behavior of the interface and ultimately the implant, remain avenues of active investigation.

The clinical significance of elevated metal content in body fluids and remote organs of patients with metallic implants needs to be further elucidated. Considerably more work will be required to discern the specific chemical forms and distribution of metal degradation products associated with the various forms of implant degradation. Additionally uncharacterized is how these degradation products interact with proteins *in vivo* in terms of: (1) metal-ion/protein complexes; (2) nanometer-particle/protein complexes (ion-like particles); and (3) particle/protein-biofilm complexes. Although much has been revealed regarding the deleterious end effects of particulate debris (e.g., osteolysis) there remain very few ways of testing people to determine which type of implant and materials are right for them. Therefore, both an understanding of the constituents of orthopedic implant degradation and their biological effects is necessary to ultimately determine threshold levels of debris and circulating metal ions, and measures of biologic reactivity (e.g., metal-LTT testing) that can be used to clinically determine when intervention is required to fix a downward spiral before too much bone loss and inflammation occurs. The importance of this evaluation of orthopedic biomaterial performance is growing as the use of orthopedic biomaterials is increasing, as new orthopedic implants are being developed (Figure II.5.6.7), and as expectations of implant durability and performance increase (Black, 1996; Jacobs et al., 1996).

CHAPTER II.5.7 DENTAL IMPLANTATION

Jack E. Lemons[1] and Carl E. Misch[2]

[1]University Professor, Schools of Dentistry, Medicine and Engineering, University of Alabama at Birmingham, Birmingham, AL, USA

[2]DDS, MDS, Misch International Institute, Beverly Hills, MI, USA

PATIENT PROFILES, DENTAL NEEDS, AND SURGICAL IMPLANTS: 1950S–2010S

Functional, aesthetic, and general health compromises have been correlated with the loss of oral dentition. The dental profession has developed a wide range of treatments to deal with dentition losses and oral diseases; however, a significant percentage of the world population continues to lose teeth progressively with dental diseases and aging. In recent decades, since the 1950s, the modern era of treatments based on surgical implants has evolved. Significant advances in quality and quantity have occurred during each decade. In the USA, a larger population of completely edentulous individuals existed in the 1950s, and many implant treatments were initially designed to support full arch implant supported removable dentures (Misch, 1999). A prominent design was the subperiosteal type (Figure II.5.7.1A,B,C), where a cast cobalt alloy metallic framework was fabricated and implanted under the periosteum and fitted to surface features of the bone anatomy (Rizzo, 1988). Posts extended through the gingival and mucosal soft tissues and the implant denture was directly supported on bone without significant soft tissue contact. The surgical and implant fabrication procedures were technically demanding for the various subperiosteal implant designs. A group of dentists and supporting staff emerged as the experts in this subdiscipline.

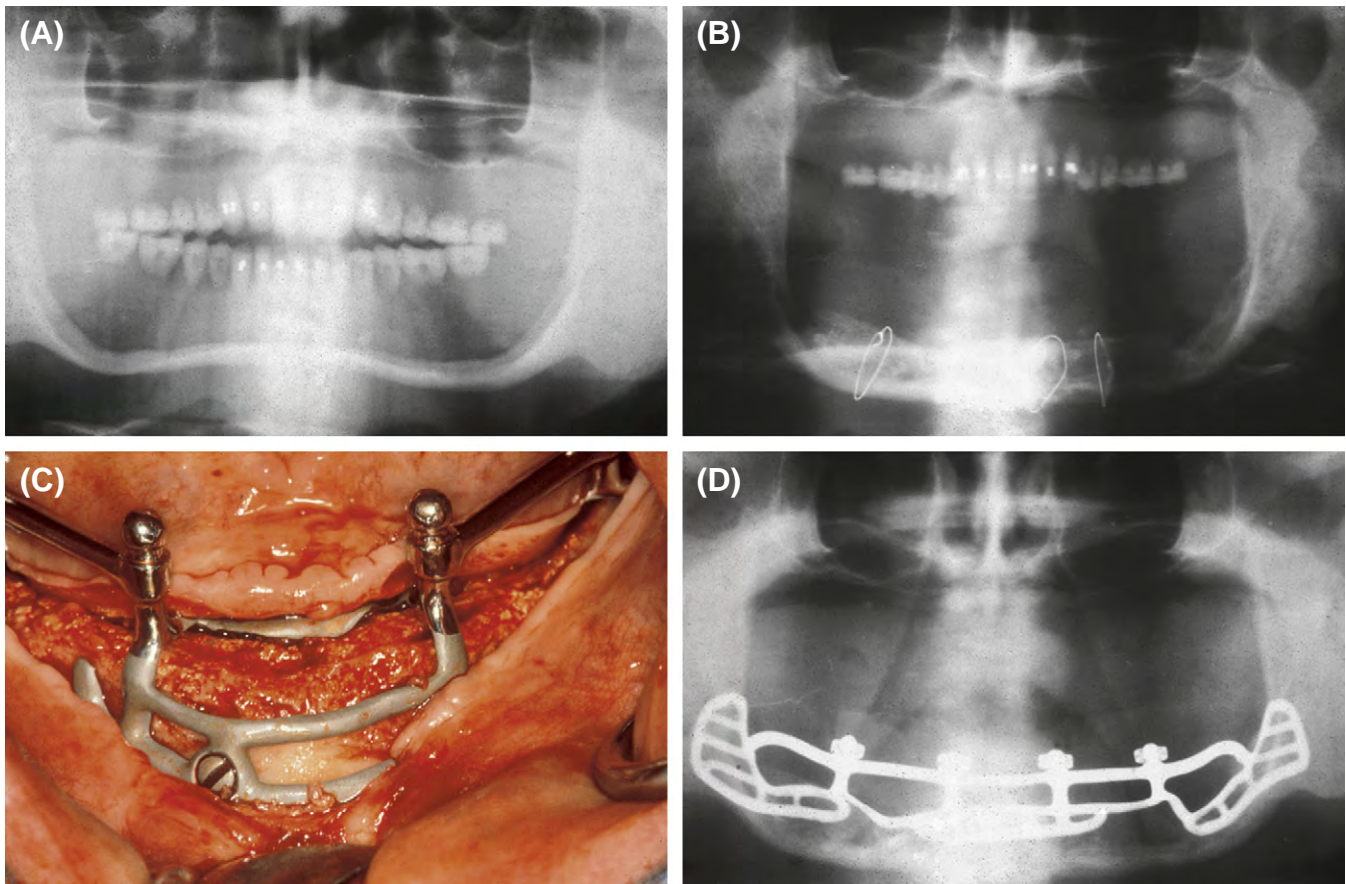
Early subperiosteal systems were shown to function through implant-to-soft tissue interfaces and many


FIGURE II.5.7.1 **A,** A panoramic radiograph of a severely resorbed mandible, measuring less than 3 mm in height. **B,** A postoperative panoramic radiograph of an iliac crest bone graft wired around the atrophic mandible (1983). **C,** Reentry after 6 months into the iliac crest bone graft and a subperiosteal implant inserted (1983). **D,** Postoperative panoramic radiograph of the iliac crest graft after maturity and the subperiosteal implant (1987).

supported the relative benefits of fibrous tissue integration (James, 1983). A subdiscipline network of education evolved with the subperiosteal designs; however, many dental professionals started to support the merits of other types of implant designs. In all situations, the dental implant "experts" were required to coordinate a wide range of technologies, including implant design, fabrication, finishing, and placement, plus the various aspects of intra-oral prosthetic restorations and long-term maintenance. Some supported the concept of plate (blade) form implant designs (Figure II.5.7.2), where the body of the implant was placed into a surgically prepared slot in the bone (Weiss, 1986). In part due to implant design, and in part due to "immediate restoration" and oral function, many of the plate form and related designs of dental implant systems were shown to function through fibrous tissue and/or fibrous–osseous type tissue interfaces (James and Keller, 1974). Some called the interfacial tissue zone a "pseudo-ligament," and described properties somewhat similar to the natural tooth periodontal ligament. One aspect of the plate form implant was the intention to have a condition like the tooth-to-bone interfacial zone. With systems evolution, treatments extended from fully endentulous to partially edentulous regions of the mandibular and maxillary arches.
FIGURE II.5.7.2 Plate (blade) form implant design.

The dental community followed multiple avenues for dental implant designs and intraoral restorations, depending on their backgrounds, the patient population being treated, and recognized needs for improved

treatments. One system was called the Ramus Frame (Figure II.5.7.3A,B,C), another the Transosseous and/ or the Staple design (Figure II.5.7.4). Each had relative merits which have been described in articles and books associated with dental implants.

As another extension of pre-1950s studies, some in the dental implant profession supported root-form type designs (Figure II.5.7.5 and Figure II.5.7.6), often made in the shape of helical formed wires, pins, rods, screws or plateaus for the body sections of the implants that

FIGURE II.5.7.6 Radiograph of Root-Form Implants Supporting Intraoral Bridge Reconstructions.

were placed into the bone (called endosseous or endosteal devices) (Cranin, 1970; Branemark et al., 1977; Small, 1980; Schnitman, 1987; Misch, 1999). Early in development, dental implants were primarily uniblock (single piece) systems combined with existing (known) intraoral restorative procedures for removable, fixed, and fixed-removable intraoral prosthetics.

The range of materials and biomaterials used for dental implants included available surgical implant grade metallics, ceramics, polymerics, mechanical mixtures, and composites. During this period, groups championed different concepts where the implants were made from metallics, and one of the more popular root forms supported primarily by dental specialists was the two-stage endosteal screw type implant. The abutment and implant components were assembled after a controlled period of post-surgical healing of bone and soft tissues. One of these early designs was fabricated from vitreous carbon, and initial studies supported the merits of this biomaterial for this application (Rizzo, 1988; Meffert et al., 1992). These approaches were popularized internationally, and the use of dental implants continued to increase with experience and time. During the 1980s and 1990s multiple clinical trials were completed showing the relative merits of implant-based treatments. One aspect of this evolution was the impact from the biomaterial and biomechanical disciplines which strongly influenced the overall enhancements of implant bulk and surface properties (Lemons, 1999).

As an example of interdisciplinary coordinations, the original subperiosteal and plate form dental implants have been redesigned in shape, surface biomaterial, and the surgical-restorative techniques to provide an osseous integrated dental implant system (now called Custom Osseous Integrated Implant or COII for these systems) (Baker et al., 2010). This same philosophy is being extended into on-going and planned (future) investigations in implant dentistry.

ANATOMICAL AND IMAGING CONSIDERATIONS

The overall maxillary and mandibular bone anatomies and regions for possible dental implant treatments are described in prior books. In general, the subperiosteal implants were placed onto the surface anatomy of the fully edentulous and axillary or mandibular bone. In part because of bone structure, subperiosteal implants in mandibular regions, when compared to maxillary implants, were more stable over time. The plate-form implants were initiated primarily for use in the edentulous posterior mandible, while the anterior, maxillary, and mandibular regions were selected for initial studies of root-form implant placement. This was in part because of available dimensions of bone, the magnitudes of functional forces, and avoidance of neurovascular regions.

Most of the different implant designs were eventually utilized wherever edentulous regions existed. Overall, the intent was to provide a stable, functional, and aesthetic dentition. Access to the oral regions and the number of teeth per individual (up to 32) resulted in larger numbers of dental implants compared to other types (hips, knees, etc.) of implant-based treatments for musculoskeletal disorders.

To define the bone anatomies, dentists in the earlier periods utilized radiographic imaging procedures that were normally available for the evaluation of teeth and supporting bone. Periapical (zone) radiographs were extended to full arch panographic images to better describe the overall bone and tooth relationships. With the advance of the science and technology of imaging, dental radiographic imaging evolved to routine use of computed tomography, with cone bean and other technologies to minimize radiation dose to the head and neck regions. This imaging has now been extended to computer-based software and hardware systems for design and manufacture (CAD-CAM). This approach also now extends from treatment planning, surgical guides, and abutment connections, to multiple types of intraoral prosthetics, and procedures for longer-term maintenance (Misch, 1999).

BIOMATERIALS

The various biomaterials used for the construction of dental implant systems are summarized in Tables II.5.7.1–II.5.7.4. This summary includes the nominal bulk compositions, mechanical properties, and surface conditions as described in national and international standards. A wide range of surface modifications have been, and continue to be, utilized for the body sections of dental implants. Many have been based on calcium phosphate compounds which are summarized in Table II.5.7.5. A review of the biomaterials and surface alterations of dental implant systems shows the wide range of surface conditions that continue to be preferred by the profession. To simplify these considerations, the surface modifications have been categorized as those that subtract or add mass to the substrate. More details on bulk and surface characteristics will be included in the next section. Multiple articles and books, again, exist about the relative merits of different biomaterials and surface modifications.

TABLE II.5.7.1	Engineering Properties of Metals and Alloys Used for Surgical Implants*				
Material	Nominal Analysis (w/o)	Modulus of Elasticity GN/m² (psi μ 10⁶)	Ultimate Tensile Strength MN/m² (ksi)	Elongation to Fracture (%)	Surface
Titanium	99+Ti	97 (14)	240–550 (25–70)	>15	Ti oxide
Titanium–aluminum–vanadium	90Ti–6Al–4V	117 (17)	869–896 (125–130)	>12	Ti oxide
Cobalt–chromium–molybdenum (casting)	66Co–27Cr–7Mo	235 (34)	655 (95)	>8	Cr oxide
Stainless steel (316L)	70Fe–18Cr–12Ni	193 (28)	480–1000 (70–145)	>30	Cr oxide
Zirconium	99+Zr	97 (14)	552 (80)	20	Zr oxide
Tantalum	99+Ta	—	690 (100)	11	Ta oxide
Gold	99+Au	97 (14)	207–310 (30–45)	>30	Au
Platinum	99+Pt	166 (24)	131 (19)	40	Pt

GN/m², Giganewton per meter squared; *ksi*, thousand pounds per inch squared; *MN/m²*, meganewton per meter squared; *psi*, pounds per inch squared; *w/o*, weight percent.
*Minimum values from the American Society for Testing and Materials Committee F4 documents are provided. Selected products provide a range of properties.

TABLE II.5.7.2	Engineering Properties of Some Inert Ceramics Used as Biomaterials*		
Material	Modulus of Elasticity GN/m² (psi μ 10⁶)	Ultimate Bending Strength MPa (ksi)	Surface
Aluminum oxide			
Polycrystalline	372 (54)	300–550 (43–80)	Al_2O_3
Single crystal (sapphire)	392 (56)	640 (93)	Al_2O_3
Zirconium oxide zirconia (PSZ)	195–210 (28–30)	500–650 (72–94)	ZrO_2
Titanium oxide (titania)	280 (41)	69–103 (10–15)	TiO_2

GN/m², Giganewton per meter squared; *psi*, pounds per inch squared; *MPa*, megapascal; *ksi*, thousand pounds per inch squared.
*These high ceramics have 0% permanent elongation at fracture.

TABLE II.5.7.3	Engineering Properties of Bioactive and Biodegradable Ceramics*		
Material	Modulus of Elasticity GPa (psi μ 10⁶)	Ultimate Bending Strength MPa (ksi)	Surface
Hydroxyapatite	40–120 (6–17)	40–300 (6–43)	$Ca_{10}(PO_4)_6(OH)_2$
Tricalcium phosphate	30–120 (4–17)	15–120 (2–17)	$Ca_3(PO_4)_2$
Bioglass or Ceravital	40–140 (6–20)	20–350 (3–51)	$CaPO_4$
AW ceramic	124 (18)	213 (31)	$CaPO_4 + F$
Carbon	25–40 (4–6)	150–250 (22–36)	C
Carbon–silicon (LTI)	25–40 (4–6)	200–700 (29–101)	CSi

GPa, Gigapascal; *psi,* pounds per inch squared; *MPa*, megapascal; *ksi*, thousand pounds per inch squared; *LTI*, low-temperature isotropic.
*These ceramics and carbons have 0% permanent elongation at fracture.

TABLE II.5.7.4	Engineering Properties of Polymers (Some Medical Grades)*		
Material	Modulus of Elasticity GPa (psi μ 10⁵)	Ultimate Tensile Strength MPa (ksi)	Elongation to Fracture (%)
PTFE	0.5–3 (0.07–4.3)	17–28 (2.5–4)	200–600
PET	3 (4.3)	55 (8)	50–300
PMMA	3 (4.3)	69 (10)	2–15
PE	8 (1.2)	48 (7)	400–500
PP	9 (1.3)	35 (5)	500–700
PSF	3.5 (5)	69 (10)	20–100
SR	0.1 (0.014)	5 (1.1)	300–900
POM	3 (4.3)	70 (10.1)	10–75

GPa, Gigapascal; *psi*, pounds per inch squared; *MPa*, megapascal; *ksi*, thousand pounds per inch squared; *PTFE*, polytetrafluoroethylene; *PET*, polyethylene terephthalate; *PMMA*, polymethylmethacrylate; *PE*, polyethylene; *PP*, polypropylene; *PSF*, polysulfone; *SR*, silicone rubber; *POM*, polyoxymethylene (IME, intra mobile element).
*Polymer properties exhibit a wide range depending on processing and structure. These values have been taken from general tables.

TABLE II.5.7.5	Names, Formulae, and Atomic Ratios for Some Calcium Phosphate Materials		
Mineral or General Name	Formula	Ca:P Ratio	Applications
Monetite (DVP)	$CaHPO_4$	1	Nonceramic bone substitute particulate
Brushite (DCPD)	$CaHPO_4 \cdot 2H_2O$	1	Phase of some $CaPO_4$ biomaterials
Octacalcium phosphate (OCP)	$Ca_8(HPO_4)_2(PO_4)_5 H_2O$	1.33	Phase of some $CaPO_4$ biomaterials
Whitlockite (WH)	$Ca_{10}(HPO_4)(PO_4)_6$	1.43	Phase of some $CaPO_4$ biomaterials
Beta-tricalcium phosphate (b-TCP)	$Ca_3(PO_4)_2$	1.48	Biodegradable $CaPO_4$ ceramic for bone substitute and coatings; also a phase of some $CaPO_4$ biomaterials
Defective hydroxyapatite (DOHA) biomaterials	$Ca_9(HPO_4)(PO_4)_5(OH)$	1.5	Component of some $CaPO_4$ biomaterials
Hydroxyapatite (HA)	$Ca_{10}(PO_4)_6(OH)_2$	1.67	Major mineral phase of bone; when fired as a ceramic, named *HA*

TISSUE INTEGRATION: BIOMATERIAL AND BIOMECHANICAL ASPECTS

The science, technology, and clinical development of surgical implant-to-bone integration has for decades been a central area of emphasis (Misch, 1999; Rizzo, 1988). Practical aspects of the inability to physically separate bone-to-implant interfaces for ceramic and metallic oxide implant interfaces led to considerable interest in why this occurred, and thereby to many basic and applied studies. One part of these studies was based on element and force transfers for conditions of stable *in vivo* function. Dental implant treatments, over four decades have, in part, contributed to a major change in the philosophy of dental implant-based treatments for replacement of tooth loss. From a historical perspective, early reports of tissue integration for dental implants, in general, were complicated by the factors of clinical placement and restoration. Most implants were placed under variable conditions, and were immediately (hours to weeks) subjected to biomechanical function. Immediate intraoral restoration resulted in force transfers (stresses and strains) between the implant body and the supporting tissues during the period of initial tissue healing. Therefore, this discussion of tissue integration of dental implants will include both material and mechanical aspects of device function.

Experience prior to 1960 for a wide range of materials showed implant-to-tissue regions, where significant higher magnitude loads were transferred, that were fibrous soft tissue (scar-like) interfaces (James and Keller, 1974; James, 1983; Weiss, 1986). These zones were relatively dense collagenous structures that contained limited numbers of cells and blood vessels. Dental implants fabricated from steel, gold, platinum, and cobalt alloys, upon review of tissue interfaces after months to years of clinical function, showed soft tissue scar-like zones of contact (Lemons, 1999). In contrast, early experience with some dental implants fabricated from higher purity aluminum oxides (alumina and sapphire forms), carbons, calcium phosphate compounds, and reactive group metals and alloys (primarily titanium in the 1960s) demonstrated a mixture of direct bone-to-implant contact and soft tissues when evaluated histologically by optical microscopy methods. These interfacial conditions were described as

osseo- or osteo-integrated and special conditions to routinely achieve these conditions were developed (Rizzo, 1988). A central focus developed for analyses of titanium, with oxidized surfaces contiguous with endosteal regions of oral bones. Multiple journal articles, books, conference proceedings, etc., described these and other conditions of tissue integration (Misch, 1999).

Several central conditions were defined, i.e., bulk and surface conditions for synthetic biomaterials that did not elicit a foreign-body response; surgical procedures to minimally traumatize the surgical site; and functional stresses and strains at the implant-to-bone interface where biomechanical microstrains were within the physiological limits of the bone during healing and longer-term function.

Considering these conditions, multiple requirements were developed for all levels of implant devices including diagnosis, surgery, restoration, and maintenance of dental implants. Analysis of the interface zone at nano-, micro-, and macrolevels of resolution demonstrated the importance of careful control of implant bulk and surface properties, and cleanliness, surgical methods and site dimensions, times and conditions of intraoral abutment placement, intraoral restoration, and maintenance (cleaning) of the percutaneous transition zone. As an example, of biomaterial properties, if unit area of implant, bone, and force were modeled, the interfacial strain magnitude would depend directly on any applied forces (the force vector direction and magnitude), the smoothness/roughness of the contact zone, attachment (bonding), and the elastic moduli of the implant biomaterial and the bone. Limited attachment (bonding) has been shown for some bioactive surfaces (e.g., calcium phosphates, glasses, etc.); however, most ceramics such as alumina, zirconia, and titania, and most surface oxidized metallics have demonstrated contact, but minimal or no chemical-type bonding. Most have reported that chromium oxides found on iron and cobalt alloys related to passivation were separated from the bone by a zone of non-osseous (fibrous) tissue. Surface roughness (irregularities) were shown to provide conditions for interdigitation under conditions of microscopic contact with mineralized bone, and microscopic regions of force transfer, plus potential advances for early healing (depositions

of blood clot, fibrin, integrins, etc.) Microtopography was proposed to be critical for conditions of loading as a resistance to microscopic shear at the interface.

Returning to the role of implant and tissue moduli, conditions of unit area and force led to a method for evaluating relative strain magnitudes at the interfacial zone. If the interface is non-interdigitated and non-chemically bonded, strain magnitudes of the contact zone for each part would be proportional to the elastic modulus of each part. On a comparative basis of the biomaterial relative to compact bone, ceramics of alumina and zirconia have moduli of more than 10×, alloys 5–10×, with unalloyed titanium the lower magnitude, carbon and calcium phosphates about 0.5–2×, and polymerics lower by 50–1000× difference. The polymerics in general have moduli that are more similar to soft tissues. Clearly, the overall macroscopic shape, size, and geometry of the implant, the implant biomaterial and surface, the macro- and micro-anatomy of the bone, and the clinical conditions of function have been shown to directly influence the specific properties and conditions at the device interface. In this regard, dental implants over the years have included a very wide range of the circumstances listed above. However, in general, longer-term bone integration has been shown for implants fabricated from ceramic and metallic biomaterials which have included a range of physical features (macro- and microgeometries, microtopographies over a range of micro-dimensions and shapes often classified as pins, rods, screws, finns, plates, etc.) with and without surface modifications.

Implant survival statistics support high percentages (above 90%) remaining functional for decades. In the 2010s dental implants are expanding as a treatment of choice; where a tooth is lost, an implant is placed. Many propose this as the best and most cost-efficient way to maintain dental health over the longer-term. Therefore, the demand for dental implant treatments in society at large has increased, and the professional society and dental school programs are now offering basic education and training at the dental medicine (DMD) undergraduate level. These treatments have evolved to a "standard of care" status.

Many different implant biomaterials and designs have been studied; however, the larger numbers of applications have now become root-form designs placed, restored, and maintained for function through osteointegrated interfaces with bone. The biomaterials are now mostly titanium and alloys with a wide range of surface modifications for influencing interfacial tissue regions. Surface modifications include compositional (primarily oxides, calcium phosphates, and fluoride) and micro-topographical features (degrees of roughness). These concepts also extend to the gingival and mucosal soft tissue to implant interfacial systems.

Interest has also been ever increasing in the use of synthetic-active biologic combinations for enhancing tissue quantity, quality, and healing characteristics. Many dentists now restore the dental implants to limited functional use immediately after surgical placement. Some call this "back to the future." Research and development at many levels supports possibilities for hard and soft tissue and tooth regeneration through tissue-engineered regenerative medicine approaches. If accomplished, the need for current dental implants based on synthetic biomaterials may be decreased accordingly. Most say that considerable science needs to be completed to accomplish the regeneration of anatomical replicates of functional and healthy teeth. Early research is most promising, and rapid advancements in regenerative approaches are anticipated.

INTRODUCTION

Description and Definition of Adhesives, and Related Terminology

In the context of biomaterials, adhesion science and technology assume high importance. It is useful to commence with the slightly wider concept of *bonding*. It is evident that many biomaterial devices are structured from multiple components, and these need to retain their mutual integrity during clinical service. In this context, the bonds in question may include metallic welds, although these would not be considered within the domain of adhesion, any more than screw attachments that have a role in some implants.

The most challenging issue is the creation of a durable interfacial bond between a biomaterial and its host tissue. In addition to the function of bonding, *per se*, an adhesive biomaterial may be required to fulfil a *space-filling* role – replacing some or all of any lost natural tissue. In the former case, the function may be termed *grouting*. This is, for example, the primary function of bone cements in orthopedics. A further ideal function of an adhesive is that of *sealing*; that is, the prevention of ingress of moisture, air, biological fluids, bacteria or other species through the adhesively bonded zone.

Adhesive is a general term, and in specific contexts may be replaced by designations such as cement, glue, paste, fixative, and bonding agent. Some adhesives may be designed to exhibit further functions, such as antibacterial action, delivery of drugs or beneficial ions, such as the antibacterial ion Ag^+ or fluoride (F^-). Fluoride is a component of dental preventative treatments which initiates the partial replacement of hydroxyapatite (HA) – the tooth enamel's normal crystalline composition – with fluorapatite (a related crystal which incorporates F^-). Fluorapatite is more resistant to decay than HA.

Sometimes the converse of adhesion, namely *abhesion*, is necessary in clinical treatment. This "non-stick" feature is required with blood-compatible biomaterials, and is exhibited by non-fouling surfaces covered with polyethylene glycol (PEG).

During the past half-century there has been a strong convergence of the ancient technologies of adhesives and the modern science of adhesion – based especially on advances in surface science and the understanding of molecular adhesive mechanisms. This progress has been stimulated by widespread industrial uses and biomedical applications of adhesives. The former have been driven by advances in polymer science, and the adoption of lightweight alloy and non-metallic composite materials in the aerospace and automobile industries. Nevertheless, the stringent biomedical requirements for adhesives have led to some specialized developments.

The diverse biomedical *contexts* (host environments) of adhesives each require appropriate materials and techniques. Biological hosts differ principally as to whether they consist of *hard* or *soft* tissues. Connected with this are the *timescales* required for adhesive/bonding durability. These may vary from days, in the case of wound-closure adhesives, to decades of years, in the cases of bone cements and dental restorations. The aim of this chapter is to give a sound introduction to the physico-chemical and materials science aspects of adhesives and sealants, together with a description of current systems utilized in a range of surgical practice. It does not attempt a detailed study of the molecular biological interactions of adhesives.

More details on the background to adhesion and adhesives can be found in a number of texts (Kinloch, 1987; Comyn, 1997; Pocius, 1997; Mittal and Pizzi, 1999; Eliades et al., 2005; Matinlinna and Mittal, 2009). General information on wound closure and surgical adhesives is given in Sierra and Salz (1996) and Chu et al. (1997). The proceedings of a conference on adhesion in dentistry provide an important set of contemporary reviews (Armstrong et al., 2010; Braga et al., 2010; Mair and Padipatvuthikul, 2010; Marshall et al., 2010; Perdigão, 2010; Scherrer et al., 2010; Söderholm, 2010; Tagami et al., 2010; Van Meerbeek et al., 2010).

THE LOGIC OF ADHESION PROCEDURES

Inspection of a wide range of industrial, domestic, and biomedical adhesives shows the generally common presentation as some form of fluid agent that incorporates a means of conversion into a solid form. The vast majority of such adhesives are designed for application to *adherends* that are fairly rigid solid surfaces. However, there is often an educational gap in the understanding of why *fluid* adhesives are necessary for application to solid adherends, and why they must undergo *solidification* reactions. Hence, we shall outline the straightforward logic of such an adhesive design strategy.

Our starting point – in chemistry – is the existence of *electromagnetic forces* between, as well as within, molecules. Additional to the *primary* bond types (covalent, ionic, and metallic), these *secondary* intermolecular forces include hydrogen bonds and van der Waals bonds, both dipolar and dispersion types. There is a wide variation in the relative strength of these bonds, covalent bonds being the strongest; even weak bonds can have a massive cumulative effect if they have a high number density, as with the H bonds between water molecules.

However, it is characteristic of intermolecular forces and interaction energies that they diminish rapidly with separation, often depending on the inverse 6th power of the separation distance (r). For example, the net interaction energy (U) between two permanent dipole moments

(μ_A, μ_B) within neighboring molecules or surfaces is determined by the overall average of the product:

$$\left[U(r) \times e^{-U(r)/kT} \right]$$

where k is Boltzmann's constant and T is temperature. When:

$$\left(\frac{\mu_A \cdot \mu_B}{\varepsilon' \cdot r^3} \right) \ll KT$$

then:

$$U_{average} = -\frac{2}{3} \frac{\mu_A^2 \cdot \mu_B^2}{r^6} \times \frac{1}{KT}$$

Where ε is the permittivity of the medium.

Hence, if two solid surfaces are brought into sufficiently close proximity, at moderate temperatures, there is the possibility of interaction energy between them.

Nevertheless, there is a further topological factor; namely that even macroscopically smooth surfaces are microscopically rough. Hence, two solids in close proximity at the nanoscale may be akin to a superimposed pair of mountain ranges. The actual contact regions between the two solids are restricted to the "mountain peaks," and a major proportion of each total solid area is not in contact and is held apart *beyond* the distance zone over which the interaction energies are significant. The *effective intimate contact area* between the two surfaces is then too small to *directly* realize the potential of the intermolecular forces. It follows that rigid contact between the two solids fails to deliver an appreciable net interaction force. However, there are some exceptions to this outcome when one or more of the contacting solids exhibits plastic flow under mechanical stress. Thus, pieces of gold foil may become self-adherent under compressive stress. Similarly, waxes can mutually bond when temperature is raised slightly.

To achieve adhesive bonding in the general case of two rigid solids, such as a tooth enamel surface and an orthodontic bracket, it is necessary to apply a fluid adhesive between them. Moreover, the fluid must be of appropriate chemical formulation to initially wet both surfaces, exhibiting a low *contact angle*. One or both surfaces may have been subjected to some form of pre-treatment or *conditioning* with an *etchant* or *primer* that, *inter alia*, may have modified surface porosity. In this case, the adhesive fluid may be drawn into the solid surface layers by capillary action.

The presence of a suitable fluid between two solids greatly enhances the potential for intermolecular force interactions at each solid–fluid boundary. Further, if for example, the solid is a calcified tissue and the fluid incorporates carboxylic acid groups, then *primary* bonds may be created at the interface. Such primary and/or secondary bonds can immediately generate a measureable resistance to *tensile* loading of the solid interface. This may be augmented by the Laplace pressure difference arising from the fluid surface tension. Nevertheless, such solid pairs weakly bonded by a fluid can be readily disrupted by *shear* forces.

In the general case, therefore, to achieve an adhesive bond zone stable against shear forces, it is imperative to convert the adhesive agent from a fluid to a solid. In this process, it is desirable for the adhesive agent to exhibit high dimensional stability in relation to the interface with one or more adherends. There are several physico-chemical mechanisms available for achieving adhesive solidification, or *setting*, including:

- Phase transformation on cooling;
- Solvent evaporation;
- Polymerization (and cross-linking) of fluid monomers or oligomers;
- Acid–base reaction.

Phase transformation has not been applied with biomedical adhesives, as the requisite temperatures (normally above 100°C) are beyond the biologically-tolerable range. Polymerization of monomer systems is the most widely used approach. However this is susceptible to *polymerization shrinkage phenomena* and thus stress-development (see the section on Stress-Development in Adhesive Joints due to Polymerization Shrinkage). Acid–base reactions are present in the setting of polycarboxylate and glass–ionomer cements.

The resultant interfacial bonds, generated by the above adhesion strategy, can be analyzed into different micro- or nanostructural contributions. These may include *micro-mechanical bonds* created by the interlocking of solidified adhesive "tags" (extensions) into surface porosity or roughness of the adherend. Where the microadaptation of the solid adhesive and the adherend remains molecularly intimate, the intermolecular forces can contribute; and where specific primary bonds are generated, especially with metallic adherends, their contribution is significant.

Given the foregoing general scheme of how adhesive bonds can be generated, many of the factors that can weaken or compromise these bonds will be obvious. These include: air voids; contaminants; and weak boundary layers. This leads to consideration of *surface pretreatments* designed to avoid these problems.

ADHEREND SURFACE PRETREATMENTS TO ENHANCE BOND STRENGTH AND DURABILITY

Biomedical adhesive systems for use as, or with, biomaterials are usually accompanied by detailed instructions for use. Frequently this printed information and advice is supplemented by audiovisual material relating to the mechanisms of action and to detailed applicatory steps. The steps involve meticulous preparation of the adherend surfaces, especially in the case of hard tissues. In practice, there can be a tension between the complexity and effectiveness of the pretreatment *versus* the desire for clinical simplicity and overall speed of application.

Preparation may involve cleansing the tissues from contaminants such as blood or saliva, for if these substances remain *in situ* they can have a negative, abhesive effect. However, the goal is often not merely to remove a contaminant, but also to enhance surface free energy and

thereby promote improved wetting, spreading, and penetration of the adhesive agents. In the case of hard dental tissues, a well-established treatment is application of an aqueous phosphoric acid solution to etch and/or demineralize the outer tissue layers (as considered in the sections on Hard Tissue Adhesives: Bone and Tooth Cements; and Acid-Etch Bonding to Enamel). A converse experimental approach in former times was to hyper-mineralize calcified tissues. This was successful *in vitro*, but required clinically unfeasible pretreatment times.

When bonding to synthetic biomaterials, such as ceramics, roughening of a "fitting" surface – to be bonded – increases the effective surface area. This is often combined with application of chemical primers, such as silane coupling agents. In the case of many implants and oral prostheses, the bonding surface may undergo plasma spraying to deposit a well-attached ceramic layer, perhaps of hydroxyapatite (HA). This radically changes the chemical nature of the surface to which adhesive bonding must then be achieved.

HARD TISSUE ADHESIVES: BONE AND TOOTH CEMENTS

Auto-Polymerizing PMMA Bone Cement

Historical Background. In 1936 it was noted that mixing ground polymethylmethacrylate (PMMA) powder with the monomer (MMA) produced a dough which could be manipulated and molded; hence it became one of the first biomaterials (Weber and Chapman, 1984; Donkerwolcke et al., 1998; Kühn, 2000; Webb and Spencer, 2007). Early applications were in dentistry. This was initially employed by orthopedic surgeons as a cement or grout to improve implant fixation in 1953. However, the major breakthrough in the use of PMMA/MMA bone cement in total hip replacement (THR) was proposed by Smith and Charnley, who used it to secure fixation of the acetabular and femoral components and to transfer loads to bone (Charnley, 1960, 1970) (Figure II.5.8.1). More recent applications include percutaneous vertebroplasty applied to the osteoporotic spine, which can provide significant and prolonged relief of pain (Lewis, 2006; Webb and Spencer, 2007).

Mechanism of Setting of PMMA/MMA Dough. Methyl methacrylate (MMA) liquid (Figure II.5.8.2) is rapidly absorbed into PMMA powder, creating a tacky material that progresses to a non-tacky dough stage. These can be considered merely *physical* changes. However, benzoyl peroxide (BPO) initiator, mixed in with the powder, can be chemically activated to form free radicals, either by heating to above 60°C or by the incorporation of a suitable amine activator into the monomer, to enable room temperature auto-polymerization or "cold-cure." As activation generates free radicals from BPO, these start to react with the MMA molecules. The free radical polymerization reaction thus continues through the *propagation* stage – where chain growth occurs from multiple radical initiation sites – until this reaches the *termination* stage, where
FIGURE II.5.8.1 Cross-section of femur and interlocking bone cement showing good adaptation of the cement to the prosthesis (now removed), and a zone of interaction with the inner surface of the compact bone. (with courtesy of J. Charnley, personal communication)
FIGURE II.5.8.2 Methyl methacrylate and methyl cyanoacrylate.

polymerization is either fully complete or the free radicals are consumed. MMA polymerization is a highly exothermic process, arising from the conversion of C=C bonds. Hence, in the constrained interfemoral environment there is normally a significant temperature rise, which auto-accelerates the setting process, peaking above 56°C for 2–3 minutes *in vivo*. Sometimes higher temperatures are reached, up to 90°C, which can volatilize unreacted monomer (boiling point of MMA is 101°C). This creates voids that can later lead to mechanical failure.

Rheological Factors in Cement Delivery. While the physical absorption and chemical polymerization processes take place, the material at the early dough stage is forcibly injected into the femoral space around the metallic femoral prosthesis. The rheology of the injection process is complex. Bone cements can be formulated to yield different viscosity ranges: low; medium; and high. High viscosity cements have a short waiting/sticky phase, followed by a long working phase that is more suitable for many surgeons.

Cement in its liquid phase of curing behaves as a non-Newtonian (pseudoplastic) fluid, with viscosity decreasing as shear rate is increased. However, the viscosity of all cements increases appreciably during polymerization as the polymer chains lengthen until the material is solidified. Setting times range from 5 to 13 minutes from start of mixing (Kühn, 2000).

Mechanism of "Bonding" or Grouting. As the cement flows under pressure to penetrate the interstices of cancellous bone and adapts to the surface of the femoral stem, it can achieve micro-interlock with the bone when solidified. Nevertheless, PMMA bone cement undergoes a degree of shrinkage on polymerization. Hence another benefit of pressurized injection is partial compensation for this effect. Shrinkage is a potential major source of porosity (Gilbert et al., 2000).

Influence of Pore Distribution in Bone Cements on the Cement/Implant Interface

Implant fixation has been achieved with acrylic bone cement for many years. Although this is a successful application overall, the bond between the implant and bone cement has been shown to be the most fragile link in the construct in femoral components, with failure likely only a short time after implantation. Interfacial porosity and the formation of microcracks have been identified as factors detrimental to cement/implant performance, with pores serving as nucleation sites for these microcracks.

To decrease interfacial porosity and improve the longevity of the cement/implant bond, several authors have suggested pre-heating implants. Although cements react differently to the curing

environments, the most prevalent trend was increased mechanical properties when cured at 50°C versus room temperature. Pores were shown to gather near the surface of cooler molds, and near the center in warmer molds for all cement brands. Pore size was also influenced. Small pores were more often present in cements cured at cooler temperatures, with higher-temperature molds producing more large pores. The mechanical properties of all cements were above the minimum regulatory standards. This supports the practice of heating cemented implants to influence interfacial porosity.

Pelletier, M. H., Lau, A. C. B., Smitham, P. J., Nielsen, G., & Walsh, W. R. (2010). Pore distribution and material properties of bone cement cured at different temperatures. *Acta Biomaterialia*, **6**, 886–891. Elsevier. DOI: 10.1016/j.actbio.2009.09.016

Alternative Bone-Cements: Calcium Phosphate. In orthopedic surgery there are some alternatives to PMMA bone cement, and there is also the option of cementless fixation. Inorganic cements, notably from the Ca–P system, include HA [$Ca_{10}(PO_4)_6OH_2$] and TCP [$Ca_3(PO_4)_2$]. The biocompatibility of HA and its similarities to bone mineral have led to the study of dense HA for the augmentation of osseous defects.

Classical and Modern Dental-Bonding Cements: Conventional Acid–Base Cements. Dental cements are, traditionally, fast-setting pastes obtained by mixing solid and liquid components. Most of these materials set by an acid–base reaction, and subsequently developed resin cements harden by polymerization (Smith, 1971, 1991, 1998). The composition of these materials is shown in Table II.5.8.1. The classes and typical mechanical properties are given in Table II.5.8.2. The

TABLE II.5.8.1	Classification and Composition of Tissue Adhesives	
Type	**Components**	**Setting Mechanism**
Hard Tissue Adhesives		
Bone		
Acrylic bone cement	Methyl methacrylate and polymethylmethacrylate	Peroxide – amine initiated polymerization
Teeth		
Dental cements: Zinc phosphate	Zinc oxide powder, phosphoric acid liquid	Acid–base reactions; Zn complexation
Zinc polycarboxylate	Zinc oxide powder, aqueous poly(acrylic acid)	Acid–base reactions; Zn complexation
Glass ionomer (polyalkenoate)	Ca, Sr, Al silicate glass powder aqueous poly(acrylic acid-itaconic acid)	Acid–base reactions; Metal ion complexation
Resin modified glass ionomer	Dimethacrylate monomers. Aqueous poly(acrylic acid-methacrylate) co-monomers. Silicate or other glass fillers	Peroxide-amine or photo-initiated polymerization
Resin-based	Aromatic or urethane dimethacrylates, HEMA	Photoinitiated addition polymerization
Dentin adhesive	Etchant: Phosphoric acid (aq.) Primer: HEMA in ethanol or acetone Bond resin: Dimethacrylate monomers	Photoinitiated addition polymerization
Soft Tissue Adhesives		
Cyanoacrylate	Butyl or isobutyl cyanoacrylate	Addition polymerization
Fibrin sealants	A. Fibrinogen, Factor XIII B. Thrombin, CaC12	Fibrin clot formation
GRF glue	Gelatin, resorcinol, formaldehyde	Condensation polymerization
Hydrogel	Block copolymers of PEG, poly(lactic acid) and acrylate esters	Photoinitiated addition polymerization

TABLE II.5.8.2	Properties of Dental Cements and Sealants			
	Strength			
Dental Cement/Sealant	Compressive (MPa)	Tensile (MPa)	Elastic Modulus (GPa)	Fracture Toughness (MN$^{-1.5}$)

Dimethacrylate sealant unfilled	90–100	20–25	2	0.3–0.4
Dimethacrylate sealant filled	150	30	5	–
Dimethacrylate cement	100–200	30–40	4–6	–
Dimethacrylate composite	350–400	45–70	15–20	1.6
FIGURE II.5.8.3 Classification of major types of acid–base dental cement based upon the combinations of basic powders of either zinc oxide or alumino-silicate glass with two aqueous acidic liquids.

FIGURE II.5.8.4 Structure of the polyelectrolyte: poly(acrylic acid), as present in aqueous solution, in polycarboxylate and glass ionomer cements. The carboxyl anions COO$^-$ are bridged by divalent or trivalent metal ions during the setting process, forming a salt matrix.

FIGURE II.5.8.5 Neutralization of poly(acrylic acid) by zinc oxide to form zinc polycarboxylate cement, in which Zn^{2+} functions as a bridging ion between pairs of carboxylate groups.

relationship between principal categories is illustrated in Figure II.5.8.3.

Zinc phosphate cement is the traditional standard. This material is composed primarily of zinc oxide powder and a 50% phosphoric acid solution containing aluminum and zinc. The mixed material sets to a hard, rigid cement (Table II.5.8.1) by formation of an amorphous zinc phosphate binder. Although the cement is gradually soluble in oral fluids and can cause pulpal irritation, it is clinically effective over 10 to 20 year periods. The bonding arises entirely from penetration into mechanically produced irregularities on the surface of the prepared tooth and the fabricated restorative material. Some interfacial leakage occurs because of cement porosity and imperfect adaptation, but this is usually acceptable since the film thickness is generally below 100 μm.

Poly-Electrolyte Cements: Zinc Polycarboxylates and Glass Ionomers. Poly(carboxylic acid) cements were developed in 1967 (Smith, 1967, 1998) to provide materials with properties comparable to those of phosphate cements, but with adhesive properties to calcified tissues. Zinc polyacrylate (polycarboxylate) cements are formed from zinc oxide and aqueous poly(acrylic acid) solution (Figure II.5.8.4). The metal ion cross-links the polymer structure via carboxyl groups, and other carboxyl

groups complex to Ca ions in the surface of the tissue (Figure II.5.8.5). The zinc polycarboxylate cements have adequate physical properties, excellent biocompatibility in the tooth, and proven adhesion to enamel and dentin (Smith, 1991), but are opaque. The need for a translucent material led to the development of the glass-ionomer cements (GIC).

GICs are also based on poly(acrylic acid) or its copolymers with itaconic or maleic acids, but utilize a calcium aluminosilicate glass powder instead of zinc oxide. GICs set by cross-linking of the polyacid with calcium and aluminum ions from the glass, together with formations of a silicate gel structure. The set structure and the residual glass particles form a stronger, more rigid cement (Table II.5.8.1), but with similar adhesive properties to the zinc polyacrylate cements. Both cements are widely used clinically.

Neutralization of Bacterial Acids. Acid–base cement formulations are non-stoichiometric, having an excess of the basic powder. This is beneficial in intra-oral applications as the net basicity of the set cement retains the
FIGURE II.5.8.6 Formation of the matrix of a "resin modified" glass ionomer cement (RMGIC), by means of C=C bond polymerization, concurrently with ionic salt bridges with metal ions derived from an ion-leachable glass.

capability of neutralizing *in situ* erosive acids produced by bacterial metabolism of dietary sugars.

Resin-Modified Glass-Ionomer Cements. In these cements, the polyacid molecule contains both ionic carboxylate and polymerizable methacrylate groups (Figure II.5.8.6). It is induced to set by both an acid–base reaction and visible light polymerization. These dual-cure cements are widely used clinically. Adhesive bonding but not complete sealing is obtained, because of imperfect adaptation to the bonded surfaces under practical conditions.

Dual-Setting Resin-Based Cements. Resin cements are fluid or paste-like monomer systems based on aromatic or urethane dimethacrylates. Silanated ceramic fillers are usually present to yield a composite composition. They are normally two-component materials that are mixed to induce setting. They may also be light-cured. These set materials are strong, hard, rigid, insoluble, cross-linked polymers (Table II.5.8.1). Bonding is achieved by mechanical interlocking to surface roughness.

Self-Etching Resin-Based Cements. In recent materials, reactive adhesive monomers may also be present to avoid the necessity of using a separate dentine-bonding system, as described in the section on Bonding to Dentin via the Hybrid Inter-Phase).

Acid-Etch Bonding to Enamel

Dental enamel is a hard, stiff substrate of generally uniform chemical composition. Bonding to enamel is required either in conjunction with bonding to dentin, for cavity restoration or for bonding veneers or orthodontic brackets directly to enamel of teeth in the upper or lower dental arch. In both cases, the modern approach was pioneered by Buonocore (Roulet and Degrange, 2000; Eliades et al., 2005). This involves conditioning with an aqueous phosphoric acid etchant for about 60 seconds. Subsequent water-rinsing and air-drying leaves a visibly matt surface on the enamel – now differentially etched, with either the enamel-prism cores or the prism peripheries exposed (Figure II.5.8.7). Application of an unfilled resin (monomer mixture) or a moderate-viscosity resin-composite allows this to flow across the enamel, penetrating surface porosity. Subsequent hardening of the resin results in its retention via a multitude of microscopic tag-like resin extensions into the enamel surface.
FIGURE II.5.8.7 Surface of acid-etched dental enamel. In this image, there are alternating regions where the bundles of prism structures are viewed: (i) transversely (end-on); or (ii) semi-longitudinally. In the case of the transverse prisms, the prism peripheries have been preferentially etched, leaving the prism cores visble.

Bonding to Dentin via the Hybrid Inter-Phase

Intense Research Effort and Advances in this Area. Bonding restorative biomaterials to dentin is much more challenging than to enamel, due to the more complex, hydrated substrate. Not only may this involve caries-weakened dentin, but the cut dentin surface has a weakly attached "smear" layer. This is a layer of mixed composition, including denatured collagen, generated by the thermo-mechanical process of cutting dentin by high-speed burs. This material is mechanically weak and is smeared all over the cut surface, covering the sound dentine underneath. This must be either removed or significantly modified.

Nevertheless, recent decades of intensive worldwide research have made remarkable advances both in understanding the ultra-structure of the resultant bonds, and then devising improved formulations (Nakabayashi and Pashley, 1998; Roulet and Degrange, 2000; Eliades et al., 2005; Moszner and Salz, 2007; Matinlinna and

Mittal, 2009). At present, the outstanding challenges are to enhance the long-term durability of adhesive bonds against both intra-oral stresses and biochemical degradation (Breschi et al., 2008; Watts et al., 2009). There is also a secondary goal of formulating simpler, and thus time-saving, application protocols.

Early Unsuccessful Approaches

It was recognized early that simply applying hydrophobic resins to dentin gave little benefit. Moreover, for several decades it was deemed clinical malpractice to apply an acid etchant to dentin. Development of adhesives proceeded slowly until the critical insights concerning dentin hybridization and the hybrid-layer were achieved, as discussed in the section titled Hybrid-Layer Creation via Three-Stage Approach: Etch; Prime; Bond.

Chemistry of Etchants, Primers, and Bonding Agents

Modern effective dentine bonding systems can be considered as incorporating a three-fold set of agents, although two or even three of these functions may be combined in a simplified system. The *etchant* or *conditioner* function is provided by either an aqueous phosphoric acid gel or by acidic monomers. The *primer* function is classically achieved by a solution of a hydrophilic monomer, such as HEMA, in a solvent such as acetone or ethanol. Subsequently, a "*bonding agent*" consisting of unfilled resin monomers is applied to the dentine.

Hybrid-Layer Creation via Three-Stage Approach: Etch; Prime; Bond

The optimal approach is to use a separate acid etchant, and to apply this to the dentin for about 10 seconds, which removes the smear layer (Figure II.5.8.8). This demineralizes the outer dentin layers, leaving residual type I collagen fibrils and proteoglycans. Washing the dentine removes the acid and salt residues. However, drying results in collapse or compaction of the collagen. The second agent, the primer, has the role of re-expanding the collagen, thereby restoring its porosity (Figure II.5.8.9). This permits the third agent – unfilled hydrophobic "bond" monomers – to permeate and seal the collagen. When these are photo-cured they form an entangled interpenetrating network (IPN) with the collagen fibers. The resultant interfacial IPN region, typically 4 μm in thickness, is known as the hybrid zone. Effectively, the polymerized resin is taking the place of the original mineral phase in this region. The strength of this bonding zone depends on the continuing integrity of its component elements, principally the collagen fibrils and the polymerized monomers.
FIGURE II.5.8.8 Dentin surface following etching with phosphoric acid solution. The dentine tubules are clearly visible.
FIGURE II.5.8.9 Cross-section of acid-etched and demineralized dentin. The collagen fibrils are visible (arrowed) within a tubule.

The Quest for Simplified Clinical Procedures

Clinical success depends on understanding the rationale of each step and meticulous observance of manufacturer's instructions. The market has led to availability of simplified systems, where two or more steps may be combined into one, including self-etching systems (Figure II.5.8.10). Earlier "one step" systems of this type gave reduced performance, but newer products incorporating clever delivery devices are more successful. Nevertheless, there are many systems available where a simplification of clinical application procedures is done to the detriment of bonding efficacy.

Aging and Stability of the Bonded Interface

When properly applied, good adaptation and bonding of the adhesive and restorative material to dentin can be achieved in the short- and medium-term. Also, a good initial seal of the interfacial zone can be achieved. However, a number of potential weaknesses have been identified (Breschi et al., 2008).

1. *Insufficient resin impregnation of dentin:* There are circumstances where the demineralized collagen is not fully supported by infiltrated resin, leaving a mechanically weak zone.
2. *High permeability of the bonded interface:* The hybrid zone is susceptible to "nano-leakage" by small molecules and ions, which may provide a pathway for degradation reactions over time.
3. *Sub-optimal polymerization:* The efficiency of polymerization of the infiltrated monomer may be compromised by the presence of water and dissolved oxygen, thereby weakening the IPN structure.
4. *Phase separation:* Monomer mixtures *in situ* of varying hydrophilicity may spontaneously phase separate upon polymerization.
5. *Activation of endogenous collagenolytic enzymes:* Recent studies have revealed that dentin matrices may be slowly degraded over time by dentin-derived proteolytic enzymes, particularly matrix metalloproteinases (MMPs). Collagen integrity within the hybrid layers may be promoted by incorporation of chlorhexidine, an anti-bacterial agent with MMP-inhibiting properties.

Inhibitors for the Preservation of the Hybrid Interfacial Zone Between Adhesives and Human Dentin

The outstanding resistance of the collagenous dentin matrix against thermal and proteolytic disruption has been attributed to the high degree of intermolecular cross-linking and tight mechanical weave of this specialized connective tissue. However, great attention to the potential proteolytic activity of dentin has been raised since complexed and active forms of matrix metalloproteinases (MMPs) were identified in either non-mineralized or mineralized compartments of human dentin. MMPs belong to a group of zinc- and calcium-dependent enzymes that have been shown to be able to cleave native collagenous tissues at neutral pH in the metabolism of all connective tissues. Galardin is a synthetic MMP-inhibitor with potent activity against MMP-1, -2, -3, -8, and -9. It also partially preserved the mechanical integrity of the hybrid layer created by a two-step etch-and-rinse adhesive after artificial aging.

Breschi, L., Martin, P., Mazzoni, A., Nato, F., & Carrilho, M. et al. (2010). Use of a specific MMP-inhibitor (galardin) for preservation of hybrid layer. *Dent. Mater.*, **26**, 571–578. Elsevier: DOI: 10.1016/j.dental.2010.02.007
Incorporation of Anti-Bacterial Functionality

Efforts have been made for some time to incorporate anti-bacterial agents in either composites or dentin-adhesives, with the latter showing greater promise (Imazato, et al. 1998, 1999; Imazato, 2003).

Stress-Development in Adhesive Joints due to Polymerization Shrinkage

Inevitability When Using Methacrylate Matrix Composite Biomaterials. As already noted, adhesive layers, when solidified by polymerization, are accompanied by shrinkage phenomena. In restorative dentistry, tooth cavities – caused by carious decay – are now principally repaired by tooth-coloured polymer–ceramic composites, instead of silver amalgam fillings. These bulk materials also exhibit setting shrinkage which exacerbates the interfacial stresses on the adhesive joints. This is an inescapable feature of the currently dominant dimethacrylate "resin" composites. Despite numerous attractive properties of these biomaterials, many adverse clinical problems can arise if this shrinkage problem is not adequately managed (Watts et al., 2009). It is a major potential cause of adhesive failure.

Molecular Origins of Shrinkage and Polymerization-Kinetics

When methacrylate monomers undergo polymerization, this involves the conversion of C=C double bonds to C–C single bonds. The original monomer molecules are no longer separated by a mean intermolecular (van der Waals) distance, but become connected via the C–C bonds. This implies a closer packing of the molecular units – or in other terms, molecular densification. For example, with methyl methacrylate (MMA), the volume change per mole of methacrylate groups is:

$$\Delta V_{C=C} = 22.5 \ cm^3 \ mole^{-1}$$

This localized molecular shrinkage normally occurs throughout the bulk of the material and so produces a macroscopic shrinkage.

For multi-methacrylate monomers of higher C=C functionality (*f*), and for a *degree of conversion* (DC) that may be less than 100%, the volumetric shrinkage is given by:

$$\varepsilon_{vol} = 22.5 \times DC \times f \times \frac{V}{V_m} \times 100$$

where: *V* is volume and V_m is molar volume. This can easily be generalized for a mixture of monomers (Silikas et al., 2005).

Both methacrylate and acrylate polymerization occur by a free radical mechanism. This may be activated by various means, although *photo-activation* using visible blue light is the most widespread option in dentistry, with *chemical activation* being essential for bone cements (see Mechanism of Setting of PMMA/MMA Dough).

In dimethacrylate dental monomers, there are two C=C polymerizable groups at either end of the molecule. Statistically, both C=C groups react in a high proportion of cases, generating a tightly cross-linked matrix network. However, some monomers only react via one C=C group, leaving the other C=C group unreacted and pendant. This is because following a rapid auto-acceleration phase, the material vitrifies and the chain-end free radicals become locally trapped within the glassy network. The *rate* of polymerization then rapidly diminishes (auto-deceleration) towards zero (Watts, 2005). Thus, at 37°C, the *degree of conversion* of monomer is only about 65%. Nevertheless, physical properties are otherwise satisfactory.

Factors that Affect the Magnitude and Vector Direction of Shrinkage Stress

When an adhesively-bonded resin-composite is placed between two or more opposing cavity walls, then the material is not able to shrink freely upon polymerization. Therefore, providing adhesive bonding is achieved to the walls, a state of "shrinkage-stress" will be generated in the restored tooth system. However, material at or in proximity to a free, un-bonded surface will be able to shrink freely, with minimal local-stress generation.

Different tooth cavity sizes and shapes involve differing cavity configuration factors (C_f) of bonded to non-bonded interfacial surface areas.

Hence:

$$C_f = Area_{\ bonded} \ / \ Area_{\ non-bonded}$$

other factors being equal, cavities with a high **C**-factor will be more highly prone to shrinkage stress (Figure II.5.8.11).

Nevertheless, it has been recognized recently that other factors are seldom equal. In particular, the mass (or volume) of setting material commonly varies between different cavity shapes or designs. It is the composite mass that drives the shrinkage stress magnitude, and so if this is reduced appreciably, the shrinkage stress will also be reduced (Watts et al., 2009).

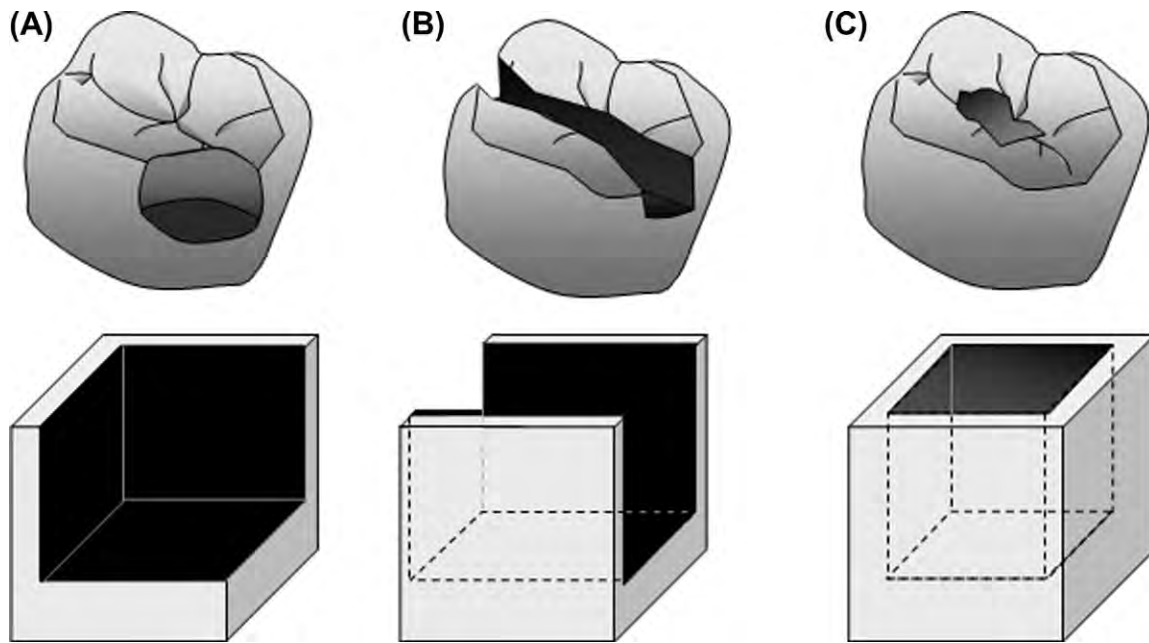
In complex cavity shapes, Finite Element Analysis (FEA) has been fruitfully applied to determine the distribution and vector directions of shrinkage stress. This requires realistic tooth and cavity shapes, and allowance being made for the visco-elastic character of both the setting material and dentin tooth tissue. In the interior of a cavity, the repair biomaterial is subject to a state of generalized plane strain, whereas close to


FIGURE II.5.8.11 Schematic cavities in molar teeth. Cavity (C) shows a greater ratio of bonded to non-bonded area than is the case with cavities (A) and (B). This has consequences for the magnitude of shrinkage stress established at the biomaterial–tissue interfaces within each cavity, for a given mass of a specific material.

the cavity opening, the material is subject to a state of plane stress.

Strategies to Minimize Shrinkage Stress in Bonded Cavities of Low Compliance

The *compliance* of the cavity walls is a further significant factor. When the cavity walls are relatively thick, then the compliance will be low and strategies must be sought to minimize shrinkage-stress. One common clinical practice is to apply the material in a succession of layers, either parallel, or at an angle, to the base of the cavity. These layers are adhesively bonded to the walls and photo-cured in sequence. This can reduce the net effect of shrinkage stress. The effect of shrinkage stress within restored molar teeth can be directly measured by detection of inward displacement of cavity walls and tooth cusps (Watts et al., 2009).

Development and Chemistry of New Low Shrinkage Monomers, Including Siloranes

The perceived significance of the above shrinkage problem has led to intense efforts to produce improved formulations, including novel monomer chemistry. An innovative approach is the development of four branched silorane monomers (Figure II.5.8.12) that are photo-cured via a cationic polymerization mechanism (Weinmann et al., 2005). These materials exhibit less than 1% shrinkage on setting, and are strongly hydrophobic. They require a specialized system adhesive to bond to enamel and dentin.

Soft Tissue Adhesives and Sealants

Performance Requirements. Most soft tissue adhesives are intended to be temporary. That is, they are removed or degrade when wound healing is sufficiently advanced for the tissue to maintain its integrity. Effective adhesion can be obtained on dry skin or wound surfaces by using wound dressing strips with acrylate-based adhesives. However, on wound surfaces that are wet with tissue fluid or blood, the adhesive must be able to be spread easily on such a surface, provide adequate working time, develop and maintain adhesion, desirably provide hemostasis, facilitate wound healing, and maintain biocompatibility. Positive antimicrobial action would be an additional advantage (Ikada, 1997).

Historical Overview. Few, if any, systems comply with all these requirements. Currently, there are two principal systems in widespread clinical use – cyanoacrylate esters and fibrin tissue adhesives. Another system, based on a gelatin-resorcinol-formaldehyde (GRF) combination, still receives limited use (Table II.5.8.3). For many years there have been studies undertaken using bioadhesives, especially polypeptides from marine organisms (mussel adhesive) (Sierra and Salz, 1996; Chu et al., 1997). An important new development by Messersmith and co-workers (Brubaker et al., 2010) has led to synthesis of branched polyethylene glycol (PEG) cores with endgroups derivatized with catechol, a functional group abundant in mussel adhesive proteins.

(A)

(B)
FIGURE II.5.8.12 (A) Structure of a 4–branched silorane molecule. The 3–member functional epoxide groups react via a cationic mechanism to give a ring–opening polymerization. This by itself creates molecular expansion upon setting, and can be used to formulate low –shrinkage materials. (B) A four arm catechol–terminated PEG (cPEG) adhesive precursor inspired by the protein glues of marine mussels. This rapidly forms adhesive hydrogels under oxidizing solution conditions.

The Relationship Between Soft Tissue Adhesion and Drug Delivery

Soft tissue adhesives are not only required for surgical wound healing, but also for the controlled delivery of drugs to specific sites, of which the mucosal membranes are particularly suitable. The process of mucoadhesion involving a polymeric drug delivery platform is a complex one that includes wetting, adsorption, and interpenetration of polymer chains among various other processes. The success and degree of mucoadhesion bonding is influenced by various polymer-based properties, such as the degree of cross-linking, chain length, and the presence of various functional groupings. The attractiveness of mucosal-targeted controlled drug delivery of active pharmaceutical ingredients has led formulation scientists to engineer numerous polymeric systems for such tasks. Formulation scientists have at their disposal a range of *in vitro* and *in vivo* mucoadhesion testing setups in order to select candidate adhesive drug delivery platforms. As such, mucoadhesive systems have found wide use throughout many mucosal covered organelles for delivery for local or systemic effect. Evolution of such mucoadhesive formulations has developed from first-generation charged hydrophilic polymer networks to more specific second-generation systems based on lectin, thiol, and various other adhesive functional groups.

TABLE II.5.8.3	Characteristics of Soft Tissue Adhesives		
Property	**Cyanoacrylate**	**Fibrin Glue**	**GRF**
Ease of application	Poor	Excellent	Poor
Set time	Short	Medium	Medium
Tissue bonding	Good	Poor	Excellent
Pliability	Poor	Excellent	Poor
Toxicity	Medium	Low	High
Resorbability	Poor	Good	Poor
Cell infiltration	Poor	Excellent	Poor

(After Ikada, 1997.)

Cyanoacrylate Esters

Chemistry. These esters are fluid, water-white monomers that polymerize rapidly by an anionic mechanism in the presence of weak bases such as water or NH_2 groups. Initially, methyl cyanoacrylate (Figure II.5.8.2)

was used, but in the past two decades isobutyl and n-butyl cyanoacrylate have been found more acceptable. The higher cyanoacrylates spread more rapidly on wound surfaces, and polymerize more rapidly in the presence of blood. Furthermore, they degrade more slowly over several weeks, in contrast to the methyl ester, which hydrolyzes rapidly yielding formaldehyde that results in an acute inflammatory response.

Performance. These materials achieve rapid hemostasis, as well as a strong bond to tissue. However, the polymer film is somewhat brittle and can be dislodged on mobile tissue, and the materials can be difficult to apply to large wounds. Because of adverse tissue response and production of tumors in laboratory animals, cyanoacrylates are not approved for routine clinical use in the United States, although a commercial material based on n-butyl cyanoacrylate is approved by several other countries.

The current uses are as a surface wound dressing in dental surgery, especially in periodontics, and in life-threatening applications such as brain arteriovenous malformations. Reports of sarcomas in laboratory animals (Reiter, 1987), evidence of *in vitro* cytotoxicity (Ciapetti et al., 1994), and lack of regulatory approval have restricted their further use, in spite of work on synthesis of new types of cyanoacrylate.

Fibrin Sealants

Formulation, Presentation, and Setting Processes. Fibrin sealants involve the production of a synthetic fibrin clot as an adhesive and wound-covering agent. The concept of using fibrin dates back to 1909, but was placed on a specific basis by Matras in 1972 (Matras, 1972). The commercial materials first available consisted of two solutions that are mixed immediately before application to provide a controlled fibrin deposition. Later a "ready-to-use" formulation (Tisseel Duo) was introduced (Schlag and Redl, 1987). The essential components of these solutions are as follows:

Solution A:	Solution B:
Fibrinogen	Thrombin
Factor XIII	$CaCl_2$

Fibrinogen is at a much higher concentration ($\sim$70 mg/ml) than that in human plasma. On mixing the two solutions, using a device such as a twin syringe with a mixing nozzle, a reaction similar to that of the final stages of blood clotting occurs. Polymerization of the fibrinogen to fibrin monomers and a white fibrin clot is initiated under the action of thrombin and $CaCl_2$. Aprotinin, an inhibitor of fibrinolysis, may also be included in solution A. The composition may be adjusted to promote hemostasis, for example, or to minimize persistence of the clot to avoid fibrosis.

Advantages and Applications. There are now several commercial products available in Western Europe, Japan, and Canada; but they were not approved for use in the USA until 1998 due to the FDA concerns about viral contamination. Fibrinogen for these commercial materials is manufactured from the pooled plasma of selected donors, using processes such as cryoprecipitation. The material is subjected to in process virus activation, and routinely screened for hepatitis and HIV. To minimize these risks recent processes produce the fibrinogen in a "closed" (single donor) blood bank or utilize the patient's own blood. This autologous fibrin glue is preferred, but its quality is partly determined by the fibrinogen level in the donor plasma (Ikada, 1997). Other complications include formation of antibodies and thrombin inhibitors, as well as potential risks of BSE (bovine spongiform encephalopathy) if bovine thrombin is used. More recently, human-derived thrombin has been employed.

Originally developed during World War II to stop bleeding from battle injuries, fibrin sealants are presently used during surgery for several different purposes:

- to control bleeding in the area where the surgeon is operating;
- to speed wound healing;
- to seal off hollow body organs or cover holes made by standard sutures;
- to provide slow release delivery of medication to tissues exposed during surgery.

Fibrin sealants have several advantages over older methods of hemostasis. They speed up the formation of a stable clot; they can be applied to very small blood vessels and to areas that are difficult to reach with conventional sutures; they reduce the amount of blood lost during surgery; they lower the risk of postoperative inflammation or infection; and they are biodegradable by the body during the healing process. They are particularly useful for minimally invasive procedures, and for treating patients with blood clotting disorders.

The adhesive strength is not as high as that of cyanoacrylates, but it is adequate for many clinical situations. Thorough mixing of the ingredients and application techniques or devices that allow uniform spreading, are essential to success.

The material has been used in a wide variety of surgical techniques for hemostasis and sealing involving thoracic–cardiovascular, neurologic, plastic, and ophthalmic surgery, and as a biodegradable adhesive scaffold for meshed skin grafts in burn patients (Sierra and Salz, 1996; Ikada, 1997; Feldman et al., 1999). A symposium has reviewed clinical uses (Spotnitz, 1998). An auxiliary aspect of fibrin sealants is their use as a delivery vehicle at local sites for antibiotics and growth factors (Sierra and Salz, 1996).

Attempts to modify fibrin sealant have been directed toward: (1) improvements in ease of application and control of setting by use of a one-component light-activated product (Scardino et al., 1999); (2) improvements in strength and performance by addition of fibrillar collagen (Sierra and Salz, 1996); and (3) development of a formulation containing gelatin (Ikada, 1997).

Gelatin-Resorcinol-Aldehyde Glues

Formulations. Gelatin is an animal protein with adhesive properties and chemical similarity to connective tissue. This glue was developed in the 1960s by Falb and co-workers (Falb and Cooper, 1966; Cooper et al., 1972) as a less toxic material than methyl cyanoacrylate. The material is fabricated by warming a 3:1 mixture of gelatin and resorcina, and adding an 18% formaldehyde solution. (This glue is called "GRF.") Cross-linking of the gelatin and resorcinol by the formaldehyde takes place in about 30 seconds.

Limited Applications. The material was used in a variety of soft tissue applications, but technical problems and toxicity have limited its application in recent years to aortic dissection (Ikada, 1997). In attempts to overcome the toxicity and potential mutagenecity/carcinogenicity of the formaldehyde component, modified formulations have been developed in which other aldehydes such as glutaraldehyde and glyoxal (Ennker et al., 1994a, b) are substituted for the formaldehyde. Favorable results with this material (GR-DIAL) have been reported (Ennker et al., 1994a, b). Concerns over toxicity remain, however, and this material has not received FDA approval for commercial use. Less toxic gelatin cross-linking agents have been investigated *in vitro* without substantial improvement.

The three aforementioned types of adhesives have undergone extensive clinical trials in Europe and Japan. Fibrin sealant is the most widely used material currently. However, all of these systems have significant deficiencies. This is illustrated by their relative characteristics listed in Table II.5.8.3 (Ikada, 1997).

Bioadhesives

Bioadhesives are involved in cell-to-cell adhesion, adhesion between living and nonliving parts of an organism, and adhesion between an organism and foreign surfaces. Adhesives produced by marine organisms, such as the barnacle and the mussel, have been extensively investigated over the past 40 years because of their apparent stable adhesion to a variety of surfaces under adverse aqueous conditions. These studies have shown that these organisms secrete a liquid acidic protein adhesive that is cross-linked by a simultaneously secreted enzyme system. The bonding probably involves hydrogen bonding and ionic bonding from the acidic groups (Waite, 1989).

The adhesive from the mussel has been identified as a polyphenolic protein, molecular mass about 130,000 Daltons, which is cross-linked by a catechol oxidase system in about 3 minutes. A limiting factor in the practical use of this material is the difficulty of extraction from the natural source. The basic unit of the polyphenolic protein has been identified as a specific decapeptide (Waite, 1989; Green, 1996). Recombinant DNA technology and peptide synthesis have been used in attempts to produce an affordable adhesive with superior properties. Little information has been reported on the performance (including biocompatibility) of these materials.

Hydrogel Sealants

A new approach is the development of synthetic sealants based on poly(ethylene glycol) (PEG) hydrogels that are derived from the original work of Sawhney, Pathak, and Hubbell (1993). A family of fully synthetic, implantable, resorbable hydrogels intended for use as surgical sealants has been developed (Moody et al., 1996; Ranger et al., 1997; Alleyne et al., 1998; Tanaka et al., 1999), for barrier coatings (West et al., 1996), and for drug delivery matrices (Lovich et al., 1998). The hydrogels are formed by *in situ* deposition of aqueous formulations based on specialized dendritic macromolecules, followed by photopolymerization to highly cross-linked structures.

The macromers are reactive block copolymers consisting of a water-soluble core, such as polyoxyethylene, flanking biodegradable oligomers such as poly(lactic acid) or poly(trimethylene carbonate), and polymerizable end caps such as acrylate esters (Sawhney et al., 1993). Control of the physical properties and degradation rates is achieved by specifying the molecular structures and concentration of the reactants in the formulation (Dai et al., 2011). Photopolymerization can be effected by ultraviolet or visible light using appropriate photoinitiators. Typically, the initiator system eosin Y spirit-soluble (EYss)/triethanolamine (TEA) is employed with visible illumination in the 450–550 nm range.

In most applications for these hydrogels, strong bonding to tissue is required. This is achieved by use of a two-part sealant system consisting of primer and topcoat. Strong, durable bonding to a wide variety of internal tissues has been demonstrated (Coury et al., 1999).

New Research Directions: Biomimetic Approaches

As a result of the experience of recent decades, the problems involved in developing an adhesive system for both soft and hard tissues have been addressed and identified. A practical limitation in many systems remains ease of manipulation and application. For example, the effectiveness of the fibrin sealant is critically dependent on proper mixing of the ingredients and uniform application. It has proved difficult to reconcile short- and long-term biocompatibility needs with chemical adhesion mechanisms that use a reactive monomer system.

Where relatively temporary (less than 30 days) adhesion is required, as in wound healing, systems based on natural models that allow biodegradation of the adhesive and interface, and subsequent normal tissue remodeling, appear to merit further development.

For longer-term (years) durability in both soft and hard tissues, hydrophilic monomers and polymers of low toxicity that can both diffuse into the tissue surface, and form ionic bonds across the interface, seem to be a promising approach. Evidence has been obtained of the need for hydrophobic–hydrophilic balance in adhesive monomer systems (Nakabayashi and Pashley, 1998), and the use of hydrophilic monomers such as hydroxyethyl methacrylate in commercial materials has facilitated surface penetration.

Recent development trends in soft tissue adhesives appear to reflect these approaches. Newer materials (Chu, 1997) comprise cross-linked collagen materials, light-cured polymerizable and biodegradable

polyethylene glycols, photopolymerized derivatized collagen (DeVore, 1999), a bioresorbable hemostatic collagen-derived matrix with thrombin, and serum albumin cross-linked with a derivatized poly(ethylene glycol) sealant. The development of synthetic peptides and materials based on human recombinant components are being investigated. However, the most promising development for hydrogels inspired by mussel adhesives appears to be the approach of the Messersmith group (Brubaker et al., 2010). Rather than using natural polypeptides, the synthesis of catechol-terminated PEG solutions allows a hydogel to be formed in about 30 seconds. Upon implantation, the cPEG adhesive elicited minimal acute or chronic inflammatory response in C57BL6 mice, and maintained an intact interface with supporting tissue for up to one year. *In situ* cPEG adhesive formation was shown to efficiently immobilize transplanted islets at the epididymal fat pad and external liver surfaces, permitting normoglycemic recovery and graft revascularization. These findings establish the use of synthetic, biologically-inspired adhesives for islet transplantation at extrahepatic sites.

Another significant deployment of PEG block copolymers and hyaluronic structures to make photopolymerizable formulations is exemplified by the Tirelli group (Tirelli et al., 2002; Park et al., 2003).

On calcified surfaces, the use of hydrophilic electrolytes, such as the polycarboxylates, has demonstrated that proven ionic bonding *in vitro* can also be achieved *in vivo* (Smith, 1998). An advantage of such systems is that surface molecular reorientations can improve bonding with time (Peters et al., 1974). Encouraging preliminary results have been obtained with new glass ionomer hybrid systems, and there is considerable scope for the future developments of modified polyelectrolyte cements.

The development of more efficient adhesives and sealants that, in addition to enhancing the durability of current applications, would permit new applications such as osteogenic bone space fillers, percutaneous and permucosal seals, and functional attachment of prostheses is still a challenging problem for the future.

Finally, a major biomimetic initiative is the creation of self-healing polymer composites (Trask et al., 2007). Most materials in nature are themselves self-healing composite materials. The concept of an autonomic self-healing material, where initiation of repair is integral to the material, is now being considered for engineering applications. This bio-inspired concept offers the designer an ability to incorporate secondary functional materials capable of counteracting service degradation, whilst still achieving the primary, usually structural, requirement. So far this research has been mainly directed towards structural materials (Brown et al., 2005a,b), but it is a short step to apply these concepts and designs to the structural adhesives being designed for hard tissue bonding.

Case Study | **Nano-Controlled Molecular Interaction at Adhesive Interfaces for Hard Tissue Reconstruction[1]**

Since 2008 the use of dental amalgam to restore teeth has been forbidden in Norway, and since June 2009 in Sweden also, mainly because of environmental issues and potential health risks related to its mercury content. Other countries may soon follow, so that composites are definitely the materials of choice to directly restore teeth in the least invasive way. Although decayed/fractured teeth can be reconstructed minimally invasively and nearly invisibly using adhesive technology, the clinical longevity of composite restorations is still too short. Bonding is also indispensable in the treatment of root caries lesions, the current worldwide prevalence of which increases dramatically with age. However, tooth bonding in the relatively aggressive oral environment is far from perfect. Within a time frame of 3–5 years adhesive restorations lose their marginal seal, leading first to unesthetic discoloration, and eventually caries recurrence. This forces dentists to replace restorations too often, leading with each new intervention to further weakening of the patient's tooth and, naturally, also to higher public-health costs.

Also in orthopedic medicine, one of the main causes of aseptic loosening of cemented hip replacements is the lack of a compound stable against hydrolysis between the hydrophobic bone cement and the hydrophilic acetabular bone stock. Current hydrophobic bone cements cannot chemically bond to the hydrophilic osseous surface, and thus undergo long-term hydrolytic degradation processes, causing the bone–bone cement interface to de-bond. Bone bonding cements containing functional monomers that can directly adhere to bone, and thus can complement the current purely mechanical stabilization of orthopedic implants, would therefore be of great benefit in orthopedic surgery.

In an attempt to answer questions of direct importance to the mechanisms of bond degradation/stability, the complex biochemical interplay at the adhesive–tooth interface was studied by analyzing the chemical interaction of the functional monomers phenyl-P and 4-MET with HAp, using correlatively solid-state nuclear magnetic resonance (NMR) and X-ray diffraction (XRD). Clinical data confirmed the overall better performance of a 10-MDP-based adhesive over its precursor, a phenyl-P-based adhesive, while a 4-MET-based adhesive performed somewhat in between the other two. Direct comparison of the interfacial molecular interactions of the functional monomers phenyl-P and 4-MET with similar data obtained before for the best performing 10-MDP was expected to reveal how functional monomers interact at the adhesive interface. The hypothesis was tested that no difference in chemical interaction with HAp was found among the three functional monomers.

A time-dependent molecular interaction at the interface with stable ionic bond formation of the monomer to hydroxyapatite was found, competing in time with the deposition of less stable calcium phosphate salts. The advanced tooth–biomaterial interaction model gave not only an insight into the mechanisms of bond degradation, but also provided a basis to develop functional monomers for more durable tooth reconstruction.

GLOSSARY OF TERMS

BPO: Benzoyl peroxide
C_f: Cavity Configuration Factor
FEA: Finite element analysis
GIC: Glass ionomer cement
GRF: Gelatin-resorcinol-formaldehyde
HA: hydroxyapatite
H-bonds: Hydrogen bonds
HEMA: Hydroxy ethyl methacrylate
IPN: Inter-penetrating network
MEP: 10-methacryloyloxydecyl dihydrogen phosphate
4-MET: 4 methacrloyloxyethyl trimellitic acid
MMA: Methyl methacrylate
MMP: Matrix metalloproteinases
PEG: Polyethylene glycol
PMMA: Polymethylmethacrylate
RMGIC: Resin Modified Glass Ionomer Cement
TCP: Tricalcium phosphate
TEGDMA: Triethylene glycol dimethacrylate
THR: Total hip replacement.

CHAPTER II.5.9 OPHTHALMOLOGIC APPLICATIONS: INTRODUCTION

Roger Steinert and Rakhi Jain
Implant R&D, Abbott Medical Optics, Inc., Santa Ana, CA, USA

OVERVIEW OF EYE ANATOMY

The function of the eye is to provide sight. Briefly, images are seen when reflected or emitted light rays from an object are focused by the cornea and lens, and converted by photochemical receptors in the retina to electrical nerve impulses, which are transmitted to the visual cortex of the brain where complex, multi-layer neuronal processing creates the perception of an image. The nerve impulses from the retina are not pixel representation, but rather a complex set of data including shape, movement, and on-off encoded information that is assembled in the visual cortex.

The eye is approximately a sphere, commonly ranging in diameter from approximately 23 to 26 mm. The axial length of the globe is the length from the apex of the cornea to the retina at the macula. The eye is contained in the orbit or eye socket, within the skull. In the orbit, the eyeball is attached to six muscles for movement and surrounded by a cushion of fat. Tenon's capsule is a layer of connective tissue that encapsulates the globe and the muscles, extending to the back of the orbit. The optic nerve carries several million nerve fibers from their cell bodies in the retina to the first connection point in the brain, known as the lateral geniculate body. The outer protective tissue of the eye globe is the sclera, the "white," opaque collagen wall of the eye. The thickness of the sclera varies with the location of the globe and with age, typically ranging from 0.4 mm to 1.3 mm. The sclera is a connective tissue that protects the globe, while maintaining its shape. A schematic diagram of the cross-section of the globe is shown in Figure II.5.9.1, and ocular dimensions are summarized in Table II.5.9.1.

Light enters the eye through the dome shaped cornea that functions both as the window of the eye and the dominant lens. The cornea is the only transparent tissue in nature. The corneal diameter typically ranges from 10.5 to 12.5 mm. The anterior surface of the cornea provides the majority of the refractive component of the eye. The refractive index of the cornea is approximately 1.34. The anterior surface of cornea contributes approximately 48 diopters (D) of positive power towards the convergence of a given image on the retina. (A diopter is a unit of measurement that describes the refractive power of a lens, defined as the reciprocal of the focal length (f) of the lens in meters (D = 1/f)).

The cornea is comprised of five structurally distinct layers. From the anterior surface of the cornea to the posterior surface, the layers are epithelium, Bowman's layer, stroma, Descemet's membrane, and endothelium. The cornea is typically 500–600 microns thick, and is non-vascularized. The outermost layer of the cornea, the epithelium, is 5–6 cell layers of about 50 microns thickness. Bowman's layer is 10–15 microns of acellular collagen, separating the corneal epithelium from the cellular stroma. The stroma comprises approximately 90% of the corneal thickness. It is composed of extracellular collagen fibers, keratocyte cells that produce and repair the collagen, and glycosaminoglycans, complex chemicals interspersed between the collagen fibers. Descemet's membrane is the basement membrane of the corneal endothelium that lines the inner surface of the cornea. The corneal endothelium is a single layer of cells. In humans, the corneal endothelium does not regenerate. The distance from the posterior surface of the cornea to the anterior surface of the natural crystalline lens is referred to as the anterior chamber depth.

The endothelium is a physiologically leaky layer that allows water, ions, and glucose to pass from the aqueous humor of the anterior chamber into the stroma. The endothelium has membrane pumps that then eject the water molecules back into the anterior chamber, leaving
FIGURE II.5.9.1 Schematic representation of the cross-section of the eye (www.99main.com/~charlief/Blindness.htm).

TABLE II.5.9.1	Approximate Dimensions of Globe and Ocular Structures
Measurement	**Length, Thickness or Diameter (mm)**
Axial length of globe	23–26
Corneal diameter (white-to-white)	10.5–12.5
Equatorial diameter	23–26
Anterior chamber depth (ACD)	3–4
Anterior chamber diameter	12.0–12.5
Sulcus diameter	11.0–11.7
Natural crystalline lens diameter	9.0–10.2
Natural crystalline lens thickness	3.5–4.5
Capsular bag diameter after lens extraction	9.2–10.5
Capsular thickness	0.004–0.014
Retinal thickness	0.2–0.25

behind the nutrients necessary for the keratocytes to maintain corneal health. This mechanism is necessary to maintain the physiology of the cornea in the absence of the blood supply that nourishes all other tissues in the body. The transparency of the cornea is due to: (1) the highly organized and tightly packed collagen structure of the stroma; (2) the relative dehydration of the cornea due to the endothelial pump, preventing osmotic swelling of the stroma leading to light scattering; (3) the presence of the glycosaminoglycans, reducing light scattering by occupying spaces between collagen fibers; and (4) the lack of blood vessels.

The iris is a pigmented, vascularized tissue. The iris is responsible for controlling the amount of light that reaches the retina by varying the pupillary opening. The iris separates the anterior chamber from the posterior chamber. The ciliary body is also a pigmented, vascularized tissue. The ciliary body consists of the ciliary muscle and the ciliary processes. The ciliary body has two primary functions: (1) production of aqueous humor; and (2) accommodation, which will be discussed later. The aqueous humor is a clear fluid that fills the anterior chamber. The aqueous humor is produced by the ciliary processes in the posterior chamber of the eye and provides nutrients to the crystalline lens and cornea, as both structures do not have direct blood supplies. The composition of aqueous humor is mostly water and similar to blood plasma. The refractive index is approximately 1.34. The aqueous humor travels around the lens, through the pupil, bathes the back of the cornea, and drains into Schlemm's canal through the trabecular meshwork. The flow rate of aqueous humor is approximately 2.4 μL/min. In a simplistic view, the intraocular pressure (IOP) of the eye is maintained by the balance of the rate of aqueous humor production by the ciliary processes, and the rate of drainage through the trabecular meshwork. Normal IOPs are usually 10–20 mmHg.

The natural crystalline lens is in the posterior chamber of the eye, and resides behind the iris and pupil. The crystalline lens is connected to the ciliary body by fine suspending ligaments known as zonules. The natural crystalline lens, ciliary body, and zonules are critical structures in accommodation. Accommodation is the ability to change focus from distant to near objects. As a person's age increases, the ability of the natural crystalline lens to accommodate decreases. Hermann V. Helmholtz described the accommodative mechanism in 1855, and his theory is generally accepted today, although other theories of accommodation persist. Briefly, when the ciliary muscle contracts, the zonular fibers relax their natural state of tension on the periphery of the lens and this allows accommodation. As is well-known from geometry, the shape with the maximal volume for a given external surface area is a sphere. When zonular tension is reduced, the ovoid shape of the lens naturally moves toward a sphere, creating a greater curvature of the anterior and posterior surfaces of the lens. The lens power is therefore increased, allowing for the focus of objects closer to the eye. This will be discussed in greater detail in Chapter II.5.9B.

The natural crystalline lens is encompassed by a thin collagen membrane referred to as the lens capsule (Figure II.5.9.2). The capsule is a thin, elastic basement membrane. The thickness of the capsule varies by location. Beneath the anterior capsule and at the equator of the lens, there is a single layer of lens epithelial cells. In the natural non-cataractous lens, no cells are located on the posterior surface of the lens. The center of the lens is comprised of the nucleus, which is surrounded by lens fiber cells. Lens fiber cells synthesize proteins, crystallins, which are responsible for the refractive index of the lens. The refractive index of lens is approximately 1.42.

The retina covers approximately two-thirds of the inner wall of the posterior surface of the eye (Figure II.5.9.3). The innermost layer of the retina is in contact with the vitreous body. The retinal vasculature provides oxygen and nutrients to the inner layer of the retina. The choroid, the outermost vascular layer behind the retina, supplies oxygen and nutrients to the retinal pigment epithelium and the photoreceptors. The layers of the retina and choroid are shown in Figure II.5.9.3. There are two types of photoreceptors next to the retinal pigment epithelium: rods and cones. Cones are concentrated in the macula, the central region of the retina, and rods dominate in the peripheral region of the retina. Cones are responsible for central vision and daytime (photopic) vision, whereas rods are responsible for peripheral and dim light (scotopic) vision.
FIGURE II.5.9.2 Schematic representation of the natural crystalline lens. (Bhat et al., 2001.)
FIGURE II.5.9.3 Histological section of retina and choroid (Colthurst et al., 2000) demonstrating the 10 layers from outermost layer to inner layer: (A) retinal pigment epithelium; (B) outer and (C) inner segments of photoreceptors; (D) outer nuclear layer; (E) outer plexiform layer; (F) inner nuclear layer; (G) inner plexiform layer; (H) ganglion cell layer; (I) nerve fiber layer; and (J) internal limiting membrane.

EYE-RELATED CONDITIONS AND STATISTICS

In the United States, "legal" blindness is defined as the best-corrected visual acuity of 6/60 or 20/200 or worse in the better-seeing eye, and vision impairment (low vision) is defined as the best-corrected visual acuity less than 6/12 or <20/40 in the better-seeing eye (The Eye Diseases Prevalence Research Group, 2004).

In the US, Prevent Blindness America and the National Eye Institute estimate that approximately 2.4 million Americans over the age of 40 are visually impaired, and approximately 1 million are blind (Table II.5.9.2). The World Health Organization (WHO) estimates that approximately 269 million people live with low vision, and 45 million people live with blindness worldwide.

In the US, the leading causes of vision impairment and blindness are primarily age-related diseases, such as cataract, glaucoma, age-related macular degeneration, and diabetic retinopathy. In the US, the annual cost of the ocular problems in adults age 40 or older is approximately $51 billion (Prevent Blindness America, 2002). The most common ocular disorders are refractive errors: myopia; hyperopia; astigmatism; and presbyopia. In a normal eye (emmetrope), light is focused directly on the retina to produce an image. If the light is focused in front or behind the retina, then either an object at distance or a near object will be blurry or out-of-focus. An individual with 20/20 vision can see near and distance objects clearly. Most refractive errors can be corrected with spectacles or contact lenses. Contact lenses will be discussed in detail in Chapter II.5.9.A.

Myopia, commonly referred to as nearsightedness, is an ocular disorder in which one can focus well on near objects, but cannot focus on objects in the distance. An object in the distance will appear out-of-focus or blurry. In myopic eyes, the image is focused in front of the retina, as opposed to directly on the retina. The axial length of a myopic eye is generally longer than that of an emmetrope. Hyperopia is referred to as farsightedness, as one cannot focus on near objects, but

TABLE II.5.9.2	US Statistics on Ocular Conditions
Ocular Disease	**Number of Americans Affected**
Vision impairment/low vision	2.4 million (over age 40)
Blindness	1 million (over age 40)
Refractive error:	
Myopia (> 1D)	30.5 million (over age 40)
Hyperopia (> 3 D)	12.0 million (over age 40)
Astigmatism	Affects 30% of population
Presbyopia	Affects almost all over age 50
Cataracts	21 million (over age 40)
Primary open-angle glaucoma	2.2 million (over age 40)
Age-related macular degeneration (AMD)	1.6 million (over age 50) (late AMD)
Diabetic retinopathy	5.3 milllion (over age 18)

Source: Prevent Blindness America, 2002.
FIGURE II.5.9.4 Schematic of formation of images in myopes and hyperopes as compared to emmotropes. (I) The image is formed in front of the retina in myopia. (II) The image in formed behind the retina in hyperopia. (Kohnen et al., 2008.)

can focus on objects in the distance. That is, in hyperopic eyes, the image is formed behind the retina. A schematic of image formation in myopic and hyperopic eyes is shown in Figure II.5.9.4. Astigmatism is an ocular disorder that describes a change in the curvature of the cornea, such that the cornea is no longer spherical. Astigmatism affects approximately 30% of Americans. Presbyopia occurs as a result of a loss of accommodation. Presbyopic individuals with good distance vision, whether naturally or with glasses, contact lenses or refractive surgery, have difficulty in focusing on near objects. Presbyopia typically becomes symptomatic at age 40–45.

Cataract is the progressive clouding of the natural lens with age. Cataracts can also be due to trauma or injury, congenital defect, or can result from other underlying pathologies or medication, such as long-term steroid use. Cataracts are the leading cause of low vision in the US, and are highly treatable. Cataracts affect approximately 20.5 million people in the US over the age of 40 years. In the US, approximately 2 million cataract surgeries are performed each year. Cataract surgery is one of the most successful surgical procedures, as the success rate is above 90%. In cataract surgery, the natural crystalline lens of the eye is replaced by an artificial intraocular lens (IOL), referred to as a "pseudophakic IOL."

In cataract surgery, the natural crystalline lens of the eye is usually extracted with a procedure known as phacoemulsification. Ultrasound energy is delivered to the cataractous lens to break it up into small pieces that can be aspirated out. There are many types of IOLs: monofocal, multifocal; toric; and accommodating. Certain IOLs can also be placed in the eye without removal of the lens; these are referred to as phakic IOLs. Phakic IOLs correct refractive errors for myopes or hyperopes, while leaving the natural lens intact in individuals with a clear lens. Intraocular lenses are discussed in greater detail in Chapter II.5.9B.

Primary open angle glaucoma is the most common form of glaucoma. Other forms of glaucoma include angle-closure, secondary, and congenital. Glaucoma is typically characterized by elevated intraocular pressure (IOP), changes in the optic nerve head (increased cupping), and/or visual field loss. Vision loss is due to the death of nerve cells. The vision lost from glaucoma cannot be restored. The clinical strategy to treat glaucoma usually begins with a topical pharmaceutical treatment to lower IOP. If IOP is not managed with medication, either laser treatment or surgery to implant a glaucoma shunt or stent is performed. Two types of laser treatment are argon laser trabeculoplasty (ALT) and selective laser trabeculoplasty (SLT). Both laser treatments use a laser to create space in the trabecular meshwork to increase aqueous humor outflow. A glaucoma or aqueous shunt is comprised of a plate and a tube with or without a valve. The tube is placed in the anterior chamber, and the plate resides in the sub-conjunctival space, where the aqueous humor flows out through a sieve into the tissues where it is absorbed. The shunt also aids in aqueous humor outflow by creating another outflow path. Glaucoma treatments are discussed in Chapter II.5.9.D.

There are two types of age-related macular degeneration (AMD): dry AMD and wet AMD. Dry AMD accounts for approximately 90% of all cases and is the milder form of AMD. It develops gradually over time and usually causes mild to moderate loss of vision. Often small yellow deposits, called drusen, accumulate in the retinal pigmented epithelium (RPE) cells adjacent to the macula. The dry form may eventually develop into the wet form of AMD.

While wet age-related macular degeneration accounts for approximately 10% of all cases, it is responsible for approximately 90% of cases of severe vision loss associated with AMD. Wet AMD involves the growth of abnormal blood vessels, known as choroidal neovascularization (CNV). These abnormal blood vessels invade from the choroid under the macula, hemorrhage, and lead to major cellular damage. This causes very sudden loss of central vision. Bleeding is followed by the formation of scar tissue that leads to vision loss.

Diabetic retinopathy (DR) also affects the retina and is associated with both diabetes type 1 (juvenile onset diabetes) or type 2 (adult onset diabetes). Diabetic retinopathy affects approximately 5.3 million Americans. There are two types of diabetic retinopathy: non-proliferative or proliferative. Non-proliferative DR is less severe. Blurred vision is a result of blood vessels leaking edema fluid into the retina. Proliferative DR is usually more severe. Neovascularization (formation of new blood vessels) occurs on the surface of the retina, and sometimes reaches up into the vitreous. The new vessels are delicate and ultimately hemorrhage, resulting in profound vision loss due to blurring as a result of the blood cells. The blood in the vitreous often stimulates a fibrotic scar reaction in the vitreous which pulls on the retina, ultimately leading to traction retinal detachment. The current approved treatments for AMD and DR are pharmaceutical injections into the vitreous, and laser treatments of the hypoxic retina and/or the abnormal vessels. New implants and drug delivery systems are in development, as discussed in Chapter II.5.9.E.

Some Special Consideration for Ophthalmic Biomaterials and Commonly Used Materials

Many considerations for ophthalmic biomaterials are similar to the considerations in other disciplines, such as biocompatibility, mechanical properties and stability, material degradation, manufacturability, and implant design optimization. Some common ophthalmic biomaterials are listed in Table II.5.9.3.

Unique to ophthalmology, the functionality of ocular biomaterials is often based on the optical properties of the material. The optical properties are critical for contact lenses, artificial corneas, corneal inlays or onlays, as well as intraocular lenses. The materials for these devices must be transparent and have a refractive index equal to or greater than that of the tissue it is replacing. These materials often incorporate an ultraviolet (UV) blocker to protect the retina from UV light. Additionally, the stability of the material in the eye, lack of toxicity, and long-term functionality of the product or device over time is critical. Optical devices need to be mechanically stable, because any tilt or decentration of these optical medical devices will lead to unfavorable visual performance. As the ophthalmic industry is moving to smaller surgical

TABLE II.5.9.3	Biomaterials Commonly Used in Ophthalmology
Ophthalmic Implants	**Materials Commonly Used**
Contact lenses	Poly(methyl methacrylate) (PMMA), 2-hydroxyethyl methacrylate (HEMA) copolymers, silicone hydrogels
Inlays or onlays	Hydrogels, collagen, permeable membranes
Intraocular lenses	Optic: PMMA, hydrophobic acrylic, silicone, hydrophilic acrylic Haptic: polypropylene, PMMA, polyimide, polyvinylidene fluoride (PVDF)
Ophthalmic viscosurgical device (OVD)	Chrondroitin sulfate, sodium hyaluronate, hyaluronic acid, hydroxypropyl methylcellulose (HPMS), polyacrylamide, collagen, or combinations of these materials
Glaucoma shunts	Plates: silicone (impregnated with barium), polypropylene Tubing: silicone
Vitreous replacements	Silicone oil, gases

incisions, the materials for ophthalmic implants must be able to recover their shape after folding and unfolding, with no affect on the optical properties. This is clearly demonstrated with intraocular lenses.

Any material used for a corneal application, such as contact lenses or corneal inlays, must have acceptable oxygen and nutrient permeability. As the cornea is avascular tissue, the metabolic needs of the cornea depend on permeability to oxygen. For contact lenses, the surface wettability is important for a tear film for patient comfort. As contact lenses are implants exposed to proteins and lipid deposits in the tear film, the material must allow removal and/or be resistant to these deposits.

When designing a new ocular material or modifying an existing material, special attention should be given to the relevant standards. For example, for intraocular lenses, the biocompatibility of the material must meet the guidelines in ISO 10993-1: 2003, Biological Evaluation of Medical Devices. Part 1: Evaluation and testing, and ISO 11979-5(E): 2006, Ophthalmic Implants: Intraocular Lenses. Part 5: Biocompatibility.

A. BIOMATERIALS: CONTACT LENSES

Jean Jacob
LSU Eye Center, New Orleans, LA, USA

INTRODUCTION

Variations in eye length can disrupt the ability of the refractive elements of the eye, cornea, and interior lens to focus the light image correctly on the retina, resulting in blurred vision. In order to correct such abnormalities, lenses such as spectacles and contact lenses are added to the front of the cornea to adjust the light refraction. Contact lenses which are placed directly upon the cornea can be made of various biomaterials. Additionally, since contact lenses are in intimate contact with living tissues, they are subject to the same federal regulations that govern the use of implant materials. Currently over 128 million people use contact lenses worldwide, including between 35 and 38 million in the US (Morgan et al., 2010). People choose to wear contact lenses for many reasons, often due to the practicality of the lenses or their personal appearance. When compared to spectacles, contact lenses are less affected by wet weather, do no steam up, and provide a wider field of vision. They are also more suitable for a number of sporting activities. Additionally, some corneal conditions such as keratoconus and aniseikonia can be more accurately corrected with contact lenses than with spectacles. The materials used in contact lenses will be reviewed herein. The materials used in spectacle lenses are outside the scope of this chapter.

GENERAL PROPERTIES AND CORNEAL REQUIREMENTS

Materials used for contact lenses must meet a variety of specific physical requirements in terms of optical, mechanical, permeation, and surface properties. Since contact lenses are optical devices, 100% transmission of

visible light is a key factor. In addition to transmitting light, lens materials must be chemically stable and wettable, with high oxygen permeability and low or competitive manufacturing cost.

Since the contact lens seats in the tear film while residing against the cornea, the lens material needs have a wettable surface which allows the tear film to maintain its normal structure, both above and below the lens. Additionally, the lens material surface structure should be such that adsorption of the proteins and lipids from the tear film, biofouling, is minimized and allows any adsorbed biological factors to be removed with standard cleaning solutions. Biofouling is the process of uncontrolled accumulation of biological material, such as proteins and lipids, onto the surface of a material in contact with a biological media (Kingshott et al., 2000) (see Chapters I.2.10 and II.2.8). A common reaction to materials placed in biological environments, biofouling is especially important with regard to contact lenses, as protein and lipid deposition decreases optical quality, wear time, comfort, and even permeability. Hydrophilic surfaces, in general, are more resistant to biofouling than hydrophobic surfaces.

Conventional hydrogel materials have inherent wettability when fully hydrated. However, on the eye, two other polymer/thermodynamic factors influence material surface performance, anterior surface dehydration, and polymer chain rearrangement. First, the anterior surface of the lens can progressively lose water, especially under adverse environmental conditions such as low humidity, high wind, and high temperatures. Second, hydrated polymer chains are capable of rotating in response to changes at their surface interface, depending on their cross-link density and side-group size. When in contact with aqueous fluid such as the tear film, hydrophilic groups rotate to the surface. Conversely, when the environment becomes more hydrophobic, such as with air or tear lipid exposure during eyelid blink, the hydrophilic groups can be thermodynamically driven into the material bulk, and a more hydrophobic material surface is exposed. Both of these factors also contribute to the degree of biofouling and final material-on-eye performance.

The cornea requires oxygen to maintain its functional metabolism and transparency. Since the cornea is avascular, it receives oxygen from the ambient air during open eye conditions and the palpebral conjunctival vessels during closed eye conditions. Oxygen from both of these sources diffuses through the tear layer to the cornea. When worn, contact lenses become barriers to the transmission of oxygen to the cornea. Two factors are critical to decreasing the barrier effects of the lens: (1) transmission of oxygen through the lens; and (2) tear exchange under the lens.

The oxygen permeability of a lens material is represented by the term Dk. D is the diffusivity in cm^2/sec and k is the Henry's law solubility coefficient in cm^3 (O_2STP)/(cm^3 (polymer) mmHg). The lens material oxygen transmissibility (Dk/L) is a better representation of the ability of oxygen to cross the lens, shown by the oxygen permeability coefficient of the material divided by the average thickness of the lens (L) (Holden et al., 1990). In general, though, the literature and contact lens companies report lens oxygen permeability in terms of Dk, the units of which are called barrers (Stern, 1968). Oxygen transmissibility, Dk/t, is reported in barrers/mm.

The cornea is exposed maximally to the mean partial pressure O_2 in ambient air (about 160 mmHg at sea level) and palpebral conjunctiva vessels (approximately 55 mmHg) when the eye is open and closed, respectively. The ideal contact lens would allow complete passage of the available oxygen to the cornea. Lack of oxygen to the cornea, or hypoxia, is characterized by corneal swelling (edema), and can result in a number of other physiological conditions such as limbal hyperemia, neovacularization, corneal acidosis, epithelial keratitis, and endothelial phylemgethism. Holden and Mertz determined the critical lens oxygen transmissibility to avoid corneal edema for daily lens wear to be $24.1 \pm 2.7 \times 10^{-9}$ (cm × ml O_2)/(sec × ml × mmHg) and $87.0 \pm 3.3 \times 10^{-9}$ (cm × ml O_2)/(sec × ml × mmHg) for overnight wear (Holden and Mertz, 1984). More recent experiments and computations, taking into account additional factors, have suggested the critical oxygen transmissibility needed for corneal health might be higher still (Harvitt and Bonanno, 1999).

CONTACT LENS MATERIALS

In general, all current contact lens materials consist of carbon–carbon backbone polymeric chains with pendant groups which impart function to the material. Imagine the carbon–carbon chain as the "spine" of the polymer material, and the pendant chemical groups as the appendages; arms and legs. The final properties of the material are dependent on the number and type of pendant groups. Hydrophilic pendant groups (–OH, –COOH, –pyrrolidone, etc.) primarily attract and bind water, forming hydrogels. Pendant groups of silicon–oxygen increase oxygen permeability, as do fluorine groups. Fastening the spines or backbones together through arms or cross-links gives the polymer greater physical stability, and produces a three-dimensional network. These arms or cross-links, such as ethylene glycol dimethacrylate (EGDMA) or tetraethylene glycol dimethacrylate (TEGMA), in and of themselves may also contain chemical pendant groups to improve function. In addition to the monomers and cross-linkers, a lens formulation may also contain other monomers, such as n-vinyl pyrrolidone (VP), as a physical property modifier and solvent to facilitate processing (Refojo, 1973; Peppas, 1986,1987,1987a; Refojo, 1996).

There are essentially two main categories of contact lenses that are grouped by their basic mechanical properties: hard and soft. Hard contact lenses are rigid materials with a high modulus. Current rigid lenses are non-hydrogel materials, generally containing silicone or fluorine derivatives for high oxygen permeability, and commonly referred to as rigid gas permeable (RGP) lenses.

Soft contact lenses are generally hydrogel materials with a low modulus. Within the soft hydrogel lens category there are two basic types of lens material groups: (1) homogeneous hydrogels (see Chapter I.2.5); and (2) heterogeneous hydrogels which generally consist of a water-poor hydrophobic phase of siloxane and/or fluorocarbon moieties dispersed within a water-rich hydrophilic phase similar to the standard hydrogels. These heterogeneous hydrogels have highly enhanced oxygen transmissibility compared with the standard hydrogels of similar hydration.

Hard Contact Lenses

Hard contact lenses ride loosely on the cornea, and move with the eyelid blink more or less freely over the tear film that separates the lens from the corneal surface. The mechanical properties of hard contact lenses must be such that any flex on the lens induced by the blink recovers instantaneously at the end of the blink. Until approximately 1938, all contact lenses were made from glass, despite glass's impermeability to oxygen (see Box 1). These contact lenses were made wearable by fenestrations (small holes) in the peripheral areas which allowed limited oxygen and tear fluid exchange. With the development of clear plastics, after 1938, commercial lenses were of plexiglass, polymethylmethacrylate or PMMA.

Although relatively impermeable to oxygen, PMMA had the advantage of being lightweight and more durable to the lathing and molding techniques needed for manufacture, in addition to its excellent light transmission and biofouling resistance (Refojo, 1973). Because of the material durability, PMMA lenses were also able to be made smaller, so that they could move more freely on the cornea during blink, and allow increased exchange of the tear fluid and oxygen behind the lens. While oxygen transmission was now less of an issue for hard PMMA lenses, due to the high degree of tear exchange behind the lens with every blink, lens materials manufacturers moved on to develop more biocompatible materials that are gas permeable and more wettable.

Rigid Gas Permeable Contact Lenses

The development of copolymers of PMMA with functionalized silicone and fluorine containing macromers produced the current RGP lenses. The introduction of siloxanylalkyl methacrylates, most often methacryloxypropyl tris(trimethylsiloxy)silane (TRIS; Figure A.1), into the PMMA lens significantly increased the oxygen permeability while also increasing the hydrophobic nature of the lens. Hydrophilic co-monomers such as methacrylic acid (MAA) are commonly used in these lenses to counteract the increased hydrophobicity. For these RGP siloxanylalkyl methacrylate contact lens materials, the Dk is inversely proportional to the density of the lens (Refojo, 1996). Subtle changes in the chemical make-up of the lens polymer can strongly affect its

FIGURE A.1 Chemical structure of TRIS (methacryloxypropyl tris(trimethylsiloxy)silane; * hydrophilic modifications of TRIS developed for formation of silicone hydrogels. (Kunzler and Ozark, 1994; McCabe et al., 2004.)

clinical performance. Silcone is lipophilic and can have some effect on the extent of biofouling. Fluoro-derivates also improve oxygen permeability, but are more resistant to biofouling. Most currently marketed RGP lenses consist of perfluoroalkyl-siloxanylalkyl-methyl methacrylate type materials which have a high Dk and good surface properties (Table A.1; see Box 2). However, their Dk is not directly related to their density as with the original RGP lenses. Some newer RGP contact lenses made with styrene derivates have a high enough Dk to be used for overnight/extended wear (Benjamin and Cappelli, 2002). RGP lenses make up about 26% of all dispensed contact lenses (Morgan and Efron, 2008). Since hard contact lenses ride loosely on the cornea, they are good for patients with significant corneal astigmatism or non-spherical corneal surfaces. However, the rigid nature of these lenses is, at least initially, somewhat uncomfortable and requires some patient adaptation.

Soft Hydrogel Contact Lenses

Due to the low modulus of hydrogels, soft contact lenses drape over the cornea, conforming to its surface. Besides

the comfort this affords, this behavior limits the number of lens curvatures needed to fit the general population.

Standard Hydrogel Contact Lenses

The first commercialized hydrogel contact lens material, poly 2-hydroxyethylmethacrylate (PHEMA) with an equilibrium water content (EWC, percentage of water by weight) of approximately 40%, was based on work by Wichterle and Lim in 1959. The advantage of this material over other hydrogels, such as poly-acrylamide, was its stability to pH, temperature, and osmolarity found under physiological conditions. Additionally, Wichterle and Lim developed a spin-casting technique for hydrogel lens production in 1961 that revolutionized the contact lens manufacturing industry (Wichterle, 1978).

A wide range of hydrophilic monomers, besides HEMA, have been investigated and developed as soft contact lens material components. N-vinyl pyrrolidone (NVP), n,n-dimethyl acrylamide (DMA), vinyl acetate (VA) (post-hydrolyzed to vinyl alcohol units), and methacrylic acid (MAA) have proved to be particularly successful (Tighe, 2007). Monomers that mimic biological molecules, such as a methacrylate of phosphorylcholine, have also been commercially successful. Table A.2 lists the some of the currently marketed contact lenses and their composition and properties.

The Dk of standard hydrogel materials increases exponentially with the water content (Refojo, 1979). Therefore, these hydrogel materials have a hypothetical limit in oxygen permeability that approaches the oxygen permeability of pure water (Dk/t of water = 125 barrer). However, high water content hydrogels (>50%), while better for increased O_2 permeability, have some disadvantages in terms of increased biofouling, dehydration, and fragility due to very low modulus.

One approach to increase the effective O_2 transmission of these materials is to decrease the lens thickness. This ultrathin modality takes advantage of the law of diffusion, which states that the gas flux through a material is inversely proportional to the thickness. When applied to contact lenses, this guarantees that the O_2 flux through the lens will double when the thickness is halved for any lens type under the same wear conditions. In general, the Dk of conventional hydrogel lenses ranges between 8 and 44 barrer.

Due to their moderate oxygen permeability, conventional hydrogel lenses are limited in terms of overnight and extended wear. Sleeping in these lenses increases the risk for adverse events more than four-fold (Sankaridurg et al., 1999; Stapleton et al., 2006). However, there is a large market demand for lenses that can be worn continuously.

Silicone Hydrogel Contact Lenses

In an effort to enhance the O_2 transmissibility, while maintaining the comfort of the standard hydrogel lens, the contact lens industry developed siloxane-hydrogel contact lenses with sufficiently high Dk and water permeability to allow continuous wear for over two weeks (Table A.3). These lenses are made essentially by copolymerizing hydrophilic methacrylate or vinyl macromers with methacrylate or vinyl end-capped polydimethylsiloxanes (Figure A.2), novel co-monomers, and/or hydrophilically modified tris(trimethylsiloxy)silanes (Figure A.1). By functionalizing the silicone macromers and the

FIGURE A.2 Additional building blocks of silicone hydrogel materials: (A) and (B) silicone and fluorine macromers (Nicholson et al., 1996); and (C) novel co-monomers, Comfilcon A.

TRIS-like monomers with hydrophilic groups, the siloxane rich monomers become more compatible with the hydrophilic components of the hydrogel. The resulting lens materials have oxygen permeability values ranging from 60 to 163 barrers (Efron et al., 2010). Unlike conventional hydrogel lens materials, the relationship between Dk and the EWC is inversely proportional for silicone hydrogels (Figure A.3). In silicone hydrogels, the oxygen permeation occurs mainly through the siloxane-rich areas of the material, due to the bulkiness and chain mobility of the siloxane group ($–Si(CH_3)_2–O–$), while the water regions of the hydrogel primarily allow water and ion permeability for the lens-on-eye movement (Nicholson and Vogt, 2001; see Box 3).

Despite the increase in oxygen permeability, the first silicone hydrogels to market, balifilcon A and lotrafilcon A, and most silicone hydrogels as a group, still possess some inherent surface incompatibility. In general, silicone hydrogels have a low surface-free energy, hydrophobic and lipophilic properties, and poor wettability. Additionally, the siloxane moieties in the lens material can migrate to the lens surface, causing these moieties to accumulate on the lens portion that interact the most
FIGURE A.3 Relationship between oxygen permeability (Dk) versus equilibrium water content (EWC) of the silicone and conventional hydrogel lenses in Tables A.1 and A.2.

The development of a silicone hydrogel lens was intensely pursued by the contact lens industry for over 20 years before a successful material was achieved. The early versions of lenses stuck to the cornea surface within the first hour of wear, despite having wettable surfaces. This "suction cup" type of behavior was attributed to the lack of ion permeability and water transport through, as well as around, the lens. Unlike oxygen, ions, such as Na^{++}, require a water molecule "shell" for transport. In high water content materials the difference between water and ion permeability is negligible. However, in low water situations, as in early silicone hydrogel materials, the ionic permeability becomes critical, since the tear film on both sides of the lens behaves as a dilute salt solution. The critical minimum ion permeability for lens movement was determined by Nicholson and co-workers to be 0.2×10^{-6} cm^{2}s^{-1}, which is very similar to the reported value for PHEMA, 0.18×10^{-6} cm^{2}s^{-1}. They attributed the wearability of their Lotrafilcon A material, which has a water content significantly below that of PHEMA, to a unique physicochemical biphasic silicone–water structure where the block copolymer forms micro, channel-like co-continuous areas of pure tris-silicone and pure hydrogel, which allow the preferential exchange of oxygen and ions/water through the respective channels of the lens (Nicholson et al., 1996). Silicone hydrogel materials with water contents similar to PHEMA do not need this unique biphasic structure for on eye lens movement.

In the mid-1980s, Vistakon developed Etafilcon A (a PHEMA-based lens polymer with 3% methacrylic acid) as a daily wear lens. Initial *in vivo* wear showed a high percentage of protein adsorbing to the lens surface; however, the lenses also had a significantly decreased rate of infections compared to other lenses on the market. Investigation into the situation revealed that the pendant carboxyl groups of the methacrylic acid monomers imparted a negative charge to the lens surface. This charged surface preferentially adsorbed lysozyme, a small, positively-charged protein in the tear film with antibacterial properties (Boles et al., 1992). The coating of adsorbed lysozyme induced antibacterial properties to the surface and ultimately increased the lens biocompatibility and usefulness.

choline head-group (Figure A.4). This charged side group preferentially holds water to the lens surface, and was the first material to be approved by the FDA for use in patients with dry eyes.

The first silicone hydrogel materials to market in 1998 were surface treated with high energy gases or plasma treatments with gas mixtures (see Chapter I.2.12) to modify the surfaces without affecting the bulk material properties. Balafilcon A (Pure Vision), for example, is plasma oxidized, which causes glassy, silicate islands to form on the surface. These islands create bridges crossing over the hydrophobic balafilcon regions. The balafilcon regions that are left exposed may also be modified and have lower hydrophobicity. Furthermore, these islands are separated from each other to a degree that allows the lens material to maintain its flexibility. Lotrifilcon A & B (Night 'n Day & O$_2$ Optix), on the other hand, use a plasma coating (deposition) to combat the hydrophobicity. This treatment uniformly coats the lens surface with a 25 nm thick hydrophilic polymer produced by using glass plasma (Sweeney, 2004). Both resultant balafilcon and lotrafilcon lens surfaces have low molecular mobility, which minimizes the migration of hydrophobic silcone moieties to the surface. However, the lack of chain mobility also increases the lens modulus, creating "stiffer" materials.

Vistakon skirted the plasma treatment issues by developing silicone hydrogel materials with internal wetting agents. Galyfilcon A (Acuvue Advance) and senofilcon A (Acuvue Oasys) both use poly(N-vinyl pyrrolidone) (PVP) as an internal wetting agent which is preferentially

with the surrounding environment. These variant surface properties cause various biocompatibility issues, such as increased biofouling on the lens, and require surface modification to increase the hydrophilicity of the surface.

SURFACE MODIFICATIONS

Conventional hydrogel materials were not thought to need any surface modification, due to their inherent hydrophilicity. However, it was found that specific bulk lens material side chain moieties could impart enhanced surface properties (see Box 4). This finding encouraged the industry to develop materials with surface active side groups, surface modifying endcaps or interpenetrating networks, which not only increase surface hydrophilicity, but also attempt to direct the tear fluid/lens surface interactions for increased biocompatibility and decreased biofouling (Portoles et al., 1993). Omafilcon A (Proclear) lenses contain a hydrophilic methacrylate monomer with a zwitterion side group modeled after the phosphatidyl

FIGURE A.4 Hydrogel monomer with surface active side group based on the head-group of phosphatidyl choline.

associated with the material surface. Galyfilcon A was released as the precursor to an extended wear version, senofilcon A. Both materials are based on copolymerization of a hydrophilic variant of TRIS, HEMA, DMA, and a siloxy macromer. The incorporation of PVP into the lens produces a wettable, lubricious surface without subsequent surface treatment. Galyfilcon A lenses also have PVP in their packing solution. For senofilcon A, the PVP is incorporated as polymeric end-caps that preferentially migrate to the lens surface (McCabe et al., 2004). The results of these formulations are materials with increased surface hydrophilicity and markedly lower modulus (Table A.1).

Comfilcon A, Bioinfinity, is one of the highest water content silicone hydrogel materials (EWC = 48%), and has no surface treatment or internal wetting agent. The first marketed material produced without the use of the TRIS monomer or its variants, comfilcon is produced by polymerization of two siloxy macromers of different sizes, one of which has only one vinyl polymerization site, as well as vinyl amides such as n-methyl-n-vinyl acetamide. Comfilcon A's unexpectedly high Dk, considering its water content, is attributed to its longer siloxane chains.

SPECIALTY LENSES

There are a number of specialty applications of contact lenses, both prescriptive and cosmetic in nature. There are only three types of contact lens materials FDA approved for dry eye patients, omafilcon A, senofilcon A, and comfilcon A. The surfaces of these materials have a stabilizing effect on the tear film. Toric and astigmatic lenses are used to treat patients with irregularly shaped corneas, and are generally made out of hard or silicone hydrogel materials. Multifocal lenses were developed for the aging contact lens wearer who began to need reading glasses (presbyopia). These lenses are generally made of silicone hydrogels. Through the use of designed material geometries, either concentric rings of varying refractive index (RI) or a change in refractive index progressively across the lens surface, these lenses have varying visual correction across different focal planes. Orthokeratatomy lenses are RGP lenses used at night to reshape the cornea surface so the patient does not need visual correction during the day. Additionally, plano lenses are sold in varying colors and with multiple designs imprinted on them for cosmetic purposes.

CONTACT LENS SOLUTIONS

Effective disinfection and cleaning of contact lenses can normally be achieved using approved chemical or hydrogen peroxide systems. Multipurpose cleaning solutions are used to remove lens deposits that are adsorbed from the tear film, disinfect the lenses, prevent future biofouling, and allow lens storage. The basic steps seen with

these products are cleaning, disinfecting, and rinsing. Product efficiency varies depending on the composition, manufacturer, and length of time for surfactant cleaning and storage. Most systems use hydrophilic polymers to increase cleaning efficiency and lens surface hydration. Some of the hydrophilic polymers used, such as Poloxamer 407, actually act on the bacteria surface and not the lens to inhibit surface adhesion (Portoles et al., 1994). Hydrogel lenses are categorized by the United States Food and Drug Administration into four groupings for the purpose of evaluating effects of accessory products, i.e., cleaning solutions and rewetting drops, upon the lens material. Lenses with less than 50% water content are considered to be "low water," and those with >50% are "high water." Surfaces without fixed charges are called "non-ionic" while more reactive materials that are charged at physiological pH are termed "ionic."

B. INTRAOCULAR LENS IMPLANTS: A SCIENTIFIC PERSPECTIVE

Anil S. Patel
Retired Vice President of Research for Surgical Products for Alcon, Seattle, WA, USA

INTRODUCTION TO INTRAOCULAR LENS IMPLANTS, THE OPTICS OF THE EYE AND CATARACTS

Intraocular lenses (IOLs) are polymeric devices implanted in the globe of the eye and intended to replace the cloudy, cataractous natural lens. There are now at least 34 companies manufacturing these lenses for humans and animals, and more than 10,000,000 lenses are implanted each year. Thus, IOLs are one of the most widely used medical implants and an understanding of their biomaterials, design and application are important for the biomaterials scientist.

Vision is considered to be our dominant sense. We see in the brain through optic nerves, which carry information of the optical image formed in the eye. The physiological optics of the eye for formation of the image, the photochemical transduction in the neurosensory retina at the optical image plane, and the subsequent neural processing in the retina and the brain are quite complex and beyond the scope of this chapter (LeGrand and El Hage, 1980). As an introduction, a brief description of optical imaging of the eye is necessary.

The eye is schematically illustrated in Figure B.1. The average healthy adult eye is about 24.2 mm long axially from the anterior surface of the cornea to the retina. It can be considered as a camera, with the cornea and the natural crystalline lens as its two lenses, while the iris forming the pupil is an aperture between them, and the retina is the imaging plane. The image of an outside object of interest is formed on the retinal photoreceptors by the fixed refractive power of the cornea in combination with the variable refractive power of the natural lens, permitting imaging of any object at various far and near distances from the eye. The fixed refractive power of the cornea is about 43 diopters, which is about 70% of the total refractive power of the eye. The refractive power of the natural lens is about 20 diopters for seeing far objects. For seeing near objects, it increases as required to an upper limit, which gradually diminishes with age. When young, the refractive power of the natural lens can increase by up to 14 diopters, but by about the age of 42, this capability is less than the 3 diopters required for near reading distance. The physiology of variable refractive power of the natural lens is as follows.

As shown in Figure B.1, the natural lens has a capsular bag containing a nucleus surrounded by the cortex. It is attached by the suspensory ligaments called zonules to the ciliary muscle. For an average healthy eye, the refractive power of the cornea and its natural lens are, in combination, adequate to form a focused image on the retina for any object at 20 feet or greater distance when the ciliary muscle is relaxed. In this physiologically relaxed condition of the eye, the zonules are in tension, and the natural lens is also in tension, providing about 20 diopters of required refractive power for distant vision. For seeing an object
FIGURE B.1 Schematic representation of the eye.

at any nearer distance, the ciliary muscle appropriately contracts radially and moves anteriorly, thereby relaxing the zonules, which in turn relaxes the natural lens. This results in the needed change in the shape of the lens, and thus increases its refractive power as required for near vision. This complex mechanism, which results in the ability to increase the refractive power of the natural lens for near vision, is called accommodation (Kaufman, 1992). This ability gradually diminishes with age as the lens grows, and eventually becomes less than the 3 diopters required for near reading distance, and the eye is considered presbyopic. This presbyopia of the eye is treated with eyeglasses, contact lenses or evolving refractive surgery, in order to restore the ability to see near objects.

Further aging of the lens results in loss of its clarity as opacities begin to appear in its structures, and optical image formation deteriorates. Eventually, such a compromised natural lens is unacceptable and is called cataractous, since it is transformed to an unacceptable structure for the primary function – to allow formation of a clear image on the retina (US Department of Health and Human Services, 1983). This normal aging process related to cataract formation eventually leads to blindness, and is the leading cause of blindness in the world. In the developed world, depending upon the need for vision, cataract surgery is carried out much more promptly before the total blindness stage when the degradation in the vision by the cataractous lens reaches an unacceptable level (AAO, 1989). During a relatively safe and short-duration surgery, not only is the cataractous lens removed, but in its place a biomaterial medical device called an intraocular lens is implanted to provide the clear optical imaging function of the normal lens (Alpar and Fechner, 1986). While currently worldwide an estimated 10 million IOLs are implanted, primarily in the developed world and emerging countries, the lack of resources

and rapid increase in life expectancy accounts for an estimated 20 million cataract-related blind people in the underdeveloped world. Cataract blindness is preventable by a simple surgical procedure using the IOL implant, and the number of such procedures is expected to grow. Even then, cataracts are expected to remain the leading cause of blindness, with an estimated 40 million cases by the year 2020 (Brian and Taylor, 2001).

WHY ARE IOLS SUCCESSFUL?

Within a span of only 35 years, the number of cataract surgeries and IOL implantations has rapidly expanded for good reasons, both in terms of improvements in surgical procedure and visual outcome from the patient's perspective, as summarized below.

Prior to IOL implantation, thick spectacles of about 10 diopters refractive power were needed to attempt to restore the function of the natural lens after cataract surgery. Imaging by such external spectacle lenses and the cornea creates a 25% magnification of the resultant image on the retina, compared with imaging by the natural lens and the cornea. Thus, when a cataract develops in one eye of the patient, its functional restoration by cataract surgery and a spectacle lens is unacceptable to the brain since, for fusion of images of the two eyes, the brain requires them to be no more than 6% different in size. Thus, restoration of vision by spectacles after cataract removal required waiting for maturation of cataracts in both eyes before surgeries were carried out to achieve equal image sizes for both eyes. This resulted in significantly poor vision in the unoperated cataractous eye for a prolonged period before cataract surgery was undertaken. Additionally, cataract surgery 35 years ago was associated with other risks and poor visual outcome (as compared in Table B.1), and was thus relatively

TABLE B.1	Why Are IOLs Successful? Comparison of Cataract Surgery in the Developed World for Restoration of Vision 35 Years Ago with Spectacles and Today with Foldable IOLs		
35 years ago	**Foldable IOL today**	**Improvements (2008+)**	
• Ten days of hospitalization	• Same-day outpatient surgery in a few hours	• Convenience and cost	
• Use of general anesthesia or retrobulbar injection in the back of the eye with long needle	• Use of topical drops and intracameral anesthetic or peribulbar injection if needed	• Lowered risk and complications	
• Large >12 mm incision requiring significant stitching and resultant astigmatism	• Small 3 mm or less incision requiring no stitching	• No stitching-related surgically-induced astigmatism	
• Use of alpha-chymotrypsin enzyme to weaken zonules and cryoextraction of the entire cataractous lens through the large incision	• Use of ultrasonic phacoemulsifier and irrigating/aspirating instruments to break up and remove the nucleus and cortex, leaving behind the capsular bag with an anterior opening for insertion of IOL in the bag	• Significantly reduced complications of retinal detachment, excessive inflammation, and infection	
• No protection of cornea and intraocular tissues during surgery	• Use of a viscoelastic biomaterial to protect the corneal endothelium and other intraocular tissues	• Significantly reduced risk of losing corneal clarity and inflammation of the uveal tissues	
• Thick spectacles to restore function of the natural lens resulting in a 25% image magnification, which is incompatible with monocular cataract surgery; also resultant reduced field of vision	• No restriction on monocular cataract surgery	• No delay in cataract surgery in the first eye since IOL provides natural unchanged size of image; also unchanged field of vision	
• Need for spectacles for correction of astigmatism and to have vision for all distances	• Toric and presbyopic correcting multifocal and accommodative IOLs can eliminate need for spectacles	• Truly spectacle-free vision is now possible	
• Overall unsatisfying vision achieved several months after surgery; anxiety and fear of cataract surgery	• Satisfying vision next day after surgery; minimal anxiety and fear of cataract surgery and IOL implantation	• Minimal duration of compromised vision and interruption from occupation; prompt restoration of excellent vision	

discouraged until too late an age, when the compromised vision was totally unacceptable in a relatively advanced state of dysfunction, compared with today's practice in the developed world. Binocular vision with spectacles also had a significantly reduced field of vision and severe astigmatism, on account of the required large size of the incision for cataract surgery.

The size of the optic of the IOL and its intraocular location eliminated image size magnification and reduced visual field problems, which were present with spectacles. Foldable IOLs encouraged the development of small-incision, safer, cataract surgery techniques without surgically induced astigmatism, and thus achieved quicker and better vision after cataract surgery (Apple et al., 2000a). Table B.1 captures all the reasons for the overwhelming success of IOLs, where needed resources are available.

EMERGING FUNCTIONAL VARIATIONS OF IOLS

As a replacement of the cataractous natural lens, the majority of currently used IOLs is monofocal IOLs of fixed refractive spherical diopteric power, which cannot correct existing astigmatism as is needed for some eyes or restore accommodation as was provided by the pre-presbyopic natural lens. Aspheric IOLs, toric IOLs, multifocal IOLs, and emerging accommodative IOLs are relatively recent developments, and they will be

discussed later as IOLs with emerging variations of the optical function (Maxwell and Nordan, 1990; Sanders et al., 1992; Samalonis, 2002; Mester et al., 2003).

The eye with its natural lens is called the phakic eye. The eye after removal of the natural lens, either clear or cataractous, is called an aphakic eye. The eye with replacement of the natural lens with an IOL is called a pseudophakic eye. An ophthalmic implant placed in a phakic eye without removal of its natural lens, for example, an additional IOL in order to correct refractive error, is called a phakic IOL (Obstbaum, 2003). Surgical implantation of a phakic IOL is a form of refractive surgery that provides needed refractive correction in a myopic or hyperopic eye as an option to eyeglasses, contact lenses or corneal refractive surgery, such as LASIK. The current status of phakic IOLs will also be discussed later as a variation of optical function.

Thus, the IOL as an ophthalmic intraocular implant is now evolving to provide a variety of optical functions. The biomaterials used for such a variety of IOLs have been many, and new materials are emerging in order to meet the requirements of their various optical functions and designs.

BIOMATERIALS FOR IOLS

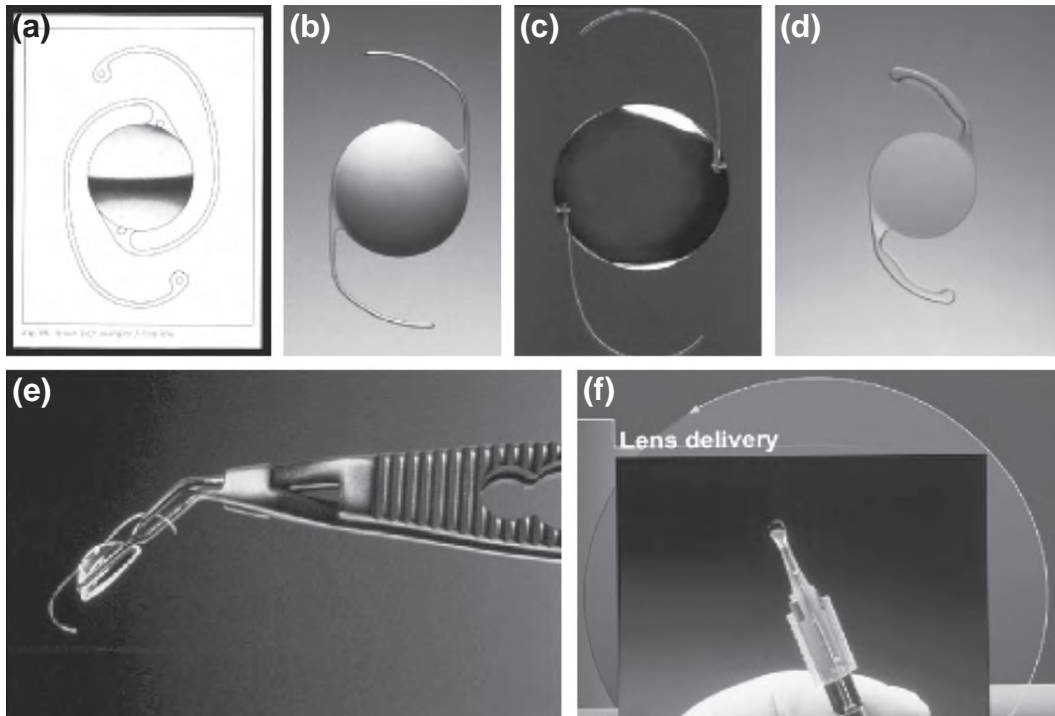
Biomaterial selection for IOLs is based on specialized requirements to maintain a stable, clear path for optical


FIGURE B.2 IOL transition occurring in developed world is best illustrated here: (a) Past: three-piece PMMA IOL; (b) Current: single-piece PMMA IOL; (c) Past: three-piece foldable IOL; (d) Current: single-piece foldable IOL; (e) Past: insertion forceps held folded IOL; (f) Current: folded IOL emerging from an injector tip cartridge.

imaging, as well as long-term safe acceptance as a permanent implant by the unique biology of the eye (Ratner, 1998; Mamalis, 2002). Additionally, the selected biomaterial is required to meet IOL design objectives, such as targeted incision size for insertion and needed mechanical fixation, typically via anchoring components called loops or haptics. The haptics permit the IOL to achieve stable location within the eye, and also permit the targeted optics design to achieve the functional goal for the IOL. Figure B.2 A-D illustrates various lens haptics.

Historical Beginning of Poly(Methyl Methacrylate) (PMMA) as an IOL Material

Harold Ridley of London, in 1949, was the first to implant an IOL made from a PMMA sheet originally formulated for canopies of British Royal Air Force airplanes (Ridley, 1951). His selection of the material was based on an accidental implantation of pieces of the canopy in pilot's eyes, which were observed by him to be quietly tolerated without noticeable inflammatory reaction or other unacceptable biological consequence. Also, since it remained optically transparent, he chose this Imperial Chemical Industry's PMMA formulation, known as Perspex CQ (Clinical Quality), to create a biconvex 10.5 mm diameter disk-shaped IOL, a historical first. This Ridley IOL was too big and bulky, weighing about 110 mg in air, compared with current IOLs, weighing about 20 mg on average (Patel et al., 1999). It was difficult to mechanically fix such a bulky IOL in the eye, and serious surgical and postoperative complications led

to the discontinuation of its use. However, this concept of the IOL implantation is recognized as a pioneering breakthrough. Also, PMMA remained the dominant IOL material for the next 40 years until the 1990s, when foldable IOLs of other materials emerged.

Evolution of Monofocal IOL Designs and Biomaterials

Although the Ridley IOL was unacceptable, it stimulated many other surgeons who created several generations of monofocal IOL designs with a much smaller optic made of PMMA, and a variety of fixation means and materials (Apple et al., 1989).

The anatomical confines of the eye's anterior chamber (AC) were selected for fixation of IOLs. Several AC-IOL designs emerged between 1952 and 1962, with a relatively heavy footplate extension of the optic which rested in the angle formed by the peripheral iris structure and the collagen fibers of the scleral tissue at the junction with the cornea (Choyce, 1958; Strampelli, 1961). While fixation of the IOL was ensured by these AC-IOL designs, the unique biocompatibility needs of the nearby cornea and iris uveal tissue were revealed. Contact of the IOL with the cornea, for example by rubbing, damaged the corneal endothelium and resulted in loss of corneal clarity. The uveal tissue responded with chronic inflammation. Since exact anatomical sizing was difficult, missized AC-IOLs aggravated the foregoing complications by protrusive erosion or loose rotation within the anterior chamber (Ellingson, 1978). These AC-IOL designs

were abandoned, and iris-fixated or -supported designs emerged between 1959 and 1973 (Binkhorst, 1959). These iris-supported IOLs introduced fixation using several biomaterials attached to the PMMA optic. Fixation structures were shaped as round loops of various materials including nylon 6, nylon 66, and polypropylene suture materials. Even platinum–iridium loops and titanium clips were used. Nylon suture degenerated in the eye (Kronenthal, 1977). Metal loops or clips were heavy, causing injury to the iris and hemorrhage within the anterior chamber (Shephard, 1977). Only iris-supported IOL designs with polypropylene loops created by Cornelius Binkhorst seemed viable. His two-loop iridocapsular IOL was implanted with the loops supported by the iris, while the optic was captured by the capsular opening (Alpar and Fechner, 1986). The nucleus and the cortex of the cataractous lens were removed earlier during surgery through this opening. This method of cataract surgery is called extracapsular cataract extraction (ECCE). Prior to this surgical technique, removal of the entire cataractous lens using an enzyme to weaken the zonules and a cryoextractor was more prevalent. This method of cataract surgery is called intracapsular cataract surgery (ICCE). Iridocapsular supported Binkhorst two-loop IOL implantation after ECCE gave encouraging results, but with the passage of 6 to 10 years late decompensation of the cornea occurred, often requiring corneal transplantation. Also, erosion of the iris, IOL dislocation with dilation of the pupil, and difficulty of implantation discouraged its use (Nicholson, 1982; Obstbaum, 1984). The Binkhorst two-loop iridocapsular IOL with ECCE is considered the forerunner of current capsular-fixated posterior chamber IOLs (PC-IOL) with ECCE using phacoemulsification.

Failure of iris-supported IOLs led to revisiting AC-IOLs in the 1970s and 1980s, with a thinner footplate and the evolution of haptics, much thinner and somewhat flexible extensions of the optic, for fixation. These haptics were an integral part of the IOL made from the same PMMA material, or the haptic could be formed using other biomaterials. Polypropylene suture material, extruded monofilament from other PMMA formulations, and polyamide materials were used for haptics. Even these newer AC-IOL designs gave unsatisfactory long-term outcomes, with undesirable corneal decompensation, chronic uveal inflammation, and eventual glaucoma (Apple et al., 1987). Many AC-IOLs with finely looped haptics were associated with micromovement and rubbing with sensitive tissues of the anterior chamber, resulting in loss of corneal endothelial cells, iris chafing, and adhesions around the haptics. While the latest AC-IOL design with a one-piece PMMA optic with integral open haptics, which were wider and yet somewhat flexible, improved the results by avoiding the complications just discussed, the search intensified for fixating the IOL in the posterior chamber where the natural lens is located.

Finally, the search for a PC-IOL led to an IOL by Stevens Shearing in 1979 with a PMMA optic and two J-shaped polypropylene haptics designed for placement behind the iris in the anatomical space called the ciliary sulcus, in front of the capsular bag (Shearing, 1979; similar to Figure B.2C). Soon, a variety of shapes of haptics emerged, with a different degree of flexibility and contact area for ease of implantation and stable fixation. Also, PMMA monofilament as a haptic material replaced polypropylene, after some concern for its degradation was raised (Apple et al., 1984). The PC-IOL designs achieved such success that manufacturing processes even created one-piece PMMA IOLs with integral flexible haptics (Figure B.2A,B).

PC-IOL implantation required the ECCE cataract surgery method and, while large numbers of IOLs were implanted with this method from 1977 to 1992, several refinements emerged to address complications of the sulcus-fixated PC-IOL. Inflammation on account of iris chafing, decentration of the IOL when one haptic was fixated in the sulcus and the other unintentionally went into the bag, and posterior capsule opacification emerged as unacceptable complications of the sulcus-fixated IOL. Placement of the entire IOL (both haptics and the optic) within the capsular bag avoided iris chafing, reduced inflammation, and improved central fixation. C-shaped haptics and the surgical technique of opening the capsular bag by manually controlled tearing called anterior curvilinear capsulorhexis provided reliable implantation of the PC-IOL in the capsular bag with good centration (Gimbel and Neuhann, 1990). As a result, a large number of surgeons with varying skill levels began to implant PC-IOLs.

By the early 1980s, Perspex CQ PMMA was replaced by most IOL manufacturers with differing PMMA formulations with UV chromophore additives, in order to protect the retina from damage by UV radiation.

Viscoelastic materials, such as sodium hyaluronate, were introduced and used to protect the corneal endothelium and other intraocular tissues (Miller and Stegmann, 1982). Even coatings for IOLs and surface modifications for IOLs were investigated in order to minimize damage to corneal endothelium due to accidental touch during insertion into the eye, as well as to minimize foreign-body reaction on the surface of the IOL. Heparin surface-modified PMMA IOLs were introduced, but since they did not solve the posterior capsular opacification complication, and also required a longer incision than needed for foldable IOLs, their use was minimal and short-lived (Philipson et al., 1990; Winther-Nielsen et al., 1998).

The ECCE method of cataract removal, which is required for PC-IOL implantation, retains the entire capsular bag except the capsulorhexis-excised anterior capsule face. There is a region near the equator of the lens capsule where the residual lens epithelial cells (LEC) with potency for mitosis and migration remain. These LECs proliferate and migrate and spread onto the anterior capsule, as well as onto the posterior capsule, and even potentially onto the IOL surface. These LECs undergo morphological changes, reducing their transparency,

resulting in anterior capsule opacification (ACO) and posterior capsular opacification (PCO), as well as contraction of the capsular bag (Amon, 2001; Kruger et al., 2001). PCO is the complication that reduces clarity of the optical path and causes degradation of the quality of image formation, to the extent that it is also called "secondary cataract" formation. While making an adequate opening in the cloudy posterior capsule using an Nd-YAG laser beam without surgically opening the eye restored the clarity of the optical path and the image quality on the retina, there are several disadvantages of this surgical procedure. They include the cost of the procedure, the degraded vision prior to it, the possibility of damaging the lens, and the potential for inducing retinal detachment because of the shockwave created by the focused laser. These disadvantages stimulated approaches to prevent PCO after PC-IOL implantation in the capsular bag. The shape of the optic was changed from convexo-plano to biconvex, and haptics were angulated to achieve complete contact of the posterior surface of the PC-IOL to the posterior capsule. Ridges were also added on the posterior surface to stop migration of LECs, without much success. Thus, Nd-YAG laser-created posterior capsulotomy remained a necessary procedure for "secondary cataracts" due to PCO. The rate of need for this posterior capsulotomy depends on the type of IOL material and design, success in surgical removal of much of the cortical contents of the lens, age-related vigor of remaining LEC, and other inflammatory stimulating factors. With some foldable IOL materials, as discussed later, and using the latest surgical techniques for ECCE with phacoemulsification, the PCO formation rate and the posterior capsulotomy as a necessary second surgical procedure have been significantly reduced.

Rationale and Emergence of Soft Biomaterials for Foldable IOLs

While PC-IOLs of PMMA material were implanted in very large numbers in the early 1980s, another ECCE surgical method drew attention. A probe with a titanium needle that is axially oscillated by an ultrasonic instrument achieved removal of the cataractous nucleus by fragmenting and aspirating it. Cortical material was aspirated out by another probe as a component of the instrument system known as an ultrasonic phacoemulsifier. It also provided necessary simultaneous irrigation into the eye to prevent collapse of the anterior chamber and damage to the cornea. Advances in this technology, with further refinement in the surgical techniques, resulted in eyes with less inflammation postoperatively. Also, the incision length required to enter and remove the cataract by this technology is only 3 mm or less, compared with an approximately 9 mm incision required for the manual ECCE extraction method for removal of the nucleus of the cataract. This reduction in incision length resulted in significant reduction in surgically-induced astigmatism. Additionally, ECCE using the phacoemulsifier spared

mechanical trauma to intraocular tissue encountered during the manual ECCE extraction method, thus minimizing tissue irritation and inflammation.

Postoperative large astigmatism induced by the relatively large 9 mm incision required for manual ECCE was degrading the optical image formation and resultant vision (Luntz and Livingston, 1977). While it was managed by surgical and suturing techniques, and by appropriate eyeglass correction, it was recognized that the surgically-induced astigmatism by a 3 mm incision to enter the eye for ECCE by phacoemulsification was negligible, but subsequent enlargement to insert the PMMA IOL with the preferred 6 mm diameter optic size increased surgically-induced astigmatism (Kohnen et al., 1995; Olson and Crandall, 1998). A soft biomaterial for designing foldable IOLs for insertion through a 3 mm incision was needed to eliminate this surgically-induced astigmatism. Additionally, foldable IOL insertion through a 3 mm incision after ECCE with phacoemulsification promised elimination of the need for stitching, and retention of the minimal postsurgical inflammation provided by this method of cataract surgery (Gills and Sanders, 1991).

In the early 1980s, a transparent polysiloxane, a formulation originally created for other industrial applications, was used as a biomaterial for foldable IOLs by Starr, Inc. (Mazzocco et al., 1986). In the subsequent 15 years, several formulations of polysiloxane with different refractive indexes, mechanical properties, and UV transmission characteristics emerged from other companies. PolyHEMA, a hydrogel material for contact lenses, was also used as a biomaterial for foldable IOLs, but fixation was difficult and it produced unacceptable postoperative complications after Nd-YAG posterior capsulotomy.

In 1994, the first new soft biomaterial for IOLs was introduced by Alcon Laboratories Inc. as AcrySof IOL. This biomaterial was specifically created to meet the desired optical, mechanical, and biological properties for foldable IOLs (Anderson et al., 1993). This copolymer of phenylethyl acrylate and phenylethyl methacrylate with a cross-linking agent and a bonded UV absorbing chromophore provided a higher refractive index of 1.55. This allowed the design of a thinner foldable IOL from this hydrophobic soft acrylate material. Its tailored mechanical properties resulted in slow unfolding of the IOL, unlike the rapid, uncontrolled, spring-like opening of early silicone IOLs with plate haptics. Early three-piece AcrySof IOLs with PMMA monofilament C-shaped haptics were folded and inserted using forceps, similar to three-piece silicone IOL designs (Figure B.2E). Subsequently IOL injectors were developed, and are currently used for most foldable IOLs (Figure B.2F). Also, AcrySof IOL is now mostly used as a single-piece foldable IOL with integral haptics of the same biomaterial as optic.

The AcrySof IOL soon became the most widely used foldable IOL, and millions of these IOLs had been implanted globally with overall satisfactory outcomes. Besides being a small-incision IOL, it unfolds gently in the

eye, remains well centered, and postoperatively results in "quieter" eyes without significant inflammation. Some minimal glistening, which is judged cosmetic, and edge-related optical photic phenomena were reported, and now have been minimized through improvements. The newer generation of silicone foldable IOLs and other hydrophobic, as well as hydrophilic soft acrylate foldable IOLs, also emerged (see Table B.2) (Apple et al., 2000a; Werner et al 2008). This success for soft, foldable IOLs, and in particular, AcrySof, is attributed not only

TABLE B.2	Types of Biomaterials for Representative IOLs in the Market or Clinical Investigation by Key Leading and Newly Emerging Manufacturers	
Manufacturer	**Type of IOL**	**Biomaterials**
Abbott Medical Optics(AMO)	Monofocal IOLs	PMMA with UV absorber
	Foldable IOLs: Monofocal Aspheric Tecnis® Multifocal ReZoom® Phakic Verisyse®	Proprietary polysiloxane and also hydrophobic copolymer of acrylates with UV absorber for optic and single piece haptics PMMA blue core monofilament haptics for multipiece IOLs
Alcon	Monofocal IOLs	PMMA with UV absorber PMMA monofilament haptics for three-piece IOLs
	Foldable IOLs: Monofocal Aspheric AcrySof® IQ®, Multifocal ReSTOR® Toric Phakic	Proprietary hydrophobic copolymer of acrylates with UV absorber only or with additional proprietary bonded yellow dye for blue-light filtering AcrySof® Natural® IOL material
Bausch and Lomb	Monofocal IOLs Foldable IOLs Monofocal Aspheric SoftPort® AO Aspheric Akreos™ AO Akreos™ MI-60 Foldable accommodative IOL movement-based Crytalens® AT-50 Phakic AC IOL	PMMA with UV absorber Proprietary polysiloxane with UV and violet light absorber, Polyamide haptics for Crystalens only Proprietary hydrophilic copolymer of acrylates with UV absorber
Calhoun Vision	Foldable monofocal Light Adjustable power IOL	Proprietary photopolymerizable polysiloxane macromers dispersed within polymerized polysiloxane matrix
Carl Zeiss Meditec	Foldable IOLs Monofocal XL Stabi®, Hydromax®, Aspheric Acri. Smart® Multifocal Acri.Lisa® Toric Phakic	Proprietary hydrophilic and hydrophobic acrylates and polysiloxane materials with UV and optional violet filtering absorbers Polyvinylidene fluoride (PVDF) haptic material
Hoya Surgical Optics	Foldable IOLs Monofocal AF-1® Aspheric AF-1 FY-AD Multifocal	Proprietary hydrophobic copolymer of acrylates with UV and optional blue filtering bonded absorbers. PMMA haptic bonded to foldable optic
Human Optics, AG	Foldable accommodative IOL movement-based	Proprietary copolymer of acrylates with UV absorber (hydrophilic)
Medenium	Foldable monofocal IOL Matrix® IOL	Proprietary hydrophobic copolymer of acrylates with UV absorber Polyvinylidene fluoride (PVDF) haptic material
Ophtec	Monofocal IOL Phakic AC-IOL Foldable Monofocal IOL Toric phakic IOL	PMMA with UV absorber Proprietary polysiloxane with bonded UV and orange absorber as optic, brown PMMA haptics Iris-fixated Artisan® IOL
Rayner IOL Ltd., (Manufacturer of Ridley IOL)	Monofocal IOL Foldable IOLs Monofocal Toric Multifocal	PMMA with UV absorber Proprietary hydrophilic copolymer of acrylates with UV absorber
Visiogen (now acquired by Abbott Medical Optics)	Foldable dual optic single piece, movement based Accommodative IOL Synchrony	Proprietary polysiloxane for two optics and a connecting spring haptic

to the above-discussed good short-term postoperative results, but also, most importantly, to long-term reduction in PCO formation and the necessary Nd-YAG posterior capsulotomy (Hollick et al., 1999). The Nd-YAG capsulotomy rate for AcrySof IOL is <5%, the lowest thus far reported for all IOLs (Apple et al., 2001). Scientific investigations have explained this, based on both the properties of its biomaterial and its design. The surface property of the material and the square-edged design of the optic are attributed as factors for reduction of PCO (Linnola, 1997; Linnola et al., 2000). These investigations led to several more IOLs from other companies (AMO, Hoya, Zeiss-Meditec, etc.) beside AcrySof IOL, which are also made of hydrophobic acrylate materials with square-edged designs. Long-term clinical evaluations are ongoing to compare these IOLs with AcrySof IOL, which is regarded as a reference IOL because of its long-term successful track record.

In addition to several proprietary hydrophobic soft acrylates and polysiloxanes, several hydrophilic soft acrylates and newer hydrogels have also been introduced as foldable IOLs. But their disadvantages, such as greater tendency for fibrotic membrane formation over the anterior surface of the IOL, ACO, and postoperative surface or deep calcification, higher PCO rates, and lack of proven advantage over hydrophobic soft acrylates or polysiloxane IOLs, had reduced their acceptance (Koch et al., 1999; Apple et al., 2000b; Werner et al., 2001; Izak et al., 2003). But recently Rayner, Bausch and Lomb, Zeiss-Meditec, and others have introduced newer hydrophilic materials with around 26% water content, and have designed IOLs with a variety of square-edged designs. These IOLs are also being evaluated for long-term performance related to calcification possibility and PCO rates (Neuhann et al., 2006; Nishi et al., 2007).

Currently, hydrophobic acrylates and polysiloxane foldable IOLs are predominantly used in developed countries. Special insertion tools have been designed and used to implant them through a 3 mm or smaller incision, the same as required for ECCE cataract extraction by phacoemulsifier. Recent improvements have further reduced the incision size for phacoemusification to 2.2 mm, with the original coaxial phacoemulsification hand piece design, and down to 1.4 mm for a bimanual technique requiring two separate incisions and the use of a sleeveless phacoemulsification tip for breaking up cataract through one very small incision, while providing irrigation separately through another small incision. This incision size is subsequently slightly enlarged depending upon the biomaterial, design, and the power in diopters of the IOL injected through them. With this improvement, foldable IOLs and their injectors are available for implantation through 1.8 to 2.4 mm for the average eye's requirement.

Though the AcrySof IOL is widely used, many surgeons find silicone IOLs also as acceptable for most cataract patients without other ocular pathology, especially when the cost of the IOL is a consideration. Silicone IOLs are made by several manufacturers. Concern has been expressed about optical complications associated with silicone oil adhesion on silicone IOLs if the use of silicone oil is required in the future for vitreo-retinal surgery (Khawly et al., 1998; Kaushik et al., 2001). IOLs fabricated from other soft hydrophobic acrylates are also now in the market (Werner et al., 2008).

Monofocal IOLs with fixed spherical refractive power, discussed earlier, remained the dominant IOL implant for replacement of the cataractous lens until recently, when aspheric foldable IOLs have gained significant momentum in the developed world. This optical function enhancement is described in the next section. Transition from hard PMMA IOLs to soft foldable IOLs for small-incision cataract surgery has mostly occurred in the developed world. This was primarily driven by improved postoperative results for patients. Therefore, this transition will be ongoing in the developing world when the necessary resources and skills are available.

IOLS WITH VARIATIONS OF OPTICAL FUNCTION

Monofocal Aspheric IOLs

Since the image formation on the retina in a pseudophakic eye is determined by the two optical lenses consisting of cornea and IOL, it can be optimized in terms of reducing overall spherical aberration by designing appropriate aspheric optics for the IOL to compensate for the corneal spherical aberration. Average corneal spherical aberration compensating AMO's Tecnis IOL (created in 2003 by Pharmacia Company), was the first such FDA-approved IOL. Night-time driving simulations, and other critical visual performance, showed some improvement leading to a "New Technology" designation and a $50 higher reimbursement by Medicare in the USA. Soon Alcon, with its AcrySof IQ, and Bausch and Lomb, with its AO Port IOL, followed by their own aspheric IOL designs for reducing spherical aberrations, also achieved the "New Technology" designation. Besides different biomaterials, they also have slightly different asphericity. Rigorous comparative evaluations of the three designs are ongoing to delineate the patient's corneal shape-dependent advantage of one design over other (Montes-Mico et al., 2009).

Monofocal Toric IOLs

Since monofocal IOLs with spherical refractive power do not correct pre-existing corneal astigmatism, it is corrected either surgically by certain techniques during the cataract surgery or postoperatively using spherocylindrical power spectacles. With the same biomaterials as those used for monofocal IOLs, toric IOLs with toric optics have recently emerged as another alternative for the

more precise correction of significant pre-existing corneal astigmatism. The axis of the cylinder for the spherocylindrical optic of the monofocal toric IOL is marked on the IOL for necessary proper alignment during cataract surgery. Postoperative rotation of a toric silicone IOL with plate haptics (from Staar Surgical) led to its redesign, since such rotation significantly compromised the optical objective of the toric IOL. Another toric single piece IOL design with somewhat flexible haptics (from Alcon Inc.) that can provide improved stable fixation has been clinically found in a comparative study to give much better results without significant rotation (Chang, 2008). AcrySof Toric IOL is now approved by various regulatory agencies, including the FDA in USA and CE marking in Europe. Its use is rapidly increasing, especially since it is considered as more profitable "premium IOL" for reimbursement purposes in the US, as will be discussed in the "Overall Summary and Future of IOLs."

Multifocal IOLs

Since monofocal IOLs optically focus on an object at only one chosen distance, with a relatively narrow depth of focus, postoperatively patients are required to wear spectacles for other distances. Even though almost all elderly cataract patients are accustomed to wearing spectacles because of their presbyopia prior to cataract surgery, the investigation of the opportunity to eliminate spectacles using multifocal IOLs began in the 1980s. With the same biomaterials as for monofocal IOLs, several multifocal optical designs using refractive optical zones or diffractive optical structures have been investigated, implementing simultaneous optical imaging for objects located at a distance, as well as near objects (Maxwell and Nordan, 1990). This optical design principle is called simultaneous vision, and has the potential to eliminate halo and other unwanted optical consequences, depending on the optical design. Multifocal IOLs with refractive optical zones are sensitive to pupil size in terms of their optical performance. The FDA-approved Array Multifocal IOL by AMO, Inc. has a radial array of alternating variable optical power to provide both distant and near optics for any pupil size (Steinert et al., 1999). Although for pupils of 3 mm diameter or larger such a design does provide multifocal vision, the near vision is reported to be suboptimal for a smaller pupil size. Also, halos appear with night-time driving when the pupil is larger, and these remain a potentially unacceptable complication for some patients (Haring et al., 2001). A redesigned Array Multifocal IOL with improvements on the earlier design is currently on the market as ReZoom IOL.

Earlier, the 3M Corporation, and, more recently, AMO (who acquired Pharmacia Corporation's multifocal IOL and now has been acquired by Abbott Medical Optics, still retaining the familiar abbreviation AMO) introduced a Tecnis diffractive optic design that provides pupil size-independent distant and near optics, but still retains potentially unacceptable halos with night-time driving. With better understanding of the cause of such halos, a unique optical design that combines a limited central apodized diffractive optical zone with refractive optics beyond it was introduced by Alcon, Inc., as the AcrySof ReSTOR® multifocal IOL to minimize night-time halo and retain pupil-independent optics for daytime (Dublineau, 2003). Carl Zeiss-Meditec also has a variety of diffractive/refractive combination optics for Acri.Lisa® multifocal IOLs. Thus, there are now many designs of multifocal IOLs (Maxwell et al., 2009).

The simultaneous vision principle based multifocal IOLs demand a more accurate selection of the necessary IOL power in order to achieve spectacle-free vision postoperatively. Also, since the vision achieved is not an actual accommodation, it is called pseudoaccommodation. Since they also correct presbyopia, they are also called "presbyopia-correcting." When used for replacement of cataract in Medicare patients in the US, they too are considered as "premium IOLs" (Maxwell et al., 2008).

Applications of multifocal IOLs for treatment of eyes without cataract, but with presbyopia, hyperopia or myopia, are now clinically carried out in certain suitable patients. For treatment of any one of these refractive errors of the eye, its noncataractous, clear natural lens is surgically removed and replaced by a multifocal IOL (Packer et al., 2002). This lensectomy is carried out by the same surgical procedure as that required for cataract surgery. The unpredictability of achieving necessary targeted refraction, cost, and acceptance of unavoidable optical effects of the simultaneous vision optics of multifocal IOLs remain key hurdles for its widespread use for treatment of refractive errors. Since the prominent use of computers in daily life has developed, satisfactory intermediate distance has become a requirement, as well as near and distance vision provided by the multifocal IOLs, and thus significant improvement has been achieved in designs by adjusting near add power, and incorporating aspheric and toric optical enhancements discussed above for monofocal IOLs.

Phakic IOLs

Currently, for correction of refractive errors of myopia or hyperopia, treatment alternatives include spectacles, contact lenses, and a variety of corneal refractive surgery procedures including LASIK. As another modality of treatment, the phakic IOL, which is an IOL to correct the refractive error of the eye, is placed in the phakic eye in addition to the natural crystalline lens. Phakic IOLs have been clinically investigated for many years with continuous improvements to achieve long-term safety and, it is hoped, widespread use. Unique designs with newer biomaterials are currently being investigated for achieving this goal.

For correction of myopia, the angle-supported phakic AC-IOL designs of PMMA, similar to earlier AC-IOLs

for cataract surgery, resulted in complications of damaged corneal endothelial cells, cataract formation, and pupil ovalization (Chen et al., 2008). More flexible, soft, and foldable phakic AC-IOL designs of hydrophobic soft acrylate material (Alcon's AcrySof Cachet Phakic AC-IOL), when properly sized, are reported to have improved acceptable results in long-term clinical investigations, and are approved in international markets except the US where FDA-required additional studies are ongoing (Knorz, 2003). Iris-fixated phakic AC-IOLs of silicone material (AMO's Verisyse®) are approved by the US FDA, and when properly implanted have also been reported to have acceptable results (Moshirfar et al., 2007). The anterior chamber of the hyperopic eye is anatomically relatively small, and thus less suitable for a phakic AC-IOL.

Phakic posterior chamber IOL designs using silicone and hydrogel materials are placed between the iris and the natural lens to correct myopic and hyperopic refractive errors. They have been clinically investigated over the past few years. Their anatomical placement has potential for iris chafing and the related complication of pigmentary glaucoma. Also, cataractogenesis of the natural lens by either metabolic disturbances or accidental touch of a surgical instrument has been reported, especially with silicone phakic PC-IOLs (Sanchez-Galeana et al., 2003). A hydrogel phakic PC-IOL (Starr's Visian ICL), after several design iterations, in its final design is reported to have fewer complications and US FDA has approved it (Sanders et al., 2004).

Accommodative IOLs

In order to provide true accommodation after cataract surgery, as well as to treat refractive errors of myopia, hyperopia, and presbyopia, a safe and effective accommodative IOL with three or more diopters of accommodation ability to replace the cataract or the natural lens has been long sought.

Designs implementing the concept of forward movement of the optic of the IOL to achieve accommodation were pursued by C&C Vision, Inc., of the US, and Human Optics of Germany (Samalonis, 2002). The Crystalens AT-45 and AT-50 of C&C Vision, which has now been acquired by Bausch and Lomb, is a silicone IOL with polyamide haptics and two hinges that permit axial forward movement of the optic for accommodation and subsequent backward movement for disaccommodation (Cumming et al., 2001). Although only 1 to 2 diopters of accommodation is reported, the results remain variable, questionable, and without scientific understanding of such amplitude from movement of a single optic (Findl and Leydolt, 2007). Since there is no other significant safety issue, even this limited success is encouraging, and the lens is approved by the FDA, and is also a "premium IOL" for reimbursement by Medicare in the US.

In order to achieve a greater magnitude of accommodation, a mechanically coupled pair of optic-based accommodative IOLs were investigated in an animal model by Hara in Japan (Hara et al., 1992), and then by Sarfarazi (Sarfarazi, 2003) in the US. A new design based on this concept called "Synchrony" has been created in silicone material by Visiogen Company (now acquired by Abbott Medical Optics (AMO)). It is currently available in Europe and under clinical investigation in the US for FDA approval. This dual optic design has an anterior +32 diopter power optic which moves and is coupled by a spring haptic to a minus power stationary optic to create much higher scientifically understandable overall +2 to +2.5 diopters of accommodation (McLeod et al., 2007).

Another concept under investigation in animal models requires removal of the contents of the natural cataractous or clear lens through the smallest possible anterior capsulotomy, and subsequently filling by an appropriate silicone polymer to achieve the needed geometrical shape and optical power (Haefliger et al., 1987). Other gel biomaterials have also been investigated, but a host of surgical, biological, and optical issues remain as hurdles to this approach to restore accommodation using the natural capsular bag, zonules, and ciliary muscle for a physiology-based truly accommodative IOL. In another variation of this approach, Nishi of Japan has reported a new design for an accommodative IOL by refilling of the capsular bag with a liquid silicone polymer (Nishi et al., 2008).

Two new concepts for accommodating IOLs based on shape changes to achieve accommodation have emerged recently. NuLens Ltd., of Israel, has a concept for NuLens which consists of a shape change using a diaphragm and a silicone gel with a claim of 8 to 10 diopters of accommodation. Power Vision Inc., of the US, has its accommodative IOL concept based on movement of a biomaterial fluid from a reservoir. Thus, a search for truly accommodative IOL may challenge interdisciplinary resources, including newer biomaterials for some of the above concepts.

Adjustable Power IOLs

For achieving the targeted postoperative refraction for any pseudophakic eye, careful measurement of the axial length of the eye and refractive power of its cornea are required before IOL implantation surgery. Subsequently, using one of many available IOL power selection mathematical formulas, the necessary IOL power is selected by the surgeon for implantation. Errors in this procedure, and deviation of the actual axial position of the IOL from that anticipated by the formula, result in postoperative residual refractive error. Most of the time, postoperative spectacle correction to address this error is acceptable, but occasionally excessive error requires explantation of the IOL to address an unacceptable imbalance of refraction between the two eyes. Also, to achieve the goal of spectacle-free vision with multifocal IOLs or phakic IOLs, achievement of targeted refraction is more critical and necessary. Thus, for many years, concepts for a

postoperative adjustable power IOL have been investigated. Several concepts requiring surgical re-entry into the eye were investigated, but did not result in products because of concern for safety and cost. A new, unique biomaterial-based light adjustable IOL by Calhoun Vision, Inc. is being pursued clinically in the human eye (Schwartz, 2003; Olson et al., 2006). This approach is attractive, since it does not require surgical re-entering of the eye for adjustment of the refractive power of the already implanted IOL. This new biomaterial technology consists of an IOL which is implanted as a polymerized silicone matrix containing nonpolymerized silicone macromers, with an attached photoinitiator dispersed within it for subsequent staged photopolymerization (Maloney, 2003). The IOL is implanted as per current practice for IOL power selection for the targeted refraction. Postoperatively, the achieved refraction is measured. Depending upon sign and magnitude of the refractive error, for necessary adjustment of power of the IOL, the IOL is judiciously exposed to long UV radiation from a slit-lamp based LAL® light delivery instrument, leading to partial photopolymerization. Spatial intensity distribution is used for either exposing the central optical zone, to increase the power of the IOL or exposing the peripheral optical zone, to decrease the power of the IOL. After the required duration for redistribution of the remaining unpolymerized macromers in the IOL, the patient is re-examined for the consequent change in the shape and, hence, power of the IOL toward the targeted correction of the refractive error. If the IOL power adjustment is not achieved, the procedure of partial polymerization is repeated with needed adjustment until targeted refraction is achieved. At this stage, as a final step, the entire optic is exposed to UV radiation for complete "lock-in" of the shape of the IOL. After the safety of this IOL was established in rabbit eyes, clinical investigation required to establish safety and efficacy in terms of accuracy, precision, and reproducibility were done in Mexico, and US FDA-required clinical investigations are being pursued (Olson et al., 2006). It is also now available and used in Germany and certain other European countries. Additional applications of this technology for custom aspheric monofocal and aspheric multifocal IOLs are being identified and pursued.

Visible Light Filtering IOLs

Earlier, the Menicon and Hoya corporations of Japan, for their PMMA IOLs, and in 2003 Alcon, Inc., for its AcrySof Natural IOL and Hoya for its AF-1 IOL and several other manufacturers, have each incorporated a yellow dye into their foldable IOL materials in order to filter visible blue light, in addition to complete blocking of UV radiation (Brockmann et al., 2008) for protection of the retina. Bausch and Lomb Company have introduced a violet-light filtering IOL as a more conservative approach to retinal protection. The most widely used

AcrySof Natural IOL mimics the UV-visible transmission of a young adult human natural lens (Cionni, 2003). In 2002 a significant scientific discovery found previously unknown intrinsically photosensitive retinal ganglion cells (ipRGC) which play a significant role in photoentrainment of the circadian rhythm. A concern was raised for possible filtering of light required by these cells when yellow tinted blue light-filtering IOLs are implanted. This was carefully investigated (Patel and Dacey, 2009), with the conclusion that since the action spectrum for photoentrainment of the circadian rhythm is sufficiently wide, and peaks at much higher wavelengths, there is no such concern. The scientific rationale for such a yellow-tinted IOL is to prevent unnatural excessive blue color perception, and to protect the more susceptible aging retina after cataract surgery (Davison and Patel, 2005). Blue light toxicity to the retina is mediated by age-related accumulation of lipofuscin (Carson et al., 2008), and is considered one of the potential risk factors of age-related macular degeneration (AMD), a serious sight-threatening disease. A recent European Eye Study has found an association between blue light and AMD (Fletcher et al., 2008). While a prospective randomized trial is needed to confirm this relationship, there is an increasing concern for light as a risk factor for AMD in eyes with IOLs, since they remain for a much longer duration after their implantation in pediatric cataract patients, as well as in younger adults for presbyopia correction. Also, an increasing number of elderly patients live much longer after cataract surgery as it is done today worldwide. A recent paper (Davison et al., 2011) have reviewed all recent studies related to the consequences on photoreception, as well as evidence for potential photoprotection provided by the blue light-filtering IOLs. This review provides a contemporary clinical perspective for their use as a potential simple measure against the dreaded AMD, for which we have currently only expensive treatment with limited effectiveness. Thus, a relatively simple incorporation of a safe bonded yellow dye into a biomaterial for IOLs provides an illustration of how IOL biomaterials can be tailored to achieve a potentially significant impact on the prevention of a sight-threatening disease as an additional function, along with the primary function of the IOL for optical imaging.

OVERALL SUMMARY AND FUTURE OF IOLS

In a relatively brief span of a few decades, IOLs have emerged as one of the most successful biomaterial-based implants. They are considered a safe and effective means to prevent the leading cause of age-related degradation of vision due to cataracts, which eventually leads to functional blindness. Currently, an estimated 10 million IOLs are implanted annually for cataract replacement, mostly in the developed world and in some regions of the developing world where resources are available. If

the prevailing rate of cataract surgery in the US is projected for the approximately six billion population of the world, then it is estimated that 45 million IOLs are needed annually! Few ophthalmologists and little money have led to delayed (or no) cataract treatment in the developing world, resulting in a tragic backlog of 20 million cataract-related blind people. Thus, with expected continuous global development and simultaneous increases in population, as well as life expectancy, and with increasing demand for good vision, the future of IOLs for cataract surgery is ensured.

The successful developments of IOLs have been the outcome of interdisciplinary team efforts by creative surgeons, scientists, and engineers in both academia and industry, and also economics of reimbursement by healthcare systems. In the year 2005, the Center for Medicare and Medicaid Services (CMS) in the US made a momentous ruling which shifted their policy (Mamalis, 2005) related to reimbursement of IOLs. This ruling allowed cost sharing between Medicare (Government) and the patient for significantly improved IOLs which was not allowed prior to this ruling, and Medicare paid as if it was a standard monofocal IOL. CMS now lists several significantly improved IOLs, such as presbyopia-correcting (multifocal and accommodative) IOLs and astigmatism-correcting IOLs. They are called "premium IOLs" at a free market price set by the manufacturer, and the patient will pay any cost difference between it and the reimbursement by CMS which will continue, but is only limited to that for a conventional standard monofocal IOL (Maxwell et al., 2008). This new CMS policy thus encourages IOL manufacturer's to invest in R&D for competitive new innovations, since they can get their return with a free market price of IOLs without the limit of affordability set by the US government.

Starting from a biomaterial selection based on the accidental implantation of pieces of PMMA from the canopies of fighter airplanes, a variety of newer biomaterials have been specifically created to achieve the various designs and functional goals of IOLs, as outlined in Table B.2. Creative interactions and an understanding of the opportunities and issues of biomaterials, optical and mechanical designs, and evolving surgical techniques, along with improved understanding of the unique biology of the eye, have spearheaded the sophistication we see in modern IOLs. These efforts are expected to accelerate with the above described new CMS ruling in the US as an incentive for new innovative IOLs. Specifically, efforts will continue to achieve the development of truly accommodative IOLs with the capability of mimicking the physiological function of the natural lens. Multidisciplinary efforts will also continue to achieve improved phakic IOLs to correct the refractive errors of presbyopia, myopia, and hyperopia. When long-term safety and efficacy are demonstrated, phakic IOLs or truly accommodative IOLs have the potential to replace the current alternatives of spectacles, contact lenses, and a variety of corneal refractive surgery procedures, including LASIK. Thus, globally, the number of IOLs required for all functional goals could be many times greater than the given projection for IOLs needed for cataract replacement.

Further opportunities are expected for improved optical designs of IOLs for correction of corneal aberrations beyond the first generation of current aspheric IOLs. With further understanding of the optical needs for achieving optimum vision, eventually a custom IOL may evolve for each individual eye for all of the projected functions of IOLs for aphakic and phakic eyes (Kohnen, 2003). Even incorporating the additional non-optical function of postoperatively needed drug delivery is being explored as a potential opportunity. Achievement of these goals will require advances in biomaterials for IOLs, and biomaterials scientists working closely with physicists, chemists, engineers, surgeons, pharmacologists, regulatory affairs experts, and business people. The success of IOLs in improving vision worldwide genuinely showcases the strength of the biomaterials endeavor, and the highly multidisciplinary nature of this field.

C. CORNEAL INLAYS AND ONLAYS

Crystal Cunanan
Tissue Engineering at Boston Scientific, Los Gatos, CA, USA

A successful corneal inlay or onlay must satisfy a number of different requirements, and these can be categorized as optical, mechanical, chemical, and biological. In addition, it must make business sense; that is, it must be capable of volume manufacture, have a suitable profit margin, and meet an unmet or under-served market need. To date, no device is approved in the United States which meets or exceeds all the requirements in each of these categories. This chapter will describe what we have learned from previous experiences about the requirements of an ideal corneal inlay or onlay, as well as outline future directions. Hopefully, this chapter will inspire the student to take on the challenge of developing a successful corneal inlay or onlay, as such a device would provide unique advantages over other types of refractive therapies.

HISTORY OF CORNEAL INLAYS AND ONLAYS

Since 1949, ophthalmic surgeons have tried to harness the power of the cornea to change the refraction of a patient. Jose Barraquer, considered by many to be the Father of Modern Refractive Surgery, invented the microkeratome and the cryolathe, in order to perform more accurate corneal refractive procedures. Using these tools, he introduced the techniques of keratophakia, keratomileusis, and epikeratophakia, all surgical procedures performed on corneal tissue to change the curvature of the cornea, and thus alter the refractive state of the eye (Barraquer, 1949). In the case of additive procedures, such as epikeratophakia, donor corneal tissue was shaped into the desired form and then added to the patient's cornea to alter refraction. In subtractive procedures, small parts of the patient's own corneal tissue were removed to change corneal curvature.

While most of the techniques developed by Barraquer are performed by the surgeon, Drs. Herbert Kaufman and Marguerite McDonald encouraged one company to develop and commercialize a standardized epikeratophakia lenticule made from human donor corneal tissue that was unsuitable for transplant. The physicians were impressed with the wide range of refractive errors that theoretically could be treated by this approach, and they argued successfully that a standardized product manufactured by a licensed medical device company would improve clinical outcomes for patients. Finally, a device that was removable and reversible represented a unique advantage that other refractive device products and procedures could not provide. Products were developed for adult aphakia (McDonald, 1987), pediatric aphakia (Morgan, 1987), myopia (McDonald, 1987b), and keratoconus (Dietze, 1988). Despite the rather good clinical success of the product line, particularly for pediatric aphakia and keratoconus, and the repeated recommendation for approval by the Ophthalmic Device Advisory Panel of the Food and Drug Administration (ISRK, 1989), the product application was withdrawn before it obtained final FDA approval.

Epikeratophakia is still practiced today by a handful of clinicians skilled in cryolathing human donor corneal tissue, and remains an alternative for children born with cataracts who are contact lens intolerant (Halliday, 1990). The lenticule becomes repopulated by the cells from the host cornea, making it a "living contact lens" or what could also be described as a tissue-engineered corneal scaffold (Yoon, 1998; Cahill, 1999). While refractive surgical procedures in general are associated with a loss of corneal sensitivity in the region associated with the surgery (Kohlhaas, 1998), some epithelial axon terminals have been reported in primates implanted with epikeratophakia lenticules, and some measure of corneal sensitivity is restored in patients in a time-dependent manner (Koenig, 1983; Kaminski, 2002). The lenticule is removable, if necessary, and clinicians have been able to perform other refractive procedures in eyes which had undergone previous epikeratophakia (Kaminski, 2003). For children, the lenticule grows with them as they grow, avoiding the need for continued adjustment of device power with growth, as would be required for an intraocular lens implant.

Today, laser-assisted *in situ* keratomileusis or LASIK, and PhotoRefractive Keratectomy or PRK, are the most common corneal refractive procedures performed, due to their refractive predictability and rapid recovery. In the LASIK procedure, the initial corneal flap is created with either a blade system (very similar to the original Barraquer design) or with a femtosecond laser, such as the IntraLase™ system. In either case, after the corneal flap is lifted away from the corneal surface, an excimer laser is then used to reshape the corneal surface, and the corneal flap is returned over the reshaped bed. Approximately 1.2 million LASIK procedures are performed every year in the United States, with a high degree of satisfaction for most patients (95–98%), although the penetration of LASIK into the available patient population is still relatively low, at about 10% (Kalorama, 2009). Clearly there are still hurdles which remain to be addressed before refractive surgery can fulfill its promise to the 500 million people worldwide who require refractive correction.

Terminology

Don't let the language of ophthalmology scare you! Just as new techniques are developed, so are new words which describe them. Once you know the meaning of the parts, you can usually figure out the meaning of any word, no matter how long it is.

Kerato- (KEHR-uh-toh). Prefix: pertaining to the cornea
A- (AY). Prefix: without.
Epi- (EP-ee). Prefix: on top of
Photo- (FOE-toe). Prefix: With light.
Pseudo- (SU-doh). Prefix: False or imitation.
-Conus (KOH-nus). Description: Cone-shaped.
-Phakia (FAY-key-a). Description: Refers to a lens.
-Plasty (PLAS-tee). Surgical procedure. General term.
-Tectomy (TEK-tuh-mee): Surgical procedure. Removal of tissue.
-Totomy (TAH-tuh-mee): Surgical procedure. Incision into tissue.
Now put it together:

Epikeratophakia: Lens placed on top of the cornea.
Keratoconus: A cone-shaped cornea. Pathological condition where the cornea thins centrally and bulges progressively outwards.
Photorefractive keratectomy: Surgical procedure using light (laser) to remove a portion of the cornea to alter the refractive state of the eye. Also called PRK.
(Adapted from Cassin, B. (2006). *Dictionary of Eye Terminology*, 5th edn, M. L. Rubin, MD, ed. Triad Communications, Inc.)

SYNTHETIC BIOMATERIALS IN THE CORNEA

Although the human donor corneal lenticules used in the epikeratophakia procedure can be considered a biomaterial, this is not a commercially viable biomaterial. In the 1990s, the United States passed laws which

restricted the fees which could be charged for devices fabricated from human donor tissues to coverage of a "processing fee," and prohibited any profit to be made from donated tissues. There are also other non-financial disadvantages of using human donor tissues as a source material, including the lack of reproducible starting material, the potential for transmission of disease through the implant, the inability to control the material during its history (for example, time to harvest the cornea after death, the method of collection and storage, and the patient's own ocular history), and the limited supply of donor human corneas. Taken together, these disadvantages outweigh the advantages of matched physical/chemical/biological properties, removable, replaceable, and excellent healing response, although a synthetic version of an epikeratophakia lenticule will need to provide those advantages as well, if it is to be successful.

OPTICAL REQUIREMENTS

The first requirement of a corneal inlay or onlay is that it must provide optical correction of the patient's refractive error. Myopia or nearsightedness, and hyperopia or farsightedness, are two of the most common refractive errors. Astigmatism and presbyopia are also common refractive errors. Refraction is the deflection of a ray of light as a result of passing from one medium to another of different optical density (refractive index). Maximum refraction occurs when the difference between the optical densities of the two media are greatest. The cornea is the most powerful refracting surface of the human eye, because of the large difference in the refractive index between the air and the cornea. The cornea is responsible for about 70% of the refractive power of the eye. The crystalline lens, responsible for accommodation and fine focusing of an image, is responsible for about 30% of the refractive power of the eye. Table C.1 contains the refractive index values for a variety of ocular tissues and media.

Corneal inlays and onlays can provide refraction by: (1) changing the power of the cornea, using a material with a higher refractive index; and/or (2) changing

TABLE C.1	Refractive Index Values of Various Ocular Tissues and Fluids Compared to Air and Water (Hecht, 1987)
Medium	**Refractive Index (n_d)**
Air	1.000
Water	1.333
Cornea	1.376
Aqueous humor	1.336
Crystalline lens*	1.386–1.406
Vitreous humor	1.337

*Note the natural crystalline lens has a progressive gradient refractive index of 1.386 in its outer, less dense, layers and 1.406 in its denser nucleus.

the shape of the anterior surface of the cornea. Both approaches have been tried in the past 50 years, with varying success. In Barraquer's original studies, he implanted synthetic materials in the cornea, in addition to corneal reshaping with surgical methods. The only materials available to him at that time, sintered glass and polymethyl methacrylate (PMMA), were hard, impermeable materials with a high refractive index. When he placed lenticules made from these materials into the cornea, however, he found that the corneal tissue above the implant became necrotic, and eventually the entire cornea over the implant disappeared, and the lens was extruded from the cornea.

BIOLOGICAL REQUIREMENTS

The reason for Barraquer's failure was not understood until 1961, when Knowles demonstrated the importance of corneal permeability on corneal physiology (Knowles, 1961). Knowles placed impermeable materials within the cornea, and observed the corneal tissue directly above the implant to begin to break down, become necrotic, and eventually dissolve over the implant. Soon it became appreciated that the cornea receives its hydration and nutrients from the aqueous humor, and not from the tear film, as had been previously believed. Glucose, in particular, was identified as an important metabolite which was provided solely from the aqueous humor. Thus, an important material property for a synthetic lens is the permeability of the material to glucose, which can be measured experimentally using a diffusion chamber.

A hydrogel is water permeable, and thus is a more appropriate plastic material for intrastromal implantation. Early studies by Dohlman and Mester demonstrated long-term implants of both high (88%) and low (38%) water content hydrogels in rabbit and cat corneas (Dohlman, 1967; Mester, 1972). Surprisingly, Dohlman experienced some corneal necrosis with the 88% water content materials, while Mester reported no cases of necrosis with the 38% polyHEMA materials he used.

The reasons for this may relate to the actual dimensions of the implants themselves. Dohlman reported using implants ranging in thickness from 0.19 mm to 0.57 mm, while Mester used implants which were 0.2 mm thick. Thus, while Dohlman was working with a higher water content material, he still saw nutritional necrosis due to the thickness of some of his lenses. While Mester used a material with a lower water content, his lenses were much thinner, and thus he saw no nutritional deprivation.

Another potential difference between the two studies included the influence of the shape of the device on the corneal tissues. Dohlman cast his material as a flat sheet, and punched disks of material from this sheet for implantation. Mester, however, cast his material in molds which were curved, to better match the curvature of the cornea.

While no controlled studies have been reported to look at the influence of lens mechanical mismatch on corneal tissue, similar observations have been reported in other types of implants in other implant locations (Matlaga, 1976).

COMMERCIAL ATTEMPTS AT SYNTHETIC CORNEAL INLAYS AND ONLAYS

Given the early successes of Dohlman and Mester, and armed with the new understanding of corneal physiology, the ophthalmic industry embraced the notion of synthetic corneal inlays and onlays with a passion. At least four major ophthalmic companies and a number of start-up ventures began developing synthetic implants for refractive keratoplasty. These programs took one of two approaches: (1) mimic the cornea, and change refraction by changing the anterior corneal curvature or (2) change the power of the cornea with a high refractive index material.

Bernard McCarey, at Emory University, became a nearly universal resource in helping industry study their implants, and understand their materials and the requirements of the cornea. Over the 15 years that this research was conducted, Dr. McCarey worked with many world-class researchers and clinicians as he utilized the platform of intracorneal lenses (abbreviated to ICLs) to continue to advance our understanding of the cornea. Simultaneously, the interest in corneal physiology and its importance in developing a commercially successful ICL stimulated independent research in leading centers around the globe. Much of this work forms the cornerstone of our understanding today of corneal physiology and its reaction to foreign materials.

PERMEABLE INTRACORNEAL LENSES

As may be expected from Barraquer's failure with impermeable materials, most companies settled on permeable materials and utilized their understanding of hydrogels for contact lenses to develop their programs. These materials can all be described as ionically neutral, since ionically-charged hydrogels can change physical dimensions with changing pH (McCarey, 1982); high water content to match the water content of the cornea, since materials with water contents higher than the cornea are not dimensionally stable in the cornea (Beekhuis, 1985); and hopefully, adequate glucose permeability, since implants with insufficient permeability result in anterior stromal necrosis.

While no hydrogel intracorneal inlay is available for widespread correction of refractive error in the United States, there were significant learnings which occurred during those early studies. For example, the surgical technique that is utilized can strongly influence the response of the cornea to the implanted lens, and a microkeratome technique is more predictable compared to a free-handed dissection (Beekhuis, 1986; McCarey, 1986). The animal model can have an influence on the reactivity of the cornea to the implant, with rabbit eyes being the most reactive (McCarey, 1981, 1982b) followed by cat eyes (Climenhaga, 1988). The nonhuman primate model is preferred for intracorneal implant studies for several reasons, including the presence of a true Bowman's membrane, which is lacking in the rabbit, and the ability to assess refractive predictability (Watsky, 1985; McCarey, 1989, 1990). The primate model also allows long-term follow-up, and studies have been reported of long-term hydrogel intracorneal lens implants at five and eight years (Parks, 1991; Werblin, 1992; McDonald, 1993). Because of the difficulties in using cats and nonhuman primates in animal research, most studies today utilize the pig model when a long-term implant is needed. The pig cornea is similar in size and curvature, making it possible to use clinical instruments and methods for flap formation.

Animal studies have enabled histological evaluation to be conducted at various time points and correlated to the clinical presentation of the eye. For example, scattered zones of abnormal fibroblast activity at the posterior interface of the lens with the stroma are fairly typical in the rabbit model (McCarey, 1982b). Keratocytes may also line the anterior stromal face, but an

acceptable reaction would not contain irregular areas or masses which would scatter light and interfere with vision, and the ultrastructure of these cells remains normal. By contrast, development of intrastromal corneal crystals is not a normal occurrence (Parks, 1993). These crystals are composed of lipid, and can occur in eyes that have experienced surgical trauma or chronic metabolic stress (Rodrigues, 1990). Animal studies are also good at detecting material problems, such as inadequate biocompatibility of the material (Beekhuis, 1987). A biocompatibility problem would occur shortly after implantation, 3–12 days in the primate model, and would present as severe edema and inflammation throughout the cornea. Fibrin clots can form in the anterior chamber with marked iritis and conjunctival hyperemia. Significant stromal edema can be followed by the development of lipid crystals in the cornea. Gradual stromal thinning is a concern that, if it does not stabilize, will lead to ulceration. Stromal thinning may lead to epithelial thinning by two weeks postoperatively, with ulceration occurring by the sixth week. Causes of biocompatibility problems can include chemical or biological contamination, which may trace back to the source polymer itself. Since many companies used contact lens formulations, there may be contaminants in the contact lens material which are tolerated when the lens is on the tear film, but are irritating to the eye when implanted. Care must be taken to recognize the higher standards of quality and purity that an implanted lens requires, compared to a contact lens. Another common source of contaminants is from the manufacturing process, either residual solvent or more likely, residual cleaning or polishing agents. Such lessons are well-known to those accustomed to making intraocular lenses, but not necessarily at a contact lens company or a start-up venture with inexperienced personnel.

Surgical complications can also arise, and difficulty with the microkeratome incision in animals is more frequent than one would care to admit. Today, the possibility of using a femtosecond laser to create the flap may lead to a more precise placement of the lens, and less surgical trauma. These early studies used large diameter, thick lenses, and sutures were used to secure the corneal flaps. Sutures can create irritation, and occasionally result in additional complications, particularly if the suture penetrates the anterior chamber. Today, using modern LASIK procedures should improve the quality of ICL implantation, without the need for sutures. Finally, there is the potential to include foreign-bodies in the lamellar bed, such as fragments or burrs from the microkeratome blade, powder from gloves, and residues from surgical instruments. While these contaminants can also develop in a standard LASIK procedure, that situation is different because there is living tissue surrounding the foreign-body which, with time, will ensure its removal (either through phagocytosis or extrusion). When a lens is present, however, the foreign-body is trapped against an inert surface, preventing its removal and causing

increased inflammation in the underlying stroma. Haze, edema, and inflammation posterior to the lens (but not anterior to it) could be signs of trapped debris at the interface. While the refractive surgery suite is not an operating room *per se*, in the case of ICL implantation, each case should be treated as an intraocular procedure.

Other complications which can occur include mechanical complications, resulting in implant fibrosis, formation of an iron line in the epithelial layer, and decentration of the implant with or without extrusion. Optical complications can also be studied in the primate model, and one can detect overcorrection or undercorrection, induced corneal astigmatism, and development of a refractive nomogram prior to human cases, which should increase the success rate of early clinical trials. Two high water content hydrogels were studied in clinical trials after extensive animal studies, and both studies demonstrated the biocompatibility of the two materials in the human cornea for as long as six years (Steinert, 1996; Barraquer, 1997). ICL technology did not provide stable vision for myopic patients, although the aphakic patients in both series were well-corrected. Both studies encountered difficulties with the surgical procedure, as these studies were conducted before LASIK became popular. Figure C.1 shows the appearance of an eye with an implant two years postoperatively. Note the crystal-clear cornea and the rather deep implantation of the lens. Because of the concurrent development and success of the excimer laser, both companies involved in these clinical trials decided to close out the studies and focus their efforts on laser vision correction.

Intracorneal implants have given us additional tools to study the processes of nutrient transport in the cornea (McCarey, 1990b), and to build upon the work of Klyce (1979) and Baum (1984) in understanding the roles of each of the cell types within the cornea in corneal hydration and normal physiology. Recently, Fischbarg
FIGURE C.1 Slit-lamp photomicrograph of an eye after two years implantation of a high water content hydrogel material, implanted for hyperopia correction. Note the clear lens in the slit beam with only a trace amount of scattered light around the edges of the implant. This example highlights the excellent biocompatibility that can be obtained with synthetic materials in the human cornea. (From Ismail (2006), reprinted with permission.)

(2004) and Li (2006) have expanded upon these earlier studies to examine the roles of receptors in corneal physiology, and to model the transport of a number of ions across the cornea in normal maintenance and in response to physiological stresses. Larrea et al. have modeled simultaneously the oxygen and glucose fluxes through the cornea to determine the optimum depth of an intracorneal lens implant (Larrea et al., 2007). Continued work in this area may someday help us to better understand the development of lipid and iron deposits in the cornea, as well as to develop early predictors of corneal stress in cases which may be in danger of stromal ulceration or excessive haze development.

IMPERMEABLE INTRACORNEAL LENSES

Despite the evidence associated with stromal necrosis and impermeability, several companies continued to pursue impermeable, high refractive index materials, most notably poly methyl methacrylate (PMMA) and polysulfone. Given the refractive indices of 1.489 and 1.633, respectively, this is an appreciable difference compared to high water hydrogels with refractive indices of around 1.385, and would enable a greater degree of optical correction compared to a hydrogel ICL. Polysulfone intraocular lenses were being implanted in Europe with suitable biocompatibility (Lane, 1986), and as intracorneal lenses they demonstrated a predictable and consistent change in refraction (McCarey, 1987).

To determine if an impermeable lens could be tolerated in the cornea at all, a systematic study of the influence of lens diameter and implant depth was conducted in cats (Climenhaga, 1988). Lenses of 4, 5, 6, and 7 mm diameter were implanted at depths ranging from 45% to 95% of corneal thickness. These lenses averaged 180 microns thick at the center and had an edge thickness of less than 100 microns. The lenses were implanted into a freehand dissected pocket and followed for up to 20 months. With time, central corneal opacities developed in 100% of the eyes, following a diameter-dependent pattern where 7 mm lenses developed stromal opacities within one month, and 4 mm lenses required 12 months to develop opacities in the majority of lenses. Ultimately, however, anterior stromal deposits developed in nearly all lenses by 13 months, and an average of 28% of eyes developed stromal melting. The stromal deposits which developed appeared first as a fine, stippled haze that became increasingly confluent as granular deposits coalesced into a continuous white opacity in the anterior stroma centered over the lens. In some eyes the opacities developed fine, elongated, spicule-shaped crystals over the center of the lens, and sometimes behind the lens. These deposits developed from months 1 to 14, depending on lens diameter, and continued to grow with time. In contrast, peripheral deposits developed at a different rate, with 40% of all lenses exhibiting a hazy gray ring around the lens periphery by 2 months. By 9 months,

100% of lenses exhibited edge deposits. Both central and peripheral deposits were consistent with lipid deposition in the cornea. The authors concluded that because opacities developed in all lens diameters and implantation depths, the metabolic demands of the cornea were not met, and thus no safe limit existed at which these ICLs could be used predictably in cat eyes.

The clinical study in Europe on polysulfone ICLs eventually reached the same conclusion after 12 years' implantation (Horgan, 1996). Research has shown that fenestrated polysulfone lenses can survive in the cornea of cat eyes at one year, however, with 100% anterior stromal clarity over the fenestrated portion of the lens (Lane, 1991). The fenestrations ultimately filled in with normal stromal tissue and keratocytes. Due to the difference in refractive index between the polysulfone lens and the surrounding tissue, however, these fenestrated lenses were not clinically useful.

SYNTHETIC MATERIALS FOR CORNEAL ONLAYS

Despite the extensive development of tissue lenses for epikeratophakia, and their rather good clinical outcomes, progress on a synthetic corneal onlay or total synthetic cornea has met with far less success. This is not for lack of trying, and the industry's efforts to create a successful synthetic epikeratophakia lens have been substantial, but this investment was insufficient to overcome the technical hurdles that were encountered.

Many of the technical requirements of a synthetic onlay mirror that of a synthetic inlay, such as permeability, optical clarity, dimensional stability, and manufacturability. The distinct difference, however, is in the added requirement of supporting a robust and healthy epithelium across the lens, and this is the hurdle which has proved insurmountable, at least up to this point.

When the synthetic lenticule is placed on the cornea, it is placed directly onto Bowman's membrane, after the corneal epithelium has been removed. This creates a breech in the sterile barrier function of the eye, and it is paramount that the lens supports rapid and stable re-epithelialization in order to restore the integrity of the sterile barrier of the eye. This creates a real conundrum, as the hydrogel materials that have been used for intracorneal implants do not support cell adhesion and growth (Cunanan, 1991). While surface modification of these materials was tried extensively (Cunanan, 1996), these efforts failed to provide a robust stable surface treatment that corneal epithelial cells would recognize and adhere to long-term. Although many treatments looked satisfactory in an organ culture system designed to test the outgrowth potential of different materials (Pettit, 1990), these treatments failed to support cell migration and adhesion in an animal implant model. The ideal conditions in the cell culture system did not adequately challenge the materials being tested, and it is believed that

the biomolecules used to encourage cell migration and attachment were degraded by proteases in the tear film, which are an integral part of the eye's natural defense mechanisms. Protease inhibitor eye drops were developed with some success at protecting the biological signaling proteins tethered to the lens surface; however, as soon as the eye drops were discontinued, the epithelium sloughed off the lens. Such an approach is a band-aid effort to stop the proteolytic degradation occurring on the lens surface, and it was insufficient to address the fundamental problem of cell migration and adhesion.

CORNEAL INLAYS AND ONLAYS TODAY

Despite the long history of failures, and the many challenges that have been encountered, development of a successful corneal inlay or onlay still represents a very attractive market opportunity. Because the implant is additive, rather than subtractive, such as with PRK or LASIK, the implant can be removed and the patient is usually left in their original condition. This is highly desirable to help overcome the fears of many patients who have not undergone LASIK surgery today because of their reluctance to undergo an irreversible procedure (Kalorama, 2009). These additive technologies do not interfere with the clinicians' use of other refractive therapies, as an adjunct or replacement technology, as the patient's needs change with aging. This is an important factor in the adoption of any new technology.

Today, there are four basic approaches being taken in developing implants for refractive correction. The first device concept, thin intracorneal rings or ring segments fashioned from PMMA, is used in the peripheral anterior stroma to alter the corneal curvature (Figure C.2). These implants do not experience permeability failure because they are only a narrow ring of material, and leave the central cornea untouched. While these devices

FIGURE C.2 Photomicrograph of an eye after Intacs® implantation. Note the clear corneal tissue around the implant, indicating excellent biocompatibility. This patient experienced pain after implantation due to the physical compression of an ocular nerve by the rigid PMMA ring. (From Randleman et al., (2006), reprinted with permission.)

had been originally developed as a treatment for myopia, the advent of the excimer laser and PRK/LASIK have limited the use of these implants to patients who are contraindicated for LASIK surgery, such as keratoconus patients and in patients with thin corneas that may develop keratoconus after LASIK surgery, also called keratectasia (Ertan, 2007; Pinero, 2009). These ring segments provide a mechanical reshaping of the cornea, and thus can only correct low degrees of myopia, typically up to 2 diopters. Sometimes they can induce chronic pain, presumably by pressing against a corneal nerve (Randleman, 2006). Much like the other corneal implants, however, the intracorneal rings and segments can be removed, and the patient usually returns to their original refraction. Today, there is a program with the IntraLase™ femtosecond laser to create the circular tracks for the ring segments (Pinero, 2009b). Long-term results in this unique patient population reveal that the intrastromal ring segments are well-tolerated and provide stable vision, without late complications or loss of effect (Kymionis, 2006).

The AlphaCor™ artificial cornea is another niche product that has met with some success in a limited patient population for patients with extensive corneal haze or pain who are at high risk of graft failure with a donor cornea (Hicks, 2003). The AlphaCor™ device is a one-piece button of polyHEMA, with a clear 4.5 mm optical portion in the center surrounded by a 1.25 mm opaque spongy rim. The outer rim allows cellular ingrowth from the host tissue, thereby locking the device into place, but the surgical procedure is complicated, and the device must be implanted in a complex two-stage process completed over a 12-week timeframe. The first procedure involves placing the device in a midstromal pocket which is hand-dissected, with a 3 mm trephination through Descemet's membrane to create a clear zone in the posterior cornea. The second procedure is completed several months later, after host ingrowth has been accomplished, and involves a simple anterior stromal 3 mm trephination to create a clear optical zone in the anterior cornea. Implantation of the device can also be combined with cataract surgery, as many traumatic cases of corneal injury may also require lens replacement (Eguchi, 2004).

Complications associated with the device include problems with its poor mechanical strength and flexibility, discoloration, and formation of deposits (Hicks, 2004), infection and melting of the hydrogel (Chow, 2007), development of a retroprosthetic membrane (Chalam, 2007), development of intractable glaucoma (Ngakeng, 2008), focal calcification, and spoilage of the hydrogel material by various ophthalmic formulations that might be used for patient care (Morrison, 2006). As this device continues to be studied, there are reports of an immunologic aspect of the device failure, associated with cellular response to the porous skirt
FIGURE C.3 (a) The AcuFocus intracorneal inlay shown next to a contact lens. Note the overall small size and opaque nature of the ring. The stippling seen on the inlay is really the laser-drilled holes which prevent nutrient deprivation of the anterior cornea. (b) The inlay in a patient's eye. (From Yilmaz et al., (2008), reprinted with permission.)

(Coassin, 2007). At least some cases of retroprosthetic membrane formation can be attributed to concomitant diabetes, indicating a systemic influence on the device (Hicks, 2005).

A new type of intracorneal implant under development is the AcuFocus KAMRA™ Corneal Inlay for the treatment of presbyopia. The KAMRA™ inlay has an overall diameter of 3.8 mm, which is smaller than a contact lens. It has a 1.6 mm center aperture, which is a small opening in the center that creates a pinhole effect. The device is 5 microns thick, made of polyvinylidene fluoride and carbon, and it has 8400 random holes for oxygen and nutrition flow. The AcuFocus corneal inlay is designed to improve depth of focus, allowing the eye to see near and intermediate objects more clearly. Figure C.3 compares the KAMRA™ lens to a standard contact lens and shows the inlay implanted in a human eye (Yilmaz, 2008). Like other corneal implants, the AcuFocus implant can be removed and the patient's refraction returns to baseline levels. This device received the CE mark in 2005, and is under active clinical investigation in the United States.

Two start-up companies continue to pursue the use of hydrogel materials for intracorneal lenses. ReVision Optics has developed a 2 mm lens made from a high water content material, relying on changing the corneal curvature to provide refractive correction. Presbia is developing a 3.2 mm lens made from a low water content material, placing the implant deep in the cornea to prevent nutritional deprivation of the overlying stroma. Both companies have focused their efforts on the treatment of presbyopia, which requires a smaller refractive correction compared to other types of refractive errors.

To control centration, ReVision has worked with IntraLase™ to develop a custom pocket which holds the tiny implant, thus improving the surgical technique. Figure C.4 shows the microlens on the tip of a finger, while Figure C.5 shows the excellent biocompatibility

FIGURE C.4 Photo of the ReVision Optics micro-inlay on the tip of a finger. Note the small size of the inlay, which is optically clear and made from a high-water content hydrogel material. (Photo provided by ReVision Optics, printed with permission.)

of the microlens in a porcine cornea. Today, ReVision Optics has completed pivotal clinical trials in the US and awaits FDA approval, while it commercializes the lens in Europe. Patients receiving the ReVision lens demonstrate an impressive improvement in their near-vision acuity (90% at J1; 100% at J2) at one year. The Presbia lens has no visual correction in the central portion of the lens, surrounded by a positive-powered ring. The Presbia lens creates a bifocal effect with the high refractive index implant, and does not change the corneal curvature. The Presbia lens is CE mark approved and is undergoing US clinical trials. Table C.2 contains comparative information about the intracorneal inlays in clinical use and in development today.
FIGURE C.5 (a) A histological cross-section of an unimplanted pig cornea (H&E stain, 10×). (b) A histological cross-section of the contralateral eye of the pig after 12 months implantation of the RVO corneal inlay (H&E stain, 10×). The polymer material was lost from the section during the histological processing, leaving an open space in the corneal section. The biocompatibility of the implant is evident in both the stromal areas surrounding the implant, as well as the overlying epithelium, which is neither hypertrophic nor thinned. (Photo provided by ReVision Optics, printed with permission.)

TABLE C.2	Comparison Between the Various Intracorneal Implants in Use and Under Development Today				
Attribute	**Intacts® Rings**	**AlphaCor™ Implant**	**AcuFocus KAMRA™**	**ReVision Optics**	**Presbia Microlens**
Polymer type	PMMA	PolyHEMA	PVDF/carbon black	Acrylic hydrogel	Acrylic hydrogel
Water content	0%	38%	0%	high	low
Implant location	Anterior periphery	Central, partial to full thickness	Anterior central	Anterior central	Posterior central
Implant exerts refractive effect by:	Changes corneal curvature by bulking up the periphery	Higher refractive index than cornea	Pinhole optics	Changes corneal curvature with central implant	High refractive index
Regulatory status:	FDA approved; CE mark	FDA approved; CE mark	CE mark; in FDA trial	CE mark; FDA trial submitted for approval	CE mark; in FDA trial

THE FUTURE OF CORNEAL INLAYS AND ONLAYS

As long as people continue to require refractive correction, there will be an incentive to develop the optimum corneal inlay/onlay. As we continue to update the requirements of these products, we can see that the field as a whole is making progress, and that there is room for more than one product or technology. New enabling technologies, such as the use of a laser to provide final, minute lens adjustments (Peyman, 2005), using advanced imaging systems capable of capturing the unique optical abnormalities inherent in each of us (Warden, 2008) may be the refinement needed to provide discriminating patients with the highest quality of vision possible. Continued advances in surgical techniques and procedures (Zarbin, 2004) may provide the rapid, pain-free visual recoveries that patients expect. Given the plethora of biomaterials currently available and in development (Xie, 2006; Myung, 2008; Pinchuk, 2008; Deng, 2009; Liu, 2009), a successful corneal inlay or onlay may be closer than you think. Some approaches may be considered as tissue engineering (Liu, 2008) and the reader is referred to Section II.6, "Applications of Biomaterials in Functional Tissue Engineering," for the latest information on these advances.

D. OPHTHALMOLOGIC APPLICATIONS: GLAUCOMA DRAINS AND IMPLANTS

Crystal Cunanan
Tissue Engineering at Boston Scientific, Los Gatos, CA, USA

Although biomaterials occupy a central role in any medical device, there is possibly no other area that has seen such an explosion of new materials and devices as in the treatment of glaucoma. Moving away from the larger devices made from silicone or polypropylene, the implants under development today are uniformly focused on minimally-invasive surgical methods for implantation, and include a wide variety of different materials, including metals, polymers, and biologics. Most of these devices still function primarily as drainage devices, although some new approaches have been proposed. Given the high cost of glaucoma to society, it is likely that new materials and devices will continue to be investigated to curb the onset and progression of this painless, yet debilitating, disease.

HISTORICAL PERSPECTIVE ON THE TREATMENT OF GLAUCOMA

Historically, the treatment of glaucoma has focused on the use of pharmaceutical agents, either alone or in combination, and today the pharmaceutical industry enjoys over $4 billion annual sales for glaucoma (Stuart, 2010). Given the high cost of these pharmaceuticals, which require regular oversight from a trained glaucoma specialist, the use of these agents is focused primarily in the developed countries. Sadly, people in India and Africa and other developing countries still go blind due to

glaucoma without ever being treated. This is in marked contrast to patients in the United States and Europe, where the glaucoma specialist will have exhausted every pharmaceutical, surgical, and device approach available, and patients rarely lose their vision entirely. Nonetheless, the difficulties associated with the current treatments have generated a strong interest in improving the treatment of glaucoma in all markets, especially for patients of African descent, in whom glaucoma can be most severe (Sommer, 1996; Leske, 1997).

Glaucoma is called the "silent" disease because it typically attacks eyesight subtly over time and without noticeable symptoms. It is a controllable disease if detected early, although an estimated 40% of the 65–70 million people with glaucoma do not know they have the disease, and over seven million people go blind from glaucoma each year (Quigley, 1996). Glaucoma can occur in young children, primarily due to a malformation of the anatomical structures of the eye or acutely, due to injury or a temporary closure of the ocular drainage pathways. The most common form of glaucoma is called Primary Open Angle Glaucoma (POAG) and is associated with aging, race, and other co-morbidities such as ocular and systemic hypertension. In a landmark clinical trial to determine if early treatment of patients having elevated intraocular pressure (IOP) with pharmaceutical treatments would protect against developing glaucoma, patients who received early treatment had a 54% relative reduction in risk of developing POAG within five years, compared to patients who were monitored but received no early treatment (Kass, 2002).

The hallmark of the disease is the loss of ocular neurons, which cannot be replaced, leading to loss of vision. Some neuronal loss commonly occurs with aging, and the diagnostic challenge is to determine if the neuronal loss is occurring at a higher-than-average rate, and thus poses a threat to vision. Most patients with glaucoma have higher-than-average intraocular pressure (IOP), and thus most treatments are focused on lowering pressure. A disturbing 25% of patients with glaucoma experience loss of vision without demonstrating elevated IOP, and these normal pressure glaucoma (NPG) patients pose a significant diagnostic and therapeutic challenge for clinicians. Figure D.1 shows a schematic diagram of the eye and key ocular structures. As glaucoma affects the optic nerve and is frequently associated with higher pressures, the clinician can monitor the disease in part through a careful examination of the optic nerve head, visible through the patient's pupil. In a normal patient, the optic nerve head is flat, and is termed a "disk," while in patients with elevated pressure, the optic nerve head is pushed backwards, and forms a depression called a "cup." Clinicians will monitor the extent of cupping and the ratio of cup-to-disk during regular office visits.

The traditional treatment paradigm for a glaucoma patient is shown in Figure D.2, and involves taking topical drops daily to manage disease, increasing the dose
FIGURE D.1 Schematic diagram of the eye, showing the production of aqueous humor (AH) by the ciliary body, and the normal flow out through the trabecular meshwork. In a non-diseased eye, the optic nerve head is flat and is referred to as a "disk." In a glaucomatous eye, the optic nerve head is deformed due to the pressure, forming a depression, or "cup."
FIGURE D.2 Traditional treatment paradigm where device implants are used as a last resort. Recent studies (Gedde, 2012) and new devices are challenging this paradigm, and clinicians are re-examining the use of devices earlier in the disease process.

and/or adding additional agents as the initial efficacy of the drops wears off. Within two years, 75% of all patients will be on at least two medications to try to control their IOP (Lichter, 2001). Prostaglandins are the most commonly used pharmacologic agent, which increase uveal-scleral outflow, but also turn blue eyes brown. Beta-blockers are the second agent of choice, which suppress aqueous production, but they can also have systemic effects, particularly on the cardiovascular system. Alpha-agonists and carbonic anhydrase inhibitors are older drugs that are used less often due to their side-effects, but a patient may still find themselves on several of these agents within a few years of being diagnosed with glaucoma. Even more complicating, the patient may have different drug regimens and dosing schedules for each eye, making glaucoma a patient-compliance nightmare, which only adds to the problem.

Of the nearly three million Americans with glaucoma, the traditional treatment paradigm shows only 10% of

them will move on to require surgery. The primary surgical tools include Argon Laser Trabeculoplasty (ALT) or Selective Laser Trabeculoplasty (SLT), and the average patient will require two or three different laser treatment sessions to manage their disease. Typically patients can reduce the number of medications after LT, but within a few years, they may need to add back additional pharmaceutical treatments to try and maintain IOP control. By five years, over 80% of patients treated with laser trabeculoplasty will have failed to have adequately controlled IOP (Juzych, 2004). Only about 5% of glaucoma patients are advanced into the surgical treatment phase, and the majority of these surgical cases are trabeculectomy procedures. Traditionally considered the "gold standard" for IOP management, trabeculectomy is a very invasive surgical procedure which redirects outflow drainage through a hole punched directly through the sclera. The wound healing response of the body is inhibited with anti-neoplastic agents like mitomycin C (MMC) or 5-fluorouracil (5-FU), and a successful procedure results in the formation of a bubble-like structure under the conjunctiva called a filtering bleb. Because of the MMC/5-FU that is used, the wound usually does not heal, thus providing a new pathway for outflow of fluid from the eye, with a large surface area for subsequent reabsorption of the fluid into the systemic drainage system. Bleb management and infection control are difficult challenges with these patients who must visit the glaucoma specialist up to several times a week for care. Although trabeculectomy is considered the gold standard for glaucoma management, over 45% of patients fail to demonstrate adequate IOP control after three years (Yalvac, 2004).

Traditionally, less than 1% of all glaucoma patients in the US are treated with surgical implants. The existing approved devices are large and bulky, designed to imitate the bleb of a trabeculectomy patient, but replacing the patient's tissue with silicone or polypropylene, which cannot be degraded. Figure D.3 contains an example of a typical shunt used in these cases. Patients undergoing traditional shunt implantation have had decades of declining vision, escalating treatment regimens, and increasing complication rates and severity. It is no surprise that today's patients do not consider this acceptable and are looking for new solutions to manage their disease. A recent clinical trial has demonstrated that implantation of a glaucoma drainage implant (GDI) has equivalent IOP control compared to the surgical trabeculectomy procedure, with a higher success rate and fewer complications (Gedde, 2012). This study points to the utility of using an implanted device rather than a surgical procedure for more repeatable outcomes with fewer complications. It is the impetus for looking at a change in the treatment paradigm where patients are treated with implants much earlier in the disease progression, with the potential to radically change the rate of progression of vision loss for millions of glaucoma patients worldwide.

FIGURE D.3 Photograph of the Baerveldt® shunt, one of the most popular glaucoma device implants in use today. The tube is inserted into the anterior chamber, while the wide plate area sits on top of the sclera to provide an area for outflow. (Photo reprinted with permission from Abbott Medical Optics. NEW DRAINAGE DEVICES AND MATERIALS UNDER DEVELOPMENT

Table D.1 contains a list of a number of new devices being developed to manage glaucoma patients, and compares them with the characteristics of the larger GDIs approved for use today. Before discussing their differences, it is notable to discuss their similarities. First, all new devices under development are small and are focused on using minimally-invasive procedures for implantation. The ocular trauma from the older technologies results in high complication rates, which can cloud the performance of a new device. It is unlikely that a company would succeed in obtaining regulatory approval today for a product that carried a 30–50% rate of complications (Gedde, 2012). Second, all new devices under development do not contain valves, relying instead on their small size to control outflow to an acceptable level and avoid hypotony (low IOP). The last similarity between the different new devices is that they all focus on improving outflow, although they differ widely in where and how they do this. Some devices have focused on enhancing natural outflow mechanisms through the trabecular meshwork to Schlemm's canal, while other devices are shunting fluid to the subconjunctival space, as is done with today's older and larger implants. Finally, there are other devices under development which strive to shunt fluid to new locations, such as in the supra-choroidal space.

TABLE D.1

Device/Company	Material	Bleb? MMC used?	Implant Location	Size (W x L x T; mm)	Mechanism of Action
Ahmed/New World Medical	Silicone with polypropylene valve casing	Yes; Yes	Subconjunctival	13 x 41 x 0.9 184 mm² plate area	Drains AH from the AC through tube inserted into the angle; plate keeps bleb open to allow fluid drainage.
Baerveldt®/Abbott Medical Optics	Silicone	Yes; Yes	Subconjunctival	10 x 64 x 0.84 250 mm² or 350 mm² plate area	Drains AH from the AC through tube inserted into the angle; plate keeps bleb open to allow fluid drainage.
ExPRESS®/Alcon	Stainless Steel	Yes; Yes	Trans-scleral	2.0 x 2.6 x 0.4	Drains AH from the AC to the subconjunctival bleb, as a part of a trabeculectomy procedure
MIDI Arrow/InnFocus	SIBS	Yes; Yes	Trans-scleral	1.2 x 9.5 x 0.35	Drains AH from the AC to the subconjunctival bleb. SIBS material does not trigger fibrotic healing, which can limit utility of bleb.
Aquesys®/Aquesys	ECM-based	Yes; No	Ab interno placement from angle to subconjunctival space	N.R. Fits within 25 Ga needle	Atraumatic placement with degradable biologic creates a new drainage channel from the AC to the subconjunctival space.
iStent®/Glaukos	Heparin-coated Titanium	No; No	Ab interno placement from angle to Schlemm's canal	0.5 x 1.0 x 0.25	Bypasses trabecular meshwork for direct drainage from AC to Schlemm's canal. Heparin prevents clotting on device to maintain patency.
Hydrus™ Aqueous Implant/Ivantis	Nitinol	No; No	Intra-cannicular stent in Schlemm's canal	N.R.	Stents open Schlemm's canal to 9xs normal area (approx. 150 micron diameter). Open structure prevents blockage of collector channels. Does not extend into the AC
GMS/SOLX	24-kt Gold	No; No	Suprachoroidal space	3.2 x 5.2 x 0.04	Drains AH directly from AC to the suprachoroidal space. Inert material does not trigger inflammatory response in highly vascularized suprachoroidal space.

ECM = Extra cellular matrix. N.R. = Not Reported

Aqueous Humor Production

Figure D.4 shows the ocular structures important in glaucoma. Aqueous humor (AH) is produced by the ciliary body at a rate of about 2 μL/minute (Brubaker, 1991). The AH is secreted into the anterior chamber, which has a volume of approximately 250 μL. Outflow occurs directly through the trabecular meshwork (TM), which is a layered meshwork of increasingly smaller pore size, where each trabecular beam is covered with phagocytic TM cells. It is believed that these phagocytic cells help to "clean" the AH before it passes through the TM, engulfing cells and large particles to avoid blockage of the smaller pores. After flowing through the TM, the AH flows out through Sclemm's canal, that runs circularly around the limbus of the eye. Once in the Sclemm's canal, the AH flows to collector channels, that drain into the venous system. Aqueous humor can also flow indirectly through the uveo-scleral pathway, although this accounts for only about 25% of the AH outflow in healthy eyes (Mishima, 1997).
FIGURE D.4 Schematic diagram of the ocular structures important in aqueous fluid production and outflow. Aqueous humor is produced by the ciliary body and flows around the iris and out of the eye, passing through the trabecular meshwork and into Schlemm's canal and the collector channels. (Reprinted with permission, NEI-NIH.gov, ref NEA11.)

Micro-Invasive Glaucoma Surgery (MIGS) Devices

The Alcon ExPRESS® shunt. The Alcon ExPRESS® shunt is a first generation MIGS device that relies on a small bore to the drainage pathway to avoid hypotony. The device is made from stainless steel and is placed

trans-sclerally as a part of the trabeculectomy procedure. The device is 2 mm wide and 2.6 mm long, with a 50 or 200 micron inner bore diameter. The device has a partial spearhead design to keep the implant from migrating outwards, with a flat plate against the sclera to prevent the implant from migrating inwards (see Figure D.5a). The ExPRESS device was originally developed by Optonol,
FIGURE D.5 An overview of the various devices under development today, and their reported advantages. (a) The ExPRESS® mini shunt from Alcon Laboratories (reprinted with permission); (b) The MIDI Arrow from InnVision (reprinted with permission); (c) Normal conjunctival lymphatics in a monkey, demonstrated by subconjunctival trypan blue injection. Initial lymphatics (yellow arrowheads) flow into larger structures forming collecting lymphatics (blue arrows). The distribution of conjunctival lymphatic vessels is different than conjunctival blood vessels, and is important in successful longterm drainage. The Aquesys® device has demonstrated long-term maintenance of both lymphatics and blood vessels in the conjunctiva of animals (figure reprinted with permission; Yu, 2009). (d) the iStent® trabecular meshwork bypass implant, from Glaukos Corporation (reprinted with permission); (e) the iStent inserter (reprinted with permission); (f) The SOLX GMS shunt fabricated from 24 carat gold (reprinted with permission).

and was acquired by Alcon in 2009. Today it is typically implanted with the use of mitomycin C (MMC) to inhibit proliferation and maintain a diffuse bleb. The device is approved worldwide for use in end-stage patients who have failed one or more surgical procedures.

The MIDI Arrow. The MIDI Arrow, developed by Inn-Focus LLC, is a microtube fabricated from the SIBS polymer (see Figure D.5b). The **s**tyrene-**i**sobutylene-**s**tyrene block copolymer is a stable, biocompatible material with a long, successful history of use in the Boston Scientific TAXOL™ drug-eluting stent (Pinchuk, 2008). The design is simple, with a thin tube with side fins to prevent migration of the device. The MIDI device drains the AH from the Anterior Chamber (AC) to the subconjunctival space, which is first treated with MMC to prevent fibroproliferation and maintain an open bleb. The MIDI device has been successful in significantly reducing IOP in end-stage patients.

The Aquesys® device. The Aquesys® device is a resorbable material, such as gelatin, which is placed across the trabecular meshwork through to the subconjunctival space with an *ab interno* procedure (Yu, 2003). The biocompatible tube, combined with the minimally traumatic procedure, enables the formation of a stable drainage channel with a healthy conjunctival bleb containing normal blood vessels and lymphatic drainage vessels (see Figure D.5c). Formation of a drainage network has been associated with long-term stability of the procedure in animal models (Yu, 2009). The Aquesys device is currently undergoing clinical trials.

The Glaukos iStent®. The Glaukos iStent® is a heparin-coated titanium implant that shunts fluid from the AC directly into Schlemm's canal. The device is placed into the canal through an *ab interno* approach, typically in conjunction with cataract surgery, when the surgeon will already be working inside the eye. In that case, the implantation adds little to the length of the procedure. The device is implanted with a specialized tool, similar to an intraocular lens inserter used for lens replacement after cataract surgery. Figures D.5d and D.5e show the unique snorkel-shaped device with its inserter. The device is coated with heparin to minimize deposition of fibrin and cells, as sometimes a small amount of blood can enter the anterior chamber upon implantation. The device is marketed in Europe, and recently received FDA approval.

The Ivantis Hydrus™. The Ivantis Hydrus™ device is a nitinol stent that is placed within Schlemm's canal to keep the canal open and allow drainage. In that regard it is similar to the Glaukos iStent in concept, although how the two devices keep the canal open are entirely different. The Ivantis device is still under development, but recent reports demonstrate the utility of the device in reducing IOP in patients also undergoing cataract extraction (Samuelson, 2012). The nitinol stent is biocompatible when tested in the orthotopic position in New Zealand albino rabbits for six months. Non-human primates also demonstrated biocompatibility after 13 weeks implantation, although both

implanted and sham-operated controls registered some response to the mechanical distortion which occurs during the implantation procedure (Grierson, 2012).

The SOLX GMS. The SOLX GMS device is fabricated from 24 carat gold, the rationale being to take advantage of the inert qualities of gold. As seen in Figure D.5f, the device is shaped like an elongated plate which contains many microchannels. The device is placed with the footplate in the anterior chamber to drain fluid to the suprachoroidal space. The suprachoroidal space is not the major outflow pathway for aqueous humor in the eye, but it is pressure-independent, operating constantly, albeit at lower levels. Because the device drains to the suprachoroidal space, it does not require a subconjunctival bleb nor the use of antimetabolites. The SOLX device is marketed in Europe and is under clinical investigation in the United States.

SUMMARY

The field of glaucoma therapies is undergoing a period of tremendous change and innovation, sparked by the high failure rates and complications of surgical procedures. The promising results observed with devices, as well as new surgical procedures, fewer complications, and a higher success rate are noted. As in most areas of medicine, the focus on today's devices is towards minimally-invasive procedures that elicit reduced trauma and inflammation compared to older treatments. The field remains divided as to the best course of action to take for filtration, with roughly equal developments occurring in the bleb-based subconjunctival drainage devices, Schlemm's canal stents, and the drainage plates that shunt fluid to the suprachoroidal spaces. The field also remains divided as to the best material(s) to use, and new devices employ metals such as stainless steel, gold, titanium, and nitinol; polymers such as SIBS and silicone; and biologics, either as a scaffold (gelatin), or a coating (heparin). The upcoming years promise to be exciting ones in the area of biomaterials for glaucoma devices, as the various materials and devices move into the clinic and their efficacy can be measured.

E. THE DEVELOPMENT OF A RETINAL PROSTHESIS: A SIGNIFICANT BIOMATERIALS CHALLENGE

Mark S. Humayun, Adrian P. Rowley, John J. Whalen III, James D. Weiland, and Armand R. Tanguay, Jr.
University of Southern California, Los Angeles, CA, USA

INTRODUCTION

Restoring functional vision using electrical stimulation has been a goal of ophthalmologists and vision scientists for more than two centuries (LeRoy, 1755). The difficulty confronted by scientists is that the visual system consists of roughly 10^{10} neurons, each of which may receive input from multiple, perhaps even thousands, of neurons. In spite of this, cutting across traditional interdisciplinary boundaries of medicine and engineering has enabled rapid progress in the field of prosthetic vision over the last decade, reconnecting some blind patients to the visual world. Millions of people worldwide lose their vision as a consequence of photoreceptor damage stemming from retinal degeneration (e.g., retinitis pigmentosa (RP) or age-related macular degeneration (AMD)) (Augustin 2009; Shintani 2009). The feasibility of an implantable retinal prosthesis or "bionic eye" that could partially restore vision by direct electrical stimulation of retinal neurons is supported by several studies. Under development are devices that bypass the degenerated photoreceptors and apply electrical stimulation at different locations along the visual pathway (Rizzo 2001; Asher 2007; Chader 2009). These microelectronic prosthetic devices rely on the principle of electrical activation of nerves, which is also the concept behind other successful neural stimulators, such as the cochlear implant.

The intent of this chapter on the development of a retinal prosthesis is to provide an introduction to the materials used in current devices, and the biomaterial challenges that limit the implementation of more sophisticated implants. The chapter outlines the various approaches that numerous research groups worldwide have taken to build such a device. Technical challenges remain with respect to mechanical design, hermetic packaging, polymers, metal electrodes, surgical techniques, attachment methods, stimulus parameters, and effectiveness (Bertschinger, 2008). Several research groups around the world have already implanted prototype retinal prosthetic devices in blind humans. At present, retinal prostheses are still experimental, although they are expected to become commercially available in the near future. This chapter introduces the anatomy and physiology of the visual system, especially the retina. It describes the architecture of a retinal prosthesis, and the biomaterials that scientists use to design this ground-breaking medical device.

OVERVIEW OF THE VISUAL SYSTEM

Visual perception is the ability to interpret information from the visible light spectrum that reaches the human eye. Incident photons cause phototransduction in the retina. The human eye can perceive wavelengths from 380 to 760 nm (Kaufman, 2003). The visual system is the part of the central nervous system (CNS) that enables one to assimilate information from the surrounding environment. The visual pathway includes the retina, optic nerve, optic chiasm, lateral geniculate nucleus, numerous

visual nuclei, and the visual cortex, which is located in the occipital lobe. These anatomical structures accomplish a number of complex tasks, including filtering of undesirable wavelengths and reception of desirable ones, the formation of binocular vision from monocular inputs, the construction of images over time (temporally), the identification of objects, and the evaluation of distance. The neural control of eye movement allows for resolution of the visual field during movement, the ability to resolve an object's motion, and also enables the exploration of space (Kaufman, 2003).

The eye includes a variety of tissue types that work together to facilitate sight. The eyeball, or globe, is spherical in shape and about 2.5 cm in diameter (Figure E.1). The sclera is the tough, white, outer tunic that protects the internal structures and helps maintain the shape of the eyeball. At the front of the eye is an equally strong but clear structure called the cornea. The cornea is responsible for allowing light into the eye and, combined with the crystalline lens, allows focusing of images onto the retina. The vitreous humor is a clear gel that forms more than two-thirds of the ocular volume, and occupies the vitreous cavity between the crystalline lens and the retina (Bron, 2001).

Internal to the sclera in the posterior portion of the eye is the choroid, which is a vascular structure that carries the blood to nourish the internal structures of the eye, mainly the outer photoreceptor layer of the neural retina. Finally, the retina lines the posterior two-thirds of the inside of the eye. The retina contains neurons (photoreceptors) that are sensitive to photons, as well as more conventional neurons that process the photo-stimulated signals. The macula is an oval zone of yellow coloration within the central retina. This area of the retina has the highest number of cone photoreceptors, and is reponsible for both high resolution vision and the perception of color.

The Retina

The retina is a thin (approximately 200 μm), fragile, light sensitive, neuronal tissue lining the inner surface of the posterior segment of the eye. Because of its importance
FIGURE E.1 Sketch of the eye showing the major anatomical structures. *(Courtesy* http://www.nei.nih.gov.*)*

with regard to the retinal prostheses, it will be discussed in further detail. The refractive power of the cornea and crystalline lens of the eye focuses light on the retina, which serves a similar function as the sensor in a video camera.

Light striking the retina's photoreceptors initiates a cascade of chemical and electrical events. This physiological process ultimately triggers a hyperpolarization in the photoreceptors, followed by a depolarization in the bipolar and then ganglion cells. These signals are sent to various visual centers of the brain via the ganglion cell axons, which collectively form the optic nerve. The vertebrate retina has 10 distinct layers, in which there are three major layers of neurons interconnected by synapses (Figure E.2). The outermost layer of neurons (photoreceptors) is sensitive to light. There are two types of photoreceptors, rods and cones. Rods function in low light (scotopic vision) and provide relatively low resolution black-and-white vision, while cones function in bright light (photopic vision) and allow for sharp, color vision in the central field.

Anatomy of the Vertebrate Retina

The vertebrate retina has 10 distinct layers. From innermost to outermost, they include:

1. *Inner limiting membrane* – interfaces with the vitreous humor;
2. *Nerve fiber layer* – axons of the ganglion cells exit the eye as the optic nerve;
3. *Ganglion cell layer* – contains nuclei of ganglion cells and gives rise to optic nerve fibers;
4. *Inner plexiform layer* – synaptic layer between the bipolar cells and ganglion cells;
5. *Inner nuclear layer* – contains cell bodies of the bipolar cells;
6. *Outer plexiform layer* – synaptic layer between photoreceptors and bipolar cells;
7. *Outer nuclear layer* – contains cell bodies of the photoreceptors;
8. *External limiting membrane* – separates the inner segment portions of the photoreceptors from their cell nuclei;
9. *Photoreceptor layer* – rods and cones;
10. *Retinal pigment epithelium* – nourishes the retinal neurons.

Critical to the design of a retinal prosthesis is the location of the remaining viable neurons in the affected retina. In retinal degenerative diseases, the primary target for pathology is the retinal photoreceptor cells. The pathological processes cause the photoreceptors to dysfunction and die. The bipolar and retinal ganglion neurons, however, are relatively spared. Therefore, when an image falls on the retina, it is unable to be processed into an electrical signal. The rationale of a retinal prosthesis
FIGURE E.2 A photomicrograph of a retinal cross-section shows the highly laminar structure. From top to bottom, rods and cones, outer limiting membrane (OLM), outer nuclear layer (ONL), outer plexiform layer (OPL), inner nuclear layer (INL), inner plexiform layer (IPL), ganglion cell layer (GCL), inner limiting membrane (ILM). *(Courtesy* http://webvision.med.utah.edu/.) *SEM image of a retinal cross-section of rabbit retina.*

then, is to bypass the damaged photoreceptor cells and directly stimulate the remnant, secondary neurons (bipolar cells and/or retinal ganglion cells).

Although in RP and AMD patients it is the photoreceptors that are destroyed, the remaining cells of the retina also undergo extensive and complex degenerative remodeling (Marc, 2003). Despite the fact that patients with RP and AMD suffer from the destruction of the photoreceptors, up to 80% of bipolar cells and up to 30% of ganglion cells remain viable (Humayun, 1999).

RETINAL PROSTHESES

The retina not only responds to photons, but also to electrical stimulation. Moreover, the central nervous system is able to interpret the electrical stimulation generated by electrical signals (such as from a retinal prosthesis), and convert it into an identifiable image. Recent studies on one device showed that even limited sight restoration involved a slow learning process that took months for improvement. In this particular study, light perception was eventually restored in all six patients (Chader, 2009). Thus, both basic and clinical work now has firmly established the scientific feasibility of sight restoration through electronic prosthetic devices. A number of companies around the world are working towards clinically useful devices (Chader, 2009).

Approaches to Stimulating the Retinal Tissue

Progress in the field of microelectronic prostheses has converged with advances in ophthalmic surgery to enable several groups to develop epiretinal prostheses (Caspi, 2009; Roessler, 2009). The term "epiretinal" specifies that the electrode array is intraocular and lies on the surface of the retina, in close proximity to the retinal ganglion cells. Other groups have been developing subretinal prostheses (Stett, 2007; Besch, 2008). The subretinal space is the gap created between the photoreceptors and the retinal pigment epithelium when the retina is purposefully detached. Arrays can be placed to stimulate the nearby bipolar cells in the inner nuclear layer. A wide variety of subretinal techniques exist, ranging from passive photosensitive diode arrays (Peyman, 1998) to neurotransmitter-based stimulation methods (Peterman, 2003), and to more active stimulation, using optical-to-electrical signal amplification (Palanker, 2005). The aim of subretinal stimulation is to maximize the neuronal processing of the remaining retinal circuitry by targeting the remaining functional bipolar cells.

Some researchers have directly stimulated the optic nerve, which is the cylindrical anatomical structure that exits the back of the eye. The optic nerve contains ganglion cell axons running from the retina to synapse with neurons in the lateral geniculate nucleus (LGN). The optic nerve can be reached surgically; however, the high density of the axons (1.2 million) may make it difficult to achieve a detailed pattern of stimulation (Shandurina, 1996; Veraart, 1998). A few researchers have used extraocular disc electrodes that have been sutured to the sclera (Chowdury, 2005), while others have performed transretinal electrical stimulation from the suprachoroidal space (Sakaguchi, 2004).

Select patients have been implanted with cortical and intracortical electrode arrays. There are several advantages

to directly stimulating the visual cortex; however, it is difficult to achieve simple perception even when stimulating large numbers of neurons in the case of intracortical microstimulation. The convoluted surface of the brain cortex makes for more difficult implantation, and the resultant complications can be fatal (Dobelle, 1976; Bak, 1990).

The majority of efforts in developing visual prostheses for the blind have focused on electrical stimulation of the retina. It is well-understood that there is a substantial amount of computational processing within the LGN (Dan, 1996) and the visual cortex that control the visual signal (Hubel, 1962). Targeting stimulation early in the visual pathway (e.g., the surviving bipolar and retinal ganglion cells) better utilizes the remainder of the visual system.

The Architecture of a Retinal Prosthesis

Common features of retinal prostheses include hermetic casing of electronics, electrode array interfaces, and a cable that connects the two components. The following describes the architecture of one particular design of an epiretinal prosthesis, shown in Figure E.3 (Argus™ I, manufactured by Second Sight Medical Products, Inc.). This specific model consists of an implanted unit and an external unit. The external unit consists of a small camera, similar to a webcam, which is worn in a pair of glasses and connects to a belt-worn visual processing computer (not shown). Power and signal information are sent from this processor through a wire cable to an external transmitter coil. This coil couples electromagnetically (wirelessly) to a secondary coil that is implanted under the skin. Other groups have designed the secondary coil and

electronics to be sutured around the eye (Roessler, 2009). The coils allow information to be sent inductively. The implanted unit consists of an extraocular (electronic case) and an intraocular component (electrode array). From the secondary coil, power and signal information are sent through a subcutaneous cable across the eye wall to the intraocular electrode array which, in this particular case, is attached to the epiretinal surface via a retinal tack. The electrode array consists of disc shaped platinum electrodes in a square layout (Margalit, 2002). Stimulation can be presented to the patient using two different protocols. The first is the camera mode, which uses real-time video captured from the video camera. The visual processing computer then encodes the brightness of the various regions of the camera's field of view into various amplitudes of stimulation current. The other method is the direct stimulation mode, which allows the researchers to send stimulation signals to each electrode independently. This is important as it enables neuroscientists to perform precisely controlled psychophysical tests (Horsager, 2009).

Role of Materials in Retinal Implants

The role of materials in retinal implants is to ensure that the electronic system can effectively deliver stimulating current to the retina, while not significantly damaging the surrounding tissue. Delicate retinal tissue can be affected by infection and inflammation, and thus any introduced device can cause acute and delayed (foreign-body) types of immunologic reactions. Also, patients can have hypersensitivity reactions to polymers and metals. Toxic substances from fabrication equipment, such as oxidants,
FIGURE E.3 Illustration of epiretinal prosthesis system. *(Courtesy Department of Energy 2008.)*
FIGURE E.4 The components of a flexible electrode array. *(Adapted from* Kelly, 2009.*)*

catalysts, and contaminants, may be left as residues on implants and can cause inflammation (Margalit, 2002). The tissue can have deleterious effects on the implant, including degradation of the polymers, corrosion of the metals (Jansen, 1991), mechanical dislocation of the implant (Yuen, 1990), and damage to the electronic components from the saline environment, should the hermetic case fail. The main implant components to be discussed are the hermetic case, the conducting feedthroughs, the bond pads, the conductive leads, the electrodes, and the flexible polymer substrate (Figure E.4). Other implant components are primarily electrical (e.g., microchips), and will not be discussed in this chapter.

Hermetic Case

The microelectronic case is one of the most critical elements involved in the development of a retinal prosthesis. It must provide two primary functions: (1) protect the microelectronics from the surrounding environment; and (2) allow the internal electronics to communicate with both the environment and the other external electronic components. All retinal prostheses will consist of various electronic components, and the protective casing for each component should last for the lifetime of the patient, which may be several decades after implantation. In most implantable devices, the hermetic package takes the form of a case in which the electronics are placed.

The first basic function of the microelectronic case is to form a barrier between the various semiconductor devices and the saline environment (Tummala, 1989; Nichols, 1994; Najafi, 2003). A high quality barrier that is virtually impermeable is considered hermetic. In practice, hermeticity is a matter of degree, and standards have been established, for example, to measure the rate at which a case will leak water vapor. For implantable microelectronics, the environment is essentially saline. Sodium will irreparably damage microcircuits in a matter of days, through processes such as corrosion, ion diffusion, and delamination. The field of reliability testing of microelectronics has established failure modes and exposure limits for water vapor (Nichols, 1994; Najafi, 2003). The casing

material is typically formed from ceramic, metal or glass, since these materials are among the least permeable to water. Examples of materials commonly used for the case include titanium, which forms a stable oxide (TiO_2), alumina (Al_2O_3), and glass (e.g., Pyrex) (Tummala, 1989).

The hermetic case also has a second basic function; it must allow electrical signals to communicate between circuitry inside the case and the neural interface outside the case. This communication is facilitated by feedthroughs (also called vias or interconnects), which are electrical conductors. The most vulnerable points in the casing are at the multiple conductor feedthroughs and their interface with the insulating case material (Margalit, 2002). The materials that surround feedthroughs must be electrically insulating to prevent cross-talk among feedthroughs, so ceramic or glass is commonly used for this portion of the case. Metal can be used for the case, provided that it is not in contact with the feedthroughs. Although this may seem like a relatively simple part of an active implantable medical device, companies exist solely for the purpose of developing better and more reliable feedthroughs.

A variety of technologies has been developed to create different hermetic case constructs (Tummala, 1989; Honma, 2002; Najafi, 2003). Much of the original technology was developed by the cardiovascular device industry. Titanium and stainless steel cans have been the benchmark for creating hermetic containers. Cardiovascular devices typically only employ a small number of stimulating electrodes, and the devices themselves are several cubic centimeters in volume; therefore, feedthroughs exiting the case can be large, a topic that will be discussed in more detail later.

Recent advances in hermetic case design have been focused on decreasing the case and feedthrough size. One method involves placing multiple wires comprised of platinum (Pt) through a ceramic insulator (e.g., Al_2O_3), and then heating the materials at high temperatures (Backous, 2002). There is a limit to the number of conductors that can pass through the seal, based on area. As the number of conductors increases, so too does the chance of a leak. Another hermetic case technique uses a high electric field to bond silicon and glass (anodic bonding) (Ziaie, 1997). Solder bonding can be used to adhere aluminum/silicon

to glass. This hermetic method provides more than 10 mega Pascals of bonding strength (Cheng, 2000). More recently, yttria-stabilized tetragonal zirconia polycrystals (Y-TZPs) and a titanium alloy Ti-6Al-4V have also been used as the ceramic and metal components of the seal. Both materials have strong mechanical properties and biocompatibility. A brazing method involving titanium nickel (TiNi)-clad braze filler material is used to create a tight hermetic seal (Jiang, 2005).

Metal Feedthroughs

Metallic feedthroughs are the conducting elements of a hermetic casing that allow the internal microelectronics to communicate with the outside environment or other electronic components. The microelectronics industry has investigated and developed a number of feedthrough fabrication approaches (Tummala, 1989; Honma, 2002; Najafi, 2003). However, these advances do not easily translate to biomedical applications like the retinal prosthesis, because only certain materials can be safely implanted and exposed to tissue for sustained periods of time. For example, electrochemical deposition has been investigated by the microelectronics industry as a method of producing high-aspect ratio, micron-scaled feedthroughs (Honma, 2002). This work has focused primarily on materials like copper, aluminum or silver, which are not considered biocompatible materials for electrically active components like feedthroughs. Acceptable materials, like platinum and iridium, are difficult to process due to their high melting temperatures (>1400°F) and chemical nobility.

A novel high-density feedthrough approach for medical implants has been proposed (Najafi, 2003). This design uses silicon micromachining to pattern high-density feedthroughs on a silicon wafer. A glass case is anodically bonded to the wafer to protect the microelectronics. This approach significantly increases the two-dimensional area of the case size above the chip size, because the feedthroughs are coplanar with the micro-chip. The state-of-the-art in microelectronics casing has not yet been able to provide a biocompatible case design that incorporates feedthroughs with ultra-high packing densities (~50 feedthroughs mm^{-2}).

Bond Pads

The term "bond pad" refers to a metal trace feature on any kind of circuit element that will be bonded or interconnected to another part, such as a metal trace feature that will be bonded with a gold wirebond or connected with solder to a component. In the retinal prosthesis electrode array, one end of the array is called the electrode end and the other end, the bond pad end. Physically, they can be similar, that is, openings in the insulation layer to open up an exposed metal area. In the context of the electronics case, the feedthroughs are exposed on the bottom. A thin film metallization layer can cover the feedthrough and route a trace some distance away to the bonding site or bond pad. Challenges relate to the development of thin bond pads on a flexible substrate that connects to a rigid case.

Conductive Leads

The conductive leads have a separate set of design constraints. Each conducting element must individually connect a single electrode to a single output on the processor chip. The leads must be electrically isolated from each other to prevent cross-talk. Lead insulation must prevent signal leakage, and also prevent fluid penetration that might lead to corrosion and/or electrical shorting. Lastly, the composite size of all the leads for all of the electrodes must be minimized to prevent weight problems; however, the leads cannot be so small that the electrical resistance of the leads creates too much load or impedance for the system. Recently, a high density lead construct has been fabricated by thin film deposition of platinum leads on flexible parylene substrates (Rodger, 2006).

Electrodes

The significant biomaterials' challenges associated with fabricating electrodes for a retinal prosthesis are: (1) maintaining biocompatibility and electrode integrity during electrical stimulation; and (2) selecting a material that can be processed into electrode arrays with the required geometries. A variety of electrode materials have been designed and their properties reported (Robblee, 1990; Stieglitz, 2004).

Biocompatibility during Electrical Stimulation. Electrical stimulation is an electrochemical process in which current carried through the metal electrodes is transferred to the surrounding electrolyte solution (i.e., the retinal tissue) (Merrill, 2005). Electrochemical processes at the electrode–electrolyte interface determine how much charge can be transferred safely from the electrode to the surrounding tissue. Reversible charge transfer is the only way that current can be passed safely from an electrode to tissue. Irreversible reactions can result in damage to the tissue or electrode. Materials that have reversible reactions in the absence of significant irreversible reactions are well-suited for neural stimulation. In practice, any material will undergo irreversible reactions with a high enough electrode surface potential. Biphasic current pulses were created to prevent the electrode surface potential from exceeding this safe charge transfer potential range (Brummer, 1975, 1983; Roblee, 1990; Stieglitz, 2004; Merrill, 2005). The current is reversed just prior to hydrogen or oxygen gas evolution, which are irreversible reactions. The potential range over which reactions are reversible is commonly known as the "water window," because it is the window inside which water does not hydrolyze into either hydrogen gas or

oxygen gas. Charge capacity is the ability of a material to reversibly store charge via non-faradaic or reversible faradaic processes. Electrodes with higher charge capacity allow for larger current amplitudes or longer pulse widths to be used.

The goal is to identify electrodes that can transfer maximum charge, reversibly. This can be achieved through selecting a material and geometry that undergoes high double layer charging via high surface areas, through high reversible faradaic charging, and oxidizes into a conductive oxide that does not dissolve (leave the electrode surface) in solution. The noble metals were the first class of materials to be investigated for implantable electrode applications, because of their corrosion resistance properties (Brummer, 1975; Robblee, 1990). Platinum and iridium have the unique characteristic that their oxides are conductive. This means that current can be passed through these electrodes to much higher potentials. There is evidence that the precious metals (platinum, iridium, rhodium, gold, and palladium) corrode under certain conditions of electrical stimulation (McHardy, 1980), but it has also been reported that under typical stimulus regimens the dissolution levels would be non-toxic (Hibbert, 2000). Capacitive electrodes, such as tantalum oxide (Ta_2O_5), titanium dioxide (TiO_2), and barium titanate ($BaTiO_3$), are another area that has been researched, in which an oxide with a very high dielectric constant serves as a barrier to charge transfer at the electrode surface (Rose, 1985). However, because of the associated low capacitance, the charge injection limits of such capacitive electrodes are still not comparable to iridium oxide (Weiland, 2002; Wang, 2006). Iridium oxide (IrO_x) electrodes, termed "valence change oxides," have proven to be very resistant to corrosion, and can withstand more than 2 billion 10 mA current pulses without degradation (Ziaie, 1997). Using simple waveforms, a conservative charge density limit for chronic stimulation with Pt is 100 $\mu C/cm^2$ (McCreery, 1988). A titanium nitride (TiN) thin film electrode has demonstrated charge injection limits of 0.87 mC/cm^2, which is higher than both platinum and IrO_x. TiN electrodes appear to have better mechanical properties than those made from IrO_x, but they appear to reduce retinal cell survival (Guenther, 1999). Carbon nanotubes (CNTs) have interesting electrochemical and mechanical properties. They are about five times stronger than steel and recently vertically-aligned multiwalled CNT pillars were used as microelectrodes (Wang, 2006). A new material, platinum grey, has also been described that has better long-term survivability than iridium oxide with similar charge limits (Zhou, 2009; US Pat #6,974,533).

Processing Characteristics of Electrodes. In addition to the charge injection properties of the electrode material, the ability to machine, shape or otherwise process the electrode material into the desired form, geometry, and spacing is a critical aspect in materials selection. Currently, the leading candidates for stimulating electrodes are platinum and iridium oxide electrodes (Merrill, 2005). However, these materials have melting temperatures in the area of 1400°F, and hence are very difficult to deposit and process. The cost of these materials also requires that processing be highly efficient. A variety of techniques can be used. For example, metal casting has been used to make larger (>500 μm diameter) disc electrodes used in early retinal prostheses (Humayun, 2003). Thin film processing techniques (evaporation and sputter coating) have been used to fabricate microelectrodes of much smaller size (Kovacs, 1987; Rozman, 1991; Nisch, 1994; Owens, 1995; Maynard, 1997). Thin film techniques deposit material over the entire deposition chamber, and hence high vacuum techniques are not efficient. Electrochemical deposition of platinum is another area investigated for deposition of electrodes (Frazier, 1993; Whalen, 2006).

Significant research has been performed in the study of microelectrode materials for sustained implantable use. For a retinal prosthesis, the added requirements that the electrodes be fabricated in the order of <100 μm diameter with several hundred electrodes arranged in a two-dimensional, curved array with spacings in the order of 10 to 100 μm, create another level of complexity. Recent work has been reported on novel techniques for fabricating microelectrode arrays on flexible substrates meeting these criteria (Rodger, 2006). Microprocessed electrodes can be machined with these features, but their charge injection properties are limited to the mass of platinum that can be deposited. Electrochemical deposition to increase charge capacity is a real solution (Whalen, 2006; Zhou, 2007).

Polymers

An important consideration regarding the safety of electrical stimulation is the mechanical design of the intraocular electrode array. This array is in direct contact with the retinal tissue, and therefore has the potential to damage the tissue mechanically, chemically, and thermally (Piyathaisere, 2001). The retina is approximately 200 μm thick, and extremely delicate, with a Young's modulus of only 20 to 40 kPa (Chen, 2009). Therefore, any polymer material that will chronically contact such a fragile biological tissue must also have a low Young's modulus, and be extremely thin to avoid tearing, compressing or detaching the retina. In some cases, if the polymer material is too thin, it may retain sharp edges that could cut the retina. It has been shown that with optimized designs and thin polymer arrays, safe implantation can be achieved with certain materials (Ameri, 2009). The following polymers have been studied in retinal prosthesis research: PDMS; polyimide; and parylene.

- Polydimethylsiloxane (PDMS) is a group of polymeric organosilicon compounds, referred to as silicones. PDMS is well-known for its rheological properties,

and it is the most common material currently used in most breast implants. At high temperatures, PDMS acts like a viscous liquid (viscoelastic). However, at low temperatures it acts like an elastic solid, similar to rubber. As the retina is extremely delicate, the softer the interfacing polymer, the less damage the array will inflict upon the retina. PDMS has unique flexibility characteristics, with a shear elastic modulus G ~250 kPa, and a very low transition temperature Tg ~125°C. These factors, plus the ease with which it can be used in a cleanroom setting, make PDMS extremely well-suited for incorporation into microelectronic electrode arrays, such as those required for the retinal prosthesis (Lotters, 1997).

- Thermosetting polyimides are commercially available in multiple forms, such as resins, sheets, and machine parts. When polyimides first became available in the 1960s, chip carriers were based on multilayered ceramic cases. However, use of such carriers caused signal delays. Polyimides are currently being used as dielectrics for microelectronic circuits, because of their higher signal transmission speed. Thermoplastic polyimides are very often called *pseudothermoplastic*, and they are generally either aromatic heterocycles or linear. Polyimides are able to achieve a low dielectric constant while maintaining mechanical strength, thermal stability, and chemical resistance (Ghosh, 1996).

- Parylene is the generic name used for a variety of chemical vapor deposited poly(p-xylylene) polymers. Using vapor deposition polymerization, parylene can be made ultrathin, uniform, conformal, and pinhole free. It has high tensile strength, low permeability to moisture, and dielectric barrier properties. Among the parylenes, Parylene C is inert, clear, hydrophobic, biocompatible, and is the most commonly used (Kazemi, 2004).

All three of the polymers above can be metallized, and are capable of being molded into array designs that conform to the curvature of the retina. However, both polyimide and parylene have the ability to cut the retina when produced as thin sheets. Due to this issue, some retinal prosthesis designs involve coating the parylene or polyimide with silicone, which is a much softer polymer. A silicone–polyimide hybrid microelectrode array has been shown to have moderate physical properties that are suitable for implantation (Kim, 2009). The viscoelastic nature of silicone is ideally suited to interface with delicate biological tissues such as the retina. A recent study on the biocompatability of materials for use in subretinal prostheses demonstrated that poly(ethylene glycol) PEG, parylene, and poly(vinyl pyrrolidone) PVP produced less histological disruption than polyimide or polyimide coated with either amorphous aluminum oxide or amorphous carbon (Montezuma, 2006).

OTHER MATERIALS CONCERNS

Attachment

One of the disadvantages of the epiretinal prosthesis is the resulting distance from their target cells. The thickness of the nerve fiber and ganglion cell layers is at least 20–200 and 20–40 μm, respectively (Greenberg, 1998). In order to reduce the charge density to within safe limits for long-term stimulation, researchers can use either larger electrodes and thus lose resolution, or get closer to the target cells.

Retinal tacks, bioadhesives, and magnets have been some of the methods examined for epiretinal attachment. In one study, metal alloy retinal tacks (composed of cobalt–nickel–chromium–molybdenum–tungsten–iron) remained firmly affixed to the retina for up to 2.5 years. All tacks were ultimately surrounded by connective and/or glial tissue induced by firm retinal adherence; however, the retinal architecture was normal within 1 mm of the scar (Ohira, 1998). One *in vivo* study examined nine commercially available compounds for their suitability as intraocular adhesives in rabbits. One type of adhesive (SS-PEG hydrogel, Shearwater Polymers, Inc.) proved to be strongly adherent and non-toxic to the retina (Margalit, 2000). Although tacks can be surgically removed with minimal further damage to the eye, bioadhesives have remained difficult to detach from the delicate retina. However, recent studies have shown that the reversible thermosensitive glue polymerized N-isopropyl acrylamide (pNIPAM) can be used in combination with polyimide, parylene C, and PDMS. It provides effective *in vitro* retinal adhesion between 32 and 38°C, and this adhesion is completely reversible by lowering the temperature of the physiologic medium (i.e., saline) to 22°C (Tunc, 2007). Another reversible method of attachment may be achievable by immobilizing "sticky" peptides onto the surface of polymers. Disintegrins are cysteine-rich peptides ranging from 45 to 84 amino acids in length, and many of them contain an Arg-Gly-Asp (RGD) sequence, a recognition site for cell membrane adhesion proteins (integrins). Due to their extremely high integrin binding affinity, these peptides, when attached to polymers, form a strong attachment to cells (Massia, 1990). The use of low concentrations of proteolytic enzymes cleaves the peptides, and may enable microelectrode arrays to interface with the retina reversibly.

Materials Issues Unique to Subretinal Implants

Several subretinal implant designs have used microphotodiode arrays in the subretinal space. Microphotodiode array technology is completely compatible with semiconductor device integration. Microphotodiode arrays develop current in the photodiodes in response to light, and deliver it to the overlying retina. Most are designed
FIGURE E.5 Intraocular camera and associated retinal microstimulator array.

to be subretinal devices. One such example is the Artificial Silicon Retina (ASR), which does not have any external connections and is powered by incident light with wavelengths of 500 to 1100 nm (Peyman, 1998). It contains approximately 3500 microscopic light detectors called "microphotodiodes." Each has a stimulating electrode and is designed to convert light energy into electrical impulses. Early microphotodiode arrays used gold as the electrode material, which dissolved during the postoperative period. Semiconductor-based silicon microphotodiodes utilizing iridium, iridium oxide (IrOx), and platinum (Pt) electrodes have also been implanted. However, several biocompatibility issues to the subretinal approach have been encountered. These include corrosion of the device, limitation of the implant power generation by size requirements (Chow, 2002), and creation of a mechanical barrier between the retina and the choroid (Zrenner, 1999). The vascular choroidal layer provides nourishment to the outer layers of the retina. The viability of using infrared enhancement of the stimulation power has been proven (Schubert, 1999). Minimizing the stimulation electrode surface area is another partial solution for this same problem. More recently, researchers have studied the effects of four coatings (silicon oxide, iridium oxide, parylene, and titanium nitride) on the functioning of subretinal devices. Implants coated with iridium oxide and parylene were generally well-tolerated in the subretinal space, inducing only mild gliotic responses. The silicon oxide coatings produced the formation of a significant fibrotic seal around the implants, and dissolved within a period of 6 to 12 months. Titanium nitride stimulating electrodes were well preserved *in vivo* (Hämmerle, 2002; Butterwick, 2009).

DIRECTIONS FOR THE FUTURE

Intraocular Camera

Current intraocular retinal prostheses driven by an external head-mounted camera, as described above, require slow and unnatural head movements for mobility and navigation tasks. To allow for normal foveation, a more natural coupling of eye and head movements, and an expanded depth of field, one group is developing a novel intraocular camera (IOC) to work in conjunction with the epiretinal microstimulator array in a fully intraocular retinal prosthesis (Nasiatka, 2007).

The intraocular camera is designed for implantation in the crystalline lens sac, in a manner similar to that of an intraocular lens (IOL). This configuration necessitates an extremely compact, lightweight package (3.0 × 4.5 mm, <150 mg) with a focal length of approximately 2 mm (500 diopters) and an *f/#* close to unity. While these constraints appear highly aggressive, visual psychophysics experiments have provided optimal pixellation and image pre- and post-processing requirements that in turn have yielded significantly relaxed camera design constraints (Figure E.5).

The intraocular camera housing is designed to be both biocompatible and hermetic, and currently comprises a thin-walled titanium housing with a fused silica window. The CMOS image sensor array and VLSI control chips incorporated within the hermetic housing are silicon based, with oxide, nitride, and metallic overlayers. If required, feedthroughs will be provided by a ceramic (alumina) plate with platinum or palladium vias. Haptic elements to support the intraocular camera within the crystalline lens sac will be fabricated from polymeric materials (such as PMMA) similar to those used in intraocular lenses.

SUMMARY

Attempts at implanting electronic devices at various anatomical locations along the visual pathway have proven to be extremely challenging. As knowledge increases about how to stimulate neurons with microelectronics, and as both microelectronics and materials science continue to evolve, it is hopeful that one day the restoration of vision to the blind will become a scientific reality.

CHAPTER II.5.10 BIOELECTRODES

Ramakrishna Venugopalan[1] and Ray Ideker[2]
[1]Animas Corporation, a J&J Company, West Chester, PA, USA
[2]The University of Alabama at Birmingham, Birmingham, AL, USA

INTRODUCTION

Bioelectrodes are sensors used to transmit information into or out of the body. This chapter: (1) introduces the reader to the basic reactions that occur at an electrode–electrolyte interface; (2) explains how these processes define the type of electrode; (3) explores some simple equivalent circuit models for the electrode–electrolyte interface; (4) reviews the factors influencing material selection for electrodes; and finally (5) looks at some applications of such electrodes. Although the fundamentals discussed apply to both recording and stimulating electrodes, this chapter focuses on stimulating electrodes in the material selection and application sections, because of their recent emergence as effective treatment options (see pacemakers and defibrillators in Chapter II.5.3.C.) Also, see Chapter II.5.12 that addresses this subject from a somewhat different perspective.

Surface or transcutaneous electrodes used to monitor or measure electrical events that occur in the body are considered as monitoring or recording electrodes. Typical applications for recording electrodes include electrocardiography, electroencephalography, and electromyography. Electrodes used to transmit information into the body influence specific processes that occur in the body, and are considered as stimulator electrodes. In all of these applications the electrodes are used to transmit voltage or current waveforms to specific target areas in the body for either direct control of a bioelectric event or for indirect influence on the target area through a stimulated chemical change. Such stimulator electrodes are used in cardiac pacemakers and defibrillators to maintain or restore sinus rhythm, in transcutaneous electronic nerve stimulators for pain suppression, in neural stimulation systems for applications ranging from epilepsy control to auditory augmentation, in polarizing devices for intranscutaneous drug delivery, and in stimulators for tissue healing/regeneration.

ELECTRODE–ELECTROLYTE INTERFACE

In 1800 Volta demonstrated that the electrode–electrolyte interface was the source of electrical potential, and initiated his research on direct current electricity. The nonlinearity of this interface with current led Georg Ohm (1826) to use a thermopile as a source of electrical potential, and resulted in the law that bears his name. However, the origin of the term "electrode" is attributed to one of the most prolific researchers in electrochemistry, Faraday (1834). In 1879 Helmholtz established the first model for the electrode–electrolyte interface (Helmholtz, 1879). Several more complex models of this interface were proposed by Gouy (1910) and Stern (1924). This section will explain the basic reactions at the electrode–electrolyte interface, how they define a specific electrode type, and finally the make-up of this interface.

Faradaic and Nonfaradaic (Capacitive) Processes

Bioelectrodes can interact with the body fluids (electrolytes) in two primary ways – faradaic and nonfaradaic (summarized in Figure II.5.10.1). An electrode may establish ohmic contact with the surrounding environment, thereby transferring electrons across the electrode–electrolyte interface via oxidation and/or reduction reactions. All such charge-transfer processes are governed by Faraday's law (i.e., the amount of chemical
FIGURE II.5.10.1 Faradaic and nonfaradaic pathways of general electrode reactions. The charge transfer reaction at the surface is faradaic. The diffusion and the adsorption/desorption processes are nonfaradaic.

change occurring at an electrode–electrolyte interface is directly proportional to the current that flows through that interface), and hence are called faradaic processes. Electrodes at which faradaic processes occur are also known as charge-transfer electrodes. Under certain thermodynamically or kinetically unfavorable conditions an electrode–electrolyte interface may exhibit an absence of charge-transfer reactions. However, the electrode–electrolyte interface may change because of adsorption or desorption processes that occur at the interface, and transient external currents can flow due to changes in the environment. These processes at the electrode–electrolyte interface are known as nonfaradaic processes.

Polarizable and Nonpolarizable Electrodes

Electrodes in which charge transfer can occur in an unhindered manner represent truly faradaic, or perfectly nonpolarizable, electrodes; conversely, electrodes in which no faradaic charge transfer can occur are called perfectly polarizable electrodes. In the latter case, the half-cell potential of the electrode results in the formation of an electrical double layer of charge akin to two parallel plates of a capacitor, and charging or discharging of this capacitor monitors or influences a bioelectric event. Although an electrode can behave as either a polarizable or a nonpolarizable electrode under specific conditions at the interface, it will also exhibit a minimal amount of the other process (secondary) during clinical use.

Electrical Double Layer

At a given potential there will exist a charge on the metal electrode (q_M), and a charge in the solution (q_S).

FIGURE II.5.10.2 Simplistic parallel-plate Helmholtz model for electrical double layer.

The potential across the electrode–electrolyte interface and the composition of the electrolyte will determine if the charge on the electrode is positive or negative. The sum total of the charge at the interface will, however, be equal to zero at all times, i.e., $q_M = -q_S$. The charge on the metal is a result of an excess or a deficiency of electrons, and the charge in the electrolyte is due to an excess of anions or cations in close proximity to the electrode. Helmholtz (1879) established a model for this aligned array of charges, referred to as the electrical double layer (EDL). This model is illustrated in Figure II.5.10.2.

Under realistic conditions this interface is more complex than the simplified parallel-plate model. The metal electrode still forms one charge array at the electrode–electrolyte interface. On the aqueous solution side of the interface polar solvent molecules, and specifically adsorbed ions or molecules, make up the first layer. This layer, referred to as the compact, Stern or Helmholtz layer extends to the locus of the electrical centers of the specifically adsorbed ions (inner Helmholtz plane). Charged ions in the electrolyte attract their own sheath of solvent molecules, and form what are called micelles or solvated ions. Because these ions are well-insulated
FIGURE II.5.10.3 Multilayer model for the electrode–electrolyte interface. IHP, inner Helmholtz plane; OHP, outer Helmholtz plane.

they interact with the conducting electrode surface, primarily through long-range electrostatic forces. The size of these ions and their nonspecific adsorption mechanism results in the formation of a three-dimensional diffuse outer layer. This outer layer extends from the locus of the electrical centers of the solvated ions (outer Helmholtz plane) into the bulk of the solution. The resulting interfacial structure is illustrated in Figure II.5.10.3.

EQUIVALENT CIRCUIT MODELS

Helmholtz (1879) not only described the nature of the electrode–electrolyte interface, but also proposed the first equivalent circuit model for it, i.e., an idealized parallel-plate capacitor. Warburg (1899), Fricke (1932), Randles (1947), and Sluyters-Rehbach (Sluyters-Rehbach and Sluyters, 1970) contributed significantly to continued development of equivalent circuit models for specific conditions at the interface. However, their models did not account for the passage of direct current through this interface. In 1968 Geddes and Baker applied the concept of a shunting (parallel) faradaic leakage resistance across the non-faradaic components that resulted in two equivalent circuit models for the bioelectrode–electrolyte interface. These models accounted for the passage of direct current through this interface. Subsequent experimental investigations by Onaral and Schwan (1982) very strongly corroborated this concept of a shunting faradaic leakage resistance at low frequencies. Detailed analysis of different types of recording and stimulation electrodes, and corresponding equivalent circuits, are discussed by Geddes and Baker (1989) in their seminal textbook on the principles of biomedical instrumentation. A review article by Geddes (1997) provides a less rigorous historical perspective on the evolution of such circuits, their advantages, and their limitations.

Basic Circuit Elements

A voltage is developed across the electrical double layer, and is referred to as the half-cell potential for
FIGURE II.5.10.4 Basic circuit elements: (A) the half-cell potential or battery circuit element; (B) simplistic double-layer or parallel-plate capacitor circuit element; (C) hindrance to faradaic transfer or the resistive circuit element.

that electrode under specific environmental factors. It is impossible to measure the potential developed at a single electrode. Hence, an arbitrary standard electrode is used to close the circuit, and the total voltage is measured as the difference of the half-cell potentials of the two electrodes. This can be represented in terms of a voltage source element or battery, represented in Figure II.5.10.4A. The electrical double layer in its most simplistic form is represented by two charged parallel plates with an insulated gap, i.e., a capacitor circuit element (Figure II.5.10.4B). The hindrance to the charge transfer that occurs at a faradaic electrode–electrolyte interface is represented by a resistive circuit element, illustrated in Figure II.5.10.4C.

Simple Equivalent Circuits

The electrolyte/tissue surrounding an electrode will result in a resistive element, referred to as the uncompensated or series resistance (R_u), that will be a contributing factor in all cases. An ideally polarizable electrode (nonfaradaic) will be represented by a series combination of the established double layer capacitance (C_{dl}) and R_u. This is illustrated in Figure II.5.10.5A. However, this model predicts infinite impedance for direct current (0 Hz). But it is known that a direct current can be passed between an electrode–electrolyte interface. This disparity can be explained by placing a charge-transfer resistance (R_{ct}) or a faradaic leakage resistance across the model illustrated in Figure II.5.10.5A, as shown in Figure II.5.10.5B. Most physiological electrolytes diffuse in and out of the tissue surrounding an electrode. A polarizable electrode with such mass transport limitations (partial diffusion control) will have an impedance term called the Warburg impedance (Z_w) associated with it, and will result in the model illustrated in Figure II.5.10.5C. Finally, a half-cell potential (E) is associated with every electrode placed in an electrolyte, and it is placed in series with the circuit in Figure II.5.10.5C, as shown in Figure II.5.10.5D.

Electrodes on a Subject

The equivalent circuit in Figure II.5.10.5D is a very good approximation of a single electrode–electrolyte interface. However, it is known that at least a two-electrode system is required either to make measurements of or to initiate a local biological event (E_b). The equivalent circuit models
FIGURE II.5.10.5 Simple equivalent circuits: (A) equivalent circuit for an ideally polarizable electrode; (B) equivalent circuit element for a practical electrode; (C) a polarizable electrode subject to mass-transport limitations; (D) a polarizable circuit with mass-transport limitations and the half-cell potential of the electrode.
FIGURE II.5.10.6 The equivalent circuit model for a two-electrode scheme on a subject. E_b is the local biological event being monitored or initiated, and Z_s is the simplified black-box model used to represent the generic subject impedance.

to represent the subject are quite complex, because of the varying nature of tissue microstructure. Thus, a simplistic black box model (Z_s) is used to represent the generic subject impedance. The whole equivalent circuit comprising the subject impedance, the biological event, and the two electrodes is illustrated in Figure II.5.10.6.

FACTORS INFLUENCING MATERIAL SELECTION

While recording electrodes are not subject to active degradation, because of the inherent nature of the application, they are subject to degradation by the environment. Stimulation electrodes, on the other hand, are subject to degradation by the very excitation applications they are used for. All the factors listed in Table II.5.10.1 are of specific importance to material selection for electrodes (Bard and Faulkner, 1980; Fontana, 1986).

TABLE II.5.10.1	Factors Influencing Material Selection for Electrodes
Electrode	Surface area, geometry, and surface condition
Electrical	Potential, current, and quantity of charge
Environmental	Mass-transfer variables and solution variables
Engineering	Availability, cost, strength, and fabricability

Stimulating electrodes work by producing transient electric fields in their vicinity. The uniformity and precision of such electrical fields are dependent on the charge density distribution created by the stimulation electrode. Although ideally polarizable electrodes can create such fields with no chemical changes at the electrode–tissue interface, they are typically limited to less than 20 µC/cm² of true surface area for commonly used metallic electrodes (Robblee and Sweeney, 1996). Typical clinical applications require higher charge density distribution, and hence, most stimulation electrodes rely on predominantly faradaic charge transfer mechanisms for direct stimulation of a bioelectric event or a chemical reaction that would stimulate a bioelectric event. Some faradaic processes are reversible, while other processes are not (Brummer and Turner, 1977). Irreversible reactions initiate the electrolysis of water (oxygen or hydrogen evolution), oxidation of chloride ions, and corrosion or dissolution of an electrode that produces soluble metal–ion complexes (Geddes and Baker, 1989). This is undesirable, as it can result in multiple local and systemic biological responses that may change the properties of surrounding tissue or the type of surrounding tissue itself, i.e., fibrous tissue encapsulation to isolate a corroding, non-biocompatible object (Akers et al., 1997; Grill and Mortimer, 1994).

This change in property or type of surrounding tissue significantly influences the impedance at the electrode–tissue interface (Beard et al., 1992; Glikson et al., 1995; Danilovic and Ohm, 1998). This has necessitated the estimation of a property called the "reversible charge limit." The charge injection limit is the maximum quantity of charge that can be injected or transferred before irreversible chemical changes occur. The charge injection limit of any bioelectrode will depend on the reversible processes available during stimulation (environmental variables), the shape and surface morphology of the electrode (electrode variables), and finally, the geometry and duration of the stimulation waveform. An excellent review article by Robblee and Rose (1990) discusses the relative importance of the aforementioned factors in achieving reversible charge injection.

Even if careful consideration is given to the reversible charge injection limit, any implanted device (foreign body) will produce local changes in the tissue, as discussed before. Consequently, regulated-voltage stimulation (resultant current is dependent on tissue impedance) is susceptible to complex nonreproducible fluctuations,

in comparison to regulated-current stimulation (direct application of current/charge) for implanted electrode systems. The stimulation waveforms in their simplest configuration may be pulsatile or symmetric sinusoidal. The charge injected (q) by a pulsatile waveform (say a rectangular pulse) is proportional to the pulse current (i) and the time duration (t) for which it is applied, i.e., $q = it$. The charge can thus be controlled very precisely, and is independent of the frequency with which it is delivered. In contrast, the charge delivered by a symmetric sinusoidal waveform is dependent on its frequency, i.e., current amplitudes that result in an acceptable charge density at high frequency may deliver an unacceptably high charge density at low frequency. But, symmetric sinusoidal waveforms possess no net DC component, and thus have reduced residual effect on the periprosthetic tissue. The basics of simulation waveform geometry, duration, and frequency, and how they relate to a specific application can be found in the chapter on stimulation electrodes by Geddes and Baker (1989) in their textbook on biomedical instrumentation. The design of stimulation waveforms is also one of the strongest emerging research areas in interventional clinical research (Hillsley et al., 1993; Walcott et al., 1995, 1998).

ELECTRODE MATERIALS

Noble Metals

Platinum is the most popular electrode material, because it is stable, inert, and corrosion resistant. However, pure platinum is a soft metal and is typically alloyed with iridium to improve its mechanical properties, thereby facilitating construction or manufacture of small electrodes. The amount of iridium in a platinum–iridium alloy can vary from ~2% to ~30% without limiting the charge injection ability of the alloy (Robblee and Sweeney, 1996). Small diameter intracortical stimulation needles that require flexural rigidity to achieve appropriate placement are examples of bioelectrodes that would use platinum–iridium alloys. Although platinum and platinum–iridium alloys exhibit extremely high corrosion resistance, even at high injection current densities (50–150 μC/cm^2) without gas evolution or electrolyte oxidation, metal dissolution is not avoidable, and occurs at all charge densities (McHardy et al., 1980; Robblee et al., 1980).

Iridium metal can be used instead of platinum in applications that require superior mechanical properties. Although the iridium metal electrodes possess no advantage over the platinum electrodes in terms of charge injection ability, iridium oxide films exhibit significantly reduced interface impedance compared to bare metal (Glarum and Marshall, 1980). This can facilitate greater efficiency of charge flow, thus contributing to prolonged battery life of an implanted stimulation device. Multilayer oxides can be formed on iridium electrodes by cycling the electrochemical iridium potential between predetermined values versus a standard electrode. These multilayer oxides can transfer or inject significant charge densities by reversible transitions between two stable valence levels or oxides (Robblee et al., 1983), but they are susceptible to limiting charge injection densities due to the shape or type of stimulation waveform. For example, when subjected to a predominantly cathodal pulse of 0.2 msec the electrode can inject only 1000 μC/cm^2. But the electrode can inject almost 3500 μC/cm^2 when the cathodal pulses are interspersed with an anodic bias voltage. The anodic bias voltage returns the electrode/oxide to its highest stable valence state between treatments, thereby increasing the charge injection ability of the electrode (Agnew et al., 1986; Kelliher and Rose, 1989). Also, transport and conductivity limitations during the short treatment timeframes restrict the utilization of the large charge injection capacity of such electrodes.

Non-Noble Metals

Intramuscular electrodes that require high mechanical and fatigue strength may be made from non-noble metals/alloys, such as 316LVM stainless steel or nickel–cobalt-based Elgiloy and MP35N. These materials rely on thin passive films for corrosion resistance, and inject charge by reduction or oxidation of their passive films. Although large anodic pulses that push these electrodes into their transpassive[1] behavior can lead to significant corrosion, it is important to note that corrosion can result at even relatively low cathodal pulses. These electrodes are capable of injecting ~40 μC/cm^2, and are susceptible to corrosion-related failures even at that level (White and Gross, 1974).

Titanium and tantalum can form insulation oxide films during anodic polarization, and can be used for manufacturing capacitive electrodes (electrodes that inject charge without faradaic reactions at the electrode–electrolyte interface). While the titanium oxide possesses a significantly higher dielectric strength compared to tantalum oxide it is susceptible to significant DC leakage, limiting its use in electrode applications. Capacitive electrodes based on tantalum–tantalum pentoxide have limited charge storage capacity (100–150 μC/cm^2), and can be used only in applications above a particular geometric size (0.05 cm^2) for neural prosthesis applications (Rose et al., 1985).

Also, the translation of micro- or nanofabrication technology (Wise and Najafi, 1991) from the semiconductor to the biomedical community has resulted in multielectrode arrays (Mastrototaro et al., 1992; Johnstone et al., 2010; Jones et al., 2010) to either control or monitor different functions of a single event or multiple events.

---

[1]If the potential is high enough, passive metals can enter a transpassive state with current/voltage characteristics different from the passive state.

APPLICATIONS

Cardiology

The pumping of the heart is controlled by regular electrical impulses generated by a group of special cells in the sinus node. The propagation of these impulses in a specific sequence causes the heart to contract, pump blood, and subsequently relax/expand once the signal passes. Any disorganization of this complex generation and propagation of electrical impulses (transmembrane potentials) or abnormal change of heart rate results in a condition called an arrhythmia (James, 1994).

When an arrhythmia results in slowing down of the heart – called *bradycardia* – due to a loss of pacemaker function or disorganized, ineffective propagation (a condition called atrial fibrillation) an electronic pacemaker is used to provide electrical impulses – essentially small shocks – to pace the heart to its normal rate (Ellenbogen et al., 1995) (see Chapter II.5.3.C). When an arrhythmia results in a very rapid heart rate with disorganization of initiation and propagation of the electrical wave, leading to asynchrony of contraction, a condition called ventricular *tachycardia* (i.e., rapid rate) or ventricular fibrillation (i.e., rapid, disorganized rate) occurs (Epstein and Ideker, 1995). Ventricular fibrillation is known to cause more than 325,000 deaths in the United States annually. This condition can be rectified using shock therapy, and the corrected rhythm often can be maintained using a combination of medication and/or an electronic device called the implantable cardioverter/defibrillator (ICD), a device that administers a large shock to the heart to "reset" the rhythm to normal (Glikson and Friedman, 2001; van Rees et al., 2011; and Chapter II.5.3.C).

For the first few years after the ICD became commercially available, the electrodes were placed directly on the external heart surface during open-chest surgery (Ideker et al., 1991). These electrodes were approximately 20–60 cm^2 and constructed out of titanium mesh. More recently, the ICD electrodes have been mounted on catheters that are inserted into the wall of right ventricular chamber of the heart by way of the venous system, so that major surgery to open the chest is no longer necessary (Singer et al., 1998). These electrodes, typically 5–8 cm long, are frequently made of titanium wire wound around the catheter to form a tight coil with no space between the turns. The sealed, titanium-coated can housing the circuits and battery is used as one of the defibrillation electrodes in ICDs (Figure II.5.10.7). Articles elaborating on contemporary usage of ICD electrodes and leads are available (Haqqani and Mond, 2009; Welsenes et al., 2010).

Ventricular tachycardia or fibrillation is sometimes caused by an abnormal focus in the heart that fires prematurely or by an abnormal path of conduction of electrical impulses within the heart muscle. Ablation of that abnormal focus or abnormal path may be obtained via
FIGURE II.5.10.7 Schematic illustrating the placement configuration of an implantable cardioverter/defibrillator device.

a catheter-based procedure that therapeutically destroys ("ablates") a small area of tissue (Iskos et al., 1997; Tung et al., 2010). Ablation was originally performed by administering an intense DC shock through a catheter electrode placed next to the target tissue and a large plate on the back of the patient. This shock-damaged tissue by the direct effects of the large electric field and barotrauma caused by sudden gas bubble formation when arcing occurred between the shocking electrodes. Currently, a radio-frequency pulse applied through a platinum or platinum–iridium catheter electrode is used to kill the tissue by ablating or heating it during the application of the pulse. This technique is more localized, and causes less damage to tissue surrounding the area of anomaly.

Neurology

Significant advances in imaging modalities, minimally invasive instrumentation, and robotic guidance/placement systems (Fenton et al., 1997; Hefti et al., 1998) are facilitating three-dimensional positioning of stimulation electrodes in the brain and other sites. Electrical stimulation of the brain, spine, peripheral nerves or muscles can be used for a variety of applications including pain management, treatment for Parkinson's disease, skeletal muscle rehabilitation after stroke, swallowing rehabilitation, cerebral palsy therapies, improving posture, ankle instability treatment, multiple sclerosis, muscle therapy for chronic obstructive pulmonary disease (COPD), preventing pressure ulcers, bladder and bowel management, building muscle strength, and this is just a partial list of applications. Also see Chapters II.5.11, II.5.12, and II.5.9.E.

Stimulation within the brain must be executed without any charge transfer across the electrode–tissue interface to prevent permanent tissue damage. Capacitor

electrodes are ideal for this application. The tissue acts as the dielectric between the capacitive plates and, since the surfaces of these electrodes are oxide coated, negligible charge transfer occurs (Rose et al., 1985). Several clinical studies provide evidence that deep brain stimulation can be used to control medically refractory essential tremor (Lyons et al., 1998; Ondo et al., 1998) or untreatable Parkinsonian tremor (Ghika et al., 1998; Krack et al., 1998). Motor cortex stimulation has been shown to reduce post-stroke pain in patients when muscle contraction was inducible (Katayama et al., 1998).

The spinal cord can also be stimulated to control pain in various clinical conditions (Segal et al., 1998). Percutaneous spinal electrodes are placed in patients who are not suitable candidates for coronary bypass grafting for treatment of ischaemic pain condition such as angina pectoris (Andersen, 1997). They may also be used to control chronic back pain if surgical outcomes are not successful (Rainov et al., 1996). Transcutaneous electrical stimulation (TES) of peripheral nerves has been used to control chronic pain due to spinal cord injury or stroke damage (Taub et al., 1997). Localized stimulation of nerve endings using retinal and cochlear implants has also been attempted to enhance the loss of vision or hearing, respectively (Heetderks and Hambrecht, 1988) (see Chapters II.5.9.E and II.5.11).

Functional neuromuscular simulation (FNS) refers to the electrical stimulation of skeletal muscle for artificially controlled exercise or restoration of motor function lost due to spinal cord injury or disease (Sweeney, 1992). FNS systems are designed to provide upper-extremity control (Hoshimiya et al., 1989), lower-extremity control (Graupe, 1989) or both. FNS takes advantage of the fact that most motor neurons below the level of injury remain intact. Thus, electrical stimulation of their axons can be used to cause muscle contraction. For example, the phrenic nerve can be stimulated to control respiration or the sacral nerves can be stimulated to regulate the detrusor muscle in the bladder. Although FNS designers strive to mimic the body's control strategies, it is still extremely difficult to attain the fine gradation of force required to achieve adequate function. Review articles by Heetderks and Hambrecht (1988) and Maffiuletti (2010) are excellent sources of information on neuromuscular stimulation along with Chapter II.5.12.

Other

Catheter ablation electrodes can be used via the urethra or perineal cavity to damage/kill benign or malignant hyperplasia in the prostate (Dixon, 1995). Ablation has also been used to reduce the size of metastatic liver tumors and osteoid osteomas by damaging the irregular cells (Rosenthal et al., 1995; Solbiati et al., 1997). Cryosurgery, i.e., ablation by extreme cooling, has been used to treat refractory hepatic neuroendocrine metastases (Bilchik et al., 1997). Stimulating electrodes have also been

explored to enhance tooth movement in orthodontics or the growth of teeth. In this case, platinum and noble metals are not useful because they irritate the gingival tissue. Composite electrodes are used with biocompatible gels to keep the electrode separated from the moist gingival tissue (Beard et al., 1992).

Future Trends

Healing and Regeneration. The US Food and Drug Administration has approved a number of electrical bone-growth stimulating devices for treating nonunion fractures, and for enhancing spinal fusion (Polk, 1995), although there is still controversy on the efficacy of these methods (Mollon et al., 2008). These devices generally use one of three approaches to apply low-intensity fields to the tissues: direct current applied to the wound site through surgically implanted wire electrodes; high-frequency (>20 kHz) "capacitatively coupled" sine-wave signals applied through skin electrodes; and low-frequency pulsed electromagnetic fields (PEMFs) applied by Helmholtz-type coils strapped to the limb. The PEMF devices do not conduct current directly to the tissues and, in the strictest sense, may not be considered as electrodes.

The implanted electrodes usually consist of stainless steel or titanium wire, but may include other metals such as silver or platinum. The wires, serving as cathodes, are connected to small batteries supplying a continuous current of 2–20 μA. It is uncertain whether the resulting stimulation of bone growth is due to electrochemical changes in the tissue surrounding the cathodes or to the electric current itself (Black, 1987). Spadaro (1997) used a rabbit femur model to compare the bone growth stimulation by different metallic cathodes at the same current density. The observed differences in the degree of bone formation would seem to argue for an electrochemical, rather than an electrical, basis for the effects. Yet the same results might also be attributed to the mechanical properties of the wires; as the animals moved about, the stiffer wires would transmit more mechanical force to the bone, and this micromotion might itself elicit an osteoinductive response.

The capacitatively coupled devices use 2–3 cm diameter electrodes adjoined to the skin through a conductive gel. These are powered by a small battery pack, and produce voltage gradients in bone estimated at 1–100 mV/cm at current densities in the $\mu A/cm^2$ range. As with the implanted electrodes, the precise basis for their effects are not completely understood, but appear to involve the distribution of cations, particularly calcium, at the cell surface (Zhuang et al., 1997).

The range of these applications should expand considerably when the molecular basis for electric field–tissue interactions is better understood. Electrical stimulation can be clinically useful for stimulating wound healing (Ennis et al., 2011) and nerve regeneration. For example, platinum cuff electrodes that surround the nerve or penetrating needle electrodes may be used to stimulate peripheral

nerve regeneration (Heiduschka and Thanos, 1998). An electrode array with polymeric guidance tubules or a DC electrical field may also be applied to direct growth of new peripheral nerve axons. The nerves grow toward the cathode of the bioelectrode (Heiduschka and Thanos, 1998). It must be kept in mind, however, that this area of research remains controversial, because of frequent difficulties in reproducing experimental results and the absence of a generally accepted model.

Brain–Computer Interface (BCI). The ability to interface a computer directly to the brain via electrodes has the potential to restore functionality to those paralyzed or with vision or speech deficits. Such BCIs convert intent (i.e., the electrical signals generated in the brain associated with "I want to pick up that object") to electrical signals that can be interpreted by a computer and used to control a robotic arm to pick up the object. BCIs are classified as non-invasive (a helmet sits on the head to pick up signals) or invasive (implanted). The implanted electrode arrays can be placed on the surface of the brain (electrocorticography, ECoG) or implanted penetrating into brain tissue. The more electrodes there are in an array, the more precisely interrogation of brain electrical signs can be performed. Obviously there are material challenges associated with the mechanically soft nature of brain tissue (modulus mismatch), the geometry of the brain, the spacing of electrodes, and electrode biocompatibility (consider how biological encapsulation might impact the detection of signals that are generally less than 100 μV). Array electrodes can be fashioned from silicon, platinum, platinum–iridium, conducting polymers or from surface modified versions of these materials. An ECoG electrode was fabricated from carbon nanotubes and titanium nitride on a flexible polyimide support, demonstrating the application of many biomaterials to this complex problem (Sauter-Starace et al., 2009). Advanced BCI devices will require collaboration between biomaterials scientists, neurosurgeons, electrical engineers, computer specialists, and psychologists. Though only a few BCI devices have been implanted in humans, to date, important studies in primates have been performed demonstrating that a monkey, using only its thoughts, can control a robotic arm (Velliste et al., 2008). A few references on BCI devices and brain recording electrodes are provided here for further reading on this evolving, complex field that may, in the future, have tremendous impact for new biomaterials-based devices (Kipke et al., 2008; Kim et al., 2010; Konrad and Shanks, 2010; Lebedev et al., 2011; Schalk and Leuthardt, 2011).

SUMMARY

Although significant progress has been made in our understanding of the bioelectrode–tissue interface, it is still not possible to predict all of its properties with certainty. New materials, micro- or nanofabricating capability, computer processing power, and a better understanding of biological processes over the past two decades have significantly improved our ability to make bioelectrodes that more than adequately monitor or influence a biological event. However, it is becoming apparent at this time that even the most advanced synthetic prosthesis cannot totally restore normal function. Hence, the human impact of interventional and potential regenerative procedures made possible due to current biolectrodes will form the basis for further advances in this old, but still nascent, field.

CHAPTER II.5.11 COCHLEAR PROSTHESES

Francis A. Spelman

Department of Bioengineering, University of Washington, Seattle, WA, USA

INTRODUCTION

Cochlear prostheses help the deaf to contact the auditory environment (NIH, 1995). The problem of sensorineural deafness is immense. The probable number of users has been estimated by some as 900,000 in the US alone (Levitt and Nye, 1980). Other estimates range as high as 2,000,000 sensorineural deaf in the US. The treatment for sensorineural deaf patients is the cochlear implant (NIH, 1995). Sensorineural deaf subjects cannot perceive sound without extraordinary aid. This is because the basic transduction system is lost as a result of damage or destruction of either the cochlea or the auditory nerve (Levitt and Nye, 1980).

This chapter introduces cochlear prostheses and some of the materials issues that must be faced by their designers. The concentration of the chapter is on cochlear implants, rather than on implants in the brainstem or the midbrain. In the US approximately 120,000 people use cochlear implants, while less than 1000 have brainstem implants (Brackmann et al., 1993; NIDCD, 2003; McCreery, 2008; Wilson and Dorman, 2008). At present, cochlear implants are in clinical use, while brainstem implants are largely experimental, with limited clinical trials (McCreery, 2008). There is no discussion of tactile prostheses for the deaf (Martin, 1985). This chapter introduces the physiology of the auditory system, describes cochlear prostheses, and some of the issues related to biomaterials that bioengineers face in the design of such apparatuses.

OVERVIEW OF THE AUDITORY SYSTEM

The auditory system can be divided into its peripheral organs and the centers in the central nervous system that process the signals produced by the peripheral organs. This is a greatly abbreviated presentation. More details are found in texts like those of Geisler (Geisler, 1998) and Dallos and Popper (Dallos et al., 1996). Geisler refers to several websites that demonstrate the behavior of the periphery, e.g., http://www.neurophys.wisc.edu/animations. The sketch in Figure II.5.11.1 shows the auditory periphery with a cochlear prosthesis implanted in it (courtesy of Cochlear Pty Ltd, Sydney, Australia).

The Periphery

The auditory periphery consists of the outer ear, middle ear, and inner ear. The external ear, the *pinna*, collects changes in pressure (condensations and rarefactions) produced by the auditory signals. Those signals are generated by sound sources in the environment of the listener. Acoustic signals are guided to the middle ear along the ear canal, an entry into the head of the subject that is lined by soft tissue. The ear canal is open at its peripheral end, and bounded by the eardrum, *the tympanic membrane*, at its inner end. The length of the ear canal is about 3 cm in the human (Geisler, 1998).

The middle ear is bounded distally by the tympanic membrane and proximally by the *cochlea*, where the foot plate of the *stapes* contacts the oval window of the cochlea.[1] In the middle ear are three tiny bones that comprise the *ossicular chain*: the *malleus* (hammer), *incus* (anvil), and *stapes* (stirrup). The bones have flexible connections. They provide a mechanical advantage so that the eardrum can be driven by air and, in turn, can drive the dense fluids that are found in the cochlea. The motion of the foot plate of the stapes is about 75% of that of the tympanic membrane in the human (Geisler, 1998). Further mechanical advantage is provided by the relative areas of the tympanic membrane and the foot plate of the stapes: the tympanic membrane has about 20 times the area of the stapes (Geisler, 1998). Small pressure changes in air are transformed into larger pressures in the fluids of the cochlea. Conversely, large displacements of the eardrum produce small displacements of the footplate of the stapes.

The *cochlea* is a snail-shaped organ that is located bilaterally in the temporal bones of the head. The cochlea is oriented such that its wide base faces in a medial and posterior direction, while the axis of its spiral points laterally and anteriorly (Figure II.5.11.1).

The cochlea contains three spiraling chambers or *scalae*: the *scala tympani*, *scala vestibuli*, and *scala media*. The *organ of Corti* lies within the *scala media* on the *basilar membrane*. The *hair cells* are located on the basilar membrane (Dallos et al., 1996; Geisler, 1998). The basilar membrane is an elegant structure that acts as a mechanical Fourier analyzer; specific regions of the membrane vibrate maximally in response to the frequency of the sound waves that are imposed on the stapes. The membrane displacements produce maxima for high frequencies at the basal end and for low frequencies at the apical end of the cochlea. The hair cells residing on the membrane have *cilia* that are bent when the membrane vibrates. The hair cells synapse with the peripheral processes of the auditory nerve, the *hearing nerve* in Figure II.5.11.1. There are 25–30,000 afferent neurons that synapse with the hair cells (Geisler, 1998). The organization of the auditory nerve is by the frequencies of the acoustic signals that it receives. Indeed, the entire auditory system is tonotopically organized, that is, by frequency (Popper and Fay, 1991; Geisler, 1998).

---

[1]The terms *proximal* and *distal* refer to the brain in this case. Proximal is nearer to the brain and distal is further from the brain.
FIGURE II.5.11.1 Sketch of a cochlear implant in the ear of a human patient (Figure reproduced by courtesy of and with permission from Cochlear Ltd. PTY, Sydney, Australia). The numbered circles show components of the implanted device. (1) Is the external receiver and signal processor; (2) is the internal processor hat transmits signals via a multi-conductor cable to (3) the electrode array that resides in the scala tympani of the patient's cochlea.

Tonotopic Organization of the Auditory System

The entire auditory system parses frequency from the signals that it receives. The peripheral system begins the process (Geisler, 1998), and that anatomical organization proceeds at least to the level of the *inferior colliculus*, in the midbrain (Snyder et al., 2004). As has been illustrated dramatically by Bierer, the organization can be detected in the auditory cortex (Bierer and Middlebrooks, 2004). This organization permits investigators to test the efficacy of simulation designs experimentally in animals (Bierer and Middlebrooks, 2002, 2004; Snyder et al., 2004). Their work has enabled others to design and test midbrain implants in human subjects who suffer from tumors of the auditory nerve (Lim et al., 2008). While the tonotopic organization of the auditory system is an overarching part of its design, many subtleties, e.g., temporal analysis of fine structure, accompany the organization by frequency. Those subtleties appear to underlie the ability of the system to extract signals from noise and to decode music (Rubinstein et al., 1999; Litvak and Narayan, 2007; Wilson and Dorman, 2008).

Critical to the design of the cochlear prosthesis is the location of the peripheral processes of the auditory neurons, the cells of the auditory or hearing nerve.[2] The neurons are bipolar cells, and their peripheral processes are found in and under the *bony spiral lamina* (Popper and Fay, 1991; Spelman and Voie, 1996; Geisler, 1998), an osseous or bony structure that extends from the *modiolar* (medial) wall of the scala tympani in the cochlea. The cell bodies of the VIII nerve are located in Rosenthal's canal, a hollow structure in the modiolar bone.

The anatomy of the scala tympani has led to the design of the cochlear implant. The prosthesis is designed to stimulate the auditory neurons electrically. Placing the sites of electrodes near the neurons without violating the bony wall of the modiolus requires the electrode arrays of the implants to be located in the scala tympani (*vide infra*).

Highlights of the Central Auditory System

The tonotopic structure of the auditory system is found throughout the system. The frequency-dependent structure of the auditory signal forms the responses of single neurons in the auditory nerve (Sachs and Young, 1979). As signals are produced binaurally, those signals travel from each cochlea to the *cochlear nucleus*, where the neurons send data to the *contralateral trapezoid body*, the *ipsilateral olivary complexes*, the *inferior colliculus*, the *medial geniculate nucleus*, and the *auditory cortex* (Rubel and Dobie, 1989). The properties of the auditory nerve are well-understood, and have been for more than a decade. The properties of the cochlear nucleus are under active investigation, as are those of the higher centers of the auditory system.

This chapter focuses on the auditory periphery. It is in the periphery where cochlear prostheses are most effective, although auditory prostheses have been used in the cochlear nucleus, notably for patients who suffer from damage to the VIII nerve (Shannon et al., 1993; McCreery et al., 1997; Lim et al., 2008; McCreery, 2008).

---

[2]The auditory nerve is also known as the VIII Cranial Nerve.

Damage to the Periphery

Sensorineural deafness caused peripherally can result from serious damage to the hair cells or to the auditory nerve. Clearly, if the neurons of the hearing nerve are damaged, their peripheral processes cannot be driven, and stimulation from sites in the cochlea will not work. In those cases, central prostheses have been used experimentally (Shannon et al., 1993; McCreery et al., 1997; Lim et al., 2008; McCreery, 2008).

Damage to the hair cells can result from a number of causes. Pyman et al. cite eleven root causes in people over six years of age, and seven causes in people less than six years of age (Pyman et al., 1990). Their population was 65 people in the former case, and 29 in the latter. Large numbers of subjects had unknown causes of deafness, but there were cases of meningitis, otosclerosis, and trauma that caused the problems (Pyman et al., 1990). In another study, Hinojosa and Marion analyzed 65 ears and found six causes of congenital deafness in 19 subjects, and nine causes of acquired deafness in 46 subjects. In the latter population, otosclerosis caused the greatest damage, followed closely by bacterial infections (Hinojosa and Marion, 1983).

Damage to the hair cells from loud sounds requires special mention, since the popularity of painful audio systems in automobiles, and as portable sources of entertainment, is increasing. Hair cells can be damaged by intense sounds (Popper and Fay, 1991); chronic exposure to loud sounds should be avoided, despite the relatively small numbers cited by Hinojosa and Pyman (Hinojosa and Marion, 1983; Pyman et al., 1990).

Neural Plasticity

The auditory system responds to stimulation, both anatomically and physiologically. The central nervous system can reorganize itself in response to auditory signals (Brugge, 1991). The system is more plastic in children than in adults. That understanding has changed the application of cochlear prostheses from a focus only on adults to a large distribution of instruments for children as well (Clark, 1996). Deaf children are treated at two years of age, and in some cases at 12 months (Osberger, 1997; Skinner, 2001).

COCHLEAR PROSTHESES

Cochlear prostheses present one of the remarkable success stories of biomedical engineering. The idea of electrical stimulation of the peripheral auditory system is credited to Volta (1806), and cited in Simmons (Simmons, 1966). More modern approaches to solve the problem of deafness with a neural prosthesis were offered in the latter part of the 20th century (Djourno and Eyries, 1957; Simmons, 1966; House and Berliner, 1991).

Architecture of a Cochlear Prosthesis

General Architecture. The architecture of a cochlear prosthesis is shown in Figure II.5.11.2. The architecture shown here follows the textual architecture described on the NIDCD website. Here the receiver/stimulator described on that site is divided into a signal processor and controlled current sources (NIDCD, 2003). A microphone is the transducer that converts the auditory signal into an electrical signal. The microphone's signal is sent to an external signal processor. That signal processor decomposes the electrical information into amplitude and frequency data; the signal is filtered and analyzed to produce data about the envelope of the information within a particular frequency band (Loizou, 1999). Today's clinical processors have a small external processor behind the ear and an internal processor that is housed in a titanium case that is surgically implanted into the temporal bone of the patient (Figure II.5.11.1).

Processing techniques have been introduced commercially to provide information about the temporal fine structure of auditory signals (*vide infra*). Several bands are analyzed simultaneously to develop a vocoder model of the audio signal (Gold and Rader, 1967). The data are transferred across the skin as digital signals. An internal processor takes those data and converts them to current drive signals for the electrodes of the multi-channel electrode array. In some implementations, single current sources are used and switched between contacts, while in others multiple sources can be driven simultaneously (Loizou, 1999). The currents that are sent to the electrodes can be either analog or pulsatile signals.

Cochlear prostheses are multi-channel systems. The first implants employed single electrodes, while present devices use up to 24 contacts inside the scala tympani (House and Berliner, 1991; Loizou, 1999; Spelman, 1999). In most processing strategies, one electrode is driven at a time, although analog drives present currents to all electrodes simultaneously (Osberger and Fisher, 1999).
FIGURE II.5.11.2 Block diagram of a generic cochlear prosthesis (After Spelman (Spelman 1999)).

Recent Advances in Signal Processing

Combined Electrical and Acoustic Implants. Gantz and Turner have undertaken a series of studies of patients who have 6 mm or 10 mm cochlear electrode arrays inserted in the basal turns of the cochlea, leaving the apical turns available for acoustic stimulation (Gantz and Turner, 2004). In nine subjects they found that hearing scores doubled over those obtained with acoustic stimulation alone. The study demonstrates that, when short electrode arrays are used, acoustic information can be used to deliver low-frequency information, while high-frequency information is obtained via electrical stimulation. This approach may reduce the low-frequency limits of cochlear implants that are imposed by the anatomical necessity of placing their electrodes nearer to neurons that are sensitive to high-frequency stimuli.

Bilateral Implants. Several patients have received bilateral cochlear implants. The technique provides some improvement of the ability of patients to acquire sound in a noisy environment; that improvement is attributed mainly to the head shadow effect that is present with binaural hearing (Brown and Balkany, 2007). The major disadvantages of the approach are that it requires a second surgery, and that it doubles the cost of the hardware that is implanted.

Cochlear Nerve Implants

The family of cochlear nerve implants proposed early on by the group at Stanford introduced wire bundle arrays into the VIII cranial nerve via the modiolus of the cochlea (Simmons et al., 1979; White et al., 1984). Unfortunately, when microfabrication techniques were employed, delamination of the arrays occurred. Recent advances in microfabrication and the longevity of electrode arrays that are produced with the techniques used by integrated circuit manufacturers have led to tests of arrays that are designed to penetrate the VIII nerve, placing electrode contacts into close proximity with the target neurons (Hillman et al., 2003). The approach may permit stimulation with less current and greater specificity of excitation. The use of coatings of neural growth factors may provide specificity for both penetrating arrays in the auditory nerve and scala tympani arrays (Volckaerts et al., 2007).

Active Electrode Arrays

Groups at the University of Michigan and the Cochlear Implants Centre in Belgium have proposed building flexible integrated circuit arrays with large numbers (ca. 128) of electrodes and distributed signal processing, to reduce the number of wires that must be carried by the arrays. Up until this time, those arrays have been fabricated and tested in the laboratory, but have not been tested in chronic applications (Wise and Najafi, 2004; Volckaerts et al., 2007). The approach is more promising than earlier approaches to integrated electrode arrays that often delaminated or shattered.

Brainstem and Central Nervous System (CNS) Implants

Auditory brainstem implants were proposed for patients with acoustic neuromas in the early 1990s (Brackmann et al., 1993; Shannon et al., 1993). Those implants have been demonstrated to be safe, but not nearly as effective as cochlear implants (McCreery et al., 1997; Shannon et al., 1997; Schwartz et al., 2003; McCreery, 2008; Schwartz et al., 2008). The surgeries are more difficult, and the results not as spectacular as those produced by cochlear implants (McCreery, 2008). About 500 patients have received brainstem implants (McCreery, 2008). Surgeons have implanted electrode arrays in the cochlear nucleus within the central nervous system (CNS). Results are similar to those obtained with brainstem implants, demonstrating that the surgeries are possible and the electrode arrays are safe, but the hearing comprehension of both of the groups of subjects is similar to that achieved with single-channel cochlear implants (Lim et al., 2008).

Commercially Available Systems

The following sections are brief descriptions of the strategies that are used by the three manufacturers of cochlear prostheses that are presently available to deaf patients. All of the manufacturers have websites that provide additional information.

The Nucleus® Implant. Cochlear Pty Ltd is the largest producer of cochlear prostheses in the world. For further information on the Nucleus® prosthesis, visit www. cochlear.com. The Nucleus® has an electrode array that uses 22 or 24 electrodes. Twenty-two electrodes are placed in the scala tympani. The 24-electrode array uses two external electrodes that can be used as distant return electrodes. They permit true monopolar excitation of the internal electrodes. The Nucleus® C124R electrode array is curved in order to approximate the modiolar wall of the scala tympani, bringing the electrodes of the array into apposition with the cells of the auditory nerve. The array employs Advance Off Stylet (AOS). AOS has the curved array inserted with a straight stylet for the insertion into the first turn of the cochlea. The array is moved from the stylet into the second and possibly the third turn, where it hugs the modiolar wall (Patrick et al., 2006). The Freedom Processor is a behind-the-ear processor which can be programmed with SPEAK, ACE or Continuous Interleaved Stimulation (CIS) (see CIS described below). SPEAK and ACE are processors that extract frequency information with a high-speed Digital Signal Processing (DSP) that can sample at 180 million samples per second (Patrick et al., 2006). The auditory signal to determine the frequency bands containing the maximum energy during an interval can range from about 2 msec to a few hundred microseconds. The envelopes of the signals taken from the filters whose energy is greatest are sampled. The data are distributed to electrodes within the array, driving

between five and ten electrodes within a given sequence. One electrode or a single electrode pair is driven at each sample. The electrodes are driven with biphasic rectangular pulses that repeat rapidly (Patrick et al., 2006). As of the time of the cited 2006 article by Patrick et al., no conclusions could be drawn about the benefits of the processing used in the Freedom.

The silicone rubber electrode array, when straightened, approximates a truncated cone whose diameter varies from 0.4 mm at the apical end to 0.6 mm at the basal end. The array is composed of half-segments of platinum rings, designed to face the peripheral processes of the auditory nerve. Each ring is approximately 0.35 mm in width, and the edge-to-edge separation is about 0.4 mm. The insulated platinum/iridium wires that connect to each electrode are led back through the silicone rubber carrier of the electrodes (Patrick et al., 1990). During insertion, the array is straightened with an internal stylet (Patrick et al., 2006). The array is placed into the scala tympani via a small hole that is drilled through the temporal bone. After an initial insertion of 8.5 mm, the stiffener is withdrawn while the array is gently inserted by the surgeon. In the past, the implanted electrode array resided near the lateral wall of the scala tympani when it was implanted in the ear of a human subject (Skinner et al., 1994).

The Clarion® and the Harmony™. The Clarion® cochlear implant has been supplanted by the Harmony™ implant, with the HiResolution® signal processor of the Advanced Bionics Corporation (Sylmar, CA). For the most recent information about the Clarion® implant, visit www.bionicear.com.

The device offers several processing strategies to deliver signals to patients (Kessler, 1999). Its processor can operate with several different processing strategies. The strategies include Simultaneous Analog Stimulation (SAS), the Paired Pulsatile Sampler (PPS), and the Continuous Interleaved Sampler (CIS), as well as the MP3000 strategy (Litvak and Narayan, 2007). The microphone and amplifier drive an analog/digital converter that employs signal-compressing software, most often logarithmic compression. The compressed signal is decomposed into a set of digitally filtered signals. The digitized and filtered outputs are transmitted across the skin with an RF link to an internal processor dedicated to the acoustic signal (Koch et al., 2004). The data are demodulated and demultiplexed internally, and delivered to current sources that drive electrodes directly with the compressed and filtered analog signals (Koch et al., 2004). The sampling rate is 70,000 samples per second per channel, with an aggregate sampling rate of 90,000 samples per second. The SAS system operates similarly to the Compressed Analog (CA) systems that have been used earlier (Kessler, 1999; Loizou, 1999; Spelman, 1999). The SAS system drives several electrodes simultaneously. It still suffers from the interference that occurs as a result of field interactions among electrodes.

The Harmony™ processor provides other strategies as well. Continuous Interleaved Stimulation (CIS) was developed by Wilson and his colleagues to overcome the field interactions between channels in the Ineraid implant (Wilson et al., 1991). Biphasic pulses are delivered one-pair-at-a-time to the electrodes of the implanted array in the cochlea. The pulses are interleaved (multiplexed) in time to eliminate interactions among the electric fields in the cochlea. The rates of excitation can be varied to optimize the signals delivered to specific patients. The acoustic signal is amplified, compressed, and band-pass filtered. The outputs of the filtered signals are rectified and low-pass filtered to obtain envelope information for each of the band-pass filters. The amplitudes of the pulse pairs are varied in proportion to the magnitudes of the envelopes of the signals in specific frequency bands at the time of analysis, driving the electrodes within whose bandwidths the greatest signals are found (Litvak and Narayan, 2007). The system is similar to the SPEAK strategy in that regard, although it selects a single frequency in one band rather than a range of frequencies. The widths of the pulses delivered are constant. The Harmony™ processor updates the signals as much as 2800 times per second. Eight or sixteen electrodes are usually driven (Koch et al., 2004).

The processor developed by Advanced Bionics allows the use of paired pulsatile stimulation (PPS) (Kessler, 1999). Paired Pulsatile Simulation (PPS) drives two electrodes simultaneously with paired biphasic pulses, while maintaining the maximum physical separation between the driven electrodes. Physical separation limits field interactions between electrodes (Kessler, 1999; Zimmerman-Phillips and Murad, 1999). Multiple Pulsatile Stimulation (MPS) can drive more than two electrodes simultaneously (Koch, 2000).

Koch et al. reported on 51 postlingually deafened adults who used both HiResolution™ and conventional sound processing in the new HiRes120 system of Advanced Bionics (Koch et al., 2004). As has also been found with other systems, HiRes120 users who had relatively poor performance showed greater improvement than users who had done very well. However, 96% of the patients in the study preferred the HiRes system (Koch et al., 2004).

Advanced Bionics introduced a method to appose the electrodes of their array to the cells of the VIII Cranial Nerve in Rosenthal's Canal, which lies behind the modiolar wall of the scala tympani. They produced a pre-shaped electrode that was used jointly with a polymeric Electrode Positioning System (EPS). The EPS applied pressure to the lateral wall of the cochlea, positioning the electrode array against the modiolus. The system was used for three years and then withdrawn from production in the summer of 2002.

The Med-El Implant. The SonataTI100™ implant is offered by Med-El Corporation (Innsbruck, Austria, www.medel.com). The Med-El electrode array is slim, having 24 contacts. Med-El provides data that indicate

that their array can be placed within the entire length of the human scala tympani, 31 mm.

Med-El offers Continuous Interleaved Stimulation, and at this time they offer a high multiplexing rate of 50,704 pulses per second, extracting data with a Hilbert transform approach (Anonymous, 2003) or using zero crossings of the high-frequency data (Anonymous, 2008). Med-El has drawn on its experience using EAS (Electro-Acoustical Stimulation), and applies time and place code information for the fundamental frequency of sound to the two-to-three lower frequency channels (the apical channels). The company calls the approach Channel-Specific Sampling Sequences (CSSS), and uses it in its Opus1™ and Opus2™ processors in combination with its Fine Structure Processing (FSP) that employs Hilbert transforms to gain both envelope and fine structure from filtered signals (Anonymous, 2003).

Optical Stimulation of Auditory Neurons

Richter and his co-workers have demonstrated the feasibility of stimulating auditory neurons with optical pulses of minimum durations of 5 μsec using wavelengths of about 2 μm (Izzo et al., 2007, 2008; Richter et al., 2008). They demonstrate that the excitation of neurons is limited in spatial extent, combining that excitation with acoustic masking stimulation (Izzo et al., 2007). The approach is promising, but raises questions about signal distribution, since the investigators have used optical fibers whose diameters are 200 μm. The large diameters probably contribute to the specificity of the excitation, since the beam width of a radiator is inversely proportional to the ratio of its diameter to the wavelength of the signal transmitted. That is, the aperture of a radiating structure must be large with respect to the wavelength of the signal transmitted, if the signal must have a narrow beam (Terman, 1955). However, it is possible to distribute optical signals of 2 μm wavelengths, using optical waveguides the widths of which span 0.5 μm (Baehr-Jones et al., 2008). Since the waveguides could be either silicon-based or polymer-based, small distribution systems of large numbers of waveguides might be placed in the cochlea. However, the small dimensions of the waveguides may necessitate antenna analogs at the locations of the excitable cells to limit the spread of the optical signals, because of the small apertures of the waveguides. Another issue is that of power requirements. See the Problems section later in this chapter to address the question of the possible power consumption of optically-based cochlear stimulation.

MATERIALS AND ELECTRODE ARRAYS

Materials issues are salient in the design and construction of electrode arrays. The polymers that are used to insulate the arrays must be compatible with the tissues of the scala tympani; the electrode sites must use metals that can deliver appropriate currents to excite neurons; the mechanical characteristics of the arrays must allow safe and easy insertion into a space that is both small and complex in shape. Rebscher and co-workers describe techniques and tests designed to ensure safe insertion (Rebscher et al., 1999). Later, Wright and co-workers

demonstrated substantial insertion depth, about 17 mm, with the "Thin Lateral" electrode array, and about 16 mm with the "Helix II" electrode array of Advanced Bionics. No damage was reported to the temporal bone specimens that were used (Wright et al., 2005).

While other parts of the prosthesis are of concern, the concerns are small compared to those that surround the electrode arrays. This chapter addresses issues of electrode design and choice of materials, the electrical and mechanical properties of insulating materials, and some of the issues that are related to the tissue sheaths that surround electrode arrays in the scala tympani of the cochlea.

Electrode Arrays

Electrode arrays change electrical currents into the ionic currents that can stimulate neurons. The number of electrode sites and the strategy used to drive the contacts determines the electric fields that are generated in the scala tympani and, ultimately, the number of independent channels that can be driven simultaneously. Several people have suggested ways by which electrical currents could be combined to focus the neural stimuli. Suesserman and co-workers suggested an approach that was supported by a lumped element, electrical model of the inner ear (Suesserman and Spelman, 1993). Later, Jolly and co-workers performed experiments to demonstrate that the predicted fields could be produced in the inner ear of the guinea pig (Jolly et al., 1996), and that it might be possible to stimulate independent groups of neurons (Jolly et al., 1997). Later, Middlebrooks and Bierer, and Bierer and Middlebrooks, showed clearly that focused fields produced focused excitation of neurons in the auditory system (Bierer and Middlebrooks, 2002; Middlebrooks and Bierer, 2002).

Contacts and Focusing. Simple models of point sources of current can be used to illustrate some of the effects of driving tissue with point sources of electric current. Consider a conductive medium that is semi-infinite in extent, and bounded by a perfectly insulating surface. The current source lies on the insulating boundary at location x_0, y_0, z_0. The dimensions are given in meters. The method of images (Kong, 1986) can be used to show that the potential field produced by the source is:

$$V(x, y, z) = \frac{\rho I}{2\pi} \frac{1}{[(x - x_0)^2 + (y - y_0)^2 + (z - z_0)^2]^{0.5}}$$

where:

ρ is the resistivity of the medium, given in Ohm-m;

I is the magnitude of current, given in Amperes;

$V(x,y,z)$ is the electrical potential at location x, y, z, given in Volts.

The equation above ignores the properties of the electrode, e.g., its polarization impedance, since they are overlooked entirely by the point source approximation (Macdonald, 1987).

Point sources can't be produced. However, the equation above describes a hemispherical source of radius, r, placed on the insulating surface with the source's center at the location of the point source, x_0, y_0, z_0. As long as the potential is computed for radial distances that are greater than r, the equation above is valid, and approximates the electrode in the absence of electrochemical effects.

A special case of the potential is illustrative. Let the location of the source be at the origin of a Cartesian coordinate system. Compute the field produced along the z-axis. Let the radius of the hemisphere be 50 μm. Consider a material, like perilymph, the fluid that fills the scala tympani, whose resistivity is 0.63 Ohm-m. Then:

$$V(z) = 0.1 \frac{I}{z} \quad Volts, \qquad z > 50 \, \mu m$$

Let the current be 100 μA, a reasonable threshold for a 200 μsec pulse in an experimental animal. The potential decreases monotonically from 200 mV at the surface to 50 mV at a distance of 200 μm.

Problem 3 (at the end of this chapter) illustrates additional issues that can be addressed with this simple model. With a straightforward model of this sort, the engineer can gain a quick understanding of the benefits and limitations of using multiple sources to focus the electric fields in the cochlea. The solution to the problem shows that combinations of positive and negative currents can change the widths of fields, but that narrowing the fields will reduce peak potentials. While simple, analytical solutions give results that can be understood in ideal geometries, the more complex geometries of the cochlea require more complicated solutions (Finley et al., 1989; Suesserman and Spelman, 1993; Frijns et al., 1995).

Thinking about dipole fields leads to that conclusion. A theoretical dipole consists of a pair of positive and negative point sources of current, placed at an infinitesmal distance from each other. The potential field decreases rapidly for distances that are much larger than the separation between the electrodes. The point of the experiment is to suggest that the smaller the distance between sources of opposite polarities, the smaller will be their peak potentials at a distance. Hence, sources and sinks of electric current must be used judiciously to focus potential fields.

The point source model of an electrode is suitable for spherical electrodes if their fields are modeled for radial distances greater than the radial dimension of the sphere. The same model works for a hemispherical electrode that is attached to a planar insulator. The electrodes that are used in cochlear prostheses are often more like finite, planar surfaces, and their solutions are not straightforward except in the simplest cases (Rubinstein et al., 1987; Pearson, 1990). The potential field that is generated by a circular electrode has been understood since the time of Weber (Rubinstein et al., 1987), and was described by Wiley and Webster more than 20 years ago (Wiley

and Webster, 1982). The critical finding for the latter work is that the current density of such an electrode is non-uniform over its surface, and becomes singular at the boundaries of the electrode. Current density is singular at the edges of many kinds of planar electrodes, as was shown in an elegant demonstration by Rubinstein (Rubinstein, 1988). Recessing the electrode can eliminate the singularities of current density at its metallic surface, while singularities are found at the aperture of the recessed electrode (Rubinstein et al., 1987). However, shaping the aperture can eliminate those singularities (Suesserman et al., 1991).

Consideration of surface-mounted and recessed electrodes of finite size leads to an understanding of the potential for corrosion of such electrodes. Corrosion will be greater at the edges where the current and charge densities are high. Further, thinking about the boundary condition at the surface of a metallic electrode that the potential is constant on the surface, suggests that the field produced by an electrode of finite size will differ from that produced by a point source. Finite electrodes produce a second effect, not seen for point sources. As the observer moves closer to the source, the field approaches a constant value over the surface of the source. That is a result of the boundary condition requiring superconductors to have uniform potentials on their surfaces. Of course, the potential decreases as the observer moves laterally away from the source. Another difference between point sources and finite sources is that unused point sources have no effect on the potential fields that are near them, while finite sources must sustain constant potentials at their surfaces.

Contact Materials

What materials are suitable to make the electrode arrays that are used in cochlear implants? Noble metals, that is, gold, platinum, iridium, and some of their alloys have been used extensively (Robblee and Rose, 1990). The arrays that are available clinically employ alloys of platinum and iridium, usually 90% Pt and 10% Ir. Those alloys have been studied and used for decades (Brummer and Turner, 1977a,b; Robblee and Rose, 1990; McCreery et al., 1992). The platinum provides a material that can carry charge efficiently, while the iridium provides structural strength.

More recently, the oxides of iridium have been investigated, and have demonstrated characteristics that are markedly superior to those of platinum (Robblee and Rose, 1990; Meyer et al., 2001; Weiland et al., 2003). Electrode materials are studied with standard electrochemical techniques, notably cyclic voltammetry (Robblee and Rose, 1990) and electrochemical impedance spectroscopy (EIS) (Macdonald, 1987). The former technique provides direct evidence that shows the amount of charge density that a given material can support. EIS gives indirect evidence of the charge-carrying

capacity, but provides direct information about the voltage that is required to drive a specific current.

Charge density is a critical variable to consider in the design of a cochlear electrode array. The charge density calculation is usually based on a "geometric" surface area, which assumes that the current density is uniform across the metallic surface. While that assumption is not valid in most cases, there are few calculations of geometries that result in mixed boundary problems. For the purpose of this chapter, we will assume that geometric areas suffice, but warn the reader to be wary when calculating surface areas. That said, the measurement of the charge capacity of a particular electrode is certainly valid when it is done appropriately (Meyer et al., 2001). The charge density calculation may be in error unless great care is taken to ensure that the electrode's surface is smooth, and that the current density profile is accounted for (Robblee and Rose, 1990; Meyer et al., 2001; Weiland et al., 2003).

Concern for the charge carrying capacity of electrode sites is critical for the design of cochlear electrode arrays, since it bears directly on their safety and longevity. Platinum-iridium arrays have followed the work of Brummer and Turner (Brummer and Turner, 1977a,b), usually applying a safety factor of at least two. The charge densities are held below 150 μCoul/cm^2. Increasing the surface area of a platinum electrode with platinum black can increase the charge density by a factor of 30 (Jolly et al., 1996), but the approach has not been used outside of the laboratory.

Oxides of iridium, both activated and plated, offer real promise for cochlear electrode arrays. The charge densities measured cover a range from 4 mCoul/cm^2 to 27 mCoul/cm^2 (Meyer et al., 2001; Weiland et al., 2003; Cogan, 2008). Those charge densities are not used consistently, but a safety factor is applied for long-term operation. The charge density can be reduced by as much as a factor of 20 for long-term tests (Meyer et al., 2001). Even so, the promise of IrOx is great: the potential increase in charge density, and thus in maximum stimulus current, is nearly a factor of 10. If Pt-Ir can tolerate stimuli whose charges lie below 150 μCoul/cm^2 and IrOx can withstand a long-term stimulus of 1.2 mCoul/cm^2, it is easy to compute maximum currents if we assume that we can deal with geometric surface areas. If two electrodes whose areas are 10^{-4} cm^2 are used, and they are driven with square pulses whose durations are 200 μsec, the maximum safe current is 75 μA for the Pt-Ir electrode, and 600 μA for the IrOx electrode. The IrOx electrode can excite the auditory nerve over its full dynamic range, while the Pt-Ir electrode can barely meet a threshold value (Vollmer et al., 2001).

Another concern for cochlear implant designers is the geometry of their electrode arrays. The developers of thin-film arrays must be concerned with the traces that are used on the thin films. As the arrays get smaller, the traces must also decrease in size. While implant designers may think that the currents that they use are small (they are!), the traces are small as well. Temperature increases in the traces may well be a problem as the traces decrease in size (Brooks, 1998). UltraCAD Design, Inc. offers freeware to solve printed circuit board (PCB) trace problems with a regression relation (www.UltraCAD.com). For example, a copper trace that is 7.5 cm long, 12.5 μm wide, and 1 μm thick will have a temperature increase of nearly 1°C when it carries 800 μA. If several traces carry similar currents, temperature in the cochlea could increase artificially, possibly causing thermal damage to the tissue.

Material Properties

The choice of materials for cochlear prostheses extends beyond the selection of materials that will be used on the surfaces of electrode contacts. At issue are the compatibility of arrays with the tissues of the cochlea, and compatibility of the materials that cover the internal processors that are placed in the temporal bones of the recipients of implants. This chapter does not consider the latter, since the ceramic and titanium cases and their silicone cases have not created measurable problems at the time of this writing, at least since some early problems with infection were taken care of in the late 1970s and early 1980s. The materials used as carriers for the electrode arrays have presented issues that will be discussed below.

Advanced Bionics recalled its HiFocus™ electrode array; some attributed that recall to potential concerns with the electrode positioning system (www.leifcabraser.com/cochlear.htm), a polymeric system that placed the silicone array in contact with the modiolar wall.

Placement issues had been raised before in relation to other implants (Skinner et al., 1994; Rebscher et al., 2001). Spiral tomographs of the implanted ear showed that the electrode arrays entered the scala vestibuli by way of the basilar membrane. The composition of the fluids in the scala tympani and the scala vestibuli are dramatically different. The perilymph in the scala tympani is rich in sodium ions, while the endolymph in the scala vestibuli is rich in potassium ions (Dallos et al., 1996). Mixing the two damages, and can kill, hair cells. While that is not critical in the case of the sensorineural deaf patient, the electrode arrays are distant from the peripheral processes of the auditory neurons, and the leakage of potassium-rich endolymph will damage those neurons as well.

The silicone compounds used as substrates for the electrode arrays are well-tolerated by both humans and animals. Early investigations demonstrated that an inflammatory reaction occurs in the implanted scala tympani of the inner ear; the result is a thin cellular sheath that surrounds the electrode array in both animals and humans (Clark, 2003).

In a study of the electrode arrays produced by Cochlear Corporation and Advanced Bionics Corporation, four surgeons implanted both new and old designs of arrays into cadaveric human temporal bones. The investigators assessed the amount of trauma observed, the insertion depth, and the proximity to the modiolar wall. The arrays showed no significant difference in trauma produced by the arrays of the two corporations; the greatest difference was found among the surgeons who did the implants (Rebscher et al., 2001). The Spiral™ could be inserted further than any of the other designs, and of the new designs, the Contour™ had the furthest insertion depth. Both the Contour™ and the HiFocus™ arrays apposed the modiolar wall (Rebscher et al., 2001).

The paragraph above raises the issue of insertion depth. The advantage of a cochlear electrode array that reaches the more apical turns of the cochlea is that it can reach the tonotopic locations that decode frequencies below 1 kHz. For example, insertion of 70% of the cochlear spiral reaches the 300 Hz region of the basilar membrane (Geisler, 1998). Since the range of frequencies necessary to decode speech is 300–3000 Hz (Levitt and Nye, 1980), it is desirable to reach the low-frequency regions of the cochlea with cochlear implants.

That problem, and the need to place electrode contacts near to the modiolar wall of the cochlea, has led designers to build arrays with mechanical characteristics that make the implants conform to the anatomy of the cochlea. Rebscher and his colleagues suggested a design that elegantly made use of the mechanical properties of the wires that interconnected the electrode sites and the drive electronics (Rebscher et al., 1999). They built an array that arranged the wires to form a central, vertical beam. The beam bent easily to conform to the spiral shape of the cochlea, and the pitch of the spiraling array could be controlled by the geometry of the beam in a basal–apical direction. Advanced Bionics has employed the design in two of their arrays. *In vitro* measures of the stiffness of Cochlear and Advanced Bionics arrays showed a clear anisotropy for the latter, but not for the former (Rebscher et al., 2001). Another approach suggested the use of shape-memory wire, e.g., Nitinol™, within the array to match the cochlear spiral. The wire was shaped to fit the modiolar wall (Spelman et al., 1998), straightened for insertion into the cochlear electrode array, and electrically heated beyond its transition temperature after the array was inserted into the scala tympani. The system has not been commercialized.

The stiffness of a cochlear electrode array is important for ease of insertion, placement near the target neurons and, possibly, for insertion trauma. The arrays are mechanical beams, and their mechanical properties can be investigated with classical methods in some cases, at least to obtain information about the relative stiffness of arrays that employ different materials (Boyd, 1935; Enderle et al., 2000). For a cantilevered beam of uniform cross-section and homogeneous material, the maximum deflection that occurs when the beam is loaded at its free end is:

$$y_{max} = \frac{Pl^3}{3EI}$$

where P is the load in N; l is the length in m; E is the modulus of elasticity in Pa (N/m^2); and I is the cross-sectional area moment of inertia, m^4.

The above equation is a gross oversimplification of a complex problem. The assumptions that underlie the relationship are that the deflection produces small angles, that the cross-section is uniform, and that the material is linear and homogeneous. Cochlear electrode arrays are inhomogeneous: they contain both metallic conductors and polymeric substrates; they may be laminated. Cochlear electrode arrays are tapered. The number of conductors inside them varies with length. The angles of bending can be large, particularly in the apical turns of the cochlea. The arrays are likely to be anisotropic. Thus, for a complete analysis, more sophisticated mathematics is necessary, and may not be amenable to closed-form mathematical solutions. Numerical techniques, e.g., finite element analysis, are likely to be required for better understanding.

Measurements

Cochlear prostheses are sophisticated instruments that require thorough measurement and analysis. Since they are Class III devices from the point of view of the FDA (US Food and Drug Administration), they must be carefully tested, and the tests documented before they are used.

Each component of a cochlear implant is tested before the assembly can be applied to a human subject. For example, the processing section of the prosthesis must be tested to ensure that it can parse the auditory signal and reassemble the decomposed aggregate into a new auditory signal that can be understood readily by hearing listeners. While that is not a definitive test for its ultimate users, the deaf, it gives confidence that the processor is not introducing anomalous information. Such tests also indicate the data rates that must be transmitted across the skin to an internal processor.

The data transfer link must be tested to ensure that it can sustain the necessary data rates across an appropriate thickness of skin (about 1 cm in the adult human). Animal tests can provide confidence in this case.

The internal processor must be tested to learn whether it can select electrode sites unambiguously and reliably. The current drivers are tested to discover their linearity, repeatability, and voltage range over the full life of the battery. As batteries sag during use, does the transfer function of the current driver remain constant? Is the voltage range sufficient to drive the full dynamic range of every electrode?

The electrode array is tested carefully throughout the design to the manufacturing process. The tests include

long-term soaking, electrochemical tests (Parker et al., 1999), field tests, and neurophysiological tests (Jolly et al., 1996, 1997; Bierer et al., 2003; Snyder et al., 2004). As an electrode design is introduced, it must be placed in physiological saline solutions for several weeks to discover whether the insulating carriers promote leakage between the conductors of the arrays.

Electrochemical tests include tests of open-circuit potential, whose stability may indicate shorting across traces (Parker et al., 1999), as well as electrochemical impedance spectroscopy, which can also indicate open-circuited and short-circuited electrode sites, as well as poorly plated electrode sites (Macdonald 1987; Parker et al., 1999). (Note that Parker et al. can be downloaded from http://www.eng.monash.edu.au/ieee/ieeebio1999/p41.htm.) If more complete information about the characteristics of the electrode sites is needed, cyclic voltammetry is in order (Goodisman, 1987; Cogan, 2002).

Measurement of the electric fields produced by electrodes is useful during the initial design phase. It shows the characteristics of the potential fields that are produced by the excitation of single or multiple electrodes (Suesserman et al., 1991; Jolly et al., 1996). It also can show which electrodes have parasitic conductive paths that lie between them (Prochazka and Spelman, unpublished results).

When bench testing and *in vitro* testing are complete, and a cochlear prosthesis is ready for clinical trials, behavioral testing begins. That testing ranges from psychophysical tests (Shannon, 1992; Pfingst et al., 1997; Vandali et al., 2000; Won et al., 2007), to tests of monosyllabic words and simple sentences (Osberger and Fisher 1999; Skinner, 2001), to investigations of the understanding of contextual information (Vandali et al., 2000). Behavioral testing is the true "gold standard," since it determines the success or failure of the cochlear prosthesis.

Focusing Fields and the Interaction with Tissue

The cochlear prostheses that are in use today drive electrodes singly, with the exception of the Advanced Bionics system. That is a result of the interference between the fields that are produced by the electrodes of the devices, fields that are defined by the size of the electrodes used, their distances from the target cells, and the magnitudes and phases of the signals that are applied to each contact (Spelman et al., 1995). If fields are focused, it is likely that multiple groups of neurons can be driven simultaneously and independently (Jolly et al., 1997). It is not clear whether such independence would be preferred by patients, and whether it will provide improved speech perception (Pfingst et al., 1997). It seems logical from the operation of the normal auditory system (Sachs and Young, 1979), but Pfingst's work argues against it (Pfingst et al., 1997).

Both modeling and experimental studies suggest clear benefits that can result from perimodiolar placement of electrode arrays. The modeling studies show that the fields are clearly more limited in extent when the electrode contacts are near to the target cells (Spelman et al., 1995; Frijns et al., 1996, 2001). Use of the simple model given in the earlier section on Contacts and Focusing can demonstrate the narrowing of the field that takes place when a point source is placed near its target.

Finite-sized electrodes do not produce infinitesimally wide fields as they are approached; the fields approach the width of the electrode. However, a point can be made for either point sources or finite sources; the further from the source, the wider the field. That statement is clear for a single electrode, driven as a monopole; less clear for a tripolar configuration, driven as a quadrupole (Spelman et al., 1995). In the latter case, the width of the potential field changes less with distance than for the former case. In both cases, the peak potential in the field is larger the closer the contact or contacts are to the target. Thus, intervening tissue between the electrodes and their target neurons must be minimized or avoided entirely.

If scar tissue surrounds the implanted electrode array, then several problems can arise as a result of the foreign-body response. First, the distance between the electrodes and their target cells will increase. Second, the sheaths that surround implanted electrodes have higher resistivities than the solutions of the scala tympani, and they are anisotropic (Spelman, 2004). Third, tissue sheaths can cause an increase in the impedances of the electrodes, and a concomitant increase in the voltage required to achieve excitation, with accompanying increases in power consumption.

The effect of increasing the distance becomes greater the closer is the electrode array to the neurons of the auditory nerve. Considering the simple case of a point source driven as a monopole, the electric field is proportional to the inverse of the distance between the source and the target. For a distance of 100 μm, an increase of 50 μm represents a 50% change in the distance between the cells and the target. If there is a distance of 500 μm initially, the change is 10%. In experimental animals, sheaths of 50 μm thickness were found after a few months of implantation (Shepherd et al., 1983; Leake et al., 1990).

The introduction of connective tissue sheaths introduces multiple layers into the analysis of fields in the inner ear. Even a simple three-layered problem produces a complicated result that is not a closed-form solution, and will not be addressed here (Spelman, 1989). It is enough to say that the signal produced by the stimulating current will be attenuated and, in the case where the sheath is anisotropic, will likely direct the excitation to undesirable locations (Spelman, 2004). Other effects that could affect the excitation of tissue include motion of the tissue sheath; motion that might induce an intervening layer of perilymph between the electrode and the sheath, increasing the attenuation. However, motion within the cochlea should be small, because the organ is not subject to vasomotion and the electrode array

is fixed in place with respect to the surrounding bony tissues.

If cochlear electrode arrays could have their surfaces treated appropriately, they might resist the adhesion of cells and the growth of surrounding tissue sheaths (Dalsin et al., 2003). That approach to combating the growth of cells that are produced by inflammatory responses may prove to be successful for future developments of electrode arrays. The approach can protect the surface of the substrate of the array, but not the metallic surfaces of the electrodes themselves.

Tissue on the surfaces of the electrodes must increase their impedances. The membranous tissues behave like leaky capacitors, introducing materials with specific capacitances of 33.8 $\mu F/cm^2$ (Junge, 1977). The introduction of such capacitances can affect the impedance of the electrodes of the array, and their abilities to carry currents and stimulate cells. Thus, the materials to prevent cell adhesion to cochlear electrode arrays must be designed to maintain current-carrying capacity and low impedance, while they prevent cell adhesion and the growth of undesirable tissue sheaths.

Measures of electrode impedances have been variable with time, often increasing initially and decreasing after about four weeks. The causes are not known definitively. It may be that while sheaths of cells will increase impedances, positional changes within the cochlea cause those impedances to decrease, since the effective resistivity of the surrounding tissue decreases when the electrode array is more distant from the bony walls of the cochlea. Experiments have not been done to establish sheathing and separation effects definitively.

Costs and Benefits

That more than 120,000 people use cochlear prostheses is testimony to their effectiveness. The prostheses have improved monotonically over the past several decades, with substantial improvements in comprehension that occurred when multi-channel prostheses were developed, and more gradual improvements otherwise (Rubinstein and Miller, 1999). At the same time, cochlear prostheses have been found to be cost effective. In careful cost analyses, Cheng and his co-workers investigated cochlear implants, and found that they were competitive with other surgical interventions (Cheng and Niparko, 1999). The study accounted for the costs of surgery and rehabilitation, and considered change in the quality of life as an intangible.

FUTURE DIRECTIONS

Clearly, multi-channel cochlear prostheses will be produced and implanted in large numbers, and will be used extensively worldwide. The three major producers of implants are likely to move to more cosmetic devices. All of them presently make behind-the-ear prostheses, and

are pursuing totally implantable devices. At this time, the greatest two problems faced by the latter are battery and microphone technologies. Implantable microphones will require great attention to the issue of tissue encapsulation around the diaphragm of the microphone.

Another likely improvement will be the number of electrodes that are used in the array. Investigators have pursued a 72-contact array (Spelman et al., 1998), a device that demands a quantum change in processor technology (Clopton et al., 2002). High-density electrode arrays will require great care and attention to be paid to the issues of tissue growth and compatibility. If a high-density array and its processor are available, they could provide precise phase information that is unavailable now and that will likely make possible successful binaural cochlear prostheses (Clopton and Lineaweaver, 2001).

Optical stimulation may reduce interactions among stimulus sites. If so, it is likely to provide greater numbers of excitation sites.

Bilateral implants are likely to increase in numbers, as are combined electrical and acoustic implants. The results of tests with both modalities are quite promising (Wilson and Dorman, 2008).

SUMMARY

Cochlear implants are used by more than 120,000 people worldwide. They represent a remarkable achievement by bioengineers. This chapter has provided a brief introduction to the design of cochlear prostheses. First, the chapter reviews the operation of the normal auditory system. That review highlights the approach taken by bioengineers to the initial design of cochlear prostheses. Understanding the tonotopic organization of the auditory system has led to the design of very successful prostheses.

The chapter reviews the architecture of the hardware of the devices, and outlines some of the issues that are being addressed currently, including signal processing techniques, which attempt to stress the need to deliver information about acoustic fine structure to users, in order that they may decode sound in a noisy background and potentially hear music.

Commercial systems are reviewed, with brief descriptions of the offerings of the world's major manufacturers. The chapter addresses the material issues inherent to cochlear electrode arrays and their contacts to the auditory nerve. Finally there is a brief mention of the costs and benefits of the auditory implant and a mention of directions for the future.

ACKNOWLEDGMENTS

GLOSSARY OF TERMS

Pinna: the external ear.

Tympanic membrane: the inner boundary of the external ear canal. The membrane vibrates in response to acoustic stimulation.

The bones of the inner ear: the stirrup (stapes), hammer (malleus), and anvil (incus) provide a mechanical advantage so that low-pressure, large-displacement vibrations of the tympanic membrane can be converted into high-pressure, small-displacement signals at the oval window of the cochlea.

Cochlea: the organ that converts auditory signals into the signals that drive the central nervous system.

Scalae: the chambers of the cochlea. The hair cells reside on top of the basilar membrane within the scala media. A cochlear electrode array is placed within the scala tympani, where it drives the peripheral processes of the auditory nerve cells. The cell bodies of the auditory nerve reside in Rosenthal's Canal.

Modiolus: the axis of the cochlear spiral. The auditory nerve courses through the modiolus into the internal auditory canal, and thence to the brain.

Nuclei: several centers of the brain process signals from the inner ear. Signals pass into the cochlear nucleus, the trapezoid body, the inferior colliculus, the medial geniculate nucleus, and the auditory cortex.

CHAPTER II.5.12 THE ROLE OF BIOMATERIALS IN STIMULATING BIOELECTRODES

P. Hunter Peckham[1], D. Michael Ackermann, Jr.[2], and Christa W. Moss[1]

[1]Biomedical Engineering, Case Western Reserve University, Cleveland, Ohio, OH, USA

[2]Biodesign, Stanford University, Stanford, CA, USA

INTRODUCTION

Bioelectrodes are devices used to produce or measure electrical activity in the body for electrophysiological stimulation or monitoring. This chapter will focus on electrodes for use in stimulation. Stimulation of electrically excitable tissue is achieved by establishing electrical fields in the tissue, using electrodes. These electrodes transduce electrons (the charge carrier for the electrical circuitry used in therapeutic stimulation devices) to ions (the charge carrier in the body), allowing electric charge to be injected into tissue. The materials used for these electrodes are integral to ensuring that this charge injection occurs safely and effectively. See also Chapter II.5.10, which addresses some aspects of bioelectrodes using a different and complementary approach.

NEUROSTIMULATION

Neurostimulation therapies work by activating or inhibiting excitable tissue, such as the nervous system or heart, through the delivery of electrical currents through electrodes. Current and emerging neurostimulation therapies include devices for treating cardiac arrhythmias (Ellenbogen et al., 2000), reducing pain (Cameron, 2004), alleviating symptoms of movement disorders (Starr et al., 1998), restoring motor control to the paralyzed (Peckham, 2005), restoring sensory function to the profoundly deaf (Clark, 2003) and blind (Humayun et al, 2003; Chow et al., 2004), treating epilepsy (Binnie, 2000; Theodore, 2004), restoring lost bladder and bowel function (Jarrett, 2004; Brazzelli, 2006; Rijkhoff, 1998), and treating psychiatric disorders (Kopell, 2004). These devices have restored lost function and have extended and improved the life of hundreds of thousands of individuals worldwide.

As shown in Figure II.5.12.1, most neurostimulators conform to a similar design and consist of three primary components: an *implantable pulse generator* (IPG); one or more *leads*; and one or more *electrodes* (Peckham and Ackermann, 2009). The implantable pulse generator is hermetically sealed and houses the stimulation circuitry, a battery, and a telemetry system for communicating with an external device (e.g., for receiving programming or command signals). The lead is a conductor that carries electrical currents to the electrode, which interfaces directly with the excitable tissue.

Electrical stimulation of neurons induces *action potentials* (and therefore functional outcomes) by depolarizing the neuronal cell membranes (Ranck, 1975; Rattay, 1989), and thus activating voltage-sensitive ion channels responsible for action potential generation (Hodgkin and Huxley, 1952). The electric field generated in the tissue by the injected electrode current is directly responsible for this membrane depolarization. The type of material, shape of the electrode, and stimulation parameters all affect the size and strength of the electric field. Therefore, proper electrode design and material selection is imperative to delivering an effective therapy.

FUNDAMENTAL REQUIREMENTS OF A BIOELECTRODE

In general, an electrode has three primary components (see Figure II.5.12.1, inset), each with distinct material properties: the charge delivery surface; the insulator; and a conductor which connects to the charge delivery surface (often the same conductor from the lead). This chapter will focus on the *charge delivery surface* and the *insulator*. The charge delivery surface is the electrical interface between the implanted stimulator and the tissue. The insulator ensures the lead has the desired mechanical properties and
FIGURE II.5.12.1 Implantable neurostimulation system for vagus nerve stimulation. This figure shows the three principal components of most neurostimulators: the implantable pulse generator (IPG); the lead; and the electrode. (Photograph courtesy of Cyberonics, Inc. Inset shows a magnified image of the Huntington-type electrode with markers showing the conductor and insulator.)

isolates current flow to the desired tissue. Generally speaking, for an electrode to be a safe and effective component of a neurostimulation therapy, it must meet three fundamental requirements: the electrode must be efficacious; the electrode must not damage the tissue; and the electrode must remain intact for the life of the implant. Proper material selection is integral to fulfilling each of these. Each of these requirements is considered in more detail.

1. *Efficacy*: The electrode must deliver sufficient current to activate the target tissue. For some applications the electrode must selectively activate the target tissue without activating other excitable structures which may generate undesired side-effects (e.g., pain (Falowski et al., 2008) or undesired movements or sensation (Tamma, 2002)). Additionally, the electrode must have adequate mechanical properties: it must be of a size and shape sufficient for implantation (e.g., cochlear electrodes for the hearing-impaired must conform to the very small, spiral-shaped cochlea), and must be rigid enough for insertion into the tissue.
2. *Tissue Safety*: The electrode must not cause damage to the tissue in which it has been implanted. It must also be implanted and potentially explanted without damage to the neural tissue. Tissue damage can occur due to *active chemical processes* that occur when stimulating current is being delivered through an electrode, and *passive chemical processes* that occur when stimulating current is not being delivered through an electrode (passive biocompatibility).
3. *Electrode Integrity*: Electrode failure can occur due to mechanical or chemical stresses. Some neuroprosthetic therapies involve implantation of electrodes and leads in regions of the body where motion subjects them to large degrees of mechanical cycling (Kilgore et al., 2003; Kondziolka, 2002), making them prone to failure. As will be discussed in more detail in the section on electrochemical reversal below, some chemical reactions involved in charge injection can result in dissolution/corrosion of the electrode. Proper material selection, electrode size, and stimulation paradigm can help ensure that the electrode will not undergo irreversible corroding reactions.

PRINCIPLES OF CHARGE INJECTION

In order for a stimulating electrode to activate neural tissue, it must generate an electric field within that tissue. This electric field is generated when the electrode delivers charge to the neural tissue in the vicinity of the electrode. It is important to note that, because of the principles of conservation of charge and current (as elucidated by James Maxwell and Gustav Kirchoff), at least two electrodes are always present in a neurostimulation system: one to deliver cathodic current; and one to receive an equal and opposite anodic current. Generally speaking, cathodic currents activate neural tissue

and anodic currents inhibit neural tissue (Ranck, 1975). Therefore, one of these two electrodes is often located far from the neural tissue being stimulated (e.g., the titanium case of the IPG located in a subcutaneous pocket in the chest or abdomen). This is called monopolar stimulation.

In the metal-conducting surface of the electrode, charge is carried by electrons. In the tissue, ions such as Na^+, K^+, Cl^-, and others are the charge carrier. As shown in Figure II.5.12.2, when a stimulating current is applied, the surface of the electrode acts as a transducer, converting current flow in the form of electrons in the electrode into ionic current flow in the tissue (or *vice versa*). This transduction of current occurs via two mechanisms of charge transfer at the electrode–electrolyte interface: capacitive charge transfer and Faradaic charge transfer. This chapter will present a brief review of these processes and their implications for neurostimulation. A more in depth review has been written by Merrill et al. (2005), and is recommended for the interested reader.

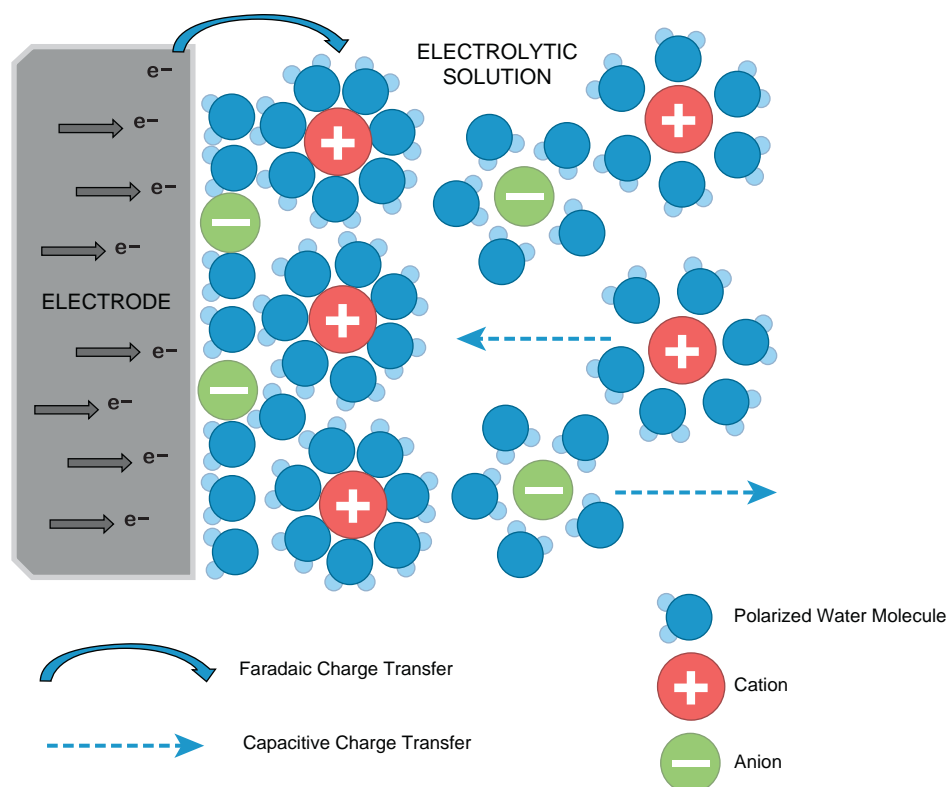
- *Capacitive Charge Transfer*: A capacitor consists of two conductors which are separated by a non-conductive material. When an electrode is placed into an aqueous environment (e.g., tissue), a so-called "capacitive double-layer" is formed at the electrode–electrolyte interface. As shown in Figure II.5.12.2, the two conductive layers of the capacitor are the electrode material, and the diffuse ion-containing aqueous solution. Charge is physically separated at the interface of these two components of the double layer, primarily because halide ions adsorb to the surface of the electrode material, acting to separate charge, and because water molecules are polar and adsorb to the surface, orienting themselves based on charge (Grahame, 1947). Capacitive charge transfer occurs when a stimulating current is delivered to an electrode, changing its net charge. Charged species in the aqueous environment react to this net change in charge by moving towards or away from the electrode. For example, at the cathode, a negative current delivers electrons to the electrode surface. These electrons result in a net negative change in charge on the electrode. This net negative charge attracts positively-charged species in the electrolyte, and repels negatively-charged species (as shown in Figure II.5.12.2). This flow of electrons and charged species within the electrolyte constitutes the capacitive electrode current. For sufficiently small stimulation currents, all delivered charge can occur via the capacitive mechanism. Some materials, such as tantalum, allow for very large capacitive current delivery (Rose et al., 1985).
- *Faradaic Charge Transfer*: Faradaic charge transfer results from reduction and oxidation reactions at the electrode–electrolyte interface. During these reactions, electrons are transferred from the electrode material to species in the electrolyte for cathodic


FIGURE II.5.12.2 Representation of the electrode–electrolyte interface during cathodic current delivery. Both Faradaic and capacitive charge transfer are depicted.

reactions (see Figure II.5.12.2) or from species in the electrolyte to the electrode material for anodic reactions. Unlike capacitive charge transfer, Faradaic exchange of electrons results in a change in the chemical species. For example, a silver electrode is oxidized to generate an electron and an aqueous silver ion in the following reaction:

$$Ag \rightleftarrows Ag^+ + e^-$$
These reduction–oxidation reactions occur when an applied electrode potential drives the energy of electrons on one side of the electrode–electrolyte interface sufficiently high or low such that it becomes equal to that of the reduction–oxidation pair species on the other side of the interface. During *cathodic stimulation* (where the electrode is driven to a negative potential), the energy level of the free electrons in the metal electrode is raised, allowing them to be transferred to unoccupied orbitals of a reactant species. During *anodic stimulation* (where the electrode is driven to a positive potential), the opposite is true. The energy level of the free electrons in the metal electrode is lowered, allowing electrons from aqueous species to be transferred to the metal interface. While noble metals are often the preferred choice of Faradaic electrode material, because of their resistance to corrosion, non-noble metals such as 316 stainless steel are also used (Memberg et al., 1989). These materials are sometimes combined with other metals to create alloys with enhanced mechanical properties,

such as platinum-iridium. Surface coatings such as iridium oxide are also sometimes used to enhance Faradaic charge delivery characteristics (Beebe and Rose, 1988). Table II.5.12.1 shows a list of electrode materials and the Faradaic reactions associated with each of them.

ACTIVE CHEMICAL PROCESSES AND ELECTROCHEMICAL REVERSAL

Faradaic electrode currents are generally conceptualized as reversible or irreversible (for the conditions under which stimulation occurs). A reversible reaction is one where the Faradaic reaction products can be recovered with a reversal in electrode current (i.e., the reverse reaction occurs in the same magnitude as the forward reaction). *Electrochemical reversal* is an important concept in electrical stimulation for two reasons: (1) Reactions that result in dissolution of the electrode material into the electrolyte can ultimately lead to the destruction of the electrode if the dissolved species are not recovered with a reversal reaction (Cogan, 2008); (2) these *active chemical processes* (referring to chemical reactions that occur due to charge injection) can produce species that may be deleterious to tissue health if not reversed. For example, free radicals produced in some reactions can damage axonal myelin sheaths (Chan et al., 1982) and DNA (Buettner, 1993). While it has been shown that some degree of irreversibility is not only tolerated by the body, but is likely the norm for chronic stimulation (Merrill et al., 2005), a primary goal in safely stimulating

TABLE II.5.12.1	Common Electrode Materials and Associated Faradaic Reactions			
Material	**Process**	**Reaction**	**Comments**	**Use**
Tantalum/ Tantalum Oxide	Capacitive	Double Layer Charging	• Electrode surface area has to be greater than 0.5cm^2	BION® injectable micro-stimulator
Titanium	Capacitive	Double Layer Charging	• Material is mechanically and chemically stable in the body • Low charge injection capacity	Cardiac pacing applications that require lower charge injection
Platinum	Capacitive Reversible Faradaic: • Oxidation/ Reduction • H Atom Plating	Double Layer Charging $Pt + H_2O \leftrightarrow PtO + 2H^+ + 2e^-$ $Pt + H_2O + e^- \leftrightarrow Pt\text{-}H + OH$ $Pt + H^+ + e^- \leftrightarrow Pt\text{-}H$	• Pseudocapactive (combination of capacitive and faradaic) processes allow for larger charge injection at safe levels than purely capacitive materials	Cochlear implants Nerve cuff electrodes
Iridium	Capacitive Reversible Faradaic: • Oxidation/ Reduction	Double Layer Charging $Ir + 2H_2O \leftrightarrow Ir(OH)_2 + 2H^+ + 2e^-$	• Increased mechanical strength over platinum	Pt/Ir electodes: Spinal cord stimulation, neuromuscular stimulation
Iridium Oxide	Reversible Faradaic: • Valence Change Oxide	$Ir(OH)_n \leftrightarrow IrO_x(OH)_{n-x} + xH^+ + xe^-$	• Multilayer film formed on electrode at tissue interface • Increases charge injection capacity of an Ir or Pl electrode by an order of magnitude	Microelectrodes

neural tissue is to recover as much reversible charge as possible by using a biphasic stimulation pulse, as shown in Figure II.5.12.3. For most neurostimulation systems, the first phase (usually cathodic for the stimulating electrode) activates the neural tissue, and the second phase reverses the capacitive and/or Faradaic charge transfer processes. Electrode material selection is also quite important in ensuring that electrochemical reversal is possible. Several electrode material properties contribute to the ability to achieve electrochemical reversibility:

• *Electrode Capacitance*: A large electrode capacitance translates into a larger fraction of charge transfer occurring via capacitive mechanisms. Capacitively transferred charge is completely reversible, since no electron exchanging chemical reaction occurs. Electrode capacitance is governed by the inherent properties of the electrode material and the area of the electrode. Materials such as titanium nitride (TiN) (Weiland et al., 2002) and tantalum/tantalum pentoxide (McCreery, 1988) can be used to produce electrodes with an interface capacitance that is sufficient for purely capacitive stimulation (without any Faradaic reaction). For some applications, these materials may be practically limited by surface area, because large surface areas are required for delivery of large amounts of charge. However, these materials have been found to be quite useful in the BION® injectible microstimulator. This stimulator is shown in Figure II.5.12.4. It is very small, and combines both the stimulation circuitry and electrode into a single unit that can be implanted with a large needle. This device minimizes
FIGURE II.5.12.3 An example of a balanced biphasic stimulation waveform. The waveform is representative of a typical voltage or current controlled stimulation pulse. The first phase of the pulse is usually cathodic, followed by an interphase wait interval, followed by a passive anodic recharge phase. The recharge phase ensures electrochemical reversal.

the number of electrical components used to reduce its size. As a safety feature, implantable stimulators require an output coupling capacitor to ensure that there is no direct current path from the implanted circuitry to the tissue that could allow tissue damage to occur in the event of an internal failure (Peckham and Ackermann, 2009). By using tantalum for the stimulating surface material the electrode itself is a capacitor, allowing for omission of a discrete capacitor (Loeb and Richmond, 2001).

• *Surface Area*: A large electrode surface area can help ensure electrochemical reversal, because both the electrode capacitance and the amount of electrode material available for reversible Faradaic reactions
FIGURE II.5.12.4 Neurostimulation electrodes. (a) Huntington-type spiral electrode; (b) Case Western spiral nerve cuff electrode; (c) Intramuscular and epimysial electrodes; (d) Peterson type electrode (photograph courtesty of J. Thomas Mortimer, Case Western Reserve University, OH, USA); (e) Medtronic Specify paddle-type and Pisces™ Quad percutaneous-type spinal cord stimulation electrodes. (Photo courtesy of Medtronic, Inc.); (f) BION® microstimulator.

are both proportional to the electrode's surface area. Unfortunately, there is an inherent trade-off regarding electrode surface area: while large surface areas allow for the safe delivery of large currents, they hinder the ability to selectively activate particular portions of neural tissue, because of the physical size of the electrode. One method to circumvent this issue is to modify the surface area of the electrode to give it a microscopically three-dimensional texture. This three-dimensional texture increases the capacitance of the electrode surface without increasing the geometric size of the electrode surface. For example, platinum gray (platinum with an area-increasing surface modification) has a surface area five times greater than standard platinum foil (Zhou, 2005).

- *Electrode-Pseudocapacity*: Electrode materials that are capable of undergoing Faradaic reactions whose products remain bound to the electrode or diffuse away from the electrode–electrolyte interface at a negligibly slow rate are said to have the property of *pseudo-capacity*. The phenomenon is referred to as such because the Faradaic reaction behaves much like a capacive transfer: the slow diffusion of reaction products ensures that most, if not all, of the Faradaic charge transfer is reversible. Platinum is perhaps the most commonly used of all electrode materials, primarily because of its pseudo-capacitive property, owed to the following reaction:

$$Pt + H^+ + e^- \rightleftarrows PtH$$
PASSIVE CHEMICAL PROCESSES AND MECHANICAL INTERACTION OF ELECTRODE AND TISSUE

Like other medical implants, an implanted bioelectrode will elicit some foreign-body response when implanted. This foreign-body response occurs due to passive chemical and mechanical interactions between the implanted device and the tissue (passive chemical interactions refer to those which occur even when stimulating currents are not delivered). The response, which involves macrophage migration to the implant site followed by fibrous encapsulation of the foreign-body, is reviewed in more detail in previous chapters of this book. There are two primary factors which contribute to the foreign-body response of an implanted bioelectrode: chemical biocompatibility and mechanical biocompatibility. Each of these will be considered in more detail.

Biocompatibility: Passive Chemical Processes

The chemical biocompatibility of an electrode is dependent on both the ability of the tissue to withstand the passive chemical interaction with the implant, and the ability of the implant to withstand the environment it is subjected to within the body. Traditionally, successful materials used in implanted devices are inert, and chemically interact as little as possible with their surroundings. A bioelectrode has additional constraints placed on the specific materials used in order for it to effectively stimulate neural tissue. As shown in the Figure II.5.12.1 insert, a bioelectrode is composed of conductive materials that deliver electrical current to target tissue, and insulating materials that limit the region of stimulation to the intended tissues. The insulating material also often serves the additional functional role of maintaining the overall shape and mechanical stability of the electrode. For example, the electrode needs to conform to the anatomy which it is intended to stimulate, and needs to have sufficient rigidity to allow for surgical implantation. As a result, the insulating material often can represent a large fraction of total electrode volume. To minimize the foreign-body response, biocompatible materials that also serve these functional requirements are often used. Commonly used materials include silicone elastomer (Silastic),

pellethanes, and polytetrafluorethylene homopolymer (Teflon®); they are discussed in more detail in preceding chapters. The selection of the conducting material is equally as important, and requires consideration of both the active and passive chemical biocompatibility. Generally, the electrode must be resistant to corrosion and minimize foreign-body response. Noble metals are often preferred, because they resist surface corrosion. Platinum and its alloys with iridium are the most widely used and studied materials. The reader is referred to (Robblee and Rose, 1990) for a further review of these metals and their associated behaviors in response to various stimulation paradigms.

Biocompatibility: Mechanical Interaction of Electrode and Tissue

The three functional requirements of a bioelectrode (efficacy, maintenance of electrode integrity, and maintenance of tissue safety) are well-represented in the mechanical structure of a bioelectrode. To be mechanically effective, the shape of a stimulating electrode must be appropriate for the anatomy of the tissue being stimulated, must maintain the orientation of the stimulating electrode(s) to the neural tissue, must have sufficient rigidity to allow for implantation, must not migrate once implanted, must not damage tissue, and must maintain a stable electrical impedance.

As discussed in the "Neurostimulation Applications" section below, the shape of the electrode must sufficiently conform to the anatomy of the tissue. This shape will depend on the type of tissue being stimulated. For example, nerve cuff electrodes (Figure II.5.12.4) generally wrap around or encircle a nerve, and have a cylindrical shape. Paddle-type electrodes (Figure II.5.12.4) are implanted in the epidural space above the spinal cord electrode for pain control, and have dimensions which allow them to fit into this thin space. The geometric orientation of the stimulating contacts of an electrode is designed to maximize the functional outcomes of a therapy. For example, the inter-contact spacing and orientation of contacts on a spinal cord stimulation electrode is sometimes optimized to minimize total current delivery or to minimize the activation of undesired structures, such as dorsal spinal roots which can cause pain when activated (Holsheimer and Struijk, 1997).

Choosing a material with an appropriate stiffness is an important aspect of electrode design. The electrode must be sufficiently stiff to allow for manipulation by a surgeon, and to maintain its anatomy-conforming shape. However, if an electrode is too stiff it can induce an inflammatory response or damage tissue (Naples et al., 1990). For example, a nerve cuff (Figure II.5.12.4a) which surrounds a peripheral or cranial nerve needs to maintain the conducting electrode contacts in close contact with a nerve to be most effective. However, the cuff needs to be loosely fitting enough to prevent occlusion of the nerve's vascular supply, which has been shown to cause axonal degeneration (Cuoco Jr. and Durand, 2000).

Early designs of fixed diameter cuffs were often very stiff and had to be larger than the nerve to prevent damage due to swelling that occurred in the period immediately following implantation (Ducker and Hayes, 1968). This sometimes resulted in damage to the nerve before long-term encapsulation took place, and likely contributed to thick encapsulation tissue between the electrode and nerve. Thick encapsulation can result in increased electrical impedance or changes in the electrode–nerve orientation which can change the effectiveness of a stimulation therapy. Newer nerve cuff designs implement structural forms that allow the cuff to expand in response to nerve swelling. These include the Case Western Reserve University self-sizing nerve cuff electrode (Figure II.5.12.4b), and the Huntington helical nerve cuff electrode (Figure II.5.12.4a) (Naples et al., 1988; Agnew et al., 1989).

Mechanical impedance matching between electrode and tissue is particularly important when interfacing with small populations of neurons, as occurs with cortical interfacing. In these applications, even thin layers of tissue encapsulation can interfere with the ability to record or stimulate the cells of interest. As a result, materials research in this field has focused on the development of polymers which will not generate a substantial encapsulation (Seymour and Kipke, 2007). Other electrodes, including percutaneous spinal cord stimulation electrodes (Figure II.5.12.4d), achieve a mechanical impedance differential by mating with a stiff metal needle for implantation (North et al., 2002). The stylus is inserted into a lumen within the electrode, allowing for implantation and steering of an electrode into the proper anatomical location by an implanting physician. Once the electrode is in place, the stylus is removed and the mechanically compliant electrode remains.

NEUROSTIMULATION APPLICATIONS

The use of electrical stimulation for medical purposes is not a new idea. It dates back to the recommended use of the electrically active torpedo fish to treat pain from headache or gout by a roman physician in 46 AD. By the 16th century, additional indications for the torpedo fish included melancholy (depression) and epilepsy. Luigi Galvani was the first to demonstrate the use of electric current to elicit a movement, by connecting a bimetallic rod to a muscle in a frog's leg (McNeal, 1977). With the advent of electric generators in the 18th century, the use of electric shocks to treat a variety of ailments surfaced.

Today, electrical stimulation of the spinal cord, peripheral nerves, and cranial nerves is used to treat a variety of diseases and disorders. This section reviews applications for electrical stimulation in clinical practice, and the electrodes used for these applications. The following applications are reviewed: peripheral stimulation for neuromuscular applications, cranial nerve stimulation, spinal cord stimulation for pain, peripheral nerve stimulation and block for pain, and genitourinary stimulation.

Neuromuscular Stimulation

The use of electrical stimulation to elicit functional movement of skeletal muscle is often called Functional Electrical Stimulation (FES). This type of stimulation has primarily been used to restore motor function in individuals suffering from paralysis resulting from injury or disease (primarily spinal cord injury or stroke). Motor FES systems target the peripheral nervous system by electrically stimulating motor neurons that innervate specific muscles of interest (Grill and Kirsch, 2000). By stimulating these motor neurons, the muscles they innervate can be activated in a coordinated fashion to re-establish functional movements, such as grasping with a paralyzed hand (Kilgore et al., 2008; Peckham et al., 2001), standing with the aid of a walker (Fisher et al., 2008; Agarwal et al., 2003), stepping (Marsolais and Kobetic, 1987), and support of a paralyzed torso through activation of the trunk musculature (Triolo et al., 2009).

While surface and percutaneous FES systems have been developed, an implantable FES system will be the focus of this section. Like other implantable neural stimulators, this type of system is composed of an IPG, leads, and electrodes (with the exception of FES systems utilizing the BION®, which will be discussed below). Uniquely, these implants may have as many as 16 leads emerging from the IPG, since this type of system must sometimes activate many muscles in locations around the body (Smith et al., 1998). Figure II.5.12.5 shows a 16-channel FES system developed at Case Western Reserve University. Several types of electrodes have been developed for use in motor FES: epimysial electrodes, intramuscular electrodes, nerve cuff electrodes, and the BION® electrode/microstimulator. The physical form, material composition, and therapeutic indications of each of these electrodes will be considered.
FIGURE II.5.12.5 16-channel implantable motor functional electrical stimulation system developed at Case Western Reserve University OH, USA.

Epimysial Electrodes

Epimysial electrodes are sutured to the surface of a muscle near the motor point, the location where a nerve inserts into the muscle. Epimysial electrodes were first considered in the 1980s and 1990s for use with an implantable FES system to restore hand grasp to individuals with spinal cord injury at Case Western Reserve University (Peckham, 2005; Keith et al., 1989). These electrodes were demonstrated to have a simple implantation procedure, and showed good mechanical integrity during muscle contraction and movement (Smith et al., 1988). An 8-channel hand grasp system marketed under the name Freehand was briefly available and implanted in more than 250 people worldwide (Peckham, 2005). This system is no longer commercially available today; however, advanced systems built upon that technology continue to use epimysial electrodes for stimulation of muscles in the upper and lower extremities.

These electrodes are constructed using molded silicone elastomer (a Dacron®-reinforced Silastic® sheeting molded in Silastic MDX4-4210 elastomer, Dow Corning, Midland, MI, USA) with a 10 mm^2 diameter stimulating disc made from 90% Platinum (Pt) and 10% Iridium (Ir) (Uhlir et al., 2004). A photograph of an epimysial electrode can be seen in Figure II.5.12.4c. The electrode leads are made in a variety of lengths, to accommodate muscles located at different distances from an implanted stimulator.

Intramuscular Electrodes

Intramuscular-type electrodes incorporate barbed structures, and are inserted into the belly of a muscle near the motor point. The small profile and suture-free implantation facilitates a less invasive percutaneous surgical approach. This type of electrode has been implemented for several applications, including the restoration of respiratory and motor function to the paralyzed (DiMarco et al., 2005; Peterson et al., 1989).

Early intramuscular electrodes were developed for restoring respiratory function in spinal cord injury. These types of systems can reduce the amount of time spent on a ventilator for someone with diaphragm paralysis. The Peterson pacing electrode is designed for insertion into the diaphragm muscle, and is composed of two helically wound, Teflon®-insulated, multi-stranded 316 stainless steel wires. A photograph is shown in Figure II.5.12.4d. Each wire is partially deinsulated to form a stimulating tip. Polymer barbs at the distal end of the electrode surround the circumference of the tip, and are designed to anchor the electrode in place, reducing electrode migration that could result from motion within the muscle (Peterson, 1989). An elastic polymer core is threaded through the center of the helix, making the electrode more stable for insertion. This can be removed after implantation to promote tissue ingrowth into the lead's

open helix, which improves the mechanical stability of the lead (Peterson, 1989).

A similar intramuscular electrode was created for use with the implantable motor FES systems. For these applications, intramuscular electrodes enable implanting surgeons to reach small or deep muscles that are challenging to reach with epimysial electrodes (Memberg et al., 1989). The primary difference between this electrode and the Peterson electrode is that Silastic® tubing is placed around the outside of the coil, rather than using a polymer core. A photograph is shown in Figure II.5.12.4e. The tubing prevents fibrotic ingrowth that may increase stiffness. Maintaining flexibility in an electrode lead is important in applications such as a hand grasp restoration, for which leads must cross the elbow joint. The electrode tip is created by wrapping 316 stainless steel, which is continuous with the lead, around the outside of the Silastic® tubing. The lead contains two redundant conductors which are insulated with Teflon® and wound together in a double helix. A polypropylene anchor is attached to the end of a tip to secure the electrode in the muscle (Memberg et al., 1989).

Nerve Cuff Electrodes

A nerve can also be stimulated directly via a cuff electrode that wraps circumferentially around the nerve. This method has been implemented with implantable clinical devices since the late 1960s, when it was used in a phrenic nerve pacing system for the restoration of respiratory function in spinal cord injury (Glenn et al., 1970). The phrenic nerve innervates the diaphragm, and like diaphragm pacing, cyclic phrenic nerve stimulation generates paced contractions for breathing.

Many nerve cuff electrodes have been designed and implemented for various neuromuscular applications, including phrenic nerve pacing for respiration (Glenn et al., 1970), peroneal nerve stimulation for the treatment of post-stroke hemiplegia (paralysis on one side of the body) (Waters et al., 1975), and restoration of motor function to individuals with spinal cord injury (Fisher et al., 2008; Polasek et al., 2007). Nerve cuff electrodes have several advantages over epimysial or intramuscular electrodes, including the ability to simultaneously activate multiple muscles using a single channel of stimulation, a reduced number of required surgical incisions, and lower power requirements to achieve muscle contraction (Naples et al., 1988; Veraart et al., 1993). However, these electrodes have not yet replaced epimysial or intramuscular electrodes, because it is difficult to selectively activate the muscles of interest in a nerve which innervates multiple muscles. New cuff electrodes, not yet implanted chronically in humans, are designed to reshape the nerve, and may help improve selectivity (Schiefer et al., 2008; Tyler and Durand, 2002).

As discussed in the section on mechanical biocompatibility above, nerve cuff electrodes interface directly with a nerve, and therefore careful mechanical design is imperative. Designs that allow for post-surgical swelling of a nerve without occlusion of vasculature have been the most successful (Naples et al., 1988; Agnew et al., 1989). These electrodes tend to be made of molded Silastic®, with one or more platinum or platinum-iridium electrode contacts exposed within the cuff. Pictures of the self-sizing nerve cuff electrode designed and built at Case Western Reserve University and the Huntington spiral nerve cuff electrode are shown in Figure II.5.12.4.

BION® Microstimulator

The BION® microstimulator is a miniature, self-contained, implantable neurostimulator. First designed at the University of Southern California and Illinois Institute of Technology as a platform technology, the BION® has been used in a variety of clinical research studies. One of several versions of the BION® is displayed in Figure II.5.12.4f. Motor applications for the microstimulator include stimulation of the peroneal nerve to correct footdrop in incomplete SCI, and stimulation of the upper extremity muscles to improve grasp in stroke (Wilson et al., 1988; Schulman et al., 2004). The design incorporates both the IPG and the electrode into a small capsule measuring 28 mm in length and 3.2 mm in diameter that can be injected into a muscle using a large needle (Carbunaru et al., 2004). The first generation BION® utilized an external RF power and communication coil placed on the skin over the microstimulator. A BION® that incorporates an integrated battery is currently manufactured by Bioness, Inc. (Valencia, CA, USA). The miniature device contains a stimulating microchip, in addition to the stimulating electrodes. An external controller allows the user to control the device during typical use.

Spinal Cord Stimulation

Stimulation of the dorsal column fibers in the spinal cord to treat pain was first introduced following the publication of a seminal "gate control" theory of pain by Melzack and Wall (Melzack, 1965). With this new theory in mind, Shealy et al. implanted the first dorsal column stimulator in an individual with terminal metastatic cancer at Western Reserve University, USA (Shealy et al., 1967). The initiating principle for the therapy was that selective stimulation of large afferent fibers in the dorsal column would "shut the gate" to small afferent fibers signaling pain. It is now clear that the mechanism of action for spinal cord stimulation, SCS, is likely more complex than the gate theory predicts, and is still not fully-understood (Falowski et al., 2008). Current research suggests that SCS affects processes at several levels of the nervous and vascular system that may play a role in pain relief. The reader is referred to the following publication for a further review of the mechanisms thought to be involved in SCS (Oakley and Prager, 2002). The most successful indications for SCS include intractable angina

(90% effective), complex regional pain syndromes I and II (84% effective), ischemic limb pain (77% effective), and low back and leg pain (62% effective) (Cameron, 2004; DeJongste, 2000).

Spinal cord stimulation therapies are currently available from three companies: Medtronic, Inc.; Boston Scientific, Inc.; and Advanced Neuromodulation Systems (ANS) – a St. Jude Medical subsidiary. Like other neurostimulation systems, each system consists of an IPG, one or more leads, and an electrode or electrode array. Two types of electrodes are used for spinal cord stimulation: percutaneous-type electrodes and paddle-type electrodes. Each of these electrodes will be discussed in further detail below.

Percutaneous Electrodes

Percutaneous electrodes were initially developed to screen potential candidates for an implantable spinal cord stimulator with paddle electrodes (North et al., 2002). The procedure was so successful that these electrodes were then adopted for long-term use. These electrodes are placed using a fluoroscopically-guided needle procedure, similar to that performed for epidural drug injection. These electrodes tend to have either four or eight cylindrical contacts, as shown in Figure II.5.12.4e. The contacts are circumferential, resulting in a stimulation current that is distributed around the entire circumference of the electrode. These circumferential contacts are required, since the orientation of the electrode cannot be easily determined during the implantation procedure, but cause current flow to non-neural tissue and a resulting higher power cost than a paddle electrode (Falowski et al., 2008). Two, or in rare cases, three electrodes can be placed in parallel to one another in order to use current steering methods to shape the electric field. Figure II.5.12.6 shows a representation of percutaneous-type electrodes using a heterogeneous field to stimulate

FIGURE II.5.12.6 Representation of two percutaneous-type electrodes exhibiting a heterogeneous field to stimulate a particular volume of the spinal cord. (Photograph courtesy of Medtronic, Inc.)

a particular volume of the spinal cord. Medtronic has three different versions of the Pisces™ Quad and Octad electrode available (four/eight contacts). These differ with respect to the spacing between electrode contacts. Each of these contacts is platinum-iridium, with polyurethane insulation between contacts. The lead is insulated in silicone rubber. Boston Scientific offers a similar lead with eight contacts, the Precision Plus™ lead. These contacts are closely spaced (1 mm separation distance).

While percutaneous electrodes have enjoyed much clinical success, their primary mode of failure is electrode migration after implantation (Rosenow, 2006). An anchor is used to tether the electrode to the surrounding ligamentous tissue to help prevent this migration. Despite electrode migration and the superior average control of stimulation with a paddle electrode, percutaneous electrodes continue to be the more popular therapeutic option, due to the relatively simple and noninvasive implantation procedure.

Paddle-Type Electrodes

Paddle electrodes were the first type of electrode used for SCS. Paddle electrodes are multi-contact arrays of platinum or platinum-iridium with a silicone rubber base. Many paddle-type electrodes have been implemented, but they generally consist of one or more columns of contacts that are oriented along the rostral–caudal dimension of the epidural space of the spinal column. The molded silicone of the electrode guarantees a fixed orientation of the multiple electrode contacts in a paddle electrode. This is ideal for utilizing so-called "current steering" techniques, where currents of varied amplitude are applied to multiple contacts to shape an electric field that will maximize therapeutic benefit. Since each of the electrodes is fixed in the same structure, they do not migrate with respect to one another, an advantage of a paddle-type electrode over percutaneous-type electrodes (which are generally used in pairs). This reportedly contributes to the better therapeutic results seen with this type of electrode (North et al., 2002). Additionally, lower current amplitudes, relative to those used with a percutaneous electrode, can sometimes be used to achieve a given therapeutic effect. This is possible because the conducting contacts of a paddle electrode are oriented towards the spinal cord, which acts to direct the current to the tissue of interest (Falowski et al., 2008). The contacts in a percutaneous electrode are omnidirectional, and thus tend to require higher stimulation currents. In addition, in a controlled randomized study of paddle verses cylindrical percutaneous electrodes for SCS, subjects with paddle electrodes reported significantly better results in terms of pain coverage by parasthesia (North et al., 2002).

Medtronic currently offers the Specify™ lead with 8 electrodes in two parallel line configurations or the Specify™ 5-6-5 lead with 16 electrodes spaced into three columns. Boston Scientific has a similar paddle lead available
known as the Artisan™, with 16 contacts aligned in two parallel columns of 8 contacts each. The first transverse tri-polar paddle electrode was made available from ANS, and consists of three columns of electrode contacts that run rostral–caudally. Tri-polar stimulation is thought to better confine stimulation to the dorsal column fibers, without activating spinal root fibers that can cause discomfort (Holsheimer and Struijk, 1997).

The primary disadvantage of a paddle electrode, and the reason that percutaneous electrodes are more frequently used, is the required implantation procedure. A paddle electrode requires a laminectomy (removal of portions of vertebrae) to be placed in the epidural space. This procedure can be performed under local anesthetic, but requires a skilled surgeon. Alternatively, percutaneous electrodes are frequently implanted by a trained anesthesiologist/pain specialist, and do not require a laminectomy.

Peripheral Nerve Stimulation and Block for Pain

Peripheral nerve stimulation (PNS) for the relief of pain has been in use since the 1960s, when Sweet and Wall first stimulated their own infraorbital nerves with needle electrodes to show decreased pain sensation (Wall and Sweet, 1967). There are two broad types of strategies for treating pain by delivery of electrical currents to a peripheral nerve: the first is to *induce* action potential activity in sensory fibers that *do not* transmit pain; and the second is to *block* action potential activity in sensory fibers that *do* transmit pain.

Activating nerve stimulation (commonly referred to as peripheral nerve stimulation, PNS) therapies involve the delivery of current pulses to an electrode near, around or within a peripheral nerve to activate large sensory afferents that do not produce a painful sensation when stimulated. These strategies produce a tingling paresthesia sensation that is associated with decreased pain in the stimulated area. The mechanisms of action are a current topic of research, but are thought to involve suppression of pain-related neural activity at the level of the spinal cord (Wall and Sweet, 1967), and/or excitation of central pain processing pathways (Bartsch and Goadsby, 2002; Le Doare et al., 2006). Activating PNS has been employed to treat numerous neuropathic pain conditions (those arising due to injury or disease of the nervous system), such as postherapeutic neuralgia (Dunteman, 2002), occipital neuralgia (Weiner and Reed, 1999), transformed migraine (Charles and Popeney, 2003), cluster headache (Burns et al., 2007), inguinal neuralgia (Stinson, 2001), fibromyalgia (Thimineur, 2007), postsurgical pain (Waisbrod, 1985), complex regional pain syndromes (Hassenbusch, 1996), hemicrania continua (Bartsch et al., 2009), and coccygodynia (Kothari, 2007). PNS has not seen the same widespread clinical deployment as spinal cord stimulation (which is an increasingly common therapy for intractable pain conditions), but there has been a recent surge in both the clinical prescription and research of PNS, as it continues to show therapeutic efficacy (Slavin, 2008).

Three types of electrodes are used for PNS: percutaneous cylindrical electrodes; paddle-type electrodes; and nerve cuff electrodes (Waisbrod, 1985) (which are less commonly used). The cylindrical and paddle-type electrodes are the very same type of electrodes which are used for spinal cord stimulation. Percutaneous electrodes are the most commonly used, due to their suitability for minimally invasive implantation with a fluoroscopically guided needle procedure. Paddle-type electrodes provide advantages over percutaneous electrodes, because they generally result in stable stimulation thresholds (Jones, 2003) and minimal electrode migration. Despite these functional advantages, this type of electrode requires a more invasive surgical procedure for implantation, and is therefore less commonly used.

Percutaneous and paddle-type electrodes are generally placed transverse to a nerve of interest to maximize the likelihood of having at least one contact in proximity to the nerve of interest (Popeney and Alo, 2003). Peripheral nerve cuff electrodes (see the previous "Neuromuscular Stimulation" section for more detail on nerve cuff electrodes) can provide significant selectivity for the nerve of interest (Tarler and Mortimer, 2004), and generally require lower currents to activate nerves than cylindrical or paddle-type electrodes (Naples et al., 1990). However, nerve cuff electrodes are not commonly used for PNS, due to the complexity of surgical implantation and because of a lack of commercially available electrodes which can be used with available IPGs.

The second strategy for treating pain (or other disorders associated with pathological or undesired peripheral nerve activity) by delivery of electrical currents to peripheral nerves is to block peripherally arising pain signals from reaching the central nervous system with an electrical nerve block. Electrical nerve block techniques are not yet used in the clinical environment, but are an area of current research with increasing interest. These techniques generally operate by electrically inactivating the sodium channels responsible for action potential conduction. Methods for achieving this include using direct (Bhadra, 2004) or alternating high frequency currents (Kilgore, 2004), and a technique referred to as "collision block," which involves proximally generated unidirectional action potentials to annihilate those traveling from the periphery (Van Den Honert and Mortimer 1981).

These techniques employ significantly different electrode designs than other PNS therapies. While other electrode designs have been used successfully (Joseph et al., 2007; Ackermann et al., 2010), most peripheral nerve block studies utilize nerve cuff electrodes. Electrodes for nerve block have a fundamentally different requirement than electrodes for activation: they must not only block peripherally generated action potentials, but they

must not generate any action potentials that will travel proximally to the central nervous system and relay a pain signal. This is generally accomplished by careful design of the blocking current waveform (Van Den Honert and Mortimer, 1981), and using a nerve cuff design that will contain the blocking currents within the nerve cuff, limiting "leakage currents" that can cause activation of fibers (Van Den Honert and Mortimer, 1981). The configuration of the conductive contacts within the nerve cuff influences the field seen by the nerve fibers, and can therefore be optimized to block the nerve with lower amplitude currents. Lower amplitudes are generally associated with less power consumption and a safer therapy, and are therefore preferred (Merrill et al., 2005).

Cranial Nerve Stimulation

Cranial nerves differ from other nerves in the body, in that they emerge directly from the brainstem, rather than from the spinal cord. These nerves stem from or innervate cells in nuclei of the brainstem, hence electrical stimulation of these nerves may have a direct impact on neural pathways in the central nervous system. Three specific cranial nerves have been identified as therapeutic targets for electrical stimulation: the cochlear nerve to restore hearing in individuals with deafness; the vagus nerve to decrease epileptic seizures and to treat depression; and the trigeminal nerve, to decrease epileptic seizures and to treat facial pain. Cochlear implants are discussed in Chapter II.5.11. Applications related to vagus nerve stimulation and trigeminal nerve stimulation are considered here.

Vagus Nerve Stimulation (VNS). Vagus nerve stimulation for the treatment of epilepsy was first proposed by Dr. Jacob Zabara in 1985 (Terry et al., 1991). The mechanism is not well-understood; however, studies suggest that stimulation of the afferent neurons in the vagus nerve alter brain function to help suppress seizures (Groves and Brown, 2005). PET scans during stimulation have shown an increase in blood flow in certain areas of the brainstem, hypothalamus, and insular cortices, and a subsequent decrease in blood flow in other deep brain structures (Mapstone, 2008). The blood flow changes to these deeper areas of the brain persist in chronic VNS, and thus may be related to the underlying mechanism of the therapy.

Approved by the FDA (US Food and Drug Administration) in 1997 after two large clinical trials, VNS therapy is used to treat pharmacologically intractable epilepsy in individuals over the age of 12. For approximately 40% of the population with epilepsy, drug therapies are unsuccessful at diminishing seizure frequency (Mapstone, 2008). This VNS therapy is targeted to this population. An implantable VNS device is available from Cyberonics, Inc. The IPG is implanted in the chest, and a lead is tunneled under the skin to the electrode that is implanted on the vagus nerve. Electrical stimulation is applied to the nerve using a Huntington helical cuff electrode. Typically, 30 seconds of stimulation at 30 Hz is applied at five minute intervals (Guberman, 2004). Studies indicate that after chronic stimulation of the recommended duty cycle, 35–45% of the patients see a decrease frequency of seizures exceeding 50%; however, only approximately 2% become seizure free (Mapstone, 2008).

VNS therapy using the Cyberonics device has also been FDA-approved for treatment-resistant depression (Critchley et al., 2007). Again, the mechanism is unclear, but the structures that exhibit blood flow changes in VNS such as the thalami are also involved in mood regulation. VNS has been used in research studies in an attempt to treat a variety of indications for which it does not yet have FDA approval. These include treatment for anxiety, cognitive deficits, and migraines (Groves and Brown, 2005).

The electrode currently used by Cyberonics for VNS stimulation is a modification of the Huntington helix discussed above (see Figure II.5.12.4a) (Agnew et al., 1989). The Huntington electrode, like the self-sizing cuff, is an open helix made of silicone rubber elastomer that can change in size in response to nerve swelling. The conducting surfaces of the electrodes are platinum-iridium ribbons that are helically wound around the nerve. The initial design used seven turns with two contacts. The current version uses two contacts with only a few turns of a helix per contact, and has a gap between the two electrode contacts (Figure II.5.12.4c). Fewer turns per helix makes it more likely for the electrode to slip off the nerve during movement, but minimizes mechanical injury to the nerve by decreasing the length of the individual helix. A third helix located proximal to the electrode contacts tethers the electrode to the nerve, and provides additional mechanical stability. The electrode is anchored in place with sutures. Two helix diameters are available: 2.0 mm and 3.0 mm.

Trigeminal Nerve Stimulation (TNS). Trigeminal nerve stimulation, TNS, has been used as a therapy to treat both intractable neuropathic pain conditions and epilepsy. Epilepsy studies have not utilized implanted electrodes, and therefore will not be considered in further detail. The technique was first used to treat pain in the 1960s (Wall and Sweet, 1967). In 1965, Melzack and Wall published the "gate control" theory of pain, which suggested that stimulation of large diameter cutaneous afferent fibers may reduce pain (Melzack, 1965). Wall adopted this idea, and in 1967 published the first study that used implanted electrodes in the infraorbital region to stimulate a cutaneous branch of the trigeminal nerve to treat trigeminal neuralgia (Wall and Sweet, 1967). Stimulation induced parethesia in particular regions of the face, eliminating pain during stimulation, and in some cases for a period after stimulation had ended as well.

Four or eight contact percutaneous-type electrodes (the same type used for spinal cord stimulation) are generally

used for the TNS pain therapy. Like in spinal cord stimulation, the electrodes are first placed for a trial period to test the effectiveness of the therapy in treating the individual's pain. The electrodes are passed under the skin but above the muscles, and pass perpendicular to the path of the nerve (Slavin et al., 2006). These electrodes are then connected to an external stimulator device. If there is at least a 50% reduction in pain, a permanent IPG system is implanted. Commonly used electrodes include the Medtronic Quad (4-channel) or the Octad (8-channel) (Medtronic, Minneapolis, MN, USA).

Genitourinary Stimulation

Electrical stimulation was first considered as a method for treating urinary retention in 1878, when Saxtroph attempted to stimulate the muscles in the bladder wall using an electrode mounted on a catheter inserted into the bladder (reviewed in Madersbacher (1990)). It was not until the middle of the 20th century that electrical stimulation for the treatment of urine voiding dysfunction became the first area of significant research in the neuromodulation field.

The lower urinary tract has two major functions: to store urine in the bladder (continence) and to void urine (micturition). The muscular layer in the bladder is innervated by parasympathetic neurons stemming from the sacral spinal segments S2–S4. Sufficient bladder emptying requires not only contraction of the bladder, but also relaxation of the urethral sphincter. Various injuries, disorders, and diseases can interrupt these pathways and cause voiding dysfunction. Research studies have explored numerous targets for electrical stimulation to improve bladder management and eliminate reliance on indwelling catheters. This section will review a variety of electrodes that have been used in the past and present in attempt to control bladder function.

Disc Electrodes

The component of the micturition circuit initially targeted for electrical stimulation with an implanted, RF powered device was the bladder wall muscle. Susset and Boctor reported success with an implant that incorporated 8 disc electrodes around the dome of the bladder of an individual with lower motorneuron (LMN) injury (Susset and Boctor, 1967). However, in individuals with a neurogenic bladder (spastic with contractions triggered at low filling volumes) from spinal cord injury, this treatment was not successful, because bladder stimulation also activated the urethral sphincter, preventing voiding in this population (Gaunt and Prochazka, 2009).

Book Electrodes

The first commercially available stimulator for bladder dysfunction, the Finetech-Brindley Bladder System, uses

so-called book electrodes implanted intradurally on the S2–S4 sacral roots of the spinal cord. These sacral roots are stimulated in a cyclical fashion to generate voiding from the bladder (Brindley, 1977). It's slotted "book" shape is designed to confine current to target spinal root without activating neighboring roots (Brindley et al., 1982). The Finetech system uses two book electrodes: an upper book and a lower book. The lower book has a single slot with three electrode contacts for tripolar root stimulation. The S4, and in some cases, S5 sacral roots were placed in the slot of the lower book. The upper book contains three slots, each with three contacts for tripolar nerve stimulation. The S3 roots are placed in the center slot. Bilateral S2 roots were placed in the lateral slots. These lateral slots are electrically connected to apply identical stimulation parameters to bilateral S2 roots. The electrode contacts are made of platinum foil and the books are formed from silicone rubber. The lead cable conductor is a platinum-iridium alloy insulated with polyimide and then coated with silicone (Brindley et al., 1986).

An issue with the initial intradural electrodes was CSF leakage out of the subdural space (Brindley et al., 1986). This complication was prevented in subsequent implants with the use of a grommet composed of fine woven polyester on the outside and silicone rubber on the inside that was then glued around the cables (Brindley et al., 1986). Alternate extradural electrodes have also been used successfully with the Brindley system, and are currently used with the version of the device marketed in the US.

Cuff Electrodes

Cuff-type electrodes have also been implemented for the Finetech-Brindley bladder voiding system. These electrodes can be implemented using a less invasive extradural electrode placement which was required for FDA approval of the device in the US. The first Finetech device with extradural electrodes was implanted in 1986 (Sauerwein et al., 1990). For this type of implant, the leads are connected to the implanted receiver and connect to three tripolar helical electrodes. The electrodes are wrapped around the roots using a strip of Dacron®-reinforced silicone rubber that is sutured closed. The leads are encapsulated in silicone rubber and the electrode contacts are platinum-iridium, like the lead cables for the book electrodes (Egon et al., 1998).

This procedure, unfortunately, requires a dorsal rhizotomy (cutting of the afferent fibers returning to the spinal cord) to limit reflex contractions of the bladder. While the rhizotomy reduces reflex bladder contractions, it also has several negative side-effects that can include the loss of reflex erection and defecation. These side-effects have limited the widespread deployment of this system (Gaunt and Prochazka, 2009), although it has been implemented in more than 2500 people worldwide, and is still commercially available in Europe.
FIGURE II.5.12.7 Illustration of implanted tined lead for Medtronic Interstim® sacral nerve stimulation therapy. Illustration shows sagittal view of sacrum with intraforaminal electrode placement. (Courtesy of Medtronic, Inc.)

Percutaneous Electrodes

In the 1980s, Tanagho et al. first showed that continence could be controlled by low-frequency, low-amplitude stimulation of the sacral roots to maintain sphincter contraction without initiating bladder contractions (Tanagho and Schmidt, 1988). Sacral nerve stimulation can successfully treat non-neurogenic bladder dysfunction including incontinence, urgency-frequency, and urinary retention. Women with Fowler's syndrome, characterized by relaxation of the urethral sphincter and frequent urine leakage, seem to respond especially well to this type of stimulation. Continuous stimulation or a cycling mode of electrical pulses is used to inhibit neural reflexes that may trigger bladder contraction (Kessler and Fowler, 2008). Results from 10 studies, reviewed in Kessler and Fowler, suggest success rates between 55 and 100%.

The sacral nerve can be reached through a relatively non-invasive procedure through the sacral foramina. Medtronic has commercialized the Interstim® therapy, which utilizes a percutaneous electrode technology similar to those developed for spinal cord stimulation. For this therapy, an IPG is typically placed in a subcutaneous pocket in either the lower abdomen or posterior pelvis. The IPG is connected to quadripolar in-line leads that are implanted next to the sacral nerve on one side of the body. Bilateral implementation showed some evidence of improved outcomes (Hohenfellner et al., 1998), but unilateral systems remain the trend to minimize the complexity of the procedure (Kessler and Fowler, 2008). As shown in Figure II.5.12.7, integrated tines fixed to the lead proximal to the cylindrical stimulating electrodes help to prevent migration. The electrode contacts are made of a platinum-iridium alloy, and the tines are made of polyurethane. The insulation for the conductor wires is fluoropolymer.

FUTURE DIRECTIONS

Stimulating bioelectrodes have evolved into highly functional, safe, and reliable implantable medical devices. The use and development of new biocompatible materials holds promise to advance neural interfacing in the spinal cord and peripheral nervous system. Specifically, developments in mechanical impedance matching, nerve tissue selectivity, and improvements in charge density capacity of electrodes are likely to result in improved neural interfaces in the near future. For example, novel polymer materials are being developed with dynamic material stiffness that are stiff when implanted, and become compliant due to changes in temperature or the presence of water once implanted (Capadona et al., 2008). These new materials could allow for ease of electrode implantation and manipulation, while maintaining a minimal foreign-body response. Progress is also being made to improve spatial stimulation selectivity within a nerve. New electrode technologies, such as the Flat Interface Nerve Cuff Electrode (FINE) (Tyler and Durand, 2002) and the University of Utah Array (McDonnall et al., 2004), may be able to selectively recruit individual fascicles within a nerve, and improve motor control in a variety of applications and reduce surgical complexity. Novel materials that allow for increased safe charge injection capacity of small electrodes will also contribute to smaller, and therefore more selective, nerve interfaces.

CHAPTER II.5.13 MEDICAL BIOSENSORS

Lisa LaFleur and Paul Yager
Department of Bioengineering, University of Washington, Seattle, WA, USA

INTRODUCTION

The term biosensor is sometimes broadly defined as a sensor used in the detection or monitoring of any medically relevant parameter, but for this chapter we will define it more narrowly to mean *a sensor that uses biological molecules*, *tissues*, *organisms or principles to measure chemical or biochemical concentrations*. Biosensors can be used in many medical and non-medical applications. Biomedical sensors are sensors that detect medically relevant parameters; these could range from simple physical parameters like blood pressure or temperature, to analytes for which biosensors are appropriate (e.g., blood glucose). This is summarized in Figure II.5.13.1. We will focus on the overlap between these two fields that we are calling medical biosensors: sensors that fulfill the criteria for both classes of sensors.

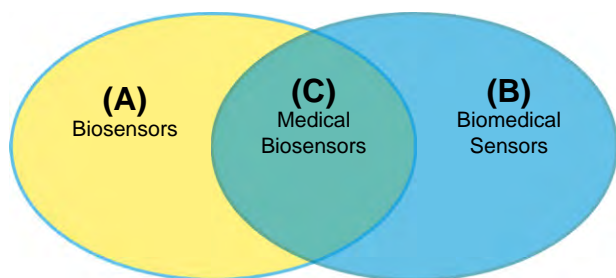
Biosensor development has been a significant activity in the last 50 years. Between 1984 and 1990 there were roughly 3000 scientific publications and 200 patents on biosensors. The number of patents doubled through 1997. The introduction of nanotechnology into the broader field of sensor development led to over 6000 articles and 1100 patents to be issued through 2004 (Luong et al., 2008).


FIGURE II.5.13.1 The Venn diagram of the relationship between biosensors (A) and biomedical sensors (B). In (A) are those sensors that use biological molecules, tissues, organisms or principles in performing its designed function. Examples might include nucleic acid-based sensors for bacteria found in a water supply or enzyme-based sensors for the sugar levels in food. In (B) are sensors used to monitor living organisms, like those for blood pressure, blood pH, blood gases, temperature, and even optical methods for monitoring tissue glucose by observing the near-infrared absorption of glucose. In (C) are the medical biosensors, which meet both criteria, such as sensors for blood glucose that utilize biomolecules like the enzyme glucose oxidase.

TABLE II.5.13.1	Chemical Indicators of Health
Small, Simple	pH (acidity)
↓	Electrolytes (ions)
↓	Blood gases (O_2, CO_2, etc.), including general anesthetics
↓	Drugs and neurotransmitters
↓	Hormones
↓	Proteins (antibodies and enzymes)
↓	Viruses
↓	Bacteria
↓	Parasites
Large, Complex	Tumors

Nanotechnology Applied to Biosensors

In the last decade some old, and some new, phenomena have been collectively labeled "nanotechnology." Some nanostructures and nanodevices have introduced new and useful capabilities to the biosensing world. Nanomaterials fall in the realm between individual atoms and bulk materials, leading to different physical and electrical properties than their bulk relatives. Some nanomaterials are uniquely suited to biosensing, including nanotubes and nanoparticles. Nanotubes are one-dimensional structures whose high surface-to-volume ratio causes their electrical conductivity to be exquisitely sensitive to surface adsorption. As such, nanotubes have been widely used in biosensors (Liu, 2008). One common application is carbon nanotube field effect transistors; antibodies or DNA strands are immobilized on the surface of the nanotube, then any corresponding antigen or complementary DNA strand-binding event can be detected by a change in the electrical conductance of the nanotube.

Another nanotechnology in common use for biosensing is nanoparticles functionalized with biomolecules. Nanoparticles are 1–100 nm in diameter, usually monodisperse, and most commonly made of Au modified by the adsorption of proteins such as antibodies. Au nanoparticles are commonly used in immunoassays. Their unique optical scattering and absorption properties can be exploited in a variety of imaging methods (Aslan et al., 2005). They have also been used to participate in enzyme reactions for which the enzyme is immobilized on the surface of the nanoparticle, and the Au reduces the enzyme as part of a desired reaction (Pandey et al., 2008). Nanotechnology promises to continue to be at the forefront of biosensor development.

BASICS OF BIOSENSING

Both biosensors and biomedical sensors fall into two general categories: physical and chemical. Physical parameters of biomedical importance include pressure,

volume, flow, electrical potential, and temperature, of which pressure, temperature, and flow are generally the most clinically significant, and lend themselves to the use of small *in vivo* sensors. Chemical sensing generally involves the determination of the concentration of a chemical species in a volume of gas, liquid or tissue. The species can vary in size from the hydronium ion to a live pathogen (see Table II.5.13.1); when the analyte is complex, an interaction with another biological entity may be required to recognize it. In general, it is necessary to distinguish this chemical species from a number of similar interferents, which can be technologically challenging, but this is an area in which biosensors excel.

Glucose Sensors: First and Foremost

Early biosensor technology was almost exclusively geared towards monitoring blood glucose in diabetics, largely because of the number of patients with the disease, and the potential for reducing morbidity and mortality by adjusting the dosage of insulin to better control the analyte. According to the World Health Organization, there were approximately 171 million people suffering from diabetes worldwide in 2000; that number is expected to at least double by 2030 (Wild et al., 2004). In the late 1950s, several paper-based biosensors were developed for semi-quantitative glucose detection by monitoring a color change when the paper was dipped in urine (Comer, 1956; Free et al., 1957). The paper was embedded with glucose oxidase and other enzymes, so that the reaction between glucose, glucose oxidase, and the other enzymes produced a color. However, urine is not an ideal sample, as there is a substantial and uncontrolled lag between the concentration of glucose in urine and the critical blood glucose level. Later, using this same chemistry, optical absorbance was utilized for more quantitative measurements (Grady and Lamar, 1959; Kingsley and Getchell, 1960). Some even went so far as to demonstrate how a device could continuously perform *in vivo* measurements (Weller et al., 1960).

The first electrochemical glucose assay was described in 1961 (Malmstadt and Pardue, 1961). It was a potentiometric sensor, monitoring the electrical potential

difference between two electrodes. Several amperometric sensors – sensors that monitor changes in electrical current in the system – were also developed in the late 1960s (Updike and Hicks, 1967). The first commercialized self-contained glucose analyzer was introduced by Yellow Springs Instrument Company in 1975; it was an amperometric sensor that monitored the production of hydrogen peroxide resulting from the breakdown of glucose by the enzyme glucose oxidase (Heller and Feldman, 2008). This demonstration that biomolecules could be part of a practical biomedical sensor spurred basic and applied research efforts for next 30 years.

Major advances have been made since the first commercial biosensors, leading to many simple self-tests that give patients the ability to control their blood sugar. The vast majority of these tests utilize blood collected from finger-sticks, which can be painful and usually must be done many times per day. Many less-painful testing techniques have been promoted over the years, but few have proven clinically or commercially viable. The optimal scenario, however, is continuous monitoring linked to therapeutic systems and centralized medical databases. Medtronic, Inc. has produced a device called the MiniMed Paradigm® that does operate continuously and connects to an automatic insulin pump. The glucose sensor is percutaneous and lasts for up to three days.

The most common mechanism for the operation of glucose sensors is the enzymatic oxidation of glucose by the enzyme glucose oxidase, as shown in Figure II.5.13.2. Potentiometric sensors measure the difference in electrical potential between two electrodes. An early potentiometric glucose sensor by Updike et al., shown schematically in Figure II.5.13.3, provides a simple example of the design and operation of such sensors (Updike and Hicks, 1967). In the case of the Updike sensor, the electrodes detected a decrease in the concentration of oxygen due to reaction with glucose.

The working platinum electrode was surrounded by a semi-permeable dialysis membrane to limit the molecules that could reach the electrode. Technological advances in materials science have led to a wide variety of very specific semipermeable membranes, including low molecular weight filters, ion-selective membranes, and others.
Electrochemical methods of glucose detection using trapped glucose oxidase were among the first to be tried clinically, but were thought to have some disadvantages for *in vivo* use: electrical wires in the body pose a risk of electrical shock. An alternative sensing modality that was thought to be safer for *in vivo* use was fiber optics. The first successful *in vivo* fiber optic measurement of pO_2 was reported by Peterson in 1984. More recently, many variations on fiber optic biosensors have been applied to *in vivo* glucose monitoring, including near-infrared non-invasive imaging (Maruo et al., 2003), fluorescence resonance energy transfer (Liao et al., 2008), and a dual sensor system by Pasic et al. that uses a reference fiber to compensate for local variations in oxygen concentration that affect the sensor's signal output (Pasic et al., 2007). This sensor system, shown in Figure II.5.13.4, has a diffusion barrier covering an immobilized enzyme, and also
FIGURE II.5.13.3 A schematic representation of the potentiometric glucose sensor developed by Updike and Hicks in 1967. Glucose oxidase is immobilized in the enzyme gel layer outside a semipermeable membrane that allows oxygen gas to pass through. The sensor detects a decrease in oxygen resulting from the reaction of glucose and oxygen to form gluconic acid and hydrogen peroxide.
FIGURE II.5.13.4 Optical fibers forming a glucose sensor system. (A) Fiber uses immobilized glucose oxidase covered by a diffusion barrier to monitor oxygen depletion. (B) Fiber measures local oxygen concentration. Signal reported is the difference between the two, accounting for variations in local oxygen concentration. (Redrawn from Pasic et al. (2007). *Sensors and Actuators B*.)

FIGURE II.5.13.2 The reaction where glucose is converted to gluconic acid in the presence of oxygen with hydrogen peroxide as a byproduct.

utilizes glucose oxidase. This sensor was designed to be implanted subcutaneously.

Due to the limited space in this chapter we can't present examples of every type of biosensor. However, Table II.5.13.2 provides an overview of the different sensing modalities, and some of the potential biosensing applications. The biosensors described throughout the rest of this chapter provide more in-depth examples of how these sensing modalities can be applied. For a more thorough review, we recommend recent reviews of the field.

Interaction of Sensor with Environment

One helpful way to classify sensors is to consider the relationship between the sensor and the analyte, as shown schematically in Figure II.5.13.5. The more intimate the contact between the sensor and the analyte, the more complete is the information about the nature of the chemical species being measured. However, obtaining greater chemical information may involve some hazard to the physical condition of the system being studied. This is not a trivial problem when dealing with human subjects.
Noncontacting Sensors. Noncontacting sensors produce only a minimal perturbation of the sample to be monitored. In general, such measurements are limited to the use of electromagnetic radiation such as light or sampling the gas or liquid phase near a sample. It may even

be necessary to add a probe molecule to the sample to make the determination.
Contacting Sensors may be either Noninvasive or Invasive. Direct physical contact with a sample allows a rich exchange of chemical information; much effort has been put into developing practical contacting sensors for biomedical purposes. A temperature probe can be in either category, but with the exception of removing or adding small quantities of heat, it does not change the environment of the sample. Few chemical sensors approach the non-perturbing nature of physical sensors. All invasive sensors damage the biological system to a certain extent, and physical damage invariably leads to at least localized chemical change. Tissue response can, in turn, lead to spurious sampling. Furthermore, interfacial phenomena and mass transport govern the function of sensors that require movement of chemical species into and out of the sensor. Restrictions on the size of the invasive sensor allowable in the biological system can limit the types of measurements that can be made; even a 1 mm diameter pH electrode is of no use in measuring intracapillary pH values.
Sample Removal Sensors. Most contacting sensors are derived from chemical assays first developed as sample removal sensors. While it is certainly invasive and traumatic to remove blood or tissue from a live animal, removal of some fluids, such as urine and saliva, can be achieved

TABLE II.5.13.2	Applications of Different Sensing Modalities to Biosensors		
Sensing Modalities	**Description of Operation**	**Potential Applications**	**Advantages/Disadvantages**
Acoustic	Binding of mass to oscillating surfaces allows propagation of acoustic waves along or under the surface or resonant condition of device	Detection of mass accumulation on surface in real-time; made selective by coating surface with polymers or binding molecules	Excellent mass sensitivity but no inherent sensitivity to chemicals; vacuum and air are best media due to inherent drag in liquids
Cantilever motion or deflection	Static deflection of cantilever caused by binding to one side or alteration in resonant frequency of cantilever	Binding of molecules to a prepared surface or presence of particles in fluids	Excellent mass sensitivity. Static deflection is slow, alteration of resonant frequency with wet samples requires encapsulation of fluid path
Amperometric	Current generated by a reaction at an electrode	Monitor redox reactions, enzyme-catalyzed reactions or generation of any charged species	Good sensitivity, wide range of detectable species; currents between electrodes can interfere with biological activity
Thermal	Coupling of reactions that produce or consume heat to detect presence of analytes or when coupled to binding reactions, as a method to detect binding	Usually in laboratory-based reactors where "thermal noise" can be minimized	Good generic sensing modality, but generally insensitive
Optical	Change in light frequency, phase intensity or lifetime in simple evanescent fields	Many configurations including placing sensitive chemistry at terminus of optical fiber material, monitoring fluorescent reaction products, and detection of nanoparticles	Excellent broad applicability, many direct and probe-based methods available. Can generate unwanted heat in a sample; fluorescent species susceptible to photobleaching; potential safety concerns over use of nanoparticles
Potentiometric	Potential changes at a surface; may be in a conventional two-electrode circuit or at the surface of a field-effect transistor	Monitor change in concentration of charged species, typically small molecules or pH changes	Relatively insensitive

FIGURE II.5.13.5 Comparisons of the interaction between the sensor (nose) and analyte (fish) for different types of detection.

TABLE II.5.13.3	Overview of Biosensor Design Considerations
What is a biochemical species that responds predictably to changes in the chemical state (i.e., glucose concentration) you want to study?	
Is there a convenient method of chemical-to-electrical transduction?	
Does binding of the biochemical species perturb the system?	
Does measurement of the biochemical species consume it?	
What other species intefere with measurement?	
How accurate and precise are the measurements?	
What is the response time of the sensor?	
Is sensor response stable and can it be calibrated?	
What are acceptable operating conditions?	
Can the sensor be made at low cost?	
What impact does the presence or operation of the sensor have on the patient?	

sensors to produce a reliable output. Table II.5.13.3 summarizes the primary design considerations that must be considered when developing a biosensor.

Selectivity Inherent to Biosensing

An advantage biosensors have over other types of sensors is that they utilize the billions of years of evolution that have produced extreme selectivity and sensitivity in the binding between biomolecules. Antigen–antibody complexes, complementary DNA strands or DNA/RNA complexes, and other specific biomolecule pairs like biotin-streptavidin are commonly used in biosensing, because of their high selectivity and sensitivity. The human body is capable of producing 10^8 distinct antibody species (Nelson and Cox, 2005). These antibodies can bind to antigens ranging from small molecules to proteins to viral capsids to bacterial cell walls. All biomolecular interactions are characterized by rates of association (binding) and dissociation (unbinding); however, the rates of dissociation for useful complexes are far less than the rates of association. Careful choice of highly selective biomolecules is central to good biosensor design.

CHALLENGES IN BIOSENSING

First, Do No Harm

The introduction to the body of a sensor is a traumatic event, although the degree of trauma depends on the site of placement. The gastrointestinal tract can clearly be less traumatically accessed than the pulmonary artery. Critically ill patients often must have catheters placed into their circulatory systems for monitoring of blood pressure and administration of drugs, fluids, and food, so that no *additional* trauma is caused by including a small flexible sensor in that catheter.

When short-term implantation in tissue is possible, there is initial trauma at the site of insertion. Longer-term implantation increases the risk of infection along the surface of the implant. When the site of implantation of the probe is the circulatory system, the thrombogenicity of the probe is of paramount importance. Surface

without trauma. Once removed, a fluid can be pretreated to make it less likely to adversely affect the functioning of a sensor. For example, heparin can easily be added to blood to prevent clotting in an optical measurement cell. Cells that might interfere with optical assays can also be removed prior to measurement. Toxic reagents and probe molecules can be added at will, and samples can be fractionated to remove interfering species. The sensor and associated equipment can be of any size, be at any temperature, and use as much time as necessary to make an accurate measurement. Further, a sensor outside the body is much easier to calibrate. This approach to chemical measurement allows the greatest flexibility in sensor design, and avoids many biocompatibility problems.

Biosensor Design Goals and Constraints

All biosensors are governed by specific chemical and biological reactions that need to be identified and closely controlled for accurate biosensing. Numerical output from a biosensor only provides information indicative of the rate-limiting step of any reaction, so the most effective biosensors must be designed to ensure that there is only one potential rate-limiting step. For example, in the potentiometric and fiber-optic glucose sensors described earlier in this chapter, the sensors were intended to measure changes in glucose, so oxygen must be in excess and the glucose oxidase concentration constant for these

chemistry, shape, and placement within the vessel have all been shown to be of great importance in reducing the risk of embolism. Also, sensors based on chemical reactions often contain or produce toxic substances during the course of their operation, so great care must be taken to ensure that these are either not released or are realeased at low enough levels to avoid significant risk to the patient.

Two major questions in the design of any sensor are how often and for how long it is expected to be used. There are several factors to be considered.

Length of Time for which Monitoring is Required. Determination of blood glucose levels must be made for the entire lifetime of diagnosed diabetics, while intra-arterial blood pressure monitoring may only be needed during a few hours of surgery.

Frequency of Measurements. Blood cholesterol only needs to be tested every few years, but for a diabetic blood glucose measurements must be done several times a day, and are most critical after meals and after administration of insulin.

Reusability of the Sensor. Some chemical sensors contain reagents that are consumed in a single measurement. Such sensors are usually called "dip-stick sensors," such as are now found in pregnancy testing kits and other rapid immunoassays. High affinity antibodies, for example, generally bind their antigens so tightly that they cannot be reused. On the other hand, most physical and chemical sensors are capable of measuring the concentration of their analyte on a continuous basis, and are therefore inherently reusable.

Lifetime of the Sensor. Chemical sensors all have limited lifetimes, because of such unavoidable processes as oxidation, and while these may be extended through low-temperature storage, *in vivo* conditions are a threat to the activity of the most stable biochemical. Most sensors degrade with time, and the requirement for accuracy and precision usually limit their practical lifetime, particularly when recalibration is not possible.

Appropriateness of Repeated Use. The need for sterility is the most important reason to avoid reuse of an otherwise reusable sensor. If it is not logistically possible or economically feasible to completely sterilize a used sensor, it will only be used on a single individual, and probably only once.

Biocompatibility. If the performance of a sensor is degraded by continuous contact with biological tissue or if the risk to the health of the patient increases with the time in which a sensor is in place, the lifetime of the sensor may be much shorter *in vivo* than *in vitro*.

As a consequence of all of these factors in the design of an integrated sensing system, the probe – that part of the sensor that must be in contact with the tissue or blood – is often made disposable. Probes must therefore be as simple and as inexpensive to manufacture as possible, although it is often true that it is the sale of consumables such as probes that can be more profitable than the sale of the device itself.

All Sensors are Affected by Biofouling

After careful choice of target species and designing your sensor to keep this species the rate-limiting factor, the next most important consideration for biosensor design is preventing sensing inaccuracy due to sampling a microenvironment created by biofilm formation. It is difficult to prevent biofilm formation on surfaces exposed to active media, such as bacterial or eukaryotic cell cultures. The growth of a biofilm on a sensor degrades its performance; in the most extreme case, the sensor can become sensitive only to conditions in the biofilm. Biofilms often consist of bacteria embedded in a secreted matrix of complex polysaccharides. While the microenvironment of these films may be beneficial to the bacteria, it is detrimental to the function of the sensor for several reasons. First, the chemistry of the film may damage structural or active components of the sensor. Second, if the film completely encloses the sensor, only the film's microenvironment is sensed, rather than the solution that surrounds it. If the living components of the film metabolize the analyte to be sensed, it may never reach the sensor. Even a "dead" film may exclude certain analytes by charge or size, and thereby lower the concentration available for sensing at the surface below the film. If a sensor used *in vitro* is fouled, it can often be removed, cleaned, and restored to its original activity. For example, carbon electrodes containing immobilized enzymes can be restored by simply polishing away the fouled surface. When sensors are used *in vitro* for monitoring the chemistry of body fluids, preprocessing can be used to reduce the accretion of biofilms that might impede the function of the sensor (Gifford et al., 2006; Li et al., 2007).

In vivo sensing has all the problems associated with *in vitro* sensing, plus the additional effects of the sensor on the body. *In vivo* sensors do not have the luxury of being able to be easily removed, cleaned, resterilized or recalibrated, then returned to the sensing site. The combination of microenvironment formation and damage to the body often limit the utility of *in vivo* sensors to short use. In some cases, it has been found that the problems are almost immediate, producing spurious results from the outset. Subcutaneous glucose needle electrodes have been found to give accurate results *in vitro* before and after producing erroneous values *in vivo*. The biological environment may simply make it impossible to perform accurate chemical measurements with certain types of sensors.

Sample removal systems are not immune to all the problems of biofouling that plague *in vivo* and *in vitro* biosensors. Whole blood samples still contain encapsulating eukaryotic cells, but even the removal of these still poses a biofouling problem for all biosensors. Human biological samples contain a wide variety of proteins, fats, mucins, carbohydrates, and other highly fouling substances. The biological materials most responsible for biofouling, and some of their adhesion and encapsulation mechanisms, are described thoroughly throughout this text.

BIOFOULING PREVENTION METHODS

Methods to minimize the effects of biofouling in biosensors are similar to those used in other biomaterials applications. However, a critical requirement in many biosensors is that the "working" surface still allows components of the sample to reach the (reactive) surface below. Therefore, inclusion of holes through the non-fouling surface can be vital.

Blocking for Biofouling Prevention

Blocking is a nearly ubiquitous method for coating the non-functionalized regions of a biosensor to prevent non-specific binding and delay biofilm formation. There are many ways to implement this process, but all include the same basic principle: an unreactive molecule is applied to portions of the biosensing surface or non-sensing regions of the biosensor, to prevent other molecules from binding to the sensing region. Blockers can be adsorbed to the surface, covalently attached, joined using a self-assembled monolayer or by any other means of keeping the surface coated. A common theme among blockers is that they present hydrophilic groups to the area around the biosensor. Some of the most common blocking materials include polyethylene glycol (PEG), non-reactive globular proteins and surfactants. Application method and uniformity of the blocking materials can have a large impact on antifouling effectiveness.

PEG. There are many variations of PEG used as blockers in biosensing: a range of molecular weights have been shown to be effective (500–2000), and a variety of structures including straight chains and branched "brushes." PEG is a hydrophilic polymer and is believed to be an effective blocker, because its structure prevents the release of bound surface water, a key component in adsorption at surfaces. Other chapters in this book provide a much more comprehensive investigation of PEG as a non-fouling material. It should be noted that PEG has been shown to *adsorb* preferentially, when dry; this is an important consideration for biosensor design (Foley et al., 2005).

Proteins as Blockers

Another common method of preventing biofouling is blocking with non-reactive proteins. Bovine serum album (BSA) and casein, a protein found in milk, are often used for this application, because of their historical effectiveness and low cost. Commercial blocking solutions using proprietary protein formulations are also available. After functionalizing the sensing surface, the blocker can be applied by soaking the biosensor or sensing surface in a protein solution or spraying the protein solution on and then rinsing off unbound protein. Different proteins will have different success at preventing biofouling for each specific sensing surface and sensor design, so it is common to test multiple blocking solutions to find the best fit

for each particular application. More about proteins for biofouling prevention can be found throughout this text.

Other Coating Materials

There are many other types of coatings that can be used to prevent undesired binding to a biosensor surface, many of which are elaborated on throughout this text. A few common examples include surfactants and hydrogels. However, for some biosensors this restricts the designer's ability to functionalize the surface in a way that is necessary to make sensing measurements. This remains an area of active research.

EFFECTS OF BIOFOULING ON SAMPLE REMOVAL SYSTEMS

For many biosensing systems, accurate and effective sensing is accomplished by a combination of preprocessing of the sample to remove problematic compounds, and thorough blocking to prevent additional non-specific binding. Non-specific binding can block target binding sites, decreasing potential signal and creating false readings, and interfere directly with the target analyte in the sample, preventing proper sensing. The rest of this section describes a variety of sensing modalities used in sample removal systems, and illustrates how biofouling prevention has been attempted in each.

Colorimetric Antigen Detection

The Yager group recently adapted a colorimetric immunoassay for the detection of antigens produced by malarial parasites: *Plasmodium falciparum* histidine rich protein II (PfHRPII), produced only by *Plasmodium falciparum*, the most deadly pathogen, and an aldolase antigen, which is produced by all four major forms of *Plasmodium* (Lafleur et al., 2008). This assay was implemented in microfluidic cards; the antigen detection was performed on a porous nitrocellulose membrane substrate. An overview of the system and biomolecular interaction is illustrated in Figure II.5.13.6.

One element of novelty in this assay was the porous substrate, which had a high surface area with the potential for high capture molecule-binding and high signal. The capture molecules anti-PfHRPII IgM and anti-aldolase IgG were spotted onto the nitrocellulose membranes, and then dried. The membranes were then soaked in a blocking solution of casein intended to bind to the rest of the membrane surface and prevent non-specific binding of the subsequent reagents. The next fluid introduced was the sample. In the preliminary work, this was antigen spiked into pooled human plasma. Plasma is a realistic matrix for this sort of assay, and contains a wide variety of other proteins that are potential interferents. The last reagent flowed through the membrane was a suspension of Au nanoparticles conjugated to anti-PfHRPII secondary antibodies (Stevens et al., 2008).
FIGURE II.5.13.6 A high surface area porous membrane is used as the substrate for a multiplexed malaria detection assay. Capture antibodies are pre-spotted onto the membrane. Sample, washes and Au-labeled detection antibodies are flowed sequentially through the membrane forming a "stack" that localizes the Au-labeled detection antibodies. Detection is performed with an inexpensive webcam.

An effective biosensor has to be both sensitive and selective, and that selectivity, in this case, largely constitutes rejection of binding of Au-labeled secondary antibody non-specifically. Nitrocellulose was chosen as the material for the substrate partly because, in our system, it bound *less* protein than some other materials of similar porosity. This decreased binding capacity affected how much capture antibody could be spotted, but also decreased how susceptible the membrane substrate was to non-specific binding of antigens, interfering proteins in the plasma or secondary antibodies, all of which affect the resulting assay signal. This sort of trade-off is very indicative of the types of choices one has to make for effective biosensor design.

Small Molecule Detection Using SPR

Surface plasmon resonance (SPR) is an optical technique that measures changes in index of refraction caused by changes in mass near specific metallic surfaces, and changes in the bulk refractive index of the fluid above the surface. The most common substrate for SPR is thin films of gold, whose loose valence electrons allow surface plasmons to be excited by appropriate wavelengths of light coupled at appropriate angles. SPR has the advantage of not requiring the target molecules to need labeling of any kind (Brockman et al., 2000).

Yager et al. developed a portable SPR system with disposable microfluidic cards for the rapid detection of phenytoin, and anti-epileptic drug, from saliva samples, shown in Figure II.5.13.7 (Yager et al., 2006; Fu et al., 2007). Saliva is a complex matrix with many interferents,
FIGURE II.5.13.7 The surface plasmon resonance (SPR) system employed by Yager et al. to detect phenytoin in saliva samples (Fu et al., 2007). The gold-coated glass substrate was covered with PEG blocker in upstream regions and capture molecules in the detection region. The signal component from the bulk material was the measurement in the PEG-coated region; it was subtracted from the total signal measured in the detection region, yielding an accurate response to the binding of anti-phenytoin antibodies.

but many small molecule concentrations track closely with blood concentrations making it a non-invasive alternative. Phenytoin was detected using an indirect immunoassay; the SPR signal did not measure binding of phenytoin itself, but the reduced rate of binding of an anti-phenytoin antibody. The saliva samples were premixed with a known concentration of anti-phenytoin antibody and then flowed over a gold substrate coated with immobilized phenytoin. Only free anti-phenytoin antibodies bound to the surface, allowing a computer to back-calculate the concentration of phenytoin in the original sample.

A combination of methods was used to combat non-specific binding in this system. Initially, the saliva

sample was processed upstream of the detection surface to remove mucins and other interferents (Helton et al., 2008). The capture surface contained an upstream region coated only with PEG-thiol blocker (the thiol allows the PEG to be immobilized on the gold substrate), followed by the detection region coated with bovine serum albumin (BSA)-phenytoin. As the sample flowed over the upstream PEG-coated region, it produced a bulk refractive index change signal that is not indicative of non-specific binding, but would contribute to a "background" signal level. This signal was subtracted from the signal detected in the BSA-phenytoin region. Many biosensors only utilize blocking to prevent erroneous signal, but this SPR detection system took advantage of sample preconditioning, blocking and subtracting the signal generated by the bulk refractive index in the PEG blocked upstream region to accurately quantify the concentration of phenytoin in saliva samples.

IgG Detection Using Resonating Cantilevers

The last example is a cantilever-based sensor. Many static cantilever approaches have been described in the last decade (Waggoner and Craighead, 2007); they are based on deflection of a cantilever due to binding to only one of its surfaces. Most such sensors have been relatively impractical. The sensor in question is based on a hollow resonating cantilever that is surrounded by air or vacuum; the signal is measured as a shift in the resonant frequency due to changes in the mass of the cantilever (Burg and Manalis, 2003). Manalis et al. have developed a resonating cantilever biosensor that allows small volumes of sample to flow through the resonating cantilever and detect biomolecular-binding events, reporting the signal as frequency shift proportional to mass of biomolecules that have been bound. By monitoring the changes in frequency with time, real-time binding can be detected. The authors demonstrated a system to detect goat IgG, and showed that human IgG and BSA would not non-specifically bind in their device (Burg et al., 2007).

The cantilevers were fabricated using traditional silicon microfabrication, with silicon dioxide walls. The analyte in this system was goat IgG, so the authors needed to immobilize an anti-goat IgG on the surface. The immobilization was achieved through a multi-step process which can be seen in Figure II.5.13.8. As each set of molecules was added, the mass changes resulted in a frequency shift. Firstly, poly-L-lysine conjugated to PEG conjugated to biotin was electrostatically adsorbed in the desired orientation (with the biotin pointing up). This layer was rinsed with buffer, and the next link in this immobilizing chain was neutravidin, a variant of the better-known streptavidin. This was again rinsed with buffer, then the biotinylated anti-goat IgG was added and rinsed.

Once the cantilever was functionalized with immobilized anti-goat IgG, samples of goat IgG ranging from

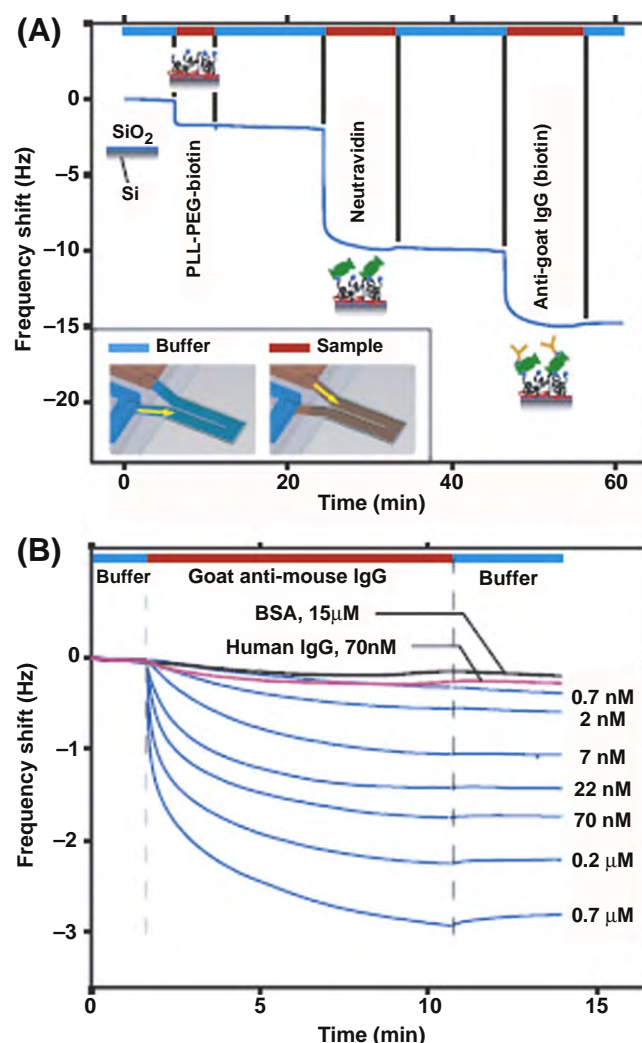
7 nM to 7 μM were tested. The sample volumes were ~10 pL. The authors reported mass detection resolution of 10^{-19} g/μm², which is equivalent to 1 protein per square micron. The authors reported that they corrected for changes in the frequency due to the density of the sample by subtracting out the shift due to just the buffer. They also tested how susceptible the sensor was to non-specific binding by testing human IgG and BSA as samples. Neither produced a significant frequency shift, indicating that neither molecule was binding to the anti-goat IgG or any other surface of the sensor.


FIGURE II.5.13.8 Graphical representation of the cantilever-based biosensor developed by Manalis et al. and data collected using this type of biosensor. (A) The multi-step layer addition required to immobilize anti-goat IgG on the sensor inner surfaces. The red segments show the different molecules being added, and the accompanying frequency shifts. The blue segments show buffer flowing, which doesn't correspond to a significant frequency shift. (B) The goat IgG samples ranging from 7 nM to 7 μM being flowed through the sensor and their corresponding frequency shifts. Human IgG and BSA produce no noticeable frequency shift, showing the sensor's resistance to non-specific binding (Reprinted by permission from Macmillan Publishers Ltd. *Weighing of biomolecules, single cells and single nanoparticles in fluid* (Burg et al., 2007)).

POINT-OF-CARE MEASUREMENTS ENABLING DISTRIBUTED DIAGNOSIS AND HOME HEALTHCARE

Continued developments in the field of biosensing are leading to more small, rapid, portable sensing options for the hospital bedside, home use, and keeping on one's person. These devices are often described as point-of-care, because detection is brought to the patient, instead of the patient being brought to a detector. More frequent measurements taken by the patient are an inexpensive way to establish a more personalized baseline and improve overall care. Well-established information networks allow easy communication between these devices and central medical databases. New smart cell phones are providing a perfect platform for data input and delivery. Together, these advances are creating a new phase of personalized medicine, sometimes called distributed diagnosis and home healthcare (D_2H_2), illustrated in Figure II.5.13.9. Continuous glucose monitors that communicate with insulin pumps are only a few steps away from a realized D_2H_2 system.

A major contributor to the ability of biosensors to become sufficiently inexpensive and small for personal use has been the development of micro-electromechanical systems built on the design and fabrication techniques of the semiconductor industry. Many of the microchips (including microprocessors, RF chips, digital signal processors, etc.) are already being mass-produced very cheaply; more unique components can be built using the same technology much more cheaply than previous generations of biosensors. Lab-on-a-chip (LOC) design is now contributing greatly to point-of-care biosensing. As a field it now has its own very popular journal. The basic principle of LOC diagnosis is to take a bench-top process usually performed in a laboratory (i.e., determine an HIV patient's CD4 count) and reduce all the steps to an automated process performed in a disposable, self-contained device. The devices are designed to be as cheap as possible for one-time use; and a more expensive and complicated system is used to control the simple disposable. LOC has the advantage of not requiring a trained technician to operate, making it ideal for POC use and a potentially large contributor to the future of home healthcare.

SUMMARY

Medical biosensors play a large and growing role in medical diagnostics and patient monitoring; this chapter is merely a brief overview of biosensors. The use of biological molecules, tissues, and organisms has made biosensors uniquely suited to many diagnostic and real-time detection challenges, and their high potential for sensitivity and specificity promises to continue this trend. Biosensors are still plagued by the ever-present problem of biocompatibility, particularly for *in vivo* use which is more complicated for sensing use because of the need for *permeable* non-fouling surfaces. Researchers are rapidly advancing the state-of-the-art in biofouling prevention, making dramatic strides in short-term implantable sensors like those described in this chapter for percutaneous glucose sensing. As biocompatibility is better-understood and controlled, longer-term, more accurate *in vivo* sensors will become commonplace.

ACKNOWLEDGMENTS

FIGURE II.5.13.9 An evolving doctor–patient interface as part of a vision of distributed diagnosis and home healthcare (D_2H_2). By utilizing the existing infrastructure for wired and wireless data communication, as well as existing capabilities for storing large amounts of patient data, it is becoming possible to allow patients to maintain an up-to-date record of many different health parameters without frequent visits to hospitals and physicians.

CHAPTER II.5.14 BURN DRESSINGS AND SKIN SUBSTITUTES

Douglas L. Helm[1], Britlyn D. Orgill[1], Rei Ogawa[2], and Dennis P. Orgill[1]

[1]Division of Plastic and Reconstructive Surgery, Brigham and Women's Hospital, Boston, MA, USA

[2]Division of Plastic, Reconstructive and Aesthetic Surgery, Nippon Medical School, Tokyo, Japan

SKIN: THE LARGEST ORGAN

Skin protects the body from microorganisms and external forces, integrates complex sensory nervous and immune systems, controls fluid loss, and serves important aesthetic functions. The two layers, the dermis and the epidermis, are linked by epidermal derivatives or "appendages," such as sebaceous glands and hair follicles that invaginate into the dermis. The dermis hosts a rich vascular network that helps regulate temperature. For most minor injuries, such as a superficial paper cut, the skin is able to self-repair without scarring (Dunkin et al., 2007). Deeper skin injuries due to deep cuts, burns or degloving injuries can cause significant physiological derangement, expose the body to a risk of systemic infection, and become a life-threatening problem. Large skin deficits have motivated the development of improved technologies to replace and restore skin. Although many of these technologies were originally developed to treat burns, these technologies have been extended to other areas, including

chronic wounds and acute surgical wounds. In this chapter we will explore the factors that need to be considered when developing wound dressings and skin substitutes, and also review the technologies currently available to treat patients.

> Over 500,000 patients require treatment for burns each year in the United States. Of these 40,000 will be hospitalized and 4000 will succumb to burn injuries. Query of the National Center for Health Statistics database revealed over three million traumatic wound admissions each year. It is estimated that 10% of these will require advanced wound care, representing 300,000 wounds (American Burn Association, 2007).

The Use of Skin Substitutes and Burn Dressings Depends on the Depth of the Wound

Epidermal appendages are lined with keratinocytes that migrate across the wound and divide to form a multilayered epidermis with a cornified barrier layer. This healing response is commonly seen in split-thickness donor sites with depths of 0.008–0.020 inches. When these injuries are kept clean and moist, healing occurs within 7–21 days. Similarly, superficial and mid-dermal burns heal over similar time periods, if they do not become infected and are dressed properly. Injuries and burns that extend into the deep dermis or through the entire dermis will heal only after a prolonged time or may become chronic wounds. To treat skin loss, autologous skin grafts are often useful, and can be provided as full-thickness or split-thickness skin grafts. Full-thickness grafts are applied to small wounds, and consist of the entire epidermis and dermis; the donor site is closed with sutures. Split-thickness grafts are applied to larger wounds and can be expanded through a meshing process that allows them to cover a larger area. Microscopically, blood vessels from the wound revascularize the graft. Donor sites cause scars and are painful, and for large skin losses there may not be enough donor skin to cover all of the excised burn. Therefore, special burn dressings and skin substitutes have been designed to help treat such cases. The ideal characteristics of a skin substitute are listed in Table II.5.14.1. Fluid loss and bacterial infection are two

TABLE II.5.14.1	Qualities of Skin Substitutes
The ideal skin substitute is:	

- inexpensive
- long lasting
- a bacterial barrier
- semipermeable to water
- elastic
- easy to apply
- painless to the patient
- non-antigenic and non-toxic
- has a durable shelf-life

major concerns when treating a patient with massive skin loss, and these two factors have influenced the technology of burn dressings and skin substitutes. Several practical issues, including ease of application, storage time, and cost, also factor into the choice made by the clinician.

Conventional Treatment: Partial-Thickness Burns

Conventional therapy for treating burns focuses on preventing wound infection through the use of topical antimicrobial agents. Silver-based dressings, such as Silver Sulfadiazine (Silvadine), have been used since their introduction in 1968 because of their infection prevention qualities. These dressings are relatively inexpensive, but tend to adhere to the wound surface and require daily dressing changes and impede epithelial growth. They can temporarily depress the white blood cell count. Silver nitrate solution is effective at treating many bacteria, but requires dressings to be continuously wet, and they tend to stain the skin and sheets black. Silver nitrate can lead to electrolyte disturbances. Mafenide acetate has excellent penetration of burn eschar, but can be painful. It has been classically used on areas where eschar is left on for a prolonged period, such as ears. These classical burn dressings do not prevent fluid loss through evaporation or exudative loss.

> Depending on the thickness, we can classify a burn as being one of three degrees. First degree burns are superficial wounds affecting only the epidermis. Second degree burns are deeper than first degree burns, and extend into the dermal layers of the skin. Second degree burns vary in seriousness, and there is debate over treatment of these wounds. Third degree burns are the deepest, and extend past the dermis into the fat.

Advanced Dressing: Partial-Thickness Burns

Acticoat™ (Smith & Nephew) is a silver antimicrobial dressing containing nano-crystalline silver that offers a slow release of silver ions over time. This product treats a broad spectrum of bacteria and is changed every 2–4 days. Indicated in both full- and partial-thickness wounds, the product is kept moist with sterile water that activates release of the silver. Studies have shown that silver-impregnated dressings such as Acticoat reduced wound-healing time and pain level in comparison to traditional silver sulfadiazine treatment (Wasiak et al., 2008).

Aquacel® Ag (ConvaTec) is a silver hydrofiber dressing. It has been useful in treating second degree burns, chronic wounds, and donor sites. In addition to the advantages of preventing wound infection, the dressing also maintains a moist wound environment by controlling wound exudate. Since it does not have to be applied as often as silver sulfadiazine (only once every other day

versus twice a day), Aquacel has received many positive reviews because the product reduces pain to the patient (Connor-Ballard, 2009).

Biobrane® (UDL Laboratories, Inc., Rockford, IL) is a temporary biosynthetic burn dressing made from porcine collagen-coated nylon mesh embedded in silicone. Designed to adhere to a clean and debrided burn wound, studies have shown this dressing to be at least as effective as topical silver sulfadiazine in the areas of pain and wound healing time. Also, the total cost of the dressing tends to be less with Biobrane than with traditional silver sulfadiazine dressing (Wasiak et al., 2008). However, other studies have shown Biobrane not to be as effective as OrCel™ or allogeneic cultured keratinocytes (Pham et al., 2007). No complications have been reported (Pham et al., 2007).

TransCyte® (Advanced Biohealing) is a transparent covering created by culturing neonatal fibroblasts on a porcine collagen coated nylon mesh, which is bonded to a semipermeable silicone membrane. TransCyte simulates the epidermis and the dermal matrix. It has FDA (US Food and Drug Administration) approval for treatment of full- and partial-thickness burns. Studies have shown that TransCyte requires fewer dressing changes when compared with silver sulfadiazine, and has overall better results in wound healing. No deaths or complications associated with the use of TransCyte have been reported (Wasiak et al., 2008).

Apligraf® (Organogenesis, Canton, MA, and Novartis, East Hanover, NJ) is created from neonatal foreskin fibroblasts and keratinocytes, and has both dermal and epidermal components. First, the dermal component is made with cultured fibroblasts with bovine type I collagen. Then, cultured keratinocytes are added, and over time are allowed to epithelialize and form a stratum corneum. Apligraf is currently FDA-approved for use in treating diabetic foot and venous ulcers, although it is also used in burn treatment. Apligraf has a cost of $51/cm^2 and a 10-day shelf-life. It is used as a covering over meshed, expanded autografts, and is designed to be applied weekly. Studies have shown that this product has a better wound healing result than with an autograft alone. No complications or deaths have been cited due to Apligraf (Pham et al., 2007).

OrCel™ (OrCel International, New York, NY), similar to Apligraf, is an allogeneic, bilayered substitute comprised of cultured human fibroblasts and keratinocytes. However, the fibroblasts in OrCel are seeded onto a preformed matrix instead of being co-cultured with collagen in solution. Also, OrCel lacks Apligraf's stratum corneum. OrCel is FDA-approved for use on split-thickness skin graft donor sites in burn victims, and in reconstructive hand surgery of patients with epidermolysis bullosa. A study performed by Still et al. found OrCel to be more effective than Biobrane with regards to wound closure time and scar appearance (Still et al., 2003). It is not currently available for clinical use.

SKIN SUBSTITUTES

Although burn dressings are successful in effectively treating some burn injuries, some wounds require more support than a temporary dressing or they are not candidates for an autograft. Therefore, a variety of skin substitutes are used to help treat full-thickness burns. Skin substitutes literally substitute either part or the entirety of the skin, and therefore have dermal and/or epidermal components. Originally, these constructs were designed for life-saving effects on very large burns. Subsequently it has been shown that both functional and aesthetic reconstructions can occur using these products. However, even the best skin substitutes available today still lack epidermal appendages, intact vasculature, immune cells, and melanocytes.

Epidermal Replacement

CellSpray® (C3) is an aerosol spray solution consisting of cells cultured from a small biopsy of the patient's own skin. The solution of cells is sprayed onto the burn injury to create an epidermal layer. It is sold as a kit that can be used by the surgeon in the office or operating room to provide cell suspensions from biopsies. It is currently available in Europe and Australia.

Epicel® (Genzyme Biosurgery, Cambridge, MA) is the best known cultured epidermal autograft on the market. The patient's own keratinocytes are expanded *ex vivo* in co-culture with murine 3T3 fibroblast feeder cells. A neoepidermis consisiting of keratinocyte layers of variable thickness is arranged into sheets that are shipped back to the patient in need. Epicel is expensive and has a 24-hour shelf-life at room temperature.

Dermal Replacement

Allograft (cadaver skin) is harvested from recently deceased individuals and used fresh or cryopreserved. It is tested for infectious agents such as hepatitis, and needs to be carefully tracked to the source. It has good take, but will undergo rejection at about 10–14 days. The rejection is primarily the epidermis; dermal elements can remain and be used as a base for thin skin grafts of cultured epidermal grafts (Cuono et al., 1987).

Integra™ (Integra Lifesciences Corp., Plainsboro, NJ) is an acellular, purely biosynthetic dermal substitute. The Integra Dermal Regeneration Template consists of two layers: the dermal layer made from (bovine) type I collagen and chondroitin-6-sulfate; and the epidermal layer made of silicone. The collagen–chondroitin dermal matrix allows in-growth of cells from the wound bed, and the artificial silicone epidermis regulates heat and fluid loss, and provides some antimicrobial protection. After integration with the wound bed, the silicone backing is removed and the neodermis acts as a recipient bed for a split-thickness autograft. Integra was the first

skin substitute to be FDA-approved, and is approved for use in full- and partial-thickness burn wounds. Integra should not be used in patients who are allergic to bovine collagen or who have infected wounds. Reports on the efficacy of Integra have been mixed. Studies have shown Integra to be better than autograft, allograft, and xenograft in the parameter of wound healing time. However, Integra was shown to be inferior to autograft, allograft, xenograft, and Biobrane with regards to wound infection and graft take.

Matriderm® (Suwelack, Germany) is a collagen–elastin matrix used for dermal replacement. In a comparative rat study it had similar wound performance to Integra (Schneider et al., 2009). It does not have a silicone layer over it, and several clinicians have used it as a one-stage replacement using a thin skin graft over the matrix acutely. It is available for use in Europe.

AlloDerm® (Lifecell, Branchberg, NJ) is a dermal matrix derived from cadaveric skin. The cadaveric tissue is aseptically processed to remove the epidermis and cellular components of the dermis that are known to lead to graft failure. A scaffold composed of collagen, elastin, fibronectin, proteoglycans, and the three-dimensional framework of the microvasculature (without the actual vessels) remains. Alloderm is used in a range of applications, including breast reconstruction, urogynecological, orthopedic, and trauma.

Cultured Epithelial Autograft was the first cultured skin substitute, and was pioneered in the 1970s by Rheinwald and Green (Rheinwald and Green, 1975). The Cultured Epithelial Autograft (CEA) enabled generation of an autograft from a very small skin sample, which would prove useful in treating patients with large surface area burns. However, the use of CEAs has been limited due to expense, friability, and lack of a dermal layer. Although still used (e.g., Epicel), other available biological dressings for patients with extensive burns have made the use of CEAs impractical.

COMPOSITE AUTOLOGOUS TISSUE AND SKIN TRANSFER

In certain cases of severe burns, the underlying muscle and bone can be heavily damaged and suffer necrosis. Although this may happen with thermal burns, electrical burns can cause deep tissue destruction beyond the level of the skin, as the electricity conducts throughout the body on its way to a grounded surface. When muscle and bone is needed, local and free tissue transfer of muscle, fat, and bone with the overlying skin may be utilized to cover an injury site. Countless free tissue grafts have been surgically described, but the most commonly used is radial arm muscle with overlying skin to cover dorsal or palmar hand surface burns. In addition, commonly used gracilis, rectus, and latissimus muscles can also be reliably transferred, with the aid of microvascular anastamoses to a robust blood supply, to injury sites around the body.

COMBINED THERAPY WITH VACUUM ASSISTED CLOSURE (VAC)

In many cases, more than one clinical therapy must be combined to give the optimal treatment to a patient. A common situation in the area of wound healing is to combine a dressing or skin substitute with Vacuum Assisted Closure (VAC) therapy. The VAC consists of a polyurethane sponge, which is placed into the wound bed and then sealed off, so that suction can be applied through a tube. This device has had optimal results with wound healing since the suction allows excess fluid from edema to leave the wound, which prevents bacteria overgrowth, while at the same time a moist wound environment is maintained. The apparatus creates macrodeformations of pulling the sides of the wound together, and the pores in the sponge create microdeformations, stretching the cells in the wound bed and inducing proliferation and angiogenesis. The VAC device has proven to be helpful in burn care when it can be paired with a skin substitute to help hold the substitute in place and stimulate the healing response of the wound bed (Stiefel et al., 2009). Through this the VAC helps the wound site adhere to the skin substitute and have better take.

THE MARKETPLACE FOR BURN DRESSINGS AND SKIN SUBSTITUTES

Cost does play a role in the development of burn dressings and skin substitutes. Physicians must determine the optimal treatment they can provide to a patient considering the economic resources available. Also, although the development of dressings and skin substitutes for the treatment of burn injury is rewarding, our current marketplace has not proven to be supportive of this industry. One of the problems is that burn injury correlates to a very small market, and in order for a dressing or skin substitute to be truly successful it must also be able to be applied to a wider market such as that for general wound care, or the company must sell other products. For example, the company Integra, which began with one product, the Integra Dermal Regeneration Template, now also sells technologies for orthopedics and neurosciences, as well as medical instruments. Burn dressings are also very costly to produce, and it is difficult to quantify the success of a burn dressing or skin substitute because randomized clinical trials are difficult to conduct in a surgical field. Therefore, it is difficult to show quantified results to potential investors to acquire funding. Logistical factors such as time lapses in receiving FDA approval can also hold a company back from developing products (Garfein, 2009). Therefore, in the future of developing technology for burn injuries, it is imperative that cost be considered so that the dressings can continue to be produced and patients can receive the benefit of the treatment.

CHAPTER II.5.15 SUTURES

M. Scott Taylor[1] and Shalaby W. Shalaby*
[1]Poly-Med, Inc., Anderson, SC, USA

GENESIS AND COMMON USES

A suture, by definition, is any strand of material that is used to ligate (tie) blood vessels or approximate tissue. Ligatures are used to achieve hemostasis or to close a structure to prevent leakage. Suture literally means *to sew*, which is derived from the Latin *sutura*. The earliest examples of this technology trace back thousands of years, when Egyptians, Indians, and other early suture developers used readily available materials, such as silk, linen, cotton, horsehair, and animal tendons and intestines. Documented descriptions of suture materials and techniques trace to *Susruta*, written approximately 500 BCE in India (Mackenzie, 1973).

Suture needles share a parallel history, with initial versions being prepared from available materials such as sharpened pieces of bone. There have been many innovations in needle materials and design, leading to the current offering of needles that are tailored for use in various tissues and surgical sites.

The late 1800s, with the advent of synthetic "plastics," filaments, and improvements in surgical techniques, ushered in a new wave of suture materials development.

---

*Dr. Shalaby Shalaby (1938–2010) was Founder, President, and Director of R&D at Poly-Med, Inc. In his career he served as the Director of the R&D team at Ethicon, and managed the Johnson and Johnson Polymer Technology Center. He also served as a professor of Bioengineering at Clemson University, and received the Technology Innovation and Development Award from the Society of Biomaterials for his long history of development of absorbable biomaterials for drug delivery systems, tissue adhesives, wound closure devices, and other biomedical innovations. The editors and the biomaterials community will miss Shalaby very much.

Aseptic technique was introduced in 1885, and rubber gloves in 1890. Many of the most common synthetic polymers were developed in the last 100 years, and synthetic absorbable sutures were introduced in the early 1970s. Currently, sutures comprise the largest portion of wound closure technologies, with the yearly market for sutures approaching a billion dollars in the United States alone. Ethicon is the largest manufacturer of sutures; however, many small and large companies have emerged to compete with similar and novel suture offerings.

The suture device is comprised of: (1) the suture strand; (2) the surgical needle; and (3) the packaging material used to protect the suture and needle during storage. The suture strand is the only part of the device that remains in place after the surgical procedure is accomplished, and is solely responsible for securing the tissue. The needle provides a means to insert the suture strand, and the package holds the suture and needle, while protecting them from damage and providing a sterile barrier.

A common misconception is that further suture development is unnecessary due to the wide range of products currently available. In fact, there is always an opportunity for development of improved sutures and other wound closure devices. The design of surgical sutures combines knowledge of polymer chemistry, metallurgy, current surgical practice, and the proposed indication for the suture. Current advances in these fields allow for continued advances and improvements in suture technologies.

DESCRIPTION OF SURGICAL SUTURE

The suture is comprised of three distinct components. Table II.5.15.1 further describes each component, along with example permutations. The first component that identifies a suture, and the most descriptive for the performance of the device, is the strand.

The major distinguishing factor in suture strands is the absorbability of the suture. Absorbable (occasionally

TABLE II.5.15.1	Components and Permutations of the Suture Device
Component	**Description and Permutations**
Suture strand	Component of device that provides securement, only part of device that remains in tissue after implantation: • Absorbable or non-absorbable • Sized according to USP[1] or EU[2] guidelines • Braided or monofilament • Coated or uncoated • Natural or dyed
Needle	Component of device that pulls suture through tissue: • Size is based on suture diameter • Taper point, cutting, spatula, specialty • Straight, ¼ circle, ⅜ circle, ½ circle, ⅝ circle, compound curved • Coated or uncoated • Swaged or rolled
Packaging	Component that provides a sterile barrier for storage and maintains storage conditions: • Tyvek® or foil • Single suture or multipack • Dry or with plasticizing fluid • Plastic or paper folder

1	0.50	0.40
2	0.60	0.50

[1]*United States Pharmacopeia*, 2008.

denoted resorbable, biodegradable or erodible) materials are those which undergo a chemical degradation. In suture materials, this is most commonly the result of hydrolysis. With surgical gut sutures, however, the absorption is a result of enzymatic degradation. In the past, absorbable sutures have been defined as losing a significant portion of strength within a two-month period (Swanson and Tromovitch, 1982), but current advances in materials have yielded absorbable sutures maintaining measurable strength for six months or longer. Absorbable sutures lose strength long before losing mass; it may take months or years after the suture loses strength to fully absorb.

Suture is manufactured in many sizes, and is selected by the surgeon based on a number of factors, including: surgical site; patient age and weight; immune history and response; presence of disease or infection; and personal history with suture materials (Ethicon, 2001). Size is based on diameter, as defined in the *United States Pharmacopeia* (USP) (Table II.5.15.2), and often materials will exhibit slightly different performance characteristics based on size. Monofilament sutures exhibit lower tissue drag compared to braided multifilament sutures; however, many materials having high modulus and stiffness are not compliant enough to be useful as monofilament. Also, any defect caused during handling can create a weak region in the suture strand. For these reasons, multifilament braided sutures were created. As a combination of fibers with much smaller diameter, relatively stiff materials in a composite structure have a perceived compliance much lower than material properties would suggest.

Although the multifilament allows creation of suture from relatively stiff materials, there are possible drawbacks to this design. Void space in the braid creates capillarity, and potential areas to harbor bacteria. Increased surface roughness associated with a braided construction can cause damage to the implant site due to increased tissue drag. To counteract this and increase lubricity, almost all braided and a few monofilament sutures are coated. Additionally, sutures are supplied as either natural or dyed to increase visual contrast. Table II.5.15.3 identifies many of the most common sutures and examples of manufacturers.

Needles are used to place the suture in tissues, and are primarily supplied pre-attached to the suture strand. They are supplied in a variety of shapes, each of which is suited to certain applications. Needle and suture are connected at the end of the needle, which can be attached mechanically by swaging (in which the drilled end of the needle is crimped around the suture strand), rolled in a rolled-end needle or attached using an adhesive (e.g., epoxy resin or cyanoacrylate), but they can also be supplied packaged individually as an eyed needle. The basic needle description includes shape and point geometry (Table II.5.15.4 and Figure II.5.15.1). Needle shapes include straight, curved (described as a fraction of a circle), and compound curved. Figure II.5.15.2 provides an illustration of a curved needle, along with pertinent dimensional descriptions. The ideal needle is inert, as slim as possible without compromising strength, stable when held in the needle holder, sharp enough to penetrate tissue with minimum material resistance, rigid enough to not allow bending, ductile enough to not break during use, sterile, and corrosion resistant (Ethicon, 2001).

The primary purpose of the suture package is to maintain sterility during storage. For absorbable sutures, the package serves a second function as a barrier to protect the suture from moisture, which would initiate the degradation process. In the case of gut sutures, a plasticizing fluid is used to maintain compliance. Inside the pouch, the suture is contained in either a paper folder or a formed plastic tray.

The Ideal Suture is…

- Biocompatible
- Sterile
- Compliant
- Adequate knot/straight strength
- Secure and stable knot
- Strength and mass loss profiles adequate for proposed usage
- Low friction
- Adequate needle attachment strength
- Atraumatic needle design
- Non-electrolytic
- Non-capillary
- Non-allergenic
- Non-carcinogenic
- Minimally reactive
- Uniform and predictable performance

TABLE II.5.15.4	Common Suture Needles
Type and Description	
Taper point: Circular cross-section gradually increasing in diameter from the point to the needle body	
Conventional cutting: Triangular cross-section at the needle tip to provide cutting edges, allowing easy penetration into the tissue, which gradually transitions to a square needle body. One cutting edge is on the inside curvature of the needle	
Reverse cutting: Triangular cross-section at the needle tip to provide cutting edges. Flat surface on the inside curvature of the needle to minimize risk of needle tearing through the tissue

FIGURE II.5.15.2 Anatomy of a curved suture needle.

MANUFACTURING PROCESS AND INTENDED USE

Manufacture of the suture strand varies greatly, depending on the type of material. Natural materials are harvested in various ways and formed into fibers, but do not require extrusion, while synthetic materials require extrusion to form fibers. Most often melt extrusion is used, but some materials require gel spinning for fiber formation. Monofilament (single fiber) or multifilament extrusion is followed by orientation, a process in which the extrudate is heated and oriented, by drawing to reduce fiber size and align the molecular chains in the amorphous region and the crystallites therein to increase tensile strength along the fiber axis. Multifilament fibers are combined by braiding to form a suture strand, which is further stretched to tighten the construction. Monofilament and braided strands are heat treated, which could include annealing and/or relaxation, to increase dimensional stability and relieve internal stresses associated with previous processing. The suture strand, in some cases, is then surface coated to increase lubricity, improve tie down characteristics (during knot formation) or impart other desired attributes, such as reduction of capillarity and the inclusion of antibacterial agents.

Needles are typically attached to the suture strand by swaging (or crimping) the end of the needle to the strand. For small size sutures, adhesive attachment is preferred. The needle/strand combination is placed in a folder, and then in a pouch. The pouch is sealed and sterilized by high-energy irradiation or ethylene oxide gas (denoted EO or EtO). For absorbable sutures sterilized by ethylene oxide, the pouch is dried to a very low moisture level (<500 ppm), and sealed a second time to create an occlusive moisture barrier, providing protection from moisture.

Surgical Gut Sutures

Gut sutures are primarily derived from bovine intestinal serosa, but also from the submucosa of sheep or goat intestine. The base material is primarily collagen, and requires purification and strengthening before it is suitable as a suture. After harvesting, the material is cleaned and cut into ribbons. The cleaned ribbons are further processed with a dilute formaldehyde solution, which increases strength and slows the degradation rate by modifying the activity of the end groups of the collagen (Chu, 1997a). The ribbons are plied (twisted together), ground, and polished to create the final suture diameter. Natural (or plain) gut suture is now ready for packaging. Chromic gut sutures are further processed by tanning in the presence of chromium salts, which slows the rate of degradation (Chu, 1997a).

The suture is sized by centerless grinding, in which two grinding wheels remove material around the diameter of the suture. Due to the grinding process, fibrils at the strand surface can be damaged, which can lead to weak

points and inconsistent strength. Also, the fiber is easily frayed during tying (Benicewicz and Hopper, 1990). Since gut sutures are a naturally derived material, there are slight inconsistencies in performance, including initial strength and strength retention profile. The grinding and polishing process can, ultimately, result in fraying and inconsistent diameter, leading to weak spots along the suture strand. Coating gut sutures to lower their friction coefficient and propensity to fray was described by Totakura and Shalaby (1997a,b). Recent studies have discouraged the use of gut sutures, and created very stringent manufacturing requirements in Europe and Japan due to concerns over bovine spongiform encephalopathy (mad cow disease) (European Commission, 1998). These materials, however, are inexpensive compared to their synthetic counterparts, and have a long history of use, which accounts for their continued popularity. Gut sutures can be sterilized by irradiation or ethylene oxide gas permeation.

Silk Sutures

Silk suture is a protein fiber typically derived from the *Bombyx mori* silkworm (Chu, 1997a). The silk is stripped of its natural waxes and gums, and braided or twisted to construct the suture thread. As with all braided sutures, it is coated. Typically, this is in the form of a beeswax-based coating or, in some cases, a siloxane-based coating is used. Successful efforts to substitute the highly tissue-reactive beeswax-based suture with practically non-reactive synthetic polyesters led to the development of a low-reactivity silk suture which can be made antimicrobial (Nagatomi et al., 2008). Although silk is not considered an absorbable suture, the strand loses strength and mass after implantation (Van Winkle and Hastings, 1972; Stashak and Yturraspe, 1978; Benicewicz and Hopper, 1990). This material is broken down by proteolysis, and is typically undetectable after two years (Lai et al., 2009). Silk sutures can be sterilized by irradiation and ethylene oxide gas permeation.

Cotton Sutures

Cotton has only been widely used as a suture material since World War II, due to the scarcity of silk (Harms, 1948). Cotton is a cellulose material and is prepared from long-staple yarn. A wax coating is applied to improve lubricity and help reduce fraying. An interesting note is that cotton gains strength when wet (Herrmann, 1971; Stashak and Yturraspe, 1978). Cotton elicits a mild tissue response, similar to silk, and exhibits a gradual loss in tensile strength over about a two-year period (Van Winkle and Hastings, 1972). Cotton sutures are sterilized by ethylene oxide. Although not as strong as silk, cotton sutures are still available today, and are supplied as a twisted multifilament yarn.

Polyester Sutures

Non-absorbable polyester sutures are made from polymers such as poly(ethylene terephthalate) (PET) and poly(butylene terephthalate) (PBT), which are produced by condensation reaction. This involves condensation of a glycol with terephthalic acid or an ester of terephthalic acid. The repeat unit of PET is shown in Table II.5.15.5. PBT is relatively compliant compared to PET, although both are extruded into multifilament fibers and braided into suture. Both of these braided sutures are coated to improve their lubricity. PET, introduced in the 1950s, is the most commonly used polyester suture, and has well-documented properties. Polyester sutures are sterilized mostly by gamma irradiation.

Nylon Sutures

The polyamides Nylon-6 and Nylon-6,6 are both used as suture materials. Structures for both repeat units are shown in Table II.5.15.5. Nylon materials were discovered in the 1930s at DuPont, who first manufactured Nylon-6,6 through a condensation reaction using hexamethylene diamine and adipic acid. Other companies developed the similar Nylon-6, which is formed by the ring-opening polymerization of caprolactam. Nylon-6,6 is slightly limper (softer hand) than its counterpart, although mechanical properties are similar for both materials.

Nylon sutures are made into braided or monofilament sutures, although the monofilament sutures may not tie as well, and require additional knots to secure them (Stashak and Yturraspe, 1978; Bellenger, 1982; Guttman and Guttman, 1994). To counteract this, monofilaments can be packaged with a plasticizing fluid to soften the hand (Capperauld and Bucknall, 1984). Although nylon is a non-absorbable suture, the amide bond is susceptible to hydrolysis and can lose strength over time (Chu, 1997a). Nylon sutures are sterilized by gamma irradiation.

TABLE II.5.15.5	Repeat Units for Common Synthetic Non-Absorbable Sutures	
Monomer Names	**Repeat Unit Structure**	**Homo-polymer**
Ethylene	$[CH_2\text{-}CH_2]_n$	Polyethylene (PE)
Propylene	$[CH(CH_3)\text{-}CH_2]_n$	Polypropylene (PP)
Hexamethylene diamine and adipic acid	$[CO\text{-}(CH_2)_4\text{-}CO\text{-}NH\text{-}(CH_2)_6\text{-}NH]_n$	Nylon-6,6
Caprolactam	$[CO\text{-}(CH_2)_5\text{-}NH]_n$	Nylon-6
Ethylene terephthalate	$[CO\text{-}\bigcirc\text{-}CO\text{-}O\text{-}CH_2\text{-}CH_2\text{-}O]_n$	Polyethylene terephthalate (PET)

Polypropylene Sutures

Polypropylene can be made with an atactic, isotactic or syndiotactic chain conformation. The material tacticity determines how the material will crystallize, and the mechanical properties of the final device. Material used for suture applications is practically isotactic, with an intermediate density. Polymerization is accomplished by polymerization from propylene monomer using a Zeigler-Natta catalyst; the repeat unit can be seen in Table II.5.15.5. Polypropylene sutures elicit very low tissue response, and are not susceptible to hydrolysis. These sutures can also be difficult to tie securely, due to the smoothness and lubricity of the suture strand (Stashak and Yturraspe, 1978; Bellenger, 1982; Guttman and Guttman, 1994). Polypropylene is easily melt-extruded into monofilament or multifilament yarn, and is well-suited for the production of monofilament suture. Polypropylene sutures are usually sterilized by ethylene oxide, and occasionally by high energy radiation.

Ultra-High Molecular Weight Polyethylene (UHMWPE) Sutures

A relatively new material that has gained considerable popularity with orthopedic surgeons is ultra-high molecular weight polyethylene (UHMWPE) suture, which means they are a very high molecular weight polymer of ethylene (structure seen in Table II.5.15.5). The molecular weight can be difficult to determine directly, but is typically in the millions of Daltons. Introduced in the early 2000s, these ultra-strong sutures are 10–100 times stronger by weight than steel. As opposed to other synthetic suture materials, which exhibit about 40% crystallinity, UHMWPE can obtain crystallinity of greater than 85%, and can be highly oriented. The high molecular weight prevents the use of melt extrusion. Therefore, gel spinning techniques are employed to create the multifilament fibers. Gamma irradiation weakens this suture; for this reason they are sterilized by ethylene oxide (Deng et al., 1996).

Ultra-high strength sutures are much stronger than standard ones, and a smaller size will have a similar breaking load to a larger size standard suture. This allows the surgeon to use a smaller diameter suture for the same application, leaving less foreign material in the implant site. The inherent lubricity of the material results in increased tendency to slip compared to polyester sutures (Barber et al., 2009). Molded UHMWPE will also creep under load, although sutures are not under the same loading conditions and will therefore not exhibit the same level of creep as other devices made of the same materials, as in replacement joint bearing surfaces.

In addition to sutures made of only UHMWPE, there are several composite sutures that are prepared by co-braiding UHMWPE with PET, nylon or other materials. Ultra-high polyethylene suture is difficult to dye during extrusion, and its high crystallinity makes post-extrusion solvent dying difficult, so manufacturers exploited other materials that can be easily dyed as a component in the suture braid, as a means to create contrast with surrounding tissue (Teleflex Medical OEM, 2009). Also, textures imparted by combining different materials allow for more secure tying, which can be a problem with inherently lubricious UHMWPE sutures (Burkart, 2004).

Stainless Steel Sutures

For surgical procedures requiring high strength materials, such as sternal fixation and tendon repair, stainless steel is a common selection. These sutures are most often prepared from 300-series stainless steels (316L is a common variety and is used in Covidien STEEL sutures, for example). Stainless steel sutures are inert, do not exhibit capillarity, and are very strong. The high modulus of stainless steel, however, can cause irritation at the free end of the suture. These sutures are also prone to kinks, and surgeons must use extra caution during handling (Bellenger, 1982; Capperauld and Bucknall, 1984; Guttman and Guttman, 1994). Stainless steel sutures are available as a braid or monofilament (for small sizes).

Synthetic Absorbable Sutures

Monomers and Preparation of Polymers. Natural and synthetic non-absorbable materials are prepared from common materials that are also used in their fiber forms commonly used in many other industries. Synthetic absorbable sutures, which account for the largest segment of suture sales, were designed specifically for suture applications, and are currently the area with the most development possibilities. These materials are polymerized from a select group of constituent monomers, which can be combined in a vast array of configurations exhibiting unique properties. These monomers include glycolide, lactide (*d-*, *l-*, and *dl-*), *p*-dioxanone, trimethylene carbonate (TMC), ε-caprolactone, and polyethylene glycol (PEG), which become repeat units in the final polymer. Table II.5.15.6 includes the repeat unit structure of commonly used absorbable polymers, all of which degrade by hydrolysis of ester bonds. Of recent interest are sutures containing PEG, as in polyether-esters, which impart a certain degree of "swellability" to the suture. Polymers used to prepare absorbable sutures are crystalline, tough, and able to be oriented along the long axis of the fiber. Most of these are in the form of random copolymers, although some are made as block or segmented copolymers.

Polyglycolide and predominantly glycolide-based copolymers are highly crystalline stiff materials which are very susceptible to hydrolysis, leading to a faster absorption profile. Lactide-based polymers can be crystalline, but are slightly softer than glycolide-based ones, and are not as susceptible to hydrolysis. *p*-Dioxanone polymers are crystalline, but are softer than most of the glycolide- or lactide-based polymers, and are between glycolide

and lactide in sensitivity to hydrolysis. These three provide the major constituents for all synthetic absorbable sutures. TMC, ε-caprolactone, and PEG represent minor constituents in a number of sutures, and serve to alter the material properties to improve some aspect of suture performance. For example, many monofilaments are prepared from copolymers made primarily with glycolide as a hard segment and TMC or caprolactone as a softer segment, making the copolymer more flexible, while retaining strength.

Ethylene oxide is the standard method for sterilization due to the tendency of the copolymer chains to undergo scission when irradiated. Synthetic absorbable polymers degrade by hydrolysis, and are therefore sensitive to moisture. For this reason, the packaging is not only important for providing a sterile barrier, but also for protecting the suture from moisture.

Absorbable sutures are described primarily by their strength retention profile, then by absorption profile. The strength retention profile indicates the useful life of the device, and is the primary factor for selection in a particular application. The strength retention and absorption profiles for several common sutures are shown in Figures II.5.15.3 and II.5.15.4, respectively.

PGA

Dexon™, the first synthetic absorbable suture, is prepared from a homopolymer made of glycolic acid, and was released in 1971 by Davis & Geck, which is now Covidien (Benicewicz and Hopper, 1990). PGA suture is available in braided form, and is coated to improve the handling properties. Current PGA sutures exhibit about 30–50% crystallinity and retain about 65% of the initial strength after two weeks implantation, and 35% after three weeks. Absorption is essentially complete after 60–90 days (Covidien, 2005).

PDO Sutures

First introduced by Ethicon in 1983 as PDS™, monofilament sutures comprised of p-dioxanone (PDO) combine strength, flexibility, and a longer absorption profile than PGA sutures. After the initial introduction of PDS, Ethicon released PDS™ II. Reportedly, slight changes in the heat treating process resulted in greater flexibility and better handling characteristics (Chu, 1997b). PDS™ II suture retains 25% of its initial strength after 6 weeks, making it the longest-lasting commonly used

TABLE II.5.15.6	Repeat Units for Common Synthetic Absorbable Sutures	
Monomer Names	**Repeat Unit Structure**	**Homopolymer**
p-Dioxanone	$[O\text{-}CH_2\text{-}CH_2\text{-}O\text{-}CH_2\text{-}CO]_n$	Polydioxanone (PDO)
Glycolide	$[CH_2\text{-}COO\text{-}CH_2\text{-}COO]_n$	Polyglycolide (PGA)
l-Lactide	$[CH(CH_3)\text{-}COO\text{-}CH(CH_3)\text{-}COO]_n$	Polylactide (PLA)

suture currently available, allowing it to be used in slow healing tissue that previously required non-absorbable sutures (Ethicon, 2001; Capperauld and Bucknall, 1984). Also of interest are sutures prepared from PDO-based polymers, as recently discussed by Carpenter and Shalaby (2002).

High Glycolide Copolymeric Sutures

The largest segment of absorbable sutures is prepared from copolymers containing primarily glycolide in the main polymer chain. The modulus and absorption profile varies widely, based on the copolymer composition, and is quite sensitive to changes in the molecular formula.

The most well-known synthetic absorbable suture is braided Vicryl™, which is a random copolymer containing 90% glycolide and 10% lactide (Guttman and Guttman, 1994). Braided Vicryl™ retains up to 25% of its initial strength for 4 weeks, and absorption is essentially complete in 56–70 days (Ethicon, 2001). An alternate version of Vicryl™, Vicryl™ Rapide, was introduced as a faster-absorbing version of the same material. This

was accomplished by reducing the molecular weight of the fiber through a radiation sterilization process. Vicryl™ Rapide was designed as an alternative to Plain Gut suture, and loses strength within 2 weeks of implantation (Ethicon, 2008).

Most customization in this class of synthetic absorbable sutures has been in the area of monofilament sutures. Maxon™ suture, introduced in 1985 by Davis & Geck (now Covidien) is a tri-block copolymer prepared from 67.5% glycolide and 32.5% TMC (Benicewicz and Hopper, 1991). The central block is composed of a random copolymeric initiator made of 85% TMC and 15% glycolide, while the two end grafts are primarily glycolide (Casey and Roby, 1984). This composition and structure is a result of a study comparing various block structures and ratios of the constituent monomers, results of which can be seen in Table II.5.15.7. This work highlights the sensitivity of the copolymers to structure, as well as to monomer composition. Increased TMC in the central chain reduces the tensile modulus, extends the strength retention profile, and increases the time required for absorption. The small amount of glycolide in the middle block is necessary
FIGURE II.5.15.4 Maximum time for sutures to be essentially absorbed (Ethicon, 2001, 2008; Covidien, 2009a,b).

TABLE II.5.15.7	**Effect of Block Structure on PGA-co-TMC Copolymer Properties**[1]

[1]Roby et al. (1997).
[2]Breaking strength retention.

because TMC absorbs very slowly; the glycolide allows the material to degrade into short segments that can be metabolized. Maxon™ suture retains 25% of its initial strength up to 6 weeks post-implantation, and essentially absorbs by 6 months. Other unique polymer compositions that are suitable for suture applications include Monoprene®, TGS, and Glycoprene® II, which are of particular interest due to the branched structure of the polymer compared to the linear structure of all other suture polymers, providing a softer hand compared to linear polymers with similar composition and strength retention.

To fill the need for a shorter-term monofilament, Ethicon developed Monocryl™ suture. This material was developed as an alternative to gut suture (Bezwada et al., 1995), and is a tri-block copolymer containing 75% glycolide and 25% caprolactone. The initiator is reported to be a random copolymer containing 55% glycolide and 45% caprolactone, while the end blocks are primarily made of glycolide (Bezwada et al., 1995). Monocryl™ suture retains 30–40% of its initial strength after 2 weeks of implantation, and is essentially absorbed between 91 and 119 days.

This is not inclusive of all sutures currently available, but is an example of a few technologies. Major suture manufacturers are continuing development of other high glycolide copolymers, and focus remains on bringing novel, proprietary sutures to market with unique strength retention and absorption profiles.

Lactide Copolymeric Sutures

Copolymers prepared primarily of lactide exhibit extended strength retention profiles, sometimes retaining measurable strength at 6 months or longer. For this reason, lactide copolymers have been used in orthopedic applications to prepare screws and plates, for example. For slow-healing wounds, an absorbable suture having this type of extended profile may be advantageous. This was the aim when Ethicon released Panacryl™ suture, a material composed of 95% lactide and 5% glycolide. The absorption profile of this material, however, can extend to 2½ years. As of 2006, Panacryl™ has not been marketed as a suture device, although it may have use as part of other Ethicon products. An alternative to Panacryl™ is Osteoprene®, currently the only other high-lactide suture, which is used as part of a suture anchor kit, although there are other lactide-based copolymers in development for suture applications (Carpenter et al., 2002; Anneaux et al., 2003; Arthrotek, 2006).

Dyes

Sutures are provided in *natural* or *dyed* colors. The natural color of suture materials is most often white to light tan in color, with the exception of chromic gut which is

TABLE II.5.15.8	FDA-Approved Dyes for Use in Sutures[1]

[1]FDA (2007): 21 CFR Parts 73 and 74.

a darker brown color. When sutures are placed in tissue, the contrast between the suture and host tissue is low. This effect is magnified when in the presence of blood, which can make differentiation between the suture and tissue difficult. For this reason, dyed sutures are often preferred. The use of colorants is restricted by the FDA (US Food and Drug Administration), and there are a select few dyes that are approved for use in specific sutures. New dyes can be used with approval through a Color Additive Petition, which requires extensive biocompatibility and toxicology data to receive approval. For this reason, sutures are available in a select color palette, as seen in Table II.5.15.8. Synthetic sutures are dyed during the extrusion process by adding a small amount (typically less than 0.2% by weight) of powdered colorant to the polymer just prior to extrusion. Natural materials are dyed in a color solution. Processing conditions can also prohibit the use of some dyes in the suture strand. For instance, D&C Violet #2 is not used in sutures sterilized by gamma irradiation, because the dye is not stable, degrades, and loses color during exposure.

Coatings

Braided and monofilament sutures have been coated with a wide variety of materials for the primary purpose of reducing tissue drag. Coatings also fill void space, thus reducing capillarity and tendency to wick, and can act as carriers for antimicrobial agents such as triclosan. Early coatings comprised of beeswax and other natural waxes. Other coating materials for nonabsorbable sutures include silicone- and PTFE-based systems, as used on Deknatel's Tevdek® and Polydek® polyester sutures. Coatings for absorbable sutures are

typically based on absorbable copolymers, and can include polyurethanes, PEG, caprolactone copolymers, and lactide/glycolide copolymers (Mattei, 1980; Bichon et al., 1984; Ethicon, 2001). Calcium stearate and other lubricants may also be included to improve friction properties.

Coatings are generally applied through solution dip coating, and are applied at a level of 2–10 wt% of the suture strand for braids, and less than 1 wt% for monofilaments. In the case of antimicrobial sutures, a small amount of triclosan is dissolved in the coating solution, and sutures are coated in the typical fashion. If the suture is coated with too little coating, the suture will display high tissue drag and the knot will not tie smoothly, possibly fraying the suture. With a high level of coating, knot security may be compromised and the strand can loosen, thereby not securing the wound site.

Needles and Attachment

Suture needles are made from high-quality stainless steel. Typically, needles are prepared from 400-series stainless steel, though some specialties prefer 300-series needles (Hu-Friedy Mfg. Co., Inc., 2007). The manufacturing process starts with wire, which is formed to shape, and precision ground and polished to provide the final geometry. The needle end on the suture side is most typically drilled to accept the suture strand (known as a *drilled end* needle). Needles are cleaned to remove any process residue, and some are coated with silicone to reduce friction when passing through tissue.

Needles are permanently attached by a *swaging* process. Monofilament sutures are placed directly into the drilled end for swaging, but braided sutures require *tipping* to harden the end of the strand so the swaging process holds firmly onto the end of the suture. Tipping is performed with a cyanoacrylate-based adhesive on the last ½ inch of the suture strand. Also, for small size sutures, epoxy and cyanoacrylate are commonly used for needle attachment.

Packaging

Sutures are sold sterile in individual or multi-packs. Packaging for non-absorbable sutures can be in Tyvek® packaging; however, synthetic absorbable sutures are always packaged in hermetically sealed foil packaging. The sealed foil maintains a sterile barrier, as well as protecting the suture from oxygen and moisture which would initiate the degradation of the suture. This is known as a *hermetically* sealed package. Seals are designed to provide a secure seal, but also for easy opening in the surgical suite. This is often obtained by using a chevron-style peel pouch.

Inside the package is a carrier, which houses and protects the suture and needle. The carrier is made of paper or plastic, and is designed so that suture can be removed easily without tangling or otherwise damaging the suture strand. Carrier materials must be made of materials that do not adversely affect the suture. For absorbable materials, this includes drying paper carriers before insertion so that the paper does not introduce moisture in the package, leading to decreased shelf-life stability of the suture.

Common Uses of Suture

Besides wound closure and ligation, sutures are used in a variety of other medical procedures. In particular, many implants require sutures to maintain placement. Grafts require sutures for attachment at *anastomoses* (junctions between two structures, such as between an artery and a graft), and different graft types have a higher chance of surgical success with certain suture types. PET (e.g., Dacron®) grafts are typically woven and provide a tough, resilient, non-absorbable implant. Due to this construction, the suture type is not very critical. For other types of grafts, such as Gore-Tex® or naturally derived materials, the selection of monofilament sutures is indicated to reduce the chance of suture tearing (W. L. Gore & Associates, 2007). For joint repair, sutures are used in conjunction with suture anchors to reposition bone, which requires sutures with high strength, and fatigue and abrasion resistance.

Surgeons use many types of knots, depending on the tissue type and location, suture type, and placement technique. Knots can be classified as: (1) non-sliding; (2) sliding; or (3) sliding locking. The knot should be as small as possible to minimize tissue reaction, but should be strong and stable. Examples of common surgical knots include: Surgeon's Knot; Square Knot; Revo Knot; SMC Knot; Duncan Loop; and Tennessee Slider. Often, two to four additional throws are added on top of these knots to enhance knot security.

Forceps are used to assist in suture placement and knot tying. The free ends of suture are trimmed with scissors close to the knot to minimize material left at the implant site. For internal placement, it is necessary to use additional surgical tools to securely tie knots. This includes a *knot pusher*, which is available in many sizes for uses in laparoscopic, arthroscopic, and other types of procedures.

PERFORMANCE EVALUATION

There are many factors defining the performance of a suture, covering every component of the suture device. The suture must have suitable mechanical properties, which can vary widely depending on the intended application. The suture material must be sterile and biocompatible throughout the life of the device, and must be stable so that material can be stored before use. There is a large variety of analysis to prove the safety and effectiveness of the suture device. Some of the analyses are

standard test protocols that are applied to every bio-medical device, and some are designed to analyze specific functionalities of the suture.

Physical Properties

The function of the suture strand is to provide a holding force while maintaining a stable position in the implant location. There are, however, many aspects to tissue securement. The *United States Pharmacopeia* (USP) is a list of standards and requirements for the testing and production of medical devices, including several guidance documents pertaining to sutures.

Suture is defined by USP size, which is defined numerically on a scale from size 7 (largest) to 11–0 (smallest); however, the majority used is between 6–0 and 2. For size 0 and smaller, the number of 0s in the suture size increases as the diameter decreases, e.g., 00 is written as 2–0 and 0000 is written as 4–0. Smaller diameter means the suture will exhibit lower breaking load, and all sutures must meet requirements set out in the USP. The accepted practice is to use the smallest diameter suture that will adequately support the wound. This minimizes trauma caused by the placement, and ensures the minimum mass of foreign material is left in the body.

There are two basic tensile strength tests associated with sutures. USP requirements are based on the knotted tensile strength, which is always lower than the unknotted tensile strength. This ensures that the suture is strong enough to be tied during implantation without breaking. Typically, knot tensile strength is 60–80% of the unknotted (straight) tensile strength. Unknotted, or straight, tensile strength provides a good measure of the comparative mechanical properties. Beyond ultimate elongation, the tensile modulus, for monofilaments, provides a good measure of the material stiffness.

Another mechanical requirement set forth in the USP is the needle attachment strength. Suture strands are placed by pulling a needle through the tissue. The needle is fixed to the suture strand, and this junction must meet a minimum strength to ensure that the needle will not separate from the strand under typical implantation conditions.

In Vitro and *In Vivo* Performance

For absorbable sutures, strength retention profile is the key to material functionality. There are two methods for determining the strength loss profile. *In vivo* strength is typically analyzed by implanting strands of the suture subcutaneously in Sprague-Dawley rats. *In vitro* analysis involves placing suture in a physiologic buffered solution, e.g., 7.4 pH phosphate buffered solution (PBS) at 37°C. At predetermined time points, samples are collected and tested for ultimate tensile strength.

Information is reported as a percentage of the initial load. *In vitro* analysis must always be followed up with at least limited *in vivo* analysis, due to the difficulty of directly correlating performance between the two degradation conditions.

The suture strand must remain securely in place after implantation. To accomplish this, the knot needs to be stable. A single surgeon's knot is typically not sufficient to hold the suture securely, particularly in coated sutures. Additional knots are tied to increase the holding power of the knot. Contributing factors to the knot stability are friction properties associated with the suture strand. For this reason, friction is another important performance parameter.

The ideal suture provides not only tissue securement, but is also sterile and biocompatible. Medical devices must meet stringent requirements for safety, with guidance by the International Standards Organization (ISO) standard 10993-1 (ISO, 2009). According to this document, the suture strand must be tested for cytotoxicity, genotoxicity, sensitization, irritation, systemic toxicity, and sub-chronic toxicity. This represents an extensive set of *in vitro* and *in vivo* analyses. For absorbable sutures, the hydrolysis by-products, along with the polymeric material, are tested.

Suture devices are labeled *sterile*, and manufacturers must continually prove this by monitoring the effectiveness of every sterilization batch. Sterility, while not a factor in the functionality of the device, is paramount to safety. Manufacturers use spore strips, a biological indicator containing a certain number of spores, to perform this test. For the standard sterilization processes used in suture manufacturing: (1) ethylene oxide gas permeation; and (2) radiation, *bacillus atrophaeus* and *bacillus pumilus* spore strips are used, respectively, to verify sterility.

Also, for absorbable sutures, the amount of time for the tissue to absorb is a contributing factor to performance. To analyze this property, samples can be placed *in vitro* in 7.4 pH PBS at 37°C, with samples being removed at intervals and dried to constant weight. Mass loss profile is reported as a percentage of the original weight. *In vitro* test methods are only appropriate for those materials that degrade by hydrolysis, but not for sutures that are only affected by enzymatic degradation, such as gut sutures. A less quantitative method to determine absorption profile involves implantation of the suture material intramuscularly. Histological evaluation over time reveals the absorption profile. Absorption is defined as the time the suture material takes to *essentially absorb*, or lose greater than approximately 90% of its initial mass or cross-sectional area. Above this level, mass loss is difficult to analyze. Another outcome of this histological evaluation is the measure of tissue reaction to the suture, typically sampled at one week post-implantation.

In vivo analysis of sutures involves implantation in an animal model. To determine absorption and strength retention properties, a Sprague-Dawley rat model is often used. Other animal models are often employed to study the effect of surgical technique, the application of a particular suture or the suture as part of a device. This includes porcine models to compare suture technique on vascular anastomoses (Tozzia et al., 2001), rats to analyze the effectiveness of Achilles tendon repair (Kraemer et al., 2009), and rabbits to determine the effect of different suture materials in bladder surgery (Hanke et al., 1994).

Additional Performance Considerations

There are many considerations dealing with the handling of sutures that are not covered in the above testing. These include the suture *hand*, or the perceived handling characteristics. Suture hand includes the suture *drape*, which is the suture limpness (think raw versus cooked spaghetti), and the ease of knot tying. It is difficult to quantify these properties, and results are subjective.

For a medical device to be useful, it must have a proven shelf-life. Shelf-life studies track functional suture properties over standard storage conditions to determine the expiration date. Accelerated conditions are also analyzed to provide early indications of shelf-life, as specified in ASTM F1980, (ASTM, 2011). Common parameters analyzed include diameter, knot strength, and strength retention for absorbable sutures.

Thermal transitions are a contributing factor for processing conditions. Melting temperature and rheological analysis provide guidance for the melt extrusion. Glass transition temperature and information about the crystallinity endotherm, best measured with dynamic mechanical analysis (DMA) and differential scanning calorimetry (DSC) respectively, provide insight into the process temperatures to use during orientation and heat treatment. To measure the effectiveness of heat treatment and stabilization, strands of fiber are heated and measured for dimensional stability. Dimensional stability is critical, particularly for sutures sterilized by ethylene oxide gas permeation, so that fiber properties do not change due to exposure to sterilization or storage temperature.

REGULATORY CONSIDERATIONS

In order to bring a new suture to market in the United States, it must be cleared for use by the US Food and Drug Administration (FDA). Sutures are primarily considered a Class II device by the FDA, meaning new devices can be submitted using a 510(k) approach instead of a premarket approval (PMA), which significantly reduces the time-to-market (FDA, 2003). Documentation for a 510(k) submission provides data proving the new device is *substantially equivalent* to a device that is already legally marketed for the same use (known as a *predicate device*). Novel suture materials, those that do not have a substantially equivalent predecessor, may be considered a Class III device, in which case a PMA would be necessary. The purpose of a PMA is to provide adequate safety and efficacy information for a new material or a new indication for an existing material, which requires extensive pre-clinical and clinical testing, resulting in longer development times and elevated cost.

The FDA provides guidance documents to assist with the assembly of the submission packet. Accordingly, it is expected that the submission will include: (1) the design for package labeling, instructions for use (IFU), description of the device, indications, contraindications, warnings, and precautions; (2) identification of the risks associated with the use of the device and mitigation measures; (3) description of test methods and standards used during design and for release testing; (4) proof of biocompatibility following the recommendation of ISO 10993-1 standard for the biological evaluation of medical devices; and (5) a validated sterilization method (FDA, 2003). Each part of the submission can be very involved, and evidence must be provided that each section is substantially equivalent to the predicate device. For absorbable sutures, part of the above is providing evidence for the strength retention and mass loss profile. Also of interest are the various validations and studies that must be performed to show that the manufacturing process produces suture with consistent properties, and the packaged material is stable after final packaging (known as *shelf-life* or *package stability*).

The above illustrates the extent of testing necessary to bring a suture product to market, even after the product has left the initial phases of research and development. Commonly, new suture materials will take several years from conception to reach market using the 510(k) approach. When designing novel suture devices, a major consideration in material selection is the ability to show substantial equivalence for materials and indications that an extended approval process using a PMA will not be necessary.

NEWER TRENDS AND FUTURE DEVELOPMENT

In the early 2000s, Ethicon released the first of their *Plus* line of sutures containing a small amount of the antibiotic/antifungal agent Irgacare®, a brand name for triclosan. Since this time, other agents have been incorporated into sutures and explored for antimicrobial effectiveness, including chlorhexadine and octenidine (Matl et al., 2009). Also, various coating polymers have been applied to improve or extend the length of triclosan from the suture (Nagatomi et al., 2007). Therapeutic release applications have not been limited to antimicrobials, and drug release from the suture coating could be applied to a wide variety of soluble drugs and other

active agents (Zhukovsky, 2003). Modified sutures have also been used as carriers in non-traditional applications. An instance of this includes the use of suture strands to position radioactive brachytherapy seeds to treat the cancerous margins after lung resection (Fernando et al., 2005).

Medical devices are now being developed with the specific goal to repair the injured area to pre-wound functionality, and a great deal of research is developing the idea of *active* wound healing. Devices can accomplish this by initially supporting the wound through the initial healing phases, then transferring strain to the tissue to exercise and thereby improve localized healing. In other technologies, active wound healing technologies are becoming more common; an example is the recently released TIGR™ hernia mesh marketed by Novus Scientific. In the case of sutures, several patents have been issued with suture designs exhibiting biphasic functionality (Shalaby et al., 2006a). This novel class of sutures, currently in development, would provide stiffness through the initial phase of wound healing, after which the suture loosens to allow strain transfer to the wound, promoting improved wound healing.

New extrusion techniques are allowing for design of non-traditional surgical threads. Multicomponent co-extrusion is allowing for filaments with *island in the sea* and other geometries that could provide enhanced properties. In one instance, a PDO polymer was co-extruded with a softer copolymer containing *p*-dioxanone, trimethylene carbonate, and caprolactone, the fiber of which exhibited a much higher knot security compared to a standard PDO suture (Im et al., 2007). Also of interest is the creation of ultra-high strength absorbable sutures. Currently, high-lactide copolymers are being investigated for this use, with proposed applications in orthopedic areas.

A novel class of synthetic absorbable sutures includes those that swell in contact with water (Lindsey et al., 2007; Ingram et al., 2009). These materials, based on polyether-esters (such as PEG), will fill the void created by the suture needle. This technology could prove particularly useful in cardiovascular surgery, where minimized leakage at anastomosis sites is desired. Also in this class of sutures, currently under development, is USLG, a suture exhibiting an extended strength retention profile (25% strength retention after 18 weeks in 37°C PBS) (Taylor, 2010).

While traditional sutures depend on knots to secure placement of the suture strand, a novel technique involves the use of a suture with an integral securement mechanism, or barb, as seen in Figure II.5.15.5. Quill™ SRS barbed suture, marketed by Angiotech, was approved for use in 2004, and is gaining popularity in many soft tissue procedures. This alternative approach to wound closure provides a faster method of approximation, and avoids extraneous foreign material in the wound due to the bulk of a surgical knot (Angiotech Pharmaceuticals, 2009).
FIGURE II.5.15.5 Image of spiral cut barbs in Quill™ SRS suture, marketed by Angiotech Pharmaceuticals.

Beyond suture applications, these monofilaments and braids are being incorporated into a host of medical devices. For example, suture-type materials are in use as components in hemostasis devices (FemoSeal®, marketed by St. Jude), in marker devices (Hologic SecurMark® Biopsy Site Marker), in hernia mesh, and tissue engineering scaffolding.

While sutures are most commonly sterilized by gamma irradiation or ethylene oxide, there are new sterilization methods under development that may not degrade sensitive suture materials, as can be the case with both of the standard methods. Of particular interest is a new method developed and used experimentally by Shalaby and co-workers for the sterilization of radiation sensitive sutures such as polypropylene and absorbables (Shalaby, 2003, 2010). The new method is denoted radiochemical sterilization, and is a combination of low-dose gamma radiation (5–10 kGy) and radiolytically-generated formaldehyde from an oligomeric or polymeric precursor.

Alternatives to Suture

It is important to note that sutures are not the only device used for ligation and approximation. Alternative methods include staples, tapes, clips, tissue sealants, and tissue adhesives. Staples and clips can be applied quickly, and are made of non-absorbable, as well as absorbable materials. These devices can provide securement faster than sutures, but are limited in the areas of use, whereas sutures can be used for a much wider range of applications.

The most interesting of these emergent technologies is tissue adhesive. Topical tissue adhesives based on cyanoacrylates, such as Histoacryl®, Indermil®, Dermabond®, and TissueMend™ II, quickly form a strong bond to tissues. The film of adhesive, in addition to securing the wound, can act as a bacterial barrier, and affect hemostasis. There is currently no tissue adhesive approved for internal use, but development of new absorbable tissue

adhesives, such as Tissuemend™ II and HTS, may be used for just such an application. Additionally, the above absorbable tissue adhesives may be useful in areas that are traditionally difficult to treat with sutures, such as in the lung and liver (Shalaby et al., 2006b).

CHAPTER II.5.16 DRUG DELIVERY SYSTEMS

Allan S. Hoffman, Editor

A. INTRODUCTION

Allan S. Hoffman
Professor of Bioengineering and Chemical Engineering, UWEB Investigator, University of Washington, Seattle, WA, USA
(Includes contributions from the Second Edition by Jorge Heller (deceased).)

INTRODUCTION: PRINCIPLES, ORIGINS, AND EVOLUTION OF CONTROLLED DRUG DELIVERY SYSTEMS (CDDS)

A wide variety of polymeric biomaterials are components of the various formulations and devices that are routinely used for delivering drugs to the body. This section reviews the current state-of-the-art of drug delivery systems (DDS) that release drugs in a controlled manner. The major advantage of developing systems that release drugs in a controlled manner can be appreciated by examining Figure A.1, which is a plot of drug concentration in blood (plasma) versus time after delivery of the drug. This curve is known as a pharmacokinetic or PK curve. It can be seen that the blood plasma level following a single dose administration of a therapeutic

agent rapidly rises, and then gradually decays as the drug is metabolized and eliminated from the body. The separate stages of this rise and fall have been identified by pharmaceutical scientists as the *LADME* sequence, or *Liberation* of the drug from the formulation, *Absorption* of the drug into the blood, *Distribution* of the drug throughout the body, including action of the drug at various sites – especially at and within cells, *Metabolism* of the drug, usually in the liver, and finally, *Elimination* of the drug from the body, usually by excretion through the kidneys in the urine. The figure also shows drug concentrations above which the drug produces undesirable (e.g., toxic) side-effects, and below which it is not therapeutically effective. The ratio of these two levels is known as the *Therapeutic Index*, or TI, which is usually based on the dose–response of the median 50% of a large population.

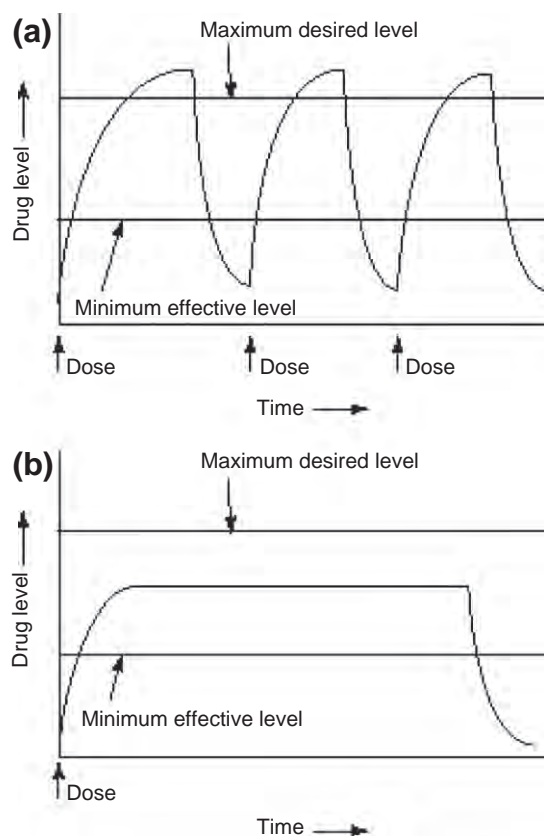
Using only a single dose administration, the time during which the concentration of the drug is above the minimum effective level can be extended by increasing the size of the dose. However, when this is done, blood plasma concentrations may rise and extend into the toxic response region, an undesirable situation. One can also administer safe doses at periodic intervals by cycling the dose in order to maintain a desired drug concentration level; however, this is inconvenient, and patient compliance is often poor. For these reasons, there has been great interest in developing controlled-release formulations and devices that can maintain a desired blood plasma level within the TI for long periods of time. These DDS


FIGURE A.1 Pharmacokinetic (PK) curves of plasma concentration of a drug versus time for two types of drug delivery systems: (a) Typical bolus PK for multiple dosing with oral tablets or injections; (b) "Zero Order" PK for one dose of controlled drug delivery from a specific formulation or device.

are called "zero order" systems, since they release drug at a constant rate.

Aside from the "assumed" therapeutic advantage of zero order controlled-release products (Note: zero order PK may not be ideal for all drugs and medical conditions, but historically that was the goal in the early days when controlled DDS were being developed), there are also compelling business reasons for the development of such products. Because of increasingly stringent US Food and Drug Administration (FDA) regulations, the cost for introducing new drug formulations has escalated to more than $200 million US dollars for each drug. It is not uncommon for this development to require more than 15–20 years of research and development work, including preclinical animal studies and human clinical trials. Thus, it is reasonable for pharmaceutical companies to attempt to maximize their financial return for each drug by research aimed at extending the patent lifetime of the drug, thereby postponing the inevitable introduction of the generic drug. One means of doing this is to patent a new controlled-release formulation with the same drug. However, the commercial feasibility of such a strategy is predicated on a demonstration that the controlled-release formulation is indeed superior in safety and efficacy to the single bolus dose formulation, and most importantly

that the cost of the controlled-release formulation is low enough to ensure a reasonable market penetration.

Successful efforts to produce pharmaceutical formulations that would prolong the action of therapeutic agents for any particular dose, thus reducing the need for frequent dosing, go back to the early 1950s with the introduction of the commercial product known as Spansules®. This product was designed to increase the duration of action of orally administered drugs, and consisted of small drug spheres coated with a soluble polymer coating. By using coatings with varying thickness, capsule dissolution times could be varied, thus prolonging the action of one dose of the therapeutic agent. Such formulations are now known as "sustained release" or "prolonged release" products. However, the pharmacokinetics of such products depended greatly on the local *in vivo* patient environment and as such, varied from patient to patient. These reasons were among the most important driving forces that led to the birth of the field of "controlled drug delivery" (CDD) in the mid- to late-1960s. There was great interest in the development of products that were capable of releasing drugs by reproducible and predictable kinetics, especially at a constant rate, yielding constant plasma drug concentrations over many hours that were safely within the TI. Ideally, such products should be designed to be unaffected by the local *in vivo* environment, greatly reducing patient-to-patient variability. Allan Hoffman has published an interesting history of the origins and early days of the controlled drug delivery field (Hoffman, 2008). The early days of this interesting history are briefly described below.

In the mid- to late-1960s, Alejandro Zaffaroni, a pharmaceutical chemist and also an entrepreneur, saw a need and a market for products that would release drugs with reproducible and predictable kinetics, independent of the patient. At the same time, and independent of each other, Dr. Judah Folkman, MD at Harvard University, published an article (Folkman and Long, 1964) in which his research suggested that a capsule made of silicone rubber (SR) could be filled with a drug and implanted in the body, where it would release drug. This concept led to the first "zero order" reservoir DDS. Zaffaroni was just in the process of founding Alza Corp. in 1968 in Palo Alto, CA, the first company dedicated to the concept of controlled drug delivery. Folkman was enlisted by Zaffaroni to head Alza's Scientific Advisory Board (see http://en.wikipedia.org/wiki/Alza).

The first CDD products developed by Alza were designs with reservoirs of constant drug concentration enclosed or covered by rate-controlling membranes. The membranes were made of one of two polymers, SR or poly(ethylene-co-vinyl acetate) (EVA). They exhibited "zero order" PK profiles (Figure A.1). A key advantage of CDDS can be appreciated by examining this figure, which illustrates changes in blood plasma levels following a single dose administration of a therapeutic agent. As shown, the blood plasma level rapidly rises, and then

exponentially decays as the drug is metabolized and/or eliminated from the body. The figure also shows drug concentrations above which the drug produces undesirable (e.g., toxic) side-effects, and below which it is not therapeutically effective. The difference between these two levels is known as the *Therapeutic Index* (TI), which is a recommended range of minimum and maximum drug concentrations in blood plasma, based on the average (or median) response of 50% of a large population to a range of specific drug doses.

Using only a single dose administration, the time during which the concentration of the drug is above the minimum effective level can be extended by increasing the size of the dose. However, when this done, blood plasma concentrations may extend into the toxic response region, an undesirable situation. Furthermore, there is still a significant fraction of the dose below the minimum effective level, which is wasted. One can also administer safe doses cyclically, e.g., by ingesting pills or administering injections at periodic intervals, in order to maintain a desired drug concentration level; however, this is inconvenient, and patient compliance is often poor. For these reasons, there has been great interest in developing controlled-release formulations and devices that can maintain a desired blood plasma level in the middle of the TI for long periods of time without reaching a toxic level or dropping below the minimum effective level. These DDS are called "zero order" systems since they release drug at a constant rate and it appears in the blood at a fixed concentration over the duration of drug delivery.

One can categorize the evolution of CDDS from the 1970s in terms of the size scale of the DDS being developed, and this is shown in Table A.1. All of the first drug delivery systems (DDS) were macro-scale devices that could be held in the hand, and each was designed to exhibit constant or zero order drug delivery rates, leading to constant plasma drug concentrations over long time durations of drug delivery. Alza applied the zero order concept to a variety of useful designs and devices and patented many of them in the 1970s, receiving FDA approval for them in the 1980s. They included drug-loaded IUDs, ocular inserts, and skin patches.

The CDD field became very popular in the 1980s, and grew to include drug-loaded, biodegradable polymer microparticles and phase-separated masses, both as degradable "depot" DDS. They were based on glycolic and lactic acid polyesters, known today as PLA (poly(lactic acid)) and PLGA (poly(lactic-*co*-glycolic acid)), and were not developed at Alza, which was pursuing another degradable polymer DDS based on polyorthoesters. These degradable DDS did not exhibit zero order kinetics, but yielded sustained release kinetics with a gradually decreasing delivery rate over time. The DDS size scale had decreased to "microscopic" with the degradable microparticles. This scale also applied to and

TABLE A.1	**Categorizing the Evolution of Controlled DDS by Size Scale**

Macroscale DDS ("Zero Order" Constant Delivery Rate DDS)
- Implants (e.g., subcutaneous or intramuscular)
- Inserts (e.g., vaginal, ophthalmic)
- Ingested DDS (e.g., osmotic pumps, hydrogels)
- Topical DDS (e.g., skin patches)

Macroscale and Microscale DDS (Site-Specific, Sustained Delivery Rate DDS)
- Surface-coated DDS (e.g., oral tablets, catheters, drug-eluting stents)
- Injected DD depots (e.g., degradable microparticles and phase-separated masses)

Nanoscale DDS (Targeted DDS)
- Injected nanocarrier DDS (e.g., PEGylated drugs, polymer-drug conjugates, PEGylated liposomes, PEGylated polymeric micelles, and drug nanoparticles, sometimes targeted by monoclonal antibodies or cell membrane receptor ligands)

included the microscopically thin, heparinized surface coatings which were developed in the 1960s, and drug-loaded polymer coatings on stents, which came much later.

In parallel with this, interest and activity was rapidly growing in nanoscopic or nanoscale injectable nanocarriers, including PEGylated drugs and PEGylated, drug-loaded polymeric micelles and liposomes. Many drug delivery scientists were also attaching antibodies to the nanocarriers, to target them to specific cells, but active targeting evolved much more slowly into the clinic. The enhanced permeability and retention effect (EPR) also provided strong rationale for the use of nanocarriers to target solid tumors.

In summary, the CDD field has grown to a multi-billion dollar, worldwide business over the past 55 years, and the scale of CDD devices and formulations themselves has shrunk from macroscopic devices to microscopically thin coatings and microparticles, and down to nanoscopic, molecular CDDS. In parallel with this, the materials and designs progressed from off-the-shelf polymeric materials and devices of simple designs, to degradable, drug-loaded, polymeric microparticles, and down to the complex world of controlled molecular weight block graft copolymers and dendrimers, intracellular druggable targets, such as nuclear DNA, cytosolic mRNA, ribosomes, and apoptotic pathways, with monoclonal antibodies and peptide ligands being used to target the drugs to specific cells.

Aside from the clear therapeutic advantage of controlled-release products, there are also compelling business reasons for the development of such devices. Because of increasingly stringent FDA regulations, the cost for introducing new drug entities has escalated to

hundreds of millions of US dollars for each drug, and it is not uncommon for this development to require more than 10 years of research and development work and clinical trials. Thus, it is reasonable for pharmaceutical companies to attempt to maximize their financial return for each drug by research aimed at extending the patented lifetime of the drug, and one means of doing this is to patent a new controlled-release formulation with the same drug. However, the commercial feasibility of such a strategy requires that the controlled release formulation is demonstrated to be superior in safety and efficacy to the single dose formulation, and most importantly, that the cost of the controlled-release formulation is low enough to ensure a reasonable market penetration.

B. INJECTED NANOCARRIERS

Allan S. Hoffman, Wayne R. Gombotz,
and Suzie H. Pun, Editors

B.1. INTRODUCTION

Allan S. Hoffman
Professor of Bioengineering and Chemical Engineering, UWEB
Investigator, University of Washington, Seattle, WA, USA

Drugs may interact with the body in three sites: (1) within the circulation or interstitial space; (2) at membrane receptors on cell surfaces or (3) at various sites within the cell. Nanoscale drug delivery systems are colloidal solutions or dispersions of nanoparticles containing drugs. The particles usually range from several tens to a few hundreds of nm in diameter. Drug-loaded nanocarriers are usually endocytosed by cells. The endosome has a proton pump in its membrane, causing the pH to drop from 7.4 to as low as 5.0. Within one to a few hours after endocytosis the endosome is "trafficked" to the lysosome, which is also at a lowered pH. The lysosome contains enzymes that are active at the low pH of that vesicle. If the drug is enzyme-susceptible, its efficacy will be determined by how efficiently it can escape the endosome before it ends up in the lysosome, where it may be enzymatically degraded. Enzymatically susceptible drugs, such as DNA, RNA, antisense oligonucleotides, peptides or proteins must escape the endosome to be effective at targets within the cell.

Nanocarriers include PEGylated drug systems where the drug may be a protein, peptide, small organic drug or a nucleic acid drug. Other nanocarrier drug systems include polymeric micelles, liposomes, polymer–drug conjugates, polymer–drug polyelectrolyte complexes (known as polyplexes or lipoplexes), dendrimers, and drug nanoparticles. These Drug Delivery Systems (DDS) are often PEGylated to enhance circulation times. Most nanosize DDS have been designed to target tumors, although there are other specific cellular targets in the body that are not in tumors. Nanosize drug carriers are injected intravenously and distributed throughout the circulation, where they may be taken up into the tumor tissue via the Enhanced Permeability and Retention (EPR) effect. This has been called "passive" targeting. Sometimes the drug action may be enhanced by targeting of specific cancer cells with antibodies or cell receptor ligands, which is designed to stimulate endocytosis into specific target cells. (This is like the "magic bullet" concept of Ehrlich, e.g., see Ehrlich, 1900, and Winau et al., 2004.) This is called "active" targeting.

Depending on the indication, an ideal nanocarrier delivery system should have some of the following properties to facilitate targeted delivery of drugs (Petrak, 1993):

- Prolonged duration of delivery due to longer circulation times compared to free drug
- Reduced drug toxicity in non-targeted tissues
- Reduced adsorption of proteins, which reduces opsonization and recognition by the immune system
- Minimal loss of drug from the nanocarrier during circulation
- Increased drug concentration at the desired site of action
- Enhanced uptake by the target tumor or by the target cells
- Release of the drug at the target site at an appropriate rate.

B.2. PEGYLATION OF DRUGS AND NANOCARRIERS

Allan S. Hoffman and Suzie H. Pun
Department of Bioengineering, University of Washington, Seattle, WA, USA

Poly(ethylene glycol) (PEG) is an unusual molecule, with good solubility in both aqueous and organic media. It has been shown that it binds approximately two water molecules per oxygen ether group (Antonsen and Hoffman, 1992). Above molecular weights (MWs) of 500–1000 it may coil randomly and transiently entrap such "bound" water molecules within the coil, which is sometimes called the "excluded volume" of PEG. MWs of 3–40 (2 × 20) kDa are preferred for protein PEGylation. The excluded volume of a PEG coil in water may prevent close approach of and recognition by the immune system and, more simply, it may prevent opsonization by protein binding and subsequent removal by the reticuloendothelial system (RES) in the liver. (The concept of PEGylation of drugs originated in the late 1960s by Frank Davis (see Davis, 2002) when he was looking for a way to reduce recognition of the new recombinant protein drugs by the immune system.) Kopecek and co-workers showed that another hydrophilic polymer, hydroxypropyl methacrylamide (HPMA), is a non-immunogenic drug carrier similar to PEG (Minko et al., 2000).

Another special property of PEG is claimed to be its inability to be a proton donor in a hydrogen bond. Both Merrill (Merrill and Salzman, 1983) and Whitesides (Ostuni et al., 2001) and their collaborators have cited this property as important to its "repulsion" of proteins. All of these effects lead to reduced renal clearance, immunogenicity and enzymolysis, and enhanced solubility, stability, and circulation times, especially for biomolecular drugs such as proteins.

Most nanocarrier drug delivery systems are comprised of a macromolecular carrier conjugated to a drug or a prodrug through a linker. These macromolecular delivery systems offer several potential advantages compared with the free drug. For protein drugs, conjugation to hydrophilic polymers such as poly(ethylene glycol) (PEG) or HPMA results in improved pharmacokinetic profiles and reduced immunogenicity. For small molecule drugs, water-soluble polymer carriers can improve drug solubility, and may also be used to target the drug passively to tumors (via the enhanced permeability and retention (EPR) effect) or actively to specific cells (via conjugation of cell specific ligands to the hydrophilic polymer). The primary application for small molecule delivery with molecular carriers has therefore been cancer treatment. Chemotherapeutic drugs may be effluxed from multidrug resistant (MDR) cells by the P-glycoprotein (P-gp) mechanism, and they are also free to extravasate and diffuse throughout the body after administration, resulting in unwanted side-effects and low therapeutic indices. By increasing the effective molecular weight of the drug through conjugation to a macromolecular carrier, P-gp efflux from cancer cells and renal clearance rates are both reduced; thus, improved tumor treatment can be achieved by a combination of enhanced circulation times plus the EPR effect. Sometimes drug efficacy can be further enhanced by active targeting of the nanocarrier to specific cancer cells. Because most chemotherapeutic drugs are hydrophobic, polymer–drug conjugates tend to form micelle-like structures in aqueous solutions and have dimensions of ~5–20 nm. In this section, several polymer nanocarriers will be discussed.

B.3. TARGETING

Patrick S. Stayton, Bilal Ghosn, and John T. Wilson
Department of Bioengineering, University of Washington, Seattle, WA, USA

INTRODUCTION

Despite great potential, many promising drugs remain limited by low stability, toxicity, inefficient administration, and the need for multiple doses. For example, while chemotherapy is effective for the treatment of malignancies, it is widely known for harmful side-effects on healthy tissues. Moreover, such factors contribute not only to poor efficacy, but also reduce patient compliance. Targeted drug delivery systems offer great promise for improving the specificity of new therapeutics and revitalizing conventional therapies limited by adverse side-effects. In this section, we discuss methods of carrier targeting and their applications in drug delivery. While conjugation chemistries are not thoroughly reviewed, more detailed information is available in other literature (Hermanson, 2008).

FIGURE B.3.1 Targeting ligands used in drug delivery and their molecular weights.

There are two general classes of targeting, passive and active. Passive targeting is dependent on the physicochemical properties of the drug/carrier system. Targeting is achieved by tailoring the properties of the delivery system to exploit physiological properties of target tissues, while simultaneously minimizing uptake into undesired tissues. This is often achieved by altering surface charge, hydrophobicity, and size and shape of the carrier system (Cai et al., 2007). Examples of passive targeting include cationic microparticles for enhanced delivery to phagocytic cells (Kanke et al., 1983), surface modification with polyethylene glycol (PEG) to provide "stealth" behavior from immune recognition (Abuchowski et al., 1977), and use of larger macromolecules or nanoparticles to exploit the enhanced permeability and retention (EPR) effect (Matsumura and Maeda, 1986).

While passive targeting can enhance delivery to tumors and/or phagocytic cells, it does not provide the high specificity found in active targeting. Active targeting is based on molecular recognition of specific receptors on cellular or extracellular targets where the effect of the drug is desired. Ligand–receptor and antigen–antibody interactions are two targeting modalities commonly employed for drug delivery. Active targeting moieties can range widely in size from small molecules such as folic acid, peptides, and carbohydrates to larger macromolecules such as antibodies and glycoproteins. Here, we will discuss the use of such moieties for targeted delivery ranging from organ-specific to cell-specific levels. Structures and molecular weights of the ligands discussed are shown in Figure B.3.1. Examples of various carriers with each ligand are summarized in Table B.3.1.

IMMUNOTARGETING

Monoclonal Antibodies

The proposed use of antibodies for drug targeting, which has been described as a magic bullet due to their high specificity, has existed for over a century (Ehrlich, 1900). Key characteristics which make antibodies a promising targeting agent include their high specificity and affinity for target, and their capability to induce specific immune responses, which include antibody-dependent cell-mediated cytotoxicity and cytolysis. The development of monoclonal antibody (mAb) technology in 1975 was a key breakthrough that enabled the use of antibodies as drugs and targeting agents (Kohler and Milstein, 1975). The first US Food and Drug Administration (FDA)-approved use of monoclonal antibodies occurred in 1986 with Muromonab CD3 (Thistlethwaite et al., 1984). While most early clinically-approved mAb therapies were purely antibody-based therapies, a few antibody–conjugate therapies have received approval since 2000, including Mylotarg and Cimzia (Schreiber et al., 2005).

Monoclonal Antibody-Targeted Liposomes

The development of antibodies for targeting nanoparticle-based drug carriers has grown greatly over the past two decades, in part due to the ability of nanoparticles to

TABLE B.3.1	Targeted Carriers Used in Drug Delivery				
Ligand Type	Carrier Type	Targeting Moiety	Drug	Target Cell/ Tissue	Reference
Monoclonal Antibody (mAb)	Liposome	Anti-H-2k IgG2A Anti-Thy1.1 IgG2A	Methotrexate-γ-aspartate	L929 cells	Heath et al., 1983

	PCL-b-PEG (Micelle)	Cyclic-RGD	Doxorubicin	Kaposi's sarcoma cells	Nasongkla et al., 2004

HPMA: hydroxypropyl methacrylate
PCL: polycaprolactone
pDMAEMA: polydimethylaminomethyl methalrylate
PEG: polyethylene glycol
PEI: polyethylenimine
PLGA: poly(lactic-co-glycolic acid)
PGD: arginine-glycine-aspartic acid

carry high drug payloads relative to molecular conjugates. As early as the 1980s, introduction of antibodies to liposomes demonstrated cell-specific uptake of liposomes coated with an anti-H-2k antibody (Huang et al., 1980). Chemical conjugation of monoclonal antibodies to liposomes for targeted delivery of encapsulated small molecules demonstrated up to 10-fold increases in tumor growth inhibition (Heath et al., 1983). Further progress with antibody-targeted liposomes, often referred to as immunoliposomes, has continued for nearly a quarter of a century. More recently, immunoliposomes have employed a polyethylene glycol (PEG)-spacer for improved circulation time and specificity. For

example, DOPE liposomes utilizing PEG-linked anti-EGFR antibodies and encapsulating Gemcitabine have demonstrated significant anti-tumor effects relative to untargeted and free drug (Kim et al., 2009).

Monoclonal Antibody-Targeted Polymeric Carriers

The use of antibodies conjugated to polymeric delivery systems has also been investigated, in part due to the tailorability afforded by polymers. This allows for numerous conjugation schemes in combination with other delivery-enhancing properties. An early study of

hydroxypropyl methacrylate (HPMA) polymers conjugated to an anti-θ mAb demonstrated a 70-fold increase in the activity of gamma globulin against targeted lymphocytes (Rihova and Kopecek, 1985). Several examples of targeting with the polymer HPMA have been previously reviewed (Kopecek and Kopeckova, 2010; Minko, 2010; Ulbrich and Subr, 2010). Conjugation of anti-thrombomodulin mAbs to the cationic polypeptide poly-L-lysine increased uptake in lung cells both *in vitro* and *in vivo*. Antibody targeting of polyethylenimine (PEI) nanoparticles also enhanced transfection efficiency and specificity for numerous cancer cell types (Chiu et al., 2004; Germershaus et al., 2006). Targeting with monoclonal and polyclonal antibodies has also been studied for polymeric micellar carriers. Initial studies in 1989 demonstrated that targeted micelles prepared with Pluronic 85 increased haloperidol efficacy by nearly 500-fold relative to free drug (Kabanov et al., 1989). Recently, conjugation of human monoclonal antibody against hypoxia inducible factor-1α (HIF-1α) to Pluronic P123 micelles demonstrated selective cytotoxicity to tumor cells when delivering Paclitaxel (Song et al., 2010).

Antibody fragments. While monoclonal antibodies have shown promise as targeting moieties, their large size (~150 kDa) may reduce penetration into certain tissues. Furthermore, mAbs may impart immunogenic side-effects, including cytokine release, thus leading to cytotoxicity. To circumvent these limitations, targeting with antibody fragments has been evaluated in a variety of forms. The two most common types of antibody fragments explored today are Fab and Fv (or scFv) fragments. Fab fragments represent the antigen binding fragment of an intact antibody containing both the variable and constant regions of both heavy and light chains. Fv, or the variable fragments, represent the portion of the antibody containing variable regions of both chains, which are shown in Figure B.3.1.

Antibody fragments have been thoroughly investigated for their potential to enhance the specificity of numerous carrier systems. Initial development of a conjugation scheme for Fab fragments to liposomes was published in 1980 using rabbit anti-human erythrocyte F(ab′)₂ fragment, resulting in a 200-fold increase in erythrocyte binding (Heath et al., 1980). Later studies focused on the use of anti-HER2 targeted immunoliposomes with both F(ab′) and scFv fragments for enhancing delivery of the cancer drug doxorubicin (Park et al., 2002). More recently, it has been shown that the circulation time of immunoliposomes is enchanced for both anti-CD19 Fab and scFv fragments relative to whole mAb, an effect responsible in part for the increased mean survival time relative to all other groups in a murine B-cell lymphoma model (Cheng and Allen, 2008).

Antibody fragment-targeted polymeric carriers have also been investigated. In initial studies, the conjugation of F(ab′) antibody fragments to HPMA demonstrated a nearly 10-fold increase in conjugate circulation times, although no *in vivo* tumor targeting was reported (Seymour et al., 1991). Later, however, conjugation of anti-OV-TL16 F(ab′) to HPMA resulted in more homogeneous affinity to target cells relative to whole antibody–polymer conjugates, resulting in enhanced plasmid DNA (pDNA) expression within targeted lung epithelium and submucosal glands (Omelyanenko et al., 1996). Recent conjugation of anti-OV-TL16 antibody fragments to PEI-*graft*-PEG polymers for gene delivery (Merdan et al., 2003) improved expression levels by up to 80-fold compared to untargeted carriers in OA3-expressing OVCAR-3 cells. Fab (anti-envelope glycoprotein, gp160) and scFv (anti-ErbB2) antibody fragments conjugated to protamine, a cationic polymer, demonstrated enhanced and specific uptake into target cells expressing the appropriate receptors (Song et al., 2005). Thus, antibody fragments conjugated to polymeric carriers provide a highly specific and effective method for targeting potent macromolecular drugs.

CARBOHYDRATES

Carbohydrates have also been evaluated as potential targeting moieties for cell- and tissue-specific drug delivery. Interactions of carbohydrates with highly-specific cell membrane receptors known as lectins provide a powerful mechanism for targeting. It has been four decades since the discovery of the first mammalian lectin (Van Den Hamer et al., 1970). In this landmark study, removal of the terminal sialic acid residues from ceruloplasmin exposed galactosyl residues and resulted in rapid clearance of the intravenously administered dose. The removal of the terminal sialic acid residues results in glycoproteins known as asialoglyocoproteins. It was later determined that the majority of accumulation for these asialoglycoproteins was in the liver (Pricer and Ashwell, 1971). The receptor was later termed the asialoglycoprotein receptor (ASGP-R), and noted to internalize the β-linked galactose-bearing ligands (Ashwell and Morell, 1974).

Several lectins demonstrating specific affinity for carbohydrates such as galactose, mannose, fucose, and lactose have been identified to date, and may contain monovalent or multivalent binding sites. ASGP receptors are classified as part of the C-class lectins, which is predominantly due to the requirement of Ca^{2+} for binding to carbohydrates. The various classifications of lectin hold unique characteristics and have previously been reviewed (Wadhwa and Rice, 1995).

Galactose-Targeted Liposomes

Targeting moieties for liposomes have most commonly utilized monosaccharides or oligosaccharides of galactose or mannose to provide specific targeting to the liver and immune cells, respectively. One of the first evaluations of galactose-based targeting was shown by Gregoriadis and Neerunjun in 1975 (Gregoriadis and Neerunjun, 1975). In these studies, incorporation

of fetuin, a desialylated glycoprotein, to the surface of liposomes increased uptake of carriers in the liver following intravenous administration. From these early studies emerged the development of galactose-targeted liposomes as tissue-specific drug delivery systems for a variety of molecules such as siRNA (Sato et al., 2007).

Galactose-Targeted Polymeric Carriers

Targeting of lectins such as ASGP-R has also been researched in a variety of polymeric systems for delivery of drugs. One of the earliest investigations again involved HPMA functionalized with D-galactosamine, which demonstrated nearly 70% uptake into the liver within 1 hour following administration relative to 10% of control conjugates functionalized with either D-mannosamine or D-glucosamine (Duncan et al., 1983). Conjugation of asialoorosomucoid (ASOR), a desialylated glycoprotein, to poly-l-lysine effectively delivered pDNA into ASGP-R positive Hep G2, but not into ASGP-R negative SK-Hep 1 cells (Wu and Wu, 1987). Recently, galactose-targeting with the polymer PBAVE demonstrated effective localization of siRNA/polymer conjugates into hepatocytes following intravenous administration (Rozema et al., 2007). The evaluation of galactose-targeting for polymeric micelles has also shown great promise for improved delivery to the liver. Introduction of galactosamine to the surface of poly(γ-glutamic acid)-poly(lactide) nanoparticles encapsulating Paclitaxel effectively enhanced uptake of nanoparticles in hepatoma tumors (Liang et al., 2006), demonstrating the potential of galactose-targeting for polymeric micellar carriers.

Mannose-Based Targeting. Mannose and its oligomeric form mannan have been examined as ligands for specific delivery to macrophages and dendritic cells. Much like the ASGP receptor, the mannose-based receptors come in many forms, and are predominantly found in cells involved in inflammation and immunity such as macrophages, dendritic cells, and endothelial cells (Irache et al., 2008). A thorough review of the receptor biology is available (Irache et al., 2008). The specificity of mannose-binding lectins on macrophages was demonstrated by evaluating the uptake of a variety of glycoproteins by rat alveolar macrophages (Stahl et al., 1980). It was noted that glycoproteins with an exposed mannose, glucose or n-acetyl glucosamine were bound by the alveolar macrophages, while glycoproteins with a terminal galactose were not.

Mannose-Targeted Liposomes

One of the earliest studies with mannose-targeted delivery demonstrated that incorporation of 6-aminomannose directed liposomes to leukocytes following subcutaneous injection, and to the lungs following intravenous injection (Mauk et al., 1980). Later studies determined that the mannosylation of liposomes resulted in improved

binding and an adjuvant or immunoenhancement effect from the carriers when used to deliver tetanus toxoid, thus providing great potential for use in vaccine delivery (Garcon et al., 1988). More recently, mannosylated liposomes encapsulating ciproflaxin (CPFX) were developed for pulmonary treatment of intracellular parasitic infections of the respiratory system (Chono et al., 2008). Dual targeting of liposomes with both mannose and transferrin has also been evaluated for improved delivery across the blood–brain barrier (Ying et al., 2010).

Mannose-Targeted Polymeric Carriers

Mannose-based targeting of polymeric carriers has also been evaluated. Introduction of mannosamine to HPMA was shown to increase uptake by liver macrophages following intravenous administration in mice (Seymour et al., 1987). Later, mannosylated poly-l-lysine conjugates were shown to effectively increase specific uptake of the anti-leishmanial drug allopurinol riboside, improving drug efficacy 50-fold for the treatment infection with *L. donovani* (Negre et al., 1992). Kim and colleagues recently reported enhanced treatment of a colon adenocarcinoma model by delivery of pDNA encoding for the cytokine IL-12 via a mannosylated chitosan carrier (Kim et al., 2006). Targeted delivery with mannose analogs has also been evaluated with polymeric micellar carriers. Mannose conjugation via a PEG-spacer to PLGA (poly(lactic-*co*-glycolic acid) micelles encapsulating Amphotericin B was shown to enhance drug uptake in J774.A1 macrophages, and *in vivo* uptake in the liver, spleen, and lymph nodes (Nahar and Jain, 2009).

NUTRIENT-BASED TARGETING

Folate/Folic Acid

Folate, or vitamin B9, is a small molecule that binds to folate-binding proteins (FBP) with a high affinity. Exploitation of folate as a targeting ligand for delivery of macromolecules was initially demonstrated in 1991 to increase macromolecule uptake in KB cells, a human carcinoma line (Leamon and Low, 1991). Interest in folate as a targeting ligand increased as it was demonstrated that folate receptors were overexpressed in ovarian cancer cells (Campbell et al., 1991), and subsequently many other carcinomas (Weitman et al., 1992). Given these characteristics and the relatively small size of folate, the promise for this vitamin as a targeting ligand for cancer therapeutics and diagnostics has spawned a plethora of research in the area of material science.

Folate-Targeted Liposomes and Polymeric Carriers

While initially studied as a direct conjugate to macromolecules, folate has been evaluated for targeting in a variety

of drug delivery systems. Initial studies with folate conjugated to liposomes demonstrated a 37-fold increase in cellular uptake by KB cells relative to untargeted liposomes (Lee and Low, 1994). Folate-targeted liposomes have also been shown to increase uptake and therapeutic efficacy when used to deliver doxorubicin (Lee and Low, 1995) and antisense oligonucleotides (Wang et al., 1995). More recently, uses of folate-targeted liposomes have also been shown to serve as potential carriers for molecular probes, such as quantum dots for cancer diagnosis (Yang et al., 2009).

Conjugation of folate to polymeric carrier systems also enhances targeted uptake. Early studies of folate-targeted polymeric carriers for pDNA include folate-poly-l-lysine (Mislick et al., 1995) and folate/PEI (Guo and Lee, 1999). Conjugation of folate via PEG spacers to poly-dimethylaminomethyl methacrylate (pDMAEMA)/pDNA polyplexes resulted in significant two-fold increases in gene expression levels in OVCAR-3 relative to untargeted polyplexes (van Steenis et al., 2003). Similar conjugation of folic acid to micelles has also been studied with a variety of polymers. Introduction of folate as a targeting moiety to PEG-PLGA diblock micelles also enhanced doxorubicin-mediated cytotoxicity to KB cells, reducing the IC$_{50}$ for the drug by nearly 30% relative to untargeted micelles, and reduced tumor cells *in vivo* by nearly 30% as compared to free DOX/untargeted micelles (Yoo and Park, 2004).

Transferrin

Transferrin (Tf), an 80 kDa glycoprotein found in serum, binds and transports iron into cells via receptor-mediated endocytosis. Unlike many other receptor-mediated pathways, following endocytosis and release of its iron payload, both the receptor and transferrin are rapidly exocytosed from the cell and released to repeat the process (Ciechanover et al., 1983). Similar to a number of receptors, overexpression of the Tf receptor, (TfR) has been noted in numerous malignant cell lines, and has thus been proposed as a potential targeting ligand for cancer therapy (Trowbridge, 1988; Thorstensen and Romslo, 1993). As early as 1985, transferrin conjugation to the diphtheria toxin was shown to significantly enhance its efficacy (Okeefe and Draper, 1985). A nearly eight-fold increase in the circulatory half-life of the chemotherapeutic drug neocarzinostatin was also demonstrated following its conjugation to transferrin (Kohgo et al., 1988). These early studies demonstrated the potential for transferrin-targeted delivery.

Transferrin-Targeted Drug Delivery Systems

One of the earliest studies of transferrin-targeted carriers demonstrated the use of transferrin conjugated to the surface of both pH-sensitive and insensitive liposomes, where results demonstrated that enhancement of efficiency was dominated by the presence of transferrin (Brown and Silvius, 1990). Transferrin introduced to the surface of phosphatidylethanolamine directed effective delivery to leukemia HL60 cells (Sarti et al., 1996), while transferrin-polylysine conjugated liposomes were effective at enhancing the delivery of α-interferon (α-INF) (Liao et al., 1998). PEGylation of liposomes can further enhance efficacy when using the transferrin-targeting agent (Eavarone et al., 2000; Soni et al., 2008).

Transferrin-targeting has also been applied to numerous polymeric carriers for drug delivery. Early evaluation of transferrin conjugated to HPMA resulted in a nine-fold increase in conjugate uptake compared to untargeted HPMA carriers (Flanagan et al., 1989). Transferrin conjugated to PEI demonstrated enhanced pDNA transfection up to two orders of magnitude greater than untargeted carrier in primary melanoma cell lines (Wightman et al., 1999). Transferrin is perhaps most promising as a targeting ligand for carrier delivery across the blood–brain barrier, such as with transferrin-targeted PEG-polyamidoamine dendrimer for the delivery of pDNA to the brain (Huang et al., 2007). The conjugation of transferrin to PEG-g-PEI polymeric micelles has also been demonstrated to increase polyion complex accumulation by 80-fold compared to free oligonucleotide (Vinogradov et al., 1999), thus further demonstrating the potential of transferrin as a targeting ligand.

PEPTIDE-BASED TARGETING

Peptides represent another potential avenue for targeted drug delivery which has received a great deal of attention over the past 20 years. The discovery of the arginine-glycine-aspartate (RGD) peptide as a cell adhesion sequence in 1994 has led to a flurry of research not only on its function, but also on the potential of RGD for enhancing drug delivery (Pierschbacher and Ruoslahti, 1984). In 1997 it was later discovered that RGD was an essential sequence for numerous extracellular matrix (ECM) proteins and membrane proteins, thus making it a major player for cellular targeting (Pfaff, 1997).

Peptide-Targeted Drug Delivery Systems

RGD-containing peptides have been used in a variety of drug carrier systems over the past two decades. Incorporation of a GRGDSPC peptide sequence to liposomes provided a nine-fold increase in platelet cells relative to untargeted liposomes (Nishiya and Sloan, 1996). Later studies evaluated the potential of RGD-targeted PEG-coated-liposomes targeted specifically for the integrin $\alpha_v\beta_3$ which is overexpressed in angiogenic epithelial cells, demonstrating enhanced circulation time and uptake of doxorubicin into angiogenic epithelial cells, increasing binding efficiencies by seven-fold (Schiffelers et al., 2002). Recent studies have demonstrated effective

delivery of a variety of agents using RGD-containing peptide targeted liposomes to a diversity of cell types, such as colon cancer cells (Garg et al., 2009).

The introduction of an RGD peptide to a small poly-l-lysine polymer for targeted DNA delivery represented one of the earliest RGD-targeted polymeric carriers demonstrating selective uptake based on the integrin-binding capacity of the carrier (Hart et al., 1995). Similarly, conjugation of RGD to PEI has demonstrated increased *in vitro* gene expression of 10- to 100-fold relative to both plain PEI and RGE-targeted (non-specific) PEI carriers (Erbacher et al., 1999). PEGylated PEI/DNA complexes modified with either RGDC or HIV-1 TAT peptides demonstrated up to a 14-fold increase in gene expression, while also mediating enhanced vector endosomal escape in RGD-targeted conjugates (Suk et al., 2006). RGD-targeting can also enhance the delivery efficiencies of polymeric micelles, such as the surface functionalization of PCL-b-PEG micelles with a cyclic RGD peptide which resulted in a 30-fold increase of doxorubicin internalization by Kaposi's sarcoma cells relative to unmodified micelles (Nasongkla et al., 2004).

SUMMARY

The goal of targeted drug delivery continues to be increasing target specificity, an evident need in the world of medicine and biotechnology. A wide range of biomolecular derivatives have been investigated with each possessing unique properties and advantages. These can include tissue or disease specificity, immunogenicity, size, ease of synthesis or isolation, and stability. Despite a century of major advances since Erlich's "magic bullet" theory, further understanding and development of active targeting remains necessary and crucial to improving drug delivery, and is vital to successful clinical translation of liposomal, polymeric, and micellar drug delivery technology.

B.4. POLYMER–DRUG CONJUGATES

Suzie H. Pun and Allan S. Hoffman
Department of Bioengineering, University of Washington, Seattle, WA, USA

INTRODUCTION

The concept of synthetic polymer–drug conjugates was developed in the 1970s. In the late 1960s and early 1970s, Frank Davis at Rutgers University NJ, USA conceived of the idea of reducing the potential immunogenicity of the new genetically-engineered recombinant proteins by PEGylating them (Davis, 2002). Helmut Ringsdorf published a prescient article on polymer–drug conjugates in 1975 that included concepts of conjugation of cell ligands and "trafficking" molecules (e.g., lipids and polyethylene glycol (PEG)) to the polymer backbone (Ringsdorf, 1975). In the mid-1970s Jindrich Kopecek and colleagues in Prague prepared poly(HPMA)–drug conjugates with a pendant, degradable tetrapeptide spacer to the drug (Kopecek et al., 1977). Later, in a collaboration with Ruth Duncan, they designed and synthesized a hydroxypropyl methacrylamide (HPMA) copolymer with doxorubicin conjugated to the HPMA backbone by a tetrapeptide spacer that was a substrate for the lysosomal enzyme, cathepsin B (Duncan, 2009). They also later conjugated a targeting ligand (galactose) to the same spacer, producing one of the first examples of a targeted, polymer–drug conjugate. This section reviews many of the different polymer–drug conjugates other than PEG, which was discussed earlier in this section.

POLY(HPMA) AS A DRUG CARRIER

The first synthetic polymer drug conjugate to be tested clinically was an HPMA copolymer (N-2-hydroxypropyl methacrylamide) conjugated to doxorubicin (Figure B.4.1A). HPMA polymers were developed by Kopecek and Bazilova (Kopecek and Bazilova, 1973), and used by Duncan and co-workers for drug delivery applications due to its biocompatibility and low blood protein-binding properties (Duncan, 2009). Functionalized copolymers were synthesized by copolymerization of HPMA with
FIGURE B.4.1 Four polymer-drug conjugates: (A) Poly(hydroxypropyl methacrylamide) (PHPMA) conjugated to doxorubicin; (B) Poly(glutamic acid) (PG) conjugated to paclitaxel; (C) Cyclodextrin backbone polymer conjugated to camptothecin; (D) Polyacetal conjugated to camptothecin.

a methacryloylated-peptidyl-nitrophenylester; this co-monomer was used for drug conjugation through an aminolysis reaction. Many clinically-tested conjugates use the Gly-Phe-Leu-Gly peptidyl linker introduced through the second co-monomer. This peptide sequence is a substrate for lysosomal thiol-dependent proteases (e.g., cathepsin B), so that drug release is designed to occur after endocytosis of the drug conjugate and trafficking to the lysosomal compartment. Because the HPMA backbone is not biodegradable, the molecular weight of the polymers is typically limited to <40 k, so that materials can be cleared renally.

Several other chemotherapeutic drugs, such as doxorubicin, paclitaxel, camptothecin, and platinates, have been conjugated to HPMA and evaluated in clinical trials with varying success. The paclitaxel and camptothecin conjugates developed by Pharmacia were halted after Phase I trials due to toxicity issues. Doxorubicin conjugates licensed to Pharmacia entered Phase II trials, and a galactose-modified copolymer was also evaluated for targeted delivery to hepatocarcinoma. Prolonged plasma circulation was achieved with this conjugate compared with free doxorubicin, and tumor accumulation was observed in metastatic breast cancer patients (Duncan, 2009). An HPMA–platinate conjugate has been evaluated in Phase II clinical trials by Access Pharmaceuticals. They reported drug efficacy with favorable safety profiles in patients (Nowotnik and Cvitkovic, 2009).

POLY(GLUTAMIC ACID) (PG) AS A DRUG CARRIER

Poly(L-glutamic acid) (PG) is a biodegradable polymer that is degraded by the lysosomal enzyme cathepsin B (Figure B.4.1B). PG has been conjugated to various anti-cancer agents, including doxorubicin, paclitaxel, and camptothecin (Li, 2002). Several drug–polymer linkages were also tested, including amides, hydrolyzable ester, hydrazone bonds, and enzymatically degradable peptide spacers. Drug activity was optimized by varying the release kinetics from the degrading polymer and evaluating drug efficacy.

Two PG–drug conjugates, PG–paclitaxel and PG–camptothecin, were evaluated clinically by Cell Therapeutics, Inc. The first to enter the clinic was a PG conjugated to paclitaxel via a glycine linker. The polymers had an average molecular weight of 38 kD with 37% by weight paclitaxel conjugated in the 2′ position of the glutamic acid by an ester bond. The drug conjugate was shown to be relatively stable in the blood circulation, and to release active drug primarily through lysosomal cathepsin B degradation of the polymer backbone after cellular uptake (Paz-Ares et al., 2008). The PG–paclitaxel conjugate delivered similar amounts of active paclitaxel compared with equivalent doses of standard paclitaxel (the "area under the curve" or AUC values were similar), but the prolonged distribution of the polymer–drug conjugate resulted in decreased maximum plasma concentration (C_{max}) compared with the standard paclitaxel dose, and also reduced myelosuppression and alopecia (Bonomi, 2007). Interestingly, Phase III studies showed that the overall survival of patients treated with PG–paclitaxel did not differ significantly from patients treated with free paclitaxel. However, a subset of patients, specifically premenopausal women, responded more favorably to the drug conjugates, perhaps due to higher estrogen levels that correlate with cathepsin B activity. An application was submitted for marketing to the European Medicines Agency by Cell Therapeutics in 2008 for this formulation; PG–paclitaxel may therefore be the first polymer–anticancer drug conjugate to be marketed. Cell Therapeutics also investigated clinically a PG-camptothecin conjugate. However, development of this material was halted after Phase I/II studies.

CYCLODEXTRIN POLYMERS AS DRUG CARRIERS

Cyclodextrins (Figure B.4.1C) are cyclic oligomers of glucose, and have been used as drug solubilizers in US Food and Drug Administration (FDA)-approved formulations. Linear polymers of cyclodextrin synthesized by condensation polymerization of bifunctionalized cyclodextrin monomers with a second comonomer have been investigated as drug carriers in clinical trials. The first material evaluated clinically by Insert Therapeutics is a cyclodextrin polymer–camptothecin conjugate (IT-101; Figure B.4.1C) (Davis, 2009a,b). Camptothecin was conjugated to the carboxylate groups of the cyclodextrin polymer through a glycine linker, resulting in a hydrolyzable ester bond (Cheng, 2003). IT-101 has molecular weight ~70 k, and is renally excreted. In aqueous solutions, IT-101 self-assembles into particles with sizes ~30–40 nm in diameter. Unlike the micellar structure depicted in Figure B.4.1, the self-assembly of IT-101 particles is likely driven by inclusion complex formation between the cyclodextrin and camptothecin molecules. Phase I clinical trials of IT-101 for treatment of advanced solid tumors showed long half-life of IT-101 in humans (~40 hours) and disease stabilization in several patients.

POLYACETALS AS DRUG CARRIERS

A biodegradable polyacetal poly(1-hydroxymethylethylene hydroxymethylformal) (Figure B.4.1D) conjugated to camptothecin (XMT-1001) has also been investigated in clinical trials. This molecular carrier, under development by Mersana Therapeutics, delivers camptothecin via a two-phase drug release mechanism (Yurkovetskiy et al., 2004). A camptothecin derivative is first released from the polymeric backbone; this lipophilic derivative is active but not as potent as camptothecin. This derivative is then hydrolyzed into camptothecin. It is hypothesized that the dual-release approach may result in improved tumor delivery. XMT-1001 entered Phase I clinical trials in 2007.

B.5. LIPOSOMES

Wayne R. Gombotz
Immune Design Corp., Seattle, WA, USA

The first observation that ordered structures are obtained when water-insoluble lipids, such as phospholipids, are mixed with an excess of water was made by Bangham and co-workers in the 1960s (see historical review by Bangham, 1983). These ordered structures eventually self-assembled as concentric, closed spherical membranes known as liposomes or vesicles. Such liposomes can consist of one or a multiplicity of bilayer membranes. Liposomes with a single lipid bilayer are typically 25–100 nm in size, and are called small unilamellar vesicles (SUV) as shown in Figure B.5.1. Multilamellar vesicles (MLV) have several concentric bilayers and are larger in size,

FIGURE B.5.1 Formation of a single unilamellar vesicle (SUV) liposome. (NanolifeNutra® website.) Note that the addition of "water" could be an aqueous solution of the drug, which will end up in the core of the liposome if it is very hydrophilic or in the lipid bilayer if it is very hydrophobic, or it may partition between those two phases depending on its relative hydrophilic/hydrophobic character.

with diameters up to several microns. A good review has recently been published (Gregoriades, 2003).

Stable liposomes from phospholipids are formed only at temperatures above the gel-to-liquid crystalline phase transition temperature (Tc) of the phospholipid, which represents the melting point of the acyl chains. The Tc of phospholipids is also dependent upon the nature of the polar head group, and on the length and degree of unsaturation of the acryl chains (Gregoriadis and Senior, 1980). A variety of phospholipids have been used to prepare liposomes, the most common ones being distearoyl (with a saturated hydrocarbon chain) and dioleoyl phosphatidylcholine (with an unsaturated hydrocarbon chain) (Scherphof et al., 1979).

Liposomes are employed as drug delivery vehicles for their ability to protect encapsulated drugs from degradation, and to improve the biodistribution of drugs, thereby reducing systemic toxicity. Liposomes are able to entrap water-soluble solutes in the aqueous inner core. Lipophilic drugs may be entrapped in the lipid bilayers by combining such drugs with the phospholipids used during preparation of the vesicles. The encapsulation within or association of drugs with liposomes alters the pharmacokinetic properties of the drug, and this may be exploited to achieve targeted therapies with improved efficacy.

Vesicles larger than about 200 nm are rapidly cleared from the blood, and end up in the macrophages of the reticuloendothelial system (RES). This can be exploited to deliver antiparasitic and antimicrobial drugs to the mononuclear phagocytic system (Alving et al., 1978). To reduce phagocytic uptake of liposomes and increase their circulation times, liposomes can be coated with polyethylene glycol (PEG) or sialic acid surfactants. In the former case, PEG is conjugated to a phospholipid such as phosphatidylethanolamine, which inserts into the liposome's lipid bilayer, "PEGylating" the liposome. Sialic acid surfactants may be similarly used. These polymers form a water-retaining coating around the liposome, and prevent recognition by the reticuloendothelial system (RES) (Gregoriades, 1995a). Such liposomes have been termed "stealth liposomes." To impart cellular specificity to liposomes, antibodies may be conjugated directly to them (Torchilin et al., 1979). PEGylated or stealth liposomes with target recognition properties have also been synthesized (Gregoriades, 1995b), and they are the most

commonly used today. Such "active targeting" requires the identification of suitable receptors on the surface of the target cells and appropriate ligands on the surface of the liposome that can recognize this target. When the liposome is PEGylated, the targeting ligand is conjugated to the outer end of the PEG molecules.

Four major factors control the *in vivo* behavior and biodistribution of liposomes. First, liposomes will leak drug if cholesterol is not included in the vesicle membrane. Cholesterol increases the packing density of phospholipids in the lipid bilayer and stabilizes the liposome structures (Damen, 2005). Second, large liposomes are cleared more rapidly than small liposomes, due to rapid elimination by the RES system (Senior, 1987). Third, charged liposomes are cleared more rapidly than uncharged liposomes, again typically by RES removal. Finally, the half-life of a liposome increases as the liposome dose is increased (Ostro and Cullis, 1989). Since the RES is the primary mode of clearance, saturation of the phagocytic cells with high liposome doses can increase circulation time of remaining liposomes.

Many anticancer drugs exhibit toxic side-effects, which make them ideal candidates for targeted delivery by liposomes. Some of these drugs are also subject to P-glycoprotein (P-gp) efflux from cancer cells, which are multi-drug resistant (MDR) cells. The use of nanocarriers such as liposomes avoids this effect, since the carriers are entrapped within the tumor tissue by the enhanced permeability and retention (EPR) effect, and subsequently may be taken up into cancer cells by endocytosis, avoiding the P-gp efflux mechanism. An early publication on PEGylated liposomes was by Klibanov and co-workers (Klibanov et al., 1990). The first liposomal product was approved by the US Food and Drug Administration (FDA) in 1995. It was a PEGylated liposome-doxorubicin product called Doxil® for the treatment of ovarian cancer (Muggia et al., 1997; Lyass et al., 2000). Doxorubicin-loaded "stealth" liposomes circulate for prolonged periods of time and accumulate within tumors (Papahadjopoulos et al., 1991). Non-stealth liposomes made from high Tc lipids such as distearoyl phosphatidylcholine also accumulate within tumors, and have been marketed as the product called DaunoXome®, a liposomal daunorubicin formulation, for the treatment of Kaposi's sarcoma (Forssen, 1997).

Liposomes have been developed successfully as vaccine adjuvants, potentiating both cell-mediated and humoral immunity (Gregoriades et al., 1996). Liposomal adjuvants act by slowly releasing antigen upon intramuscular injection, and by passively accumulating within regional lymph nodes. They can be prepared by encapsulating soluble antigens, microbes, cytokines or DNA. There are two liposome-based vaccines approved in Europe, Epaxal® for the prevention of hepatitis A and Inflexa® V for immunization against influenza. Both of these vaccines contain two influenza viral antigens, hemagglutinin and neuraminidase. These antigens are exposed on the liposome surface and also anchored in the liposome membrane, and this design mimics the outer coat of the influenza virus. In addition, Epaxal® contains the whole cell hepatitis A virus RG-SB strain adsorbed to the surface of the liposome, while Inflexal® V has HIN1, H3N2, and B2 influenza strains on its surface.

Table B.5.1 summarizes many of the current commercially available liposome products. Of the four therapeutic products listed, all of the drugs are encapsulated within the liposome except AmBisome®, which consists of a unilamellar bilayer liposome with the hydrophobic drug, amphotericin B, intercalated within the lipophilic membrane. Amphoterecin B, a polyene antibiotic, is associated with extensive renal toxicity in the treatment of systemic fungal infections. By passively targeting the liver and spleen, AmBisome® reduces renal and general toxicity of the drug (Gray and Morgan, 1991). Another product, Abelcet®, although technically not a true liposome, consists of amphotericin B complexed with two phospholipid molecules in a 1:1 drug-to-lipid molar ratio. The two phospholipids, L-α-dimyristoylphosphatidylcholine and L-α-dimyristoylphosphatidylglycerol, are present in a 7:3 molar ratio. Abelcet® is used to treat a variety of serious fungal infections, and acts in a similar manner to AmBisome®; it also exhibits reduced kidney toxicity. It is often used in patients who cannot tolerate or who do not respond to regular amphotericin treatment.

Cationic liposomes have also been used for the delivery of DNA, a topic that is discussed in more detail in the section in this chapter on gene therapy, and polyplexes and lipoplexes for nucleic acid drug delivery.

TABLE B.5.1	Examples of Commercially Approved Liposome Products			
Product	**Company**	**Active Agent**	**Indication**	**Year Approved**

B.6. POLYMERIC MICELLES

Wayne R. Gombotz[1] and Allan S. Hoffman[2]
[1]Immune Design Corp., Seattle, WA, USA

[2]Professor of Bioengineering and Chemical Engineering, UWEB Investigator, University of Washington, Seattle, WA, USA

INTRODUCTION

Amphiphilic (or amphipathic) block copolymers can self-assemble into supramolecular structures in aqueous media, adopting a variety of morphologies that include spheres, rods, vesicles, and lamellae. This section focuses on spherical polymeric micelles because of the extensive investigation of these materials as drug delivery vehicles. For details on other structures formed from amphiphilic block copolymers, the reader is directed to excellent published reviews (Discher et al., 2007; Letchford and Burt, 2007).

Most micelles are assembled from amphiphilic, A–B, block copolymers, i.e., block copolymers composed of a hydrophilic and a hydrophobic segment, although micelles can also be constructed from graft copolymers with a soluble hydrophilic main chain and insoluble hydrophobic side chains. The earliest papers on A–B block copolymer micelles designed for drug delivery were jointly developed by the groups of Kataoka and Okano (e.g., Yokoyama et al., 1990a,b). Polymeric micelles have a fairly narrow size distribution, and have a core shell structure where the core contains the hydrophobic segments surrounded by an outer shell of the hydrophilic segments; the outer shell is often referred to as the "corona." Micelle formation is driven by the decrease in system free energy resulting from the sequestering of hydrophobic segments from aqueous environments as they release their hydrophobically bound water, with an associated large entropy gain (for a detailed review see Allen et al., 1999). Above the critical micelle concentration (CMC), micelles exist in equilibrium in solution with single polymer chains (unimers). Below the CMC, micelles dissociate into unimers, and it has often been speculated that when polymeric micelles containing drugs are injected into the blood they are rapidly diluted below the CMC and dissociate. This is a concern with their clinical use. Some micelles are kinetically stable below the CMC due to their slow dissociation.

Polymeric micelles have excellent potential as drug delivery systems (DDS), because they offer the ability to solubilize poorly water-soluble drugs and thus increase drug bioavailability (Sutton et al., 2007). Micelles are typically 10–100 nm in size, and therefore they can passively target tumors due to the enhanced permeability and retention (EPR) effect. Like liposomes, micelles can also be actively targeted by attachment of specific ligands at the ends of the hydrophilic block segment (Torchilin, 2004; Sutton et al., 2007). Many types of targeting ligands have been conjugated to micelles including small organic molecules, peptides, carbohydrates, antibodies, and aptamers. Table B.6.1 provides a summary of the types of ligand-targeted micelles that have been reported in the literature for cancer treatment. Several excellent reviews on polymeric micelles in drug delivery have

been published (Kataoka et al., 2001; Torchilin, 2001). Encapsulation of a drug within a stable polymeric micelle will significantly alter drug pharmacokinetics, and can lead to an increase in drug targeting to tumor tissues. Once a micelle reaches the target site by either passive targeting (e.g., EPR) or active targeting via ligands, it becomes critically important that the drug is released from the micelle carrier and elicits its desired cytotoxic effect. Several strategies have been developed in which the micelles are engineered to trigger drug release by certain stimuli at the tumor site. These include drug release facilitated by a pH change, temperature change, ultrasound, acid-labile bonds in the linkage between the drug and the polymer forming the micelle, an ionizable component within the micelle structure, and chemical reactivity (Sutton et al., 2007).

Polymeric micelles designed for delivery of drugs and imaging agents can be divided into four classes that share a similar molecular architecture (Koo et al., 2005a). These include: (1) phospholipid micelles; (2) Pluronic® micelles (which are A–B–A triblock copolymers, in contrast to the others which are A–B structures); (3) poly (L-amino acid) micelles; and (4) polyester micelles.

In contrast to typical phospholipids used to form liposomes, such as phosphatidylcholine, polyethylene glycol (PEG)-conjugated phospholipids self-assemble into nanosize micelles. These micelles are simple to prepare and have relatively low toxicity; they also have prolonged circulation times (Sethi et al., 2003). A number of therapeutic agents have been incorporated and stabilized in these micelles, including paclitaxel (Krishnadas et al., 2003), diazepam (Ashok et al., 2004), camptothecin (Koo et al., 2005b), and vasoactive intestinal peptide (Onyuksel et al., 1999).

Although other hydrophilic polymers can be used to solubilize and stabilize hydrophobic drugs (Torchilin and Papisov, 1994), poly(ethylene glycol) or PEG remains the polymer of choice. However, a variety of polymers have been used to form the water-insoluble block in the micelle core. This block may be a water-insoluble hydrophobic polymer or a water-insoluble ionic complex, such as between a nucleic acid drug and a polycation block. The insoluble core blocks thus may be comprised of poly(propylene oxide) (Kabanov et al., 1989), poly(L-lysine)-nucleic acid complexes (Katayose and Kataoka, 1998), hydrophobic esters of poly(aspartic acid) (Yokoyama et al., 1990a,b), γ-benzoyl-L-aspartate (Kwon et al., 1997), γ-benzyl-L-glutamate (Jeong et al., 1998), polycaprolactone (Kim et al., 1998), poly(D,L-lactic acid) (Ramaswamy et al., 1997), and poly(ortho esters) (Toncheva et al., 2003). Polyion complex cores were described by Harada and Kataoka (1995), and metal ion complex cores were published in 2003 (Nishiyama et al., 2003).

A recent generation of targeted micelles is based on systems with multiple functionalities. Bae, Kataoka, and collaborators conjugated doxorubicin to the aspartic acid residues of a PEG-polyaspartic acid (PEG-pAsp) copolymer via a hydrazone linkage to improve drug loading and create a pH-triggered drug release system (Bae et al., 2003). Folic acid was then added as a targeting ligand to increase uptake and ultimate cytotoxicity of the formulation to folate receptor presenting cells (Bae et al., 2005). Torchilin designed a pH-controlled and targeted micelle system with two targeting ligands on the PEG-phospholipid micelles. The first is an antibody attached to the end of a longer 3.4 kD PEG chain, the second is a targeting ligand such as TAT peptide attached to shorter PEG 2 kDa chains (Sawant et al., 2006). Filamentous micelles with nanometer diameters, but lengths up to several microns, are worth mentioning because of their improved *in vivo* biodistribution compared with

spherical micelles. Discher and co-workers have shown that these "filomicelles" have a wormlike structure that can remain in the circulation for at least a day after intravenous (IV) injection (Christian et al., 2009). In their studies, filomicelles formed from PEG-polycaprolactone (PCL) diblock copolymers were loaded with paclitaxel. Intravenous injection of the paclitaxel filomicelles nearly doubled the maximum tolerated dose (MTD) of the drug in normal mice compared to paclitaxel-loaded spherical micelles. They were also shown to effectively deliver both paclitaxel and a near-infrared imaging agent to solid tumors, where they produced sustained tumor shrinkage and tumor cell apoptosis.

Polymeric micelles have principally been used as drug carriers in tumor-targeting applications. Clinical data have been reported on three polymer micelle systems, SP1049C (Danson et al., 2004), NK911 (Matsumura et al., 2004), and Genexol-PM (Kim et al., 2004). All three micelle formulations have stabilizing PEG coronas to minimize opsonization and uptake by the reticuloendothelial system (RES) of the liver, enhancing blood circulation times.

Pluronics® or Poloxamer® polyols are thermally-responsive tri-block copolymers of polyethylene glycol (PEG or PEO) and polypropylene glycol (PPO) with the formula PEO–PPO–PEO. They have been used as polymeric micelle drug carriers (Wang and Johnston, 1991). While many of these block copolymers have transition temperatures (called "cloud points") well above body temperature, when aqueous solution concentrations rise above around 16% some copolymer compositions will exhibit thermally-induced transitions around body temperature. Pluronic polyols L61 and F127 have recently been used as polymeric micelles in Phase I clinical trials for delivering anticancer drugs, where they may avoid the membrane-bound P-glycoprotein (P-gp) efflux pump, and thereby overcome the multidrug resistance (MDR) of certain cancer cells (Kabanov et al., 1989). P-gp efflux is a phenomenon whereby free anti-neoplastic drugs are pumped out of a cell, resulting in failures of chemotherapy regimes (Batrakova et al., 1996). Nanocarriers in general can avoid this phenomenon; however, one major disadvantage of Pluronic® polyol polymeric micelles in particular is that they are not degradable.

SP1049C is a Pluronic®-micelle encapsulating doxorubicin. In a Phase I study it exhibited a slower clearance of doxorubicin compared to free doxorubicin (Danson et al., 2004). A subsequent Phase II study showed that among 19 eligible patients with adenocarcinoma of the esophagus, nine partial responses (47%) and eight stable diseases (42%) were achieved (Armstrong et al., 2006). The investigators concluded that the micellar doxorubicin was active in this group of patients, and recommended studies combining doxorubicin with other active agents. In an earlier Phase II study this system was shown to avoid the P-gp drug efflux mechanism.

Cells that exhibit the P-glycoprotein (P-gp) efflux phenomenon with free drugs are called multi-drug-resistant or MDR cells. It has generally been concluded that drugs delivered by nanocarriers are sequestered in tumor tissues due to the EPR effect, and the carriers can then be endocytosed into cancer cells, avoiding the P-gp efflux effect.

NK911 is comprised of doxorubicin encapsulated in micelles based on a block copolymer of poly(ethylene glycol)-poly(aspartic acid), with a fraction of doxorubicin covalently bound and a fraction ionically complexed to the aspartic acid units (Nakanishi et al., 2001). The drug was given intravenously to patients with solid tumors every three weeks in a Phase I clinical trial. A total of 23 patients were enrolled, and a maximum tolerated dose (MTD) of 67 mg/m^2 and a dose-limiting toxicity of neutropaenia were observed.

Genexol-PM (where PM = polymeric micelle), a formulation comprised of paclitaxel encapsulated in a polymeric PEG-(PLA) (poly D,L lactic acid) micelle, was approved in 2008 in South Korea for the treatment of breast and lung cancer (Kim et al., 2004; Lee et al., 2006). In a current Phase IIa pancreatic cancer trial in the US, Genexol-PM showed similar pharmacokinetics to conventional paclitaxel formulated in Cremophor® EL. In contrast, marked improvement in patient morbidity was observed. Moreover, a lower degree of myelosupression was observed with Genexol-PM, which allowed for a considerable increase in the MTD, with an MTD of 390 mg/m^2 compared to 230 mg/m^2 for Cremophor® EL.

B.7. DENDRIMERS

Wayne R. Gombotz
Immune Design Corp., Seattle, WA, USA

Dendrimers are a unique class of macromolecules comprised of a highly branched three-dimensional architecture around an inner core with low polydispersity and a high degree of functionality. The word "dendrimer" comes from the Greek "dendros", meaning trees, and "meros", meaning part. Dendrimers can range in diameter from 1 to 10 nm. On a molecular level the dendritic branching results in semi-globular structures with a high density of surface functionalities and a small molecular volume. Higher generation dendrimers occupy a smaller hydrodynamic volume compared to corresponding linear polymers of the same molecular weight as a result of their globular structure (Boas and Heegaard, 2004). The dendritic structure is characterized by layers between each focal point (or cascade) that are called generations (Figure B.7.1).

Dendrimers were first introduced in the late 1970s by Vögtle and co-workers (Buhleier et al., 1978). A "cascade" synthesis was described, in which an exhaustive Michael-type addition of acrylonitrile to an amine, followed by the reduction of the nitrile groups to primary amines, could in theory be repeated *ad infinitum* to produce highly branched macromolecules. Current dendrimer designs are based on a wide variety of linkages, including polyamines (PPI dendrimers) (Buhleier et al., 1978), polyamides and amine mixtures (polyamidoamine or PAMAM dendrimers) (Tomalia et al., 1985), poly(aryl ether) subunits (Hawker and Fréchet, 1990), carbohydrate core structures (Turnbull and Stoddart, 2002) or elements such as silicon or phosphorous (Majoral and Caminade, 1999) (Figure B.7.2).

The physical characteristics of dendrimers, including their water solubility, monodispersity, encapsulation ability, and large number of functionalizable peripheral groups, makes them ideal candidates for use as drug delivery systems (Morgan et al., 2006). Considerable interest has been shown applying dendrimers for targeted delivery of drugs, peptides, oligonucleotides, carbohydrates, and vaccines, and also as permeability enhancers able to promote oral and transdermal drug delivery (Boas and Heegard, 2004). Drugs can be physically encapsulated in the void spaces of the dendrimer's interior or chemically or physically bound onto the dendrimer surface along with targeting ligands. Several reviews have been published that discuss the potential for using dendrimers as drug delivery systems (Liu and Fréchet, 1999; Esfand and Tomalia, 2001; Boas and Heegard, 2004; Florence, 2005). Since these systems are still relatively early in their development there are no commercially available injectable products using dendrimer technology. One barrier to commercialization may be the difficulty of carrying out a large-scale synthesis and purification process that reproducibly yields a uniform composition and molecular weight of the dendrimer product.

In an *in vitro* study, a polyester dendrimer composed of glycerol and succinic acid was used to encapsulate several camptothecin anticancer drugs (Morgan et al., 2006). The cytotoxicity of the dendrimer–drug complex toward four different human cancer cell lines was evaluated, and low nmol/L IC_{50} values were measured. Significant increases in both cellular uptake and drug retention within the cells were also reported. PAMAM dendrimers conjugated to *cis*-platin were shown to act as a macromolecular carrier for platinum. The dendrimer–platinate provided a slower release of the platin, while exhibiting higher accumulation in solid tumors and lower toxicity compared to *cis*-platin alone (Malik et al., 1999). In another study, dendrimers based on a 1,4,7,10-tetra,azacyclododecane core having primary amines at its surface have been partially modified with 1-bromoacetyl-5-fluorouracil to form a labile imide linkage (Zhuo et al., 1999). Under physiological conditions, hydrolysis of the imide released the 5-fluorouracil *in vitro*.

VivaGel® is the first dendrimer drug to be tested in the clinic. The product manufactured by, Australia-based (Melbourne) Starpharma is a gel-based dendrimer–drug formulation under development as a topical vaginal microbicide to prevent the transmission of sexually transmitted infections, including HIV and genital herpes. To date, the limited clinical experience using dendrimers makes it impossible to designate any particular chemistry intrinsically nontoxic. Key factors in determining the wide adoption of future dendrimer technologies for drug delivery applications will center on reducing the costs and complexity of their manufacture, increasing reproducibility of the product, and confirming their biocompatibility and safety in man (Terrillion, 2008).

B.8. NUCLEIC ACID DELIVERY

Suzie H. Pun and Allan S. Hoffman
Department of Bioengineering, University of Washington, Seattle, WA, USA

INTRODUCTION

Nucleic acid therapy offers the potential to treat diseases with higher specificity and efficacy than traditional small molecule drugs. Nucleic acid-based drugs modulate the protein expression profiles of cells by interfering either with gene transcription or translation. This class of drugs offers high specificity of action and the potential to address the genetic causes of disease.

GENE EXPRESSION

In diseases such as hemophilia or ADA-SCID (adenosine deaminase-linked SCID), patients lack a functional protein due to a gene mutation. Expression of the missing protein can be restored by introducing the gene or messenger RNA transcript back into the desired cells. Viruses can be engineered to deliver replacement genes to cells. In non-viral delivery systems, protein replacement is typically achieved by delivering a plasmid coding for the desired gene under the control of an appropriate promoter.

GENE KNOCKDOWN

Poorly-controlled expression of proteins or expression of mutated proteins can also lead to disease. In addition, infections involve undesirable pathogen proteins in host cells. There are several potential approaches for selective gene silencing in cells.

- In traditional antisense therapy, a synthetic antisense oligonucleotide (AS-ODN) (either DNA or RNA) complementary to an mRNA transcript is introduced to cells. This drug binds to and inactivates its mRNA target. The first US Food and Drug Administration (FDA)-approved nucleic acid drug, *fomivirsen*, is an antisense therapy for cytomegalovirus retinitis. More recently, antisense oligonucleotides complementary to microRNA (miRNA) have been developed for disease treatment. miRNAs are short, noncoding RNA that regulate gene expression through partial recognition of mRNA targets.

- Catalytic DNA- or RNA-based enzymes, called DNAzymes or ribozymes, respectively, recognize target RNA through complementary base pairing, cleave the RNA, and then dissociate and become available to seek new targets. While ribozymes are naturally occurring, DNAzymes were first developed through *in vitro* selection, and offer advantages of stability and ease of synthesis over ribozymes (Tafech et al., 2006).

- Short, interfering RNA (siRNA) are ~21 base pair RNA duplexes that trigger the RNA interference (RNAi) mechanism used by microRNA to silence genes. After cytosolic delivery, siRNA are loaded into an RNA-induced silencing complex (RISC), a protein machine that recognizes and cleaves mRNA complementary to the incorporated guide strand of siRNA. Synthetic siRNA can be delivered as the nucleic acid therapeutic, or be generated in the cell by delivery of DNA that is transcribed to short hairpin RNA. Gene knockdown by the RNAi mechanism has been shown to be more potent than antisense oligonucleotides, DNAzymes or ribozymes (Grunweller et al., 2003).

Several of the oligonucleotide drugs currently in clinical trials are chemically modified in order to

(a) RNA **(b)** 2'-OH modifications **(c)** Phosphorothioates **(d)** Peptide nucleic acids
FIGURE B.8.1 Structure of RNA (a) and commonly used chemical modifications: methylation or fluorination of 2'-OH (b) phosphorothioate backbone (c). The synthetic peptide nucleic acid polymers (d) are also used as RNA mimics.

improve their bioavailability (Watts et al., 2008). Some common modifications are: replacement of the phosphodiester backbone to phosphorothioates, phosphorodiamidates or polyamides to reduce nuclease susceptibility; modification of the 2'-OH in RNA by methylation or fluorination to increase serum stability; and conjugation of ligands such as cholesterol or steroids to assist in cell permeation (Figure B.8.1). However, there are often trade-offs associated with these chemical modifications. For example, phosphorothioates tend to exhibit higher toxicity and immunogenicity *in vivo*, and 2'-O-methylation has been shown to reduce siRNA activity in some cases. Recent work has also shown that multimeric siRNA prepared by cross-linking siRNA with reducible disulfide bonds results in enhanced gene silencing without significant immunogenicity (Mok et al., 2010).

LIGAND BINDING

DNA or RNA aptamers are single-stranded oligonucleotides that fold into three-dimensional structures and are able to bind to targets such as proteins. Pegaptanib is an FDA-approved polyethylene glygol-modified aptamer that binds to $VEGF_{165}$ for treatment of age-related macular degeneration.

Rapid translation of siRNA technology from worms to humans: in 1998, RNA interference was first demonstrated in the nematode *C. elegans* by Andrew Z. Fire and Craig C. Mello. For this discovery, they were awarded the Nobel Prize in Physiology or Medicine in 2006. McCaffrey and Kay were the first to report in 2002 that siRNAs delivered by hydrodynamic injection could be used to suppress gene expression *in vivo*

in adult mice. In 2004, the first siRNA-based drug entered clinical trials as a treatment for age-related macular degeneration. Within five years, several more siRNA-based drugs were in clinical trials for diseases including hepatitis B, respiratory syncytial virus infection, and cancer (Castanotto and Rossi, 2009). The first targeted siRNA delivery formulation entered clinical trials in 2008 (Davis, 2009). There are also many diseases for which siRNA are being tested in preclinical trials, including hypercholesterolaemia and Parkinson's disease. Efficient, non-toxic, and specific delivery systems for siRNA drugs remain an important need for broad translation of this promising technology.

BIOMATERIALS AND NUCLEIC ACID DELIVERY

Viral and non-viral delivery vectors have been used successfully to deliver nucleic acids both in cell cultures and in several animal models. The basic premise is that these delivery vectors help to condense and also to protect the nucleic acid from degradation. When formulated as nanoparticles with diameters typically <200 nm, the small size of the vehicles allow for systemic administration. The delivery systems can also facilitate cell targeting and intracellular trafficking. Ideally, the biomaterials used in delivery systems should be both non-toxic and non-immunogenic. The major classes of delivery vectors are discussed in the following sections.

VIRAL DELIVERY

Several families of viruses, including retrovirus, adenovirus, adeno-associated virus, and poxvirus, have been evaluated as gene delivery vectors in clinical trials. Viruses are natural pathogens that efficiently deliver

DNA to specific cells. Viral vectors contain a modified genome within the virion structure. The modified genome contains only essential viral sequences and the desired transcription unit of the exogenous gene, thereby rendering the virus replication-incompetent (Smith, 1995). Engineered viruses are generally very efficient in overcoming the intracellular barriers to delivery, but tend to be more immunogenic than synthetic carriers. In addition, the application of some viral types may be limited due to their natural tropism. Ongoing research in the field includes efforts to reduce immunogenicity through capsid engineering or regulated expression cassettes (Nayak and Herzog, 2010). Viruses have also been retargeted to new cell types by vector engineering approaches such as pseudotyping (swapping viral attachment proteins within a given family of virus) or genetically engineering to introduce peptides for cell-targeting (Schaffer et al., 2008). Synthetic polymers have been used to help address both of the above concerns (Cattaneo et al., 2008). Hydrophilic polymers such as poly(ethylene glycol) (PEG) and poly(N-(2-hydroxypropyl)methacrylamide) (pHPMA) have been conjugated to the surface of viruses to reduce recognition by neutralizing antibodies. Bifunctional polymers have been used to both shield the surface and present new targeting ligands for changing cell tropism.

NON-VIRAL DELIVERY: INTRODUCTION

Gene therapy (pDNA), antisense oligonucleotide (asODN), and silencing RNA (siRNA) delivery systems have become very actively researched in the past several years. In particular, since DNA, RNA, and asODNs are all highly negatively charged molecules, cationic polymers and cationic liposomes have been used to ionically complex and condense in size these nucleic acid drugs for delivery into cells. Plasmid DNA complexes with cationic polymers are called polyplexes, and complexes with cationic liposomes are called lipoplexes. Together, these two methods are called non-viral delivery systems. They are much less efficient than viral carriers, but the latter may cause undesirable toxic and immunogenic responses in the body (although there is also some toxicity associated with polycations in the body).

It is not clear how and when the polycation actually releases the DNA. It is probably not an efficient process, since the polycation and the DNA must each be "reunited" with their counterions in that process. This may be one reason why non-viral systems are so inefficient. Some polyplexes and lipoplexes also tend to be unstable in serum, possibly due to disruption by proteins and lipoproteins in the circulation, and also potentially due to degradation of the DNA by nucleases. Another challenge to the stability of the polyplexes or lipoplexes may be heparan sulfate groups on cell surfaces that can compete with the nucleic acid drug for the cationic groups on the polymer or liposome, leading to some dissociation of the delivery complex.

Lipoplexes (Cationic Lipid–Nucleic Acid Complexes)

Cationic lipids are amphiphilic molecules that have a cationic head group and a hydrophobic tail group connected by either stable or degradable linkages (Hirko et al., 2003). Felgner and co-workers first demonstrated the use of cationic lipids for DNA delivery in 1987 (Felgner et al., 1987). Many cationic lipids since then have been synthesized and evaluated for nucleic acid delivery. Common head groups used in nucleic acid delivery agents include quaternary ammonium salt lipids and lipoamines. Tail groups are usually 12–18 carbon long alkyl chains or cholesteryl groups. Typical nucleic delivery formulations include a cationic lipid, a neutral "helper" lipid, and the nucleic acid. Figure 1h.2 shows the structure of DOTAP (1,2-diolyoxy-3-(trimethylammonio)propane), a lipid that was used in clinical trials, and DOSPA (N,N-dimethyl-N-([2-sperminecarboxamido]ethyl)-2,3-bis(dioleyloxy)-1-propaniminium pentahydrochloride), a major component of the commercially available Lipofectamine™. When mixed with anionic nucleic acids, the resulting self-assembled complex is called a "lipoplex." Some lipoplexes undergo a phase transition in the endosome that assists with membrane destabilization and translocation into the cytoplasm. Although cationic lipids are some of the most efficient synthetic materials used for *in vitro* delivery, *in vivo* applications have been limited due to toxicity and susceptibility to protein-induced aggregation in the blood. Lipoplexes have primarily been used in clinical trials for treatment of cancer or cystic fibrosis (Caplen et al., 1995). PEGylation of lipoplexes by including a PEG–lipid conjugate during formulation can lead to increased plasma circulation times, but often at the expense of cellular uptake efficiency. PEG conjugated to lipids via a labile bond can be incorporated in the lipoplexes; the kinetics of PEG release in these formulations depend on the length of the lipid that serves as the lipoplex anchor (Guo and Szoka, 2001). Recently, cationic lipids and lipid-like materials that facilitate siRNA delivery *in vivo* at low doses were identified through both rational design and combinatorial synthesis and screening, respectively (Love et al., 2010; Semple et al., 2010).

Polyplexes (Cationic Polymer–Nucleic Acid Complexes)

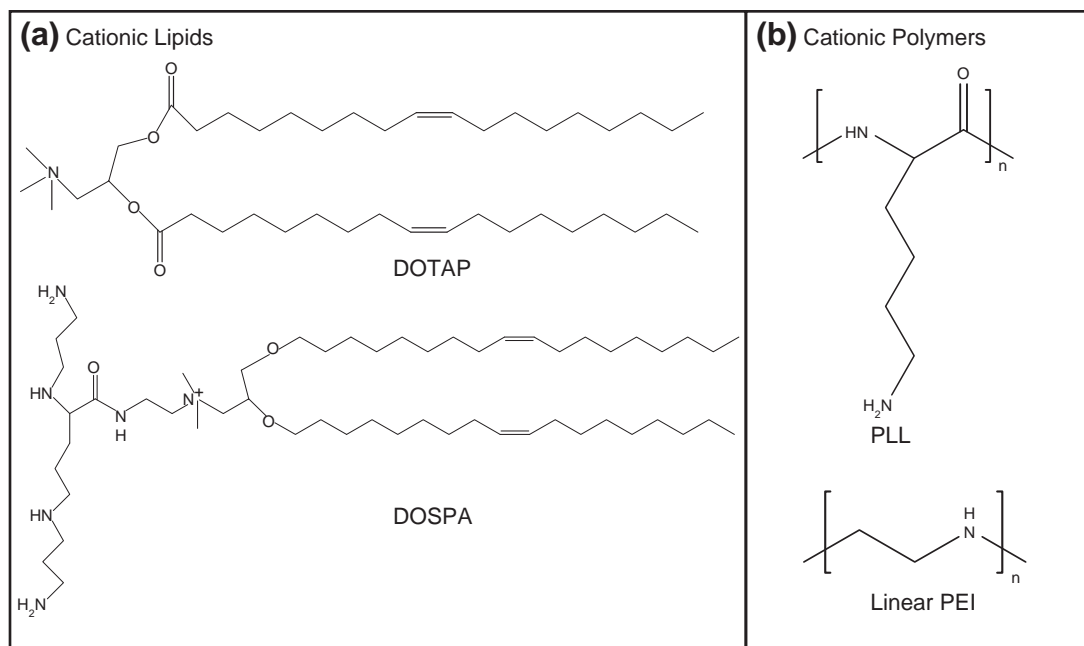
Several classes of cationic polymers have been used successfully for nucleic acid transfer *in vitro*; two commonly-used polymers, poly(L)-lysine (PLL) and polyethylenimine (PEI) are shown in Figure B.8.2 (Wu and Wu, 1987; Boussif et al., 1995; Pack et al., 2005). Other polycations include chitosan, poly(vinyl imidazole), poly(amidoamines), and acrylic copolymers of *N,N*-dimethyl aminoethyl methacrylate (DMAEMA). The polyvalency of cationic polymers allows for high-affinity interactions with polyanionic nucleic acids. In addition, the functional groups present


FIGURE B.8.2 Structures of some biomaterials commonly used in nucleic acid delivery vehicles. DOTAP: 1,2-Dioleoyl-3-trimethylammonium propane; DOSPA: 2,3-dioleyloxy-N-[2(spermine carboxamido)ethyl]-N,N-dimethyl-1-propanaminium trifluoroacetate; PLL: poly(L)lysine; PEI: poly(ethylenimine).

in polymers can be used to further modify the polymers with moieties to assist in vehicle trafficking. When mixed with nucleic acids in low salt conditions, cationic polymers will self-assemble with nucleic acids by electrostatic interactions into complexes called "polyplexes" that are typically ~50–200 nm in size. These complexes impart nuclease resistance to the packaged nucleic acids. The resultant polyplexes are typically slightly positively charged nanoparticles of ca. 50–200 nm in diameter.

Polyplexes can be internalized by cells through electrostatic interactions with the cell surface or, when functionalized with a targeting ligand, through specific ligand–receptor interactions. Once they are taken up into a cell by endocytosis, some of the amino groups on the polymers that have the appropriate pK have been postulated to buffer the acidic pH within the endosome by binding protons, and thereby causing sodium ions to enter to maintain electrical neutrality. This leads to osmotic swelling and bursting of the endosome, releasing the polyplex (or lipoplex) to the cytosol. This is called the "proton sponge" effect (Boussif, 1995), and it may be one step in the mechanism by which polyplexes (or lipoplexes) can transfect cells. (See "Escaping from endosome" for further discussion of research based on this effect.)

For *in vivo* applications, cationic polymers are typically modified, either through stable or labile bonds, with hydrophilic polymers such as PEG and pHPMA that decrease non-specific protein adsorption and impart salt stability to the colloids (Murthy et al., 2003; Walker et al., 2005). In addition, cationic polymers are often functionalized with ligands for cell-specific targeting. *In vivo* toxicity and low transfection efficiencies remain major challenges

for this class of materials. To address the former issue, several degradable cationic polymers have been synthesized to reduce *in vivo* toxicity. Polyplexes have been used in conjunction with cationic lipids in formulations termed lipopolyplexes (Gao and Huang, 1996).

Inorganic Particles

More recently, several classes of inorganic nanoparticles have been applied for nucleic acid delivery, including colloidal gold (Rosi et al., 2006), silica nanoparticles (Bharali et al., 2005), and quantum dots (Derfus et al., 2007). Nucleic acids have been either directly conjugated to the nanoparticle surface or nanoparticles have been surface modified to be cationic for electrostatic complexation with nucleic acids. In addition, protonatable groups have been conjugated to inorganic nanoparticle surfaces to mediate increased endosomal release (Yezhelyev et al., 2008). One advantage of these particles is their small size (often <40 nm) which facilitates more efficient delivery. However, the slow rate or lack of clearance of these materials *in vivo* remains a concern.

LOCAL GENE DELIVERY

Nucleic acids or nucleic acid delivery vehicles can be integrated with biomaterials for localized delivery. Examples of potential applications for this approach include controlled release of nucleic acids from stents for anti-restenosis treatment or incorporation of nucleic acids in tissue engineering scaffolds to guide new tissue formation. Nucleic acids have been successfully integrated with

substrates by embedding, direct surface immobilization or integration in layer-by-layer assemblies. Both unencapsulated nucleic acids and nucleic acid delivery vehicles have been embedded by including these components during fabrication of biomaterials such as poly(lactide-co-glycoide), collagen or fibrin matrices (Kong and Mooney, 2007). Direct surface immobilization of nucleic acids has been accomplished by adsorption of vectors to biomaterial surfaces, covalent conjugation of vectors to surfaces, binding of biotinylated vectors to avidin-modified surfaces or recognition of vector epitopes by antibody-conjugated surfaces (Bengali and Shea, 2005). Finally, layer-by-layer assemblies of oppositely-charged films of polymers allow for programmed release of nucleic acids from surfaces during film erosion (Jewell and Lynn, 2008).

EXTRACELLULAR REQUIREMENTS FOR EFFICIENT NUCLEIC ACID DELIVERY

After *in vivo* administration, nucleic acid drugs need to remain stable and active until reaching their site of action. Nucleic acids need to avoid rapid elimination, either by nuclease degradation or by renal excretion. Nuclease degradation for both DNA and RNA has been shown to occur in the order of minutes *in vitro* (Abdelhady et al., 2003; Bartlett and Davis, 2006). In addition, oligonucleotides such as siRNA also undergo rapid plasma clearance, because their size is significantly less than the renal filtration cut-off (~30 kDa). For example, unmodified siRNA has a plasma half-life of only six minutes in mice (Soutschek et al., 2004).

To address these issues, nucleic acid drugs are typically either chemically modified as discussed previously or packaged in a delivery vehicle. Delivery vehicles should be designed to avoid eliciting host immune responses, including opsonization and phagocytosis, activation of the complement cascade, and antibody recognition of vehicle motifs. At the first level, recognition of the delivery vehicles results in rapid clearance by the reticuloendothelial system. More seriously, a systemic inflammatory response can lead to organ failure. Because opsonization and activation of the complement cascade both involve adsorption of proteins to vehicle surfaces, vehicles that minimize non-specific protein binding are desirable. One approach that has been used to reduce protein interactions *in vivo* is PEGylation of the delivery vehicle. Vehicles that do not contain foreign proteins are also more likely to be biocompatible.

Most delivery vehicles are nanoparticulate to allow injection into the bloodstream. These colloidal particles, therefore, should also have high critical flocculation concentration to avoid salt-induced aggregation in the bloodstream and remain stable during circulation (Rozema et al., 2007; Meyer et al., 2009). For targets outside of the vasculature after systemic administration, the formulations have to extravasate in order to reach their targets. Vascular fenetrations in the liver, kidney, and

in some tumor sites allow for extravasation and tissue delivery. Within solid tumors such extravasation leads to "enhanced permeability and retention," or the enhanced permeability and retention (EPR) effect (Maeda et al., 2000). Another approach is to develop formulations that can undergo transcytosis in endothelial cells. For intracellular delivery, nucleic acids or their delivery vehicles need to penetrate the tissue and be internalized by their target cells. Cell binding can occur by non-specific interaction with cell surfaces, such as by electrostatic binding or by specific binding of a ligand-modified vehicle with a cellular receptor.

INTRACELLULAR REQUIREMENTS FOR EFFICIENT NUCLEIC ACID DELIVERY

With a possible exception of aptamers that may be used as cell-targeting agents, the site of action for nucleic acid-based drugs is intracellular. After internalization into the cell, a series of barriers must be overcome before the drugs reach their subcellular target (Figure B.8.3). Nucleic acids that require transcription act in the cell nucleus, while nucleic acids that require or interfere with translation are active in the cytosol. Nucleic acid drugs or their carriers are typically internalized by an endocytic pathway into vesicles. The specific uptake mechanism depends on the cell type and properties of the carrier, including size, composition, and the presence of targeting ligands. The route of internalization is important, because it affects the intracellular trafficking pathway (Khalil et al., 2006).

ESCAPING FROM THE ENDOSOME

Internalized nucleic acid drugs must be released from endosomes in order for them to be active. A common strategy used for endosome release takes advantage of the acidic environment in early and late endosomes. pH-sensitive proteins or peptides can be incorporated in delivery vehicles for selective lipid membrane disruption at low pH (Bergen and Pun, 2005).

pH-sensitive synthetic polymers that become hydrophobic in acidic conditions have also been shown to be effective in mediating endosome release, and this has led to a delivery system that mimics viruses. Viruses have evolved an efficient system for delivering DNA or RNA to the cytosol that utilizes the lowered pH within the endosome. Certain peptide sequences on the surface of the virus become hydrophobic when their acidic amino acids are protonated, causing those sequences to fuse with or cause pore formation in the endosomal membrane, allowing the virus to deliver its genomic contents to the cytosol. The Stayton/Hoffman research group has mimicked this natural action of the virus by designing and synthesizing pH-sensitive polymers, such as poly(propylacrylic acid), PPAA, that would similarly become hydrophobic at the endosomal pHs and disrupt
FIGURE B.8.3 Schematic of intracellular barriers to nucleic acid delivery. A nanoparticle carrier is used here for illustration. After cell binding and internalization the drugs must exit endocytic vesicles, be transported through the cytoplasm and be available for performing its intracellular action either in the cytosol or nucleus. Figure from Pack et al. (2005). Nat. Reviews Drug Discovery, **4**, 581–593.

the endosomal membrane (Murthy et al., 1999, 2001, 2003; Stayton et al., 2000; Cheung et al., 2001; Hoffman and Stayton, 2002; Kyriakides et al., 2002; Henry et al., 2006; Stayton and Hoffman, 2008; Convertine et al., 2009). A pendant glutathione-responsive disulfide group has been added to this acid-responsive polymer, such that when the polymer–drug complex or conjugate escapes the endosome, it releases the drug after reduction by glutathione in the cytosol (Bulmus et al., 2003). Other approaches by these same researchers have been to design and synthesize membrane-disruptive polymers that are PEGylated via acid-degradable acetal bonds; these bonds degrade within the endosome, exposing the backbone which is membrane-disruptive, leading to the release of the drug to the cytosol (Murthy et al., 2003).

Finally, pH-sensitive systems that contain a high concentration of protonatable groups with pK_a between 5–7 can enhance endosomal release through the "proton-sponge effect," whereby the pH in endosomes is buffered, eventually resulting in vesicle swelling and rupture (Boussif et al., 1995). If packaged within a delivery vector, the nucleic acids need to be accessible to their target after endosomal release. Inefficient vector unpackaging has also been shown to be a barrier to gene delivery by synthetic biomaterials (Schaffer et al., 2000). For synthetic materials that assemble with nucleic acids through charge interactions, the mechanism of intracellular unpackaging is not clear, but may occur through competitive displacement by cytosolic peptides, proteins or

nucleic polyanions such as cellular RNA (Bertschinger et al., 2006).

NUCLEAR ENTRY AND DELIVERY

For successful nuclear delivery, nucleic acids must be transported through the crowded cytoplasm and past the nuclear membrane. Several different mechanisms of nuclear delivery have been reported for various viruses, including transport of intact virus through the nuclear pore complex (NPC), and docking at the NPC followed by release of DNA. However, transfection of non-dividing cells is a major challenge for most non-viral systems.

There have been several approaches tested for facilitating nuclear delivery of plasmids. The maximum cargo size reported to date that can be successfully actively transported through NPCs is ~40 nm (Pante and Kann, 2002). First, delivery vehicles with dimensions <30 nm have been formulated in an attempt to prepare materials that can traverse nuclear pores. Second, several researchers have demonstrated varying levels of success in facilitating nuclear delivery by conjugating nuclear localization sequences either to their non-viral carrier or directly to the DNA cargo (Nagasaki et al., 2003). Finally, DNA sequences that bind to proteins with nuclear localization signal (NLS) sequences, such as transcription factors, can be included in the plasmid construct.

B.9. POLYMERIC AND ALBUMINATED DRUG NANOPARTICLES

Wayne R. Gombotz
Immune Design Corp., Seattle, WA, USA

Nanoparticles may be defined as solid colloidal particles ranging in size from 10 to 100s of nms. The nanoparticles used in drug delivery systems (DDS) are comprised of the active drug as a simple nanoparticle or polymeric nanoparticles in which the drug is dissolved, entrapped or encapsulated; usually the nanoparticles are stabilized by a surfactant (e.g., Kreuter, 2004). Although the concept of nanoparticles for drug-targeting and diagnostic purposes has been studied for decades, and a significant amount of research has been devoted to preclinical studies with a variety of different systems, there are relatively few products that have been commercially approved. An excellent review by Kreuter describes the historical development of nanoparticles, and highlights some of the major scientific contributions to the field, especially by Spieser (see Kreuter, 2007). Some of the noteworthy systems include nanoparticles made from poly(lactic-co-glycolic) acid, poly(cyanoacrylates) (Couvreur et al., 1977, 1979), and poly(isohexyl cyanoacrylate) (Kattan et al., 1992).

The French company, BioAlliance Pharma has developed a nanoparticle product called Doxorubicin-Transdrug® based on poly(isohexyl cyanoacrylate) for the treatment of resistant hepatocellular carcinomas. The product progressed into Phase II/III clinical trials, and in 2006 was granted orphan drug status by the European Medicines Agency (EMA) in Europe and the US Food and Drug Administration (FDA) in the USA. In 2008 the trials were suspended. There was an observed clinical benefit, but also more frequent and more severe pulmonary damage was observed at the maximum tolerated dose (MTD) of 35 mg/m². The premature end to the Doxorubicin-Transdrug® clinical program illuminates some of the challenges still associated with the development of nanoparticles as delivery systems for therapeutic agents.

Albumin is a major protein component in serum, and albumin nanoparticles containing lipophilic drugs have been developed for cancer therapy. Abraxane® is the first FDA-approved albumin-based nanoparticulate drug carrier containing paclitaxel for the treatment of breast cancer. It was developed to retain the therapeutic benefits of paclitaxel while eliminating the toxicities associated with the emulsifier Cremophor® EL in the paclitaxel formulation (Taxol®) (Sparreboom et al., 2005). The product has a mean particle size of 130 nm, and is supplied as a sterile lyophilized powder. Following reconstitution in 0.9% sodium chloride, Abraxane® is administered by intravenous (IV) infusion. The maximum tolerated dose of Abraxane® was 70–80% higher than that reported for Taxol®.

C. INJECTED DEPOT DDS

Wayne R. Gombotz[1] and Allan S. Hoffman[2]

[1]Immune Design Corp., Seattle, WA, USA

[2]Professor of Bioengineering and Chemical Engineering, UWEB Investigator, University of Washington, Seattle, WA, USA

INJECTED DEPOT SYSTEMS

> Injected depot systems include degradable polymers as microparticles or phase separating polymer/drug solutions. The therapeutic agent is dispersed or dissolved in the polymer matrix. A mass of polymer and drug is then deposited in the tissue space, and the drug is subsequently delivered as the polymer degrades over time.

The release of drug from injected delivery systems can be governed by several mechanisms including diffusion of drug through the polymer matrix and out, surface erosion of the polymer and/or swelling and bulk erosion of the polymer by the aqueous medium. The erosion is usually due to hydrolysis of the polymer backbone; enzymolysis is probably a rare event. Often the release rate is determined by a combination of mechanisms. For example, in a degradable microsphere system, release of the drug is often initially controlled by desorption from the surface of the microsphere, followed by diffusion of the drug through the porous channels of the polymer matrix, which in turn is influenced by the swelling rate of the system (Gombotz and Pettit, 1995). Acidic byproducts of the degradation of polyesters like poly(lactic-co-glycolic acid) (PLGA) can accelerate the degradation rate, and the bulk sometimes degrades faster than the surface due to the buffering by the aqueous medium at the surface. The physical state of an injected drug delivery system can also change as it degrades, which can further complicate release kinetics. Park has reported that water hydration in microspheres allowed the polymer morphology to change from a glass to a rubbery state by lowering the glass transition temperature. This in turn led to a faster degradation rate (Park, 1994).

Injected Microparticle Depots

The most common type of polymers used to make injected microparticle depots or microspheres are poly(lactic acid) (PLA) and poly(lactic-co-glycolic acid) (PLGA) copolymers. These polymers currently occupy a dominant place among biodegradable drug delivery systems (Heller, 1984). The literature contains many reports describing the use of PLGA microspheres for drug delivery, and many techniques have been used to

fabricate microspheres (Watts et al., 1990). Several common microsphere fabrication methods include:

- Single emulsion technique
- Double emulsion technique
- Hydrophobic ion pairing
- Prolease®-low temperature casting.

The method of choice will depend on the type of drug to be delivered, and its stability in various organic solvents. Hydrophobic drugs, for example, lend themselves well to a single emulsion technique where the drug and polymer are co-solubilized in the organic phase. Hydrophilic drugs such as proteins are not readily soluble in an organic phase, and the Prolease® method is more amenable to this type of drug (Gombotz et al., 1991). A wide variety of additives can also be included with the drugs in the microspheres. These can improve stability, modify release kinetics, increase loading efficiencies, and enhance "syringability." Terminal sterilization by gamma irradiation is preferable but for highly radiation-sensitive drug formulations, aseptic processing is necessary and can be technically challenging. The final step in microsphere fabrication involves some type of drying process such as lyophilization or vacuum drying. Prior to administration the microspheres are reconstituted and suspended in a viscous diluent such as sodium carboxymethyl cellulose (CMC). A surfactant is often incorporated in the diluent to prevent aggregation of the microspheres prior to injection through a narrow gauge needle.

Table C.1 lists the commercially approved microsphere products. LHRH analogs are the most common, and the success of these products is due to several factors that are related to both the drug and the polymers used in the systems. Chronic administration of LHRH and its analogs causes a reversible chemical shutdown of the pituitary gland, resulting in regression of hormone-responsive tumors, including prostate and breast carcinomas. The desired clinical effect is one of downregulation, and a well-defined delivery profile is not necessary as long as a sufficient quantity of drug is provided. Since the drugs were originally administered by once-daily injection, the development of a once monthly or once every three months system was desirable from a patient compliance viewpoint. An initial burst of drug was not a problem due to their low toxicity, and the LHRH analogs are stable during the microsphere fabrication process and *in vivo* after injection. Finally the PLGA polymers used in the microspheres required minimal toxicology testing.

In the late 1970s the first PLGA microspheres containing LHRH were developed and patented by Southern Research Institute in conjunction with Syntex (Sanders et al., 1985; Kent et al., 1987). This technology was licensed from Syntex by the Takeda-Abbott Pharmaceutical Co., and marketed as Lupron® Depot. The microspheres are manufactured using a water/oil/water double emulsion technique using a PLGA (75:25) copolymer with a molecular weight of approximately 14,000 Da (Ogawa et al., 1988). The initially approved product released drug for a period of one month (Okada et al., 1991) and since that time three- and four-month products have been introduced into the market.

During the 1980s, Southern Research Institute developed a [D-Trp-6 LHRH]/PLGA microsphere for DebioPharm, the first clinical PLGA–drug product. The product, called Decapeptyl®, was commercially launched in Europe in 1986 as a one-month sustained-release formulation. In October 2009, DebioPharm announced that a six-month formulation had successfully completed its European decentralized registration procedure. This product is still on the market.

In 1999 Alkermes Corp., in conjunction with Genentech, launched a PLGA-based microsphere product containing recombinant human growth hormone (rhGH) called Nutropin Depot® for the treatment of growth deficiency. The product used the Prolease® process, where micronized protein is dispersed in a lactide–glycolide solution in methylene chloride, and then atomized into liquid nitrogen that contains a frozen layer of ethanol at the bottom of the vessel. The small particles of polymer

TABLE C.1	Commercially Approved Degradable Microsphere Depot Drug Delivery Systems (DDS) Based on PLGA Copolymers			
Product	**Company**	**Active Agent**	**Indication**	**Year Approved**
Decapeptyl®	DebioPharm	Triptorelin	Prostate cancer	1986
Lupron Depot®	Takeda Abbott Pharmaceuticals	Leuprolide Acetate	Prostate cancer/ Early puberty/ anemia	1989
Procrin®	Abbott	Leuprolide Acetate	Prostate cancer/ Early puberty/ anemia	1989

Vivitrol™	Cephalon/Alkermes	Naltrexone	Alcohol dependence	2006
Somatulin®	Beaufour Ipsen	Lanreotide	Acromegaly	2007

*Nutropin Depot® has been withdrawn.

solution with dispersed protein are instantly frozen and settle on top of the frozen ethanol layer. The liquid nitrogen is then evaporated, the ethanol melts, and the particles settle into the cold ethanol, where they harden as the methylene chloride is extracted, and they are then harvested (Khan et al., 1992).

This cryogenic method was used to encapsulate rhGH using an 8 kDa, 50/50 copolymer of lactic and glycolic acid. The protein was stabilized during the encapsulation process and during *in vivo* release by complexing with zinc (Johnson et al., 1996). The product was eventually withdrawn from the market due to poor sales and the high cost of manufacturing. Another important factor was that it was painful to inject, and many patients were children.

Alkermes has also worked with several other companies to develop PLGA-based microsphere delivery systems. Together with Eli Lilly and Company they developed Risperdal® Consta, a once-weekly formulation of risperidone for the treatment of schizophrenia, and for the longer-term treatment of Bipolar I Disorder. The drug was approved in 2003. In April 2006 Alkermes and Cephalon, Inc. announced the approval of Vivitrol™, a once-monthly injectable naltrexone formulation for the treatment of alcohol dependence. The product is comprised of 337 mg of naltrexone per gram of 75:25 PLG microspheres. In May 2009, Alkermes, in collaboration with Amylin and Eli Lilly, filed an NDA for Exenatide LAR, a once-weekly injectable formulation of byetta, a synthetic peptide hormone used for the treatment of type 2 diabetes. The product exhibited significantly greater improvements in glycemic control than byetta given twice a day (Drucker et al., 2008).

PLGA microspheres have received considerable attention for the controlled release of injectable protein vaccines (Wise et al., 1987). These systems can potentially reduce the number of inoculations, reduce the total antigen dose required to achieve immune protection, and enhance the immune response (Cohen et al., 1994; McGee et al., 1994). It is important to control the diameter of the microspheres used in vaccine delivery to 5 μm or less, in order to allow them to be phagocytized by macrophages or dendritic cells.

There a several other types of biodegradable polymers used for depot drug delivery systems, including polyanhydrides, poly(orthoesters) and poly(phosphoesters). Many of these depot systems have been fabricated into surgically implanted discs, such as the Gliadel®, a polyanhydride wafer containing BCNU (1,3-bis(2-chloroethyl)-1-nitrosourea) approved for the treatment of glioblastoma multiforme. There are no approved injectable products based on these polymers (see Chapter II.5.16.D).

Alza, and later Jorge Heller, along with the company AP Pharma, developed a family of degradable polyorthoesters, one of which, (APF530), contained a drug for the prevention of chemotherapy-induced nausea and vomiting. This product was submitted to the US Food and Drug Administration (FDA), and the company subsequently received a Complete Response Letter on the APF530 NDA in March 2010. Subsequent to that date, they were in the process of preparing a resubmission to the FDA.

In the 1990s biodegradable polyester was developed by Jan Feijen at Twente University, in The Netherlands, based on a copolymer of poly(ethylene glycol) terephthalate) and poly(butylene terephthalate)(Bezedmer et al., 2000). A microparticle depot formulation of this polymer, called "Polyactive®," contains α-interferon (Locteron®) and is currently in clinical trials for the treatment of hepatitis C (De Leede et al., 2008).

Injected Phase-Separating Depot Systems

Injectable, *in situ* phase separating drug delivery systems are made from biodegradable components that are injected with a syringe into the body and, once injected, solidify to form a semi-solid depot. These systems have several advantages over injected microparticulate systems, including ease of manufacture, no need for reconstitution and suspension in a diluent prior to injection, and relatively little migration from the site of injection. A comprehensive review of these systems has been published (Hatefi and Amsden, 2002). Table C.2 shows the different categories of injectable phase separated systems based on their mechanism of solidification. The following discussion will review some of these systems.

Thermoplastic Pastes

Thermoplastic pastes are polymer systems that are injected as a melt, and upon cooling to body temperature form a semi-solid depot. A variety of polymers could potentially be used to form thermoplastic pastes, but only a few have been evaluated *in vivo*. Disadvantages of these systems include: (1) the temperature needed to form the melt upon injection, which could cause some pain and tissue necrosis; and (2) the very slow rate of drug release. Zhang et al. developed a thermoplastic triblock PLA-PEG-PLA copolymer of blends of PLA and poly(caprolactone) (PCL) for the local delivery of Taxol™ to tumors in rats (Zhang et al., 1996). Drug was delivered over months from both these systems which adversely impacted the ability of Taxol™ to inhibit tumor growth. Other groups have increased the release rate of Taxol™ from PCL by adding water soluble additives including gelatin, albumin, methylcellulose, dextran (Dordanoo et al., 1997), and methoxyPEG (Winternitz et al., 1996).

A thermoplastic injectable system comprised of a PEG-PCL copolymer was developed for delivery of drugs to the eye (Davis and Cousins, 1995). When heated to 50°C the system could be injected through a 25 gauge needle.

	Chitosan	Chenite et al., 2000
5. *In situ* solidifying organogels	Glycerol esters of fatty acids	Yim et al., 1989; Ericsson et al., 1991; Engstrom et al., 1992; Gao et al., 1998

In Situ Cross-Linked Systems

These injectable systems include thermoset polymers which are "cured" or set into their final shape after heating by the formation of covalent cross-links between polymer chains. Few applications of these systems exist for the delivery of drugs, since the conditions for curing the system can contain potentially toxic monomers or solvents, and generate temperatures that can cause tissue necrosis. Dunn et al. used prepolymers of PLA and PCL that were terminated with acrylic ester groups (Dunn et al., 1994). Prior to injection, curing was initiated by the addition of either benzoyl peroxide or *N*,*N*-dimethyl-*p*-toluidine, depending which ingredient of the co-catalyst was missing. The system was able to deliver flurbiprofen *in vitro* over a week.

Photocross-linked gels represent another type of *in situ* cross-linked injectable delivery system. Prepolymers are introduced to the desired site and then photocured *in situ* with fiber optic cables. Polymerization rates occur rapidly under physiological conditions. Hubbell et al. developed a photopolymerizable system based on PEG-oligoglycolylacrylates that gelled upon exposure to an eosin dye, a photosensitive initiator, and a light source (Hubbell et al., 1995). The system was shown to be best suited for delivery of high molecular weight protein-based therapeutic agents. Another recently developed *in situ* forming drug delivery system is based on photocross-linked poly(ε-caprolactone fumarate) (PCLF) networks loaded with tamoxifen citrate (Sharifi et al., 2009).

Networks were made from PCLF macromers, a photo-initiator and accelerator, and N-vinyl-2-pyrrolidone as a cross-linker. Cytotoxicity assays showed that while the photocross-linked PCLF network exhibited no significant cytotoxicity against MCF-7 and L929 cell lines, 40–60% of the MCF-7 cells were killed after incubation with the tamoxifen citrate loaded system.

Alginate, a linear polysaccharide that is extracted from red-brown kelp, is the most common ion-mediated gelling system that has been investigated for drug delivery, and many reports have been published on the formation of alginate microparticle formation *in vitro* (Gombotz and Wee, 1998). Since alginates form a gel upon contact with divalent cations such as calcium ions, this system can only gel upon injection where local tissue concentrations of calcium are high. The human eye is one site where the concentration of $CaCl_2$ is high enough (0.008%) to facilitate gelation. Cohen et al. demonstrated that an aqueous solution of sodium alginate could gel in the eye and subsequently be used to deliver pilocarpine in a sustained fashion (Cohen et al., 1997).

In Situ Polymer Precipitation

Another means of developing *in situ*-forming drug delivery systems is polymer precipitation in a poor solvent. Such an injectable delivery system is prepared from a water-insoluble biodegradable polymer dissolved in a water-miscible, biocompatible solvent. When this system is mixed with a drug and injected into the physiologic environment, the

solvent diffuses out into the surrounding tissues while water diffuses in, and the polymer precipitates, forming a solid polymeric implant containing entrapped drug. This method has been used in humans (Dunn et al., 1990), and in veterinary applications (Dunn et al., 1995).

The polymer most commonly used is a poly(lactic-co-glycolic acid) copolymer dissolved in *N*-methylpyrrolidone (NMP). This system is known as Atrigel®. Four formulations of PLGA dissolved in *N*-methyl-pyrrolidone and containing leuprolide acetate have been used for the treatment of prostate cancer and are marketed by Sanofi Aventis under the name Eligard®. These formulations provide patients with the option of being dosed every 1, 3, 4 or 6 months.

There are a number of other systems, such as: (1) poly(lactic acid) dissolved in a mixture of benzyl benzoate and benzyl alcohol, known as PLAD (Duenas et al., 2001); (2) poly(lactic-co-glycolic acid) copolymer dissolved in glycofurol (Eliaz and Kost, 2001); (3) poly(lactic-co-glycolic acid) copolymer dissolved in benzyl benzoate known as Alzamer®; and (4) sucrose acetate isobutyrate (SAIB) dissolved in NMP or Miglyol, known as SABER (Smith and Tipton, 1996; Tipton and Hall, 1998). A recent study evaluated the *in vivo* release of risperidone from a SAIB polymer system dissolved in ethanol combined with PLA as a release regulator (Lu et al., 2008). The addition of 10% PLA mw 9000 was able to significantly reduce the burst effect, and led to a stable plasma concentration over 25 days.

Polyacrylic acid and its derivatives have also been used as *in situ* precipitating polymers. Poly(methacrylic acid) (PMAAc) and PEG were solubilized in 50–80% ethanol and used to deliver albumin and pheniramine (Haglund et al., 1996). Upon injection the ethanol diffuses out of the system and water diffuses in, resulting in precipitation of the dissolved polymer network. A similar approach used a hydroxypropylmethylcellulose-Carbopol system and a PMAAc-PEG system for the delivery of plasmid DNA (Ismail et al., 2000). Both systems release DNA intact, but with a 35–70% drug burst effect in the first two hours followed by little to no subsequent release, indicating a strong interaction between the DNA and the polymer matrix.

Thermally-Induced Gels

A well-known example of a polymer that undergoes a sharp, thermally-induced phase separation is poly(*N*-isopropyl acrylamide) (Heskins and Guillet, 1968; Hirotsu et al., 1987). Its transition at 32°C can be shifted to higher or lower temperatures by copolymerization with more hydrophilic or hydrophobic comonomers, respectively. Thus, this material could be of interest in drug delivery applications; however, it may not be suitable due to potential cell toxicity of the homopolymer and its copolymers, although this issue has not been thoroughly investigated.

Of more interest are triblock copolymers of poly(ethylene glycol) and poly(propylene glycol), PEO–PPO–PEO, known as Pluronics® or Poloxamer® polyols, some compositions of which have already been approved for use in the body (Wang and Johnston, 1991). While many of these block copolymers have transition temperatures well above body temperature, they do exhibit transitions at body temperature in solutions at concentrations above 16 wt%. Since Pluronic® F127 has been reported to be the least toxic of these block copolymers, it has been used the most extensively for drug delivery studies with a number of low molecular weight compounds including vancomycin (Veyreis et al., 1999), mitomycin C (Miyazaki et al., 1992), melanotan-I (Bhardwaj and Blanchard, 1996), lidocaine (Paavola et al., 1999), ibuprofen (Paavola et al., 1995), and pilocarpine (Desai and Blanchard, 1998). As a result of its nondenaturing effects on proteins, Pluronic F127 gels have also been used to deliver several proteins including interleukine-2 (Morikawa et al., 1987; Johnston et al., 1992), urease (Fults and Johnston, 1990), rat atrial natriuretic factor (Juhasz et al., 1989), and transforming growth factor β-1 (Puolakkainen et al., 1995). The copolymer consists by weight of approximately 70% ethylene oxide and 30% propylene oxide, with an average molecular weight of 11,500 Da. Although Pluronic® F127 is not metabolized by the body, the gels do slowly dissolve over time and the polymer is eventually cleared.

More recently, block copolymer injectable gelling systems have been developed with biodegradable polymeric components. Such materials can be constructed from ABA block copolymers based on poly(ethylene glycol) and poly(lactic-*co*-glycolic acid) copolymers. The triblock may be designed as PLGA-PEO-PLGA or as PEO-PLGA-PEO, where the former will have a more pronounced thermal gelation capability. PLA has also been used as the hydrophobic, degradable block segment. When the block lengths and relative amounts are correctly chosen, a material is obtained that is soluble in water at room temperature, and forms a firm gel at body temperature (Jeong et al., 1999a, 2000). Such materials can be injected as a solution, having a viscosity not much different from a saline solution. In addition, since only water is used with this material, there are no organic solvent–water interface problems, and proteins can be incorporated without loss of activity. These materials are available as dry powders that are reconstituted prior to use. While the exact mechanism of thermogelling is not known with absolute certainty, it has been postulated that the hydrophobic blocks (PLGA or PLA) of the amphiphilic block copolymers lose their hydrophobically-bound water and aggregate together to form micelles that are in equilibrium with monomeric polymer chains (Jeong et al., 1999b). Then, as the temperature is increased, the equilibrium shifts to micelle formation, and above the critical gelation temperature, the micelles pack together to occupy the entire volume,

resulting in gel formation. Evidence for such a mechanism is provided by ^{13}C NMR studies, dye solubilization studies, and light-scattering studies, which all show an abrupt change in micellar diameter and aggregation at the critical gelation temperature (Jeong et al., 1999b). It has also been postulated that the water content of the gel will determine its degradation rate and release kinetics of the incorporated therapeutic agent (Jeong et al., 1999b).

A triblock copolymer based on poly(ethylene glycol) and poly(lactic-*co*-glycolic acid) copolymer is under development under the trade name ReGel®. A formulation of Paclitaxel in ReGel® is known as OncoGel®, and a Phase II dose escalation study for the treatment of patients with esophageal cancer has recently been completed with no dose-limiting toxicities, and a reported reduction in tumor burden and tumor size (DuVall et al., 2009). The company BTG is currently enrolling a Phase IIb clinical study for the same indication that should be completed in 2010.

Another recently reported biodegradable thermogelling triblock copolymer is comprised of poly(CL-co-glycolide)-PEG-poly(CL-co-glycolide) (Jiang et al., 2007, 2009). The copolymer aqueous solution (25 wt %) underwent sol–gel transition at 35°C, and as the temperature increased formed a stable gel at body temperature. After incubation in physiological buffer the gel completely degraded into a viscous liquid after 14 weeks. The gel formed an *in vitro* controlled release depot with delivery times of 12, 32, and 25 days for isoniazid, rifampicin, and bovine serum albumin respectively.

Chitosan is another naturally derived polymer that is obtained by deacetylation of chitin, a component of shrimp and crab shells. Chitosan remains dissolved in aqueous solution up to a pH of 6.2, and forms a hydrated gel-like precipitate upon neutralization to a higher pH. Chenite et al. added polyol salts bearing a single anionic head such as glycerol-, sorbitol-, fructose- or glucose-phosphate to chitosan aqueous solutions to create thermally sensitive pH-dependent gel-forming solutions (Chenite et al., 2000). This system was used for the *in vivo* delivery of biologically active growth factors, as well as encapsulation of chondrocytes for tissue engineering.

An injectable supramolecular hydrogel has been developed based on PEO or PEO block copolymers and α-cyclodextrin (CD) (Li et al., 2003a). The hydrogel formation is based on a physical cross-linking induced by supramolecular self-assembling with no chemical cross-linking reagents. An inclusion complex is formed between CD and the PEO molecules, resulting in necklace-like supramolecular structures (Li et al., 2003b). Rheologic studies of the hydrogels showed that these systems are thixotropic and display a decreased viscosity when exposed to the shear stress of an injection through a fine needle. Components of the hydrogels are biocompatible and non-toxic, and drugs can be directly incorporated into the hydrogels at room temperature without any contact with organic solvents.

In Situ Solidifying Organogels

Organogels are composed of water-insoluble amphiphilic lipids that swell in water and form lyotropic liquid crystals. The nature of the liquid crystalline phase formed depends on the structure of the lipid, the type of drug incorporated, and the amount of water in the system (Engstrom and Engstrom, 1992). The most commonly used amphiphilic lipids for drug delivery include glycerol esters of fatty acids such as glycerol monooleate, glycerol monopalmitostearate, and glycerol monolinoleate. The liquid crystalline structure formed upon injection into an aqueous medium is gel-like and highly viscous. These systems have been studied for delivery of water-soluble and -insoluble drugs, including lidocaine (Engstrom and Engstrom, 1992), somatostatin (Ericsson et al., 1991), interferon-α (Yim et al., 1989), levenorgestrel, and ethinyl estradiol (Gao et al., 1998). These systems can be formulated with a low concentration of water, and the viscosity can be reduced by mixing with vegetable oils. Reducing the viscosity in this way provides for better injectability and increases the duration of release, particularly for lipophilic drugs. Organogels are biodegradable, and degradation occurs through the action of lipases.

D. IMPLANTS AND INSERTS

Lothar W. Kleiner[1] and Jeremy C. Wright[2]
[1]Drug Delivery and Medical Device Polymer Consultant, Los Altos, CA, USA

[2]DURECT Corporation Cupertino, CA, USA

INTRODUCTION

Implantable drug delivery systems (IDDS) originated in the 1960s when silicones were used to prolong the effectiveness of a therapy. From this beginning, the potential was recognized that this mode of delivery could overcome the problems associated with oral administration of specific therapies. Despite considerable effort since the beginning, initial progress has been slow to commercialize safe and effective implants. Some of the major hurdles that needed to be overcome were stability, reproducibility, toxicity, lack of biocompatibility, carcinogenicity, lack of compatibility between drug and carrier leading to burst release or shutdown, and physician and patient acceptability. However, the appeal, activity, and approval of IDDS accelerated when the silicone-based device Norplant® was approved by the US Food and Drug Administration (FDA) in 1990. Good evidence is the proliferation of academic and industrial research, the increase in the number of published articles, and the increased number of commercialized products.

Classification of IDDS is difficult, because there will be exceptions and hybrids that may fall under more than one category. When the term IDDS is used in this section it will also refer to "inserted" implants (e.g., intraocular); however, as much as possible this section will use the classifications that are historically used: drug implants and implantable pumps that contain and deliver drug. Drug implants can be further subdivided into nondegradable and degradable systems. Other DDS will also be included, such as inserts.

History

The concept and research of implantable drug delivery systems started with Deanesly and Parkes (1937) working with chickens. IDDS formulations with drug release rates controlled by a "rate-controlling membrane" (RCM) were pioneered by Folkman and Long (1964). They proposed an implanted Silastic® capsule containing a drug for prolonged, steady-state systemic drug administration. Silicone rubber capsules containing a variety of different drugs were prepared and implanted into the cardiac muscle of dogs. These rudimentary IDDS succeeded in the controlled release of many different classes of drugs, and were shown to be "biocompatible" over the period of implantation.

Since these early days, the research using IDDS has proliferated with the use of many different carriers, biostable and bioerodible, a wide variety of different classes of drugs, many different implantation techniques and implantation sites. A vast number of review articles can be found in the literature, originating with veterinary applications and quickly followed with human therapies (Hsieh and Langer, 1981; Jaffe et al., 1981; Lewis, 1981; McCormick et al., 1981; Wheeler and Friel, 1981; Danckwerts and Fassihi, 1991; Hoffmann, 2008; del Valle et al., 2009).

Rationale

To mitigate or avoid the problems associated with oral dosage form administration, other modes of delivery such as implants and inserts evolved. Numerous design approaches have been pursued, depending upon the specific drug therapy under development (Vernon and Wegner, 2004). The primary end-goal of any design approach is to improve safety and efficacy by carefully controlling dose, and dose rate at the desired site and over the desired duration of drug delivery.

Some of the issues with oral dosage forms that can be overcome with IDDS are described in Table D.1. Benefits of IDDS are described in Table D.2 and potential drawbacks are summarized in Table D.3.

TABLE D.1	Summary of Issues with Some Oral Dosage Forms

- Drug bioavailability – Drug is not soluble enough to be absorbed by the gastro-intestinal system (GITS) or there is extensive first pass hepatic metabolism.
- Drug stability – Drug is not stable in the gastrointestinal system.
- Drug toxicity – Efficacious concentrations at the target site require systemic concentrations that are toxic or produce unacceptable side-effects.
- Duration of release – In order to be effective, the drug must be able to be delivered in a controlled and sustained manner for more than 24 hours.
- Drug half-life is too short – Drug loses its potency too quickly to be effective.

TABLE D.2	Summary of Benefits of IDDS

- Patient compliance – Patient does not need to think about taking medication throughout the dosing interval of the IDDS. Less dosing required.
- Fewer side-effects – Controlled release and usually much lower dose with improved control at site of action for extended periods of time; adverse effects away from site of action are minimized; peaks and valleys in plasma drug concentration from repeated immediate release dosing are avoided.
- Lower dose – If action is site specific, drug has to overcome fewer biological barriers, such as first pass hepatic effects, before coming to the active receptor.
- Drug stability improved – Protection of drug slows metabolization.
- Suitability over intravenous– Hospital stay may not be required for chronic illnesses.
- Easy removal – If allergic or other adverse reaction to drug is experienced, immediate removal is possible.

TABLE D.3	Summary of Potential Drawbacks of IDDS

- Regulatory issues – IDDS are more complex than oral dosage forms – this makes the regulatory path for approval longer and more expensive.
- Surgical needs – Some IDDS require minor surgery for implant and explant – this lowers patient acceptance and raises the desire for a less invasive alternative.
- Cost/benefit ratio – The IDDS may not be cost effective enough for insurance coverage. Patient and doctor acceptance is lowered.
- Training – Implantation usually requires specialized training.
- Pain and discomfort – If an IDDS has this effect, patient acceptance is lowered.

Despite all the hurdles that need to be overcome, the examples of IDDS provided in the next sections indicate that they can be manufactured cost-effectively, and administered to a desired site to achieve the goal of reliability, safety, efficacy, and patient acceptance. The examples that are provided are a small representation and not comprehensive, since it is impossible to cover all the approved applications and the ever-increasing amount of research within universities and industry. More expansive reviews can be found (Lewis, 1981, 1990; Danckwerts and Fassihi, 1991; Dash and Cudworth, 1998; Pizzi et al., 2004; Hoffman, 2008).

IMPLANTS

In the next two sections for non-degradable and degradable IDDS, most or all the key components are produced from polymeric materials. In addition to drug delivery, the components may have additional functions, such as structural support and improvement of biocompatibility or stability. Lists and descriptions of the key polymers used in approved IDDS may be found in this and other chapters in this book covering degradable and non-degradable polymers used in biomedical devices and implants (see also Mani et al., 2007; Lyu and Untereker, 2009).

Non-Degradable Systems

Several types of non-degradable implants are presently commercially available, but by far the most common are reservoir and matrix DDS systems. Matrix systems are also called monolithic systems. The non-degradable polymers used in these systems include silicones, acrylates and their copolymers, ethylene vinyl acetate copolymers (PEVA), vinylidene fluoride copolymers, and urethanes.

Applications. In this section three applications will be highlighted. They include Norplant®, Implanon®, and drug-eluting stents (DES) with a non-degradable drug delivery (DD) coating. Space limitations preclude including additional applications, therefore the reader is referred to the review by Dash and Cudworth (1998) as a good starting point to obtain additional information.

Norplant®. The most common reservoir non-degradable system is Norplant®. This IDDS was developed and trademarked by the Population Council in 1980, introduced in certain countries worldwide in 1983, approved by the US FDA in December 1990, and marketed in the US starting February 1991. Norplant® is a five-year contraceptive system consisting of the hormone levonorgestrel (LNG) filled into six thin, flexible, silicone (Silastic®) tubes that are implanted subcutaneously on the inside of a woman's upper arm, as seen in Figure D.1 (Population
FIGURE D.1 Norplant® capsule. (Source: Population Council, 1990.)

Council, 1990). As of 2009, this device is approved in over 60 countries.

Later in the US, the six-rod Norplant® proved to be cumbersome and became associated with implantation and retrieval problems due to operator inexperience. Therefore, Norplant® was removed from the US market in 2002, but it is still available in other countries with successful use by over 60 million women.

Implanon®. A similar, more recent FDA-approved IDDS system is Implanon®, which entered the international market in 1998 and the US in 2006 (Alam et al., 2008). This single-rod IDDS is 4 cm long and 2 mm wide, and consists of a PEVA core (reservoir) containing 68 mg of etonogestrel. The rod is covered with a PEVA rate-controlling membrane, and is designed to release drug to prevent ovulation for a three-year period. Protection from pregnancy can continue longer if the implant is removed and immediately replaced with a new one. This newer, long-acting system is intended for easier subcutaneous insertion and removal than Norplant®, and therefore has gained improved acceptance by patients and their providers.

Drug-Eluting Stent (DES). Another important non-degradable IDDS application is the drug-eluting stent (DES) that has revolutionized the treatment of coronary artery disease (CAD) by reducing restenosis by 60–75% across all patients when compared to bare metal stents (Kukreja et al., 2009). DES is now the standard of care in the treatment of coronary artery disease (opening a blockage in a coronary artery). A DES consists of a scaffold (the stent) coated with a polymer plus drug mixture. The stent keeps the coronary artery patent, and the coating releases a drug that inhibits smooth muscle cell proliferation and the resultant neointimal growth. The mode of release from these coatings is diffusion-controlled.

Table D.4 highlights the four major globally-marketed DES systems. All are based on a polymer coating on a metallic stent that releases drug (Virmani et al., 2009). Current DES systems are examples of matrix or monolithic drug delivery systems.

Even though DES has become the standard of care for CAD, considerable research continues to be focused on the formulation and design of DES that create less inflammation. In addition, new systems are being developed to eliminate late stent thrombosis, the evaluation of which can only be done prospectively after a particular system has been in the clinic for many years. Therefore, the reader is cautioned to remember that materials currently in use may become out of favor years later, as a result of data from registries and follow-up studies. Even more caution should be exercised in considering materials for clinical use if only preclinical or early clinical studies are available. This gives an example of the benefits of using biomaterials that have a long history of clinical use.

Biodegradable Systems

There is a strong motivation to develop or replace a non-degradable therapeutic IDDS with a biodegradable one any time the drug delivery is required for only a limited period of time. The normal healing process can be aided when the tissue surrounding an implant can return to its native state. Moreover, the explantation or retrieval procedure is eliminated for those implants that require surgery or minor surgery (referred to as "minimally invasive procedures") for implantation. The major limitations of implanted biodegradable IDDS are complexity, development cost, regulatory requirements, and availability of polymers with the exact physical properties needed (including mechanical properties and degradation kinetics). The *in vivo* degradation kinetics, degradation byproducts, and mechanism must be understood. They can be highly variable from patient to patient, depending upon the age of the patient and the state and type of the medical problem.

Many polymers that are degradable have been explored as components of IDDS; however, only a few have been commercialized. The most widely investigated in regard to available clinical data are the aliphatic polyesters based upon lactic and glycolic acids. These materials have received considerable attention since the 1970s, first as sutures, then as excipients for drug delivery, and finally as IDDS. Their desirable features include acceptable degradation products, ability to tune degradation kinetics by LA/GA ratio, and ease of fabrication. Other

TABLE D.4	Summary of Four Major, Globally-Marketed, Polymer/Drug-Coated, Drug-Eluting Stents (DES)			
Company	**Trade Name**	**Drug**	**Polymer (Drug Release Coating)**	**Platform[1]**
Johnson & Johnson	Cypher®	Sirolimus	PEVA blend with PBMA with PBMA topcoat and Parylene C primer	SS, 140 μm
Boston Scientific	Taxus®	Paclitaxel	SIBS	SS, 132 μm
Medtronic	Endeavor®	Zotarolimus	PC	CoCr, 91 μm
Abbott Vascular	Xience V®	Everolimus	PVDF·HFP with PBMA primer	CoCr, 81 μm

Abbreviations used: PEVA: Polyethylene-co-vinyl acetate; PBMA: Poly n-butyl methacrylate; SIBS: Poly(styrene-b-isobutylene-b-styrene); PC: a copolymer composed of 2-methacryloyloxyethyl phosphorylcholine, lauryl methacrylate, hydroxypropyl methacrylate, and trimethoxysilylpropyl methacrylate; PVDF·HFP: Poly(vinylidene fluoride-*co*-hexafluoropropylene); SS: stainless steel; CoCr: Cobalt/Chromium alloy.
[1]All micrometer (μm) dimensions represent stent strut thickness.

important biodegradable polymers include PEG-b-PLGA [poly(ethylene glycol)-block-poly(lactide-*co*-glycolide)] or PEG-PLLL [poly(ethylene glycol)-block-poly(L-lactide)] block copolymers, polyanhydrides, poly(ortho esters), and poly(phosphoesters) (see Chapters I.2.6 and II.5.16; Lewis, 1990; Cooper et al., 2004).

Applications. In this section only a few representative commercial biodegradable IDDS products and those that are currently in human clinical trials can be highlighted, due to space limitations. (Such implantable DDS include injectable microparticles and other depot DDS; these systems are covered in Chapter II.5.16.G). Only those systems that are fully absorbable are emphasized instead of non-degradable systems with biodegradable coatings. However, examples of biodegradable polymer coatings on a non-degradable substrate are included in the bibliography (Mani et al., 2007; Acharya and Park, 2006; Chan-Seng et al., 2009; Ormiston and Serruys, 2009; Virmani et al., 2009).

Although biodegradable IDDS have been used for the delivery of a wide range of therapeutics, the most common biodegradable IDDS include those for the treatment of cancer and cancer pain. A more recent development in 2009 is a fully bioresorbable drug-eluting stent, which is currently undergoing human clinical trials.

An example of a biodegradable IDDS for the treatment of brain tumors is the Gliadel® wafer (Perry and Schmidt, 2006). This device was approved by the FDA on June 14, 1996, and is now marketed by Eisai Co., Ltd. (Eisai Co., Ltd., 2009). Gliadel® wafers are dime-sized biodegradable polyanhydride disks, 1.45 cm in diameter and 1.0 mm thick, designed to deliver the chemotherapeutic drug, BCNU or carmustine, directly into the surgical cavity created after the tumor (high-grade malignant glioma) has been surgically excised. Up to eight wafers are implanted along the walls and floor of the cavity that once contained the tumor. Each wafer has been designed to deliver a precise dose of carmustine to the surrounding cells (Eisai Co., Ltd., 2009).

The trade name of the biodegradable polyanhydride copolymer is polifeprosan 20, it consists of poly[bis(p-carboxyphenoxy) propane: sebacic acid] in a 20:80 molar ratio and is used to control the local delivery of carmustine. Each Gliadel® wafer contains 192.3 mg of polifeprosan 20 and 7.7 mg of carmustine (1,3-bis (2-chloroethyl)-1-nitrosourea or BCNU), which is the oncolytic agent uniformly distributed in the copolymer matrix. The chemical structure of polifeprosan 20 is shown in Figure D.2.

Upon exposure to the aqueous environment in the surgical cavity, the anhydride bonds hydrolyze to release

FIGURE D.2 Polyanhydride random copolymer chemical structure; ratio n:m = 20:80.

carmustine, carboxyphenoxypropane, and sebacic acid. The carmustine released from the Gliadel® wafer diffuses into the surrounding brain tissue. More than 70% of the copolymer biodegrades within three weeks back to constituent monomers.

Another example of a biodegradable IDDS is Zoladex®, which is indicated for the palliative treatment of advanced carcinoma of the prostate, and is manufactured by Astra-Zeneca. It is supplied as a sterile biodegradable product containing the drug goserelin acetate (equivalent to 3.6 mg of goserelin) dispersed in a matrix of poly(lactide-co-glycolide) (PLGA). Goserelin acetate is a potent synthetic peptide analog of luteinizing hormone-releasing hormone (LHRH). Zoladex® is designed for subcutaneous injection, with continuous release of drug over a period of 28 days. The encapsulated drug is in the form of a 1 mm diameter cylinder preloaded in a single use syringe with a 16 gauge needle, and packaged in a sealed, light, moisture-proof aluminum foil laminate pouch containing a desiccant capsule. The encapsulated drug is released by a combination of diffusion and erosion-controlled mechanisms. Studies have shown that the PLGA is completely biodegradable and exhibits no demonstrable antigenic potential (Zoladex® IFU, 2003; Kotwal et al., 2007).

An active development area for biodegradable IDDS are biodegradable DES, which most commonly come in two versions: a biodegradable coating on a permanent scaffold and a fully bioresorbable system. Table D.5 describes some of the many types of platforms currently under development (Isenbarger and Resar, 2005; Ormiston and Serruys, 2009; Virmani et al., 2009). The rationale for this extensive activity can be summarized under the heading of patient outcome or safety. Even though DES have revolutionized the treatment of coronary artery disease, there are still late adverse effects in a very minor subset of patients. A fully bioresorbable drug-eluting vascular scaffold (BVS) has many potential advantages over a non-degradable DES. A drug-eluting BVS is designed to perform all the functions of a DES when needed for scaffolding, and then is naturally resorbed and metabolized by the body when no longer needed. This potentially reduces the need for long-term antiplatelet therapy, and allows the coronary artery to return to its native state. Late stent thrombosis is thereby abolished or greatly reduced. In addition, the disappearance of the BVS may avoid a future need for reintervention. More comprehensive discussion of BVS therapeutic advantages are found in recent literature (Oberhauser et al., 2009; Ormiston and Serruys, 2009; Serruys et al., 2009; Virmani et al., 2009).

Clinical Trial on Bioresorbable Stents. The recently published two-year outcome of human clinical trials involving drug-eluting bioresorbable vascular scaffolds (BVS) (Oberhauser et al., 2009; Serruys et al., 2009) with 30 patients showed that the BIOSORB scaffolding of the vessel lasted long enough, and that it was also transient. The device was fully bioresorbed, late lumen
TABLE D.5	Summary of Some Biodegradable Drug Eluting Stents Under Development			
Company	Trade Name	Drug	Polymer (drug release coating)	Platform
Biosensors International, Ltd.	BioMatrix	Biolimus A9	PDLLA: asymmetric abluminal coating	SS, 112 μm
Terumo Cardiovascular Systems	Nobori [1]	Biolimus A9	PDLLA: asymmetric abluminal coating	SS, 112 μm
Boston Scientific	JACTAX	Paclitaxel	PDLLA: microdots on abluminal side	SS, 96 μm
Johnson & Johnson	NEVO	Sirolimus	PLGA in small reservoirs, each acting as a depot	CoCr alloy, 89 μm
Abbott Vascular	BVS	Everolimus	PDLLA	PLLA, 152 μm
Biotronik GmbH	Lekton Motion	No drug[2]	No polymer coating[2]	Mg alloy – WE 43, 165 μm
REVA Medical[3]		No drug and Paclitaxel	No polymer coating	Tyrosine-derived polycarbonate, 200 μm
Bioabsorbable Therapeutics		Sirolimus salicylate	Salicylate linked by adipic acid	PAE salicylic acid, 200 μm

Abbreviations: BVS: Bioresorbable Vascular Scaffold; CoCr: Cobalt/Chromium alloy; PAE: poly(anhydride ester); PDLLA: Poly(D,L-lactide); PLGA: poly(lactide-co-glycolide); PLLA: Poly(L-lactide); SS: Stainless steel.

enlargement was associated with reduced plaque burden and vasomotion was restored similar to the native state of a coronary artery. Absence of foreign body reaction and vasomotion restoration are indications of a healthy vessel and suggested that late stent thrombosis risk was eliminated. The above findings need to be confirmed in larger studies that are currently underway (Serruys et al., 2009). These results also suggest that such bioresorbable scaffolds might be used more generally as a device for tissue regeneration, sometimes called "tissue engineering" (see Figure D.3).

The unique progression of scaffold area post-implantation (also called PCI, for percutaneous coronary intervention) obtained by IVUS (intravascular ultrasound) is detailed in the literature (Serruys et al., 2009). When a non-degradable DES is compared to a BVS after two years, the BVS exhibits positive remodeling and full resorption of the scaffold, while the non-degradable implants prevent the lumen from one day exhibiting positive remodeling.

Early results suggest that as biodegradable vascular stent (BVS) implants fully resorb, the vascular tissue may remodel to the original healthy native state (Nikolsky et al., 2009; Oberhauser et al., 2009; Serruys et al., 2009). It is likely that this will not occur with non-degradable drug-eluding stents (DES).

PUMP-BASED DDS

Introduction

Fully implanted pump DDS offer a number of advantages, both potential and realized. Obviously, the barrier of the GI tract and the first pass effect are avoided. Pump systems offer convenience over repeated syringe injections. Patient compliance is ensured. Release rates can be faster than diffusion-limited systems. If localized therapy is desired, the system can be implanted at the site of action; in some cases the pump can be implanted nearby the site in an easily accessible location, and

an attached catheter can be directed to the site of action. Remote adjustment of the delivery rate can be achieved with electronic transmitters attached on the skin, or an implanted sensor can be electronically-coupled to the pump to create feedback-control of drug delivery.

Osmotic Pumps

Osmosis is the movement of water through a semi-permeable membrane in response to high solute (usually ionic) concentration on the opposing side of the membrane. This transport increases the volume of solution on the opposing side of the membrane and can be described by the equation:

$$\frac{dV}{dt} = \frac{A}{l} L_p [\sigma \, \Delta \, \pi - \Delta \, P]$$

where dV/dt is the volume flux of water across the membrane, $\Delta \pi$ and ΔP are, respectively, the osmotic and hydrostatic pressure differences across the semipermeable membrane, L_p is the membrane hydraulic permeability coefficient, σ is the reflection coefficient (usually ~1), and A and l are respectively the membrane area and thickness (Theeuwes and Yum, 1976). Osmotic volume expansion has been utilized as the basis for a number of designs of implanted and ingested DDS.

> In osmotic drug delivery systems, the drug delivery rate is controlled by the diffusion of water into the osmotic device, as opposed to most other DDS, where control of the drug delivery rate is controlled by diffusion of drug out of the device.

DUROS® Implant

A schematic of the DUROS® implantable osmotic system is shown in Figure D.4. It resembles a miniature syringe, and consists of an outer cylindrical reservoir, a water diffusion rate-controlling membrane at one end, the "osmotic engine" (tablets containing primarily NaCl combined with other pharmaceutical excipients), an elastomeric piston, the drug formulation in the drug reservoir, and an exit port at the other end (diffusion moderator/orifice in Figure D.4). The outer reservoir can be

FIGURE D.4 Cross-sectional diagram of the DUROS® Implant. *(Reprinted from Wright, 2001.)*

constructed from titanium alloy or a biocompatible rigid polymer.

The DUROS® osmotic DDS can be implanted subcutaneously (e.g., the inside of the upper arm) or into other body sites. The rate-controlling membrane is composed of a polyurethane copolymer with PEG segments, designed to provide a specific water permeability and the ability not to foul during *in vivo* operation. The drug formulation consists of the drug dissolved or suspended in a pharmaceutically-acceptable solvent or solution (e.g., DMSO). The drug must remain stable in the formulation for the duration of delivery; thus, the formulation components are specific to the properties of the drug being delivered. The device is usually contained in a titanium-based metal cylinder. For site-directed therapy, a catheter can be attached to the exit port and directed to a nearby target site. When implanted subcutaneously, dimensions have ranged from 4 mm OD × 45 mm L to 10 mm OD × 45 mm L, although smaller or larger systems are possible, depending on the site of implantation, and the required drug loading and resultant duration of therapy.

The rate of drug delivery from the system, dM/dt, is given by:

$$\frac{dM}{dt} = \frac{dV}{dt} C$$

where C is the concentration of the drug in the formulation. The system delivers at a constant rate because the osmotic pressure of a saturated solution of sodium chloride (i.e., the solution present in the osmotic engine compartment after a small amount of water is imbibed) is much greater than the osmotic pressure of body tissue. The system can be designed for durations of one month or less, up to one year or even longer. The DUROS® osmotic pump system has been commercialized for the delivery of the GnRH analog leuprolide for the palliative treatment of prostate cancer (Viadur® system). The system is under development for the delivery of interferon (OMEGA DUROS® system) and sufentanil (Chronogesic® system), and site-targeted delivery of other opioids (Wright et al., 2001, 2003; Wright and Culwell, 2008; Yang et al., 2008).

INFUSION PUMPS

Another important example of an IDDS where the drug is delivered subcutaneously is a palm-sized infusion pump for the treatment of insulin-dependent diabetes. In this case, the cannula portion of the total delivery system is implanted, while the pump portion is worn outside the body. This first of many subsequent pumps was first introduced in 1983 by Pacesetter Systems Infusion Division, which in 1985 was officially spun-off as MiniMed, and acquired by Medtronic in 2001. Recent programmable versions integrate the pump with continuous glucose monitoring. The pump is capable of delivering
subcutaneous infusions of very minute amounts of insulin with automatic changes in delivery rate or dose at specified intervals. Pumps can also record infusion data history. Some pumps offer a short-syringe option, where the syringe connector is recessed inside the pump for greater patient comfort. Insulin is delivered subcutaneously through a soft cannula that sits under the skin for up to three days after being inserted virtually painlessly. Continuous glucose monitoring is made possible through a tiny glucose sensor worn up to three days at a time. It is also inserted subcutaneously with an automated insertion device. Sensor data is sent to a transmitter attached to the sensor. The transmitter sends the data to the pump through wireless technology (MiniMed Infusion Pumps, 2009; MiniMed Infusion Pump History, 2009; MiniMed Product Information, 2009). The reader is encouraged to review the prolific scientific literature on infusion pumps (e.g., Panteleon et al., 2006).

Positive Displacement Pumps

The Infusaid® pump is a fully implantable, fixed rate pump that contains a chamber for a fluorocarbon propellant separated from the drug formulation chamber by a metal bellows in a disc-shaped titanium housing (Danckwerts and Fassihi, 1991). The system contains a flow restrictor, and the vapor pressure of the propellant creates a constant pressure source at fixed temperature. The pump is approximately 9 cm in diameter by 3 cm in height. This pump has been utilized for insulin delivery, anticoagulant therapy, and cancer chemotherapy.

Peristaltic Pumps

The Synchromed® pump developed by Medtronic, Inc., is an example of a fully implantable peristaltic pump that features external microelectronic control of the delivery rate. It has been utilized for the intrathecal delivery of opioids for pain management, baclofen for the treatment of severe spasticity, and other therapies. The pump consists of an outer titanium casing that houses the pumping mechanism, the controller, the drug solution reservoir, and the battery. There is a silicone rubber septum on the system so that it can be refilled with a needle and syringe. The pump is 8.8 cm in diameter by 2.5 cm in thickness, and is implanted abdominally. A silicone catheter is tunneled to the intrathecal space. Battery life is given as 6–7 years (Krames, 1996; Medtronic, Inc., 2007; Medtronic, Inc., 2009).

Micro-Fabricated Pumps

A number of implantable delivery systems based on micro-electromechanical systems (MEMS) and micro-electronic fabrication technologies are being researched or are in development (Gardner, 2006). In one system under development by MicroCHIPS, tiny microliter-sized reservoirs are etched into a silicon wafer and filled with drug or multiple drugs. The reservoirs are covered by gold films (or other films) that are electrically connected on the chip surface. After implantation of the chip, a voltage can be applied to the gold foil of an individual reservoir, with resulting electrochemical dissolution of the film and release of the drug from the reservoir. Controlled, pulsatile or patterned release of single or multiple drugs are possible (Santini et al., 1999).

INSERTS

DDS can be placed or "inserted" into a number of body sites. Local therapy can be achieved (e.g., delivery of drugs into the eye via ocular inserts) or systemic therapy can be achieved via release of the drug and transport across a permeable biological surface into the bloodstream (e.g., sublingual tablets or mucoadhesive buccal tablets). A number of sites or routes that have been utilized for insert therapy, including ocular, transurethral, vaginal, and intrauterine. DDS for several of these routes are discussed below.

Intraocular Inserts

The Ocusert® is a reservoir and membrane system that was developed and commercialized in the 1970s by ALZA Corporation for the treatment of glaucoma. It is an elliptical-shaped planar system that is inserted into the cul-de-sac of the eye. The system consists of an inner drug reservoir containing pilocarpine, and a polyethylene vinyl acetate (PEVA) outer rate-controlling membrane. The system delivers drug at a constant, zero order rate, for one week (Heilmann, 1978).

The Vitrasert® implant was developed and commercialized for the treatment of cytomegalovirus (CMV) retinitis. The system releases ganciclovir. It consists of a compressed tablet of the drug, overcoated with polyvinyl alcohol (PVOH), then partially overcoated with PEVA, and then affixed to a PVOH suture stub. It is designed to release the drug over 5–8 months (Bausch and Lomb, Inc., 2005; Lee et al., 2008). An extensive array of other ocular implants and inserts has been investigated (Bourges et al., 2006).

Vaginal and Intrauterine Inserts

Site-specific delivery to the female reproductive tract has been pursued for treatment of diseases and disorders, and also for contraception. One of the first systems developed for contraception was the Progestasert® (ALZA Corporation). This T-shaped DD device was inserted into the uterus. The body of the system consisted of a rate-controlling cylindrical PEVA reservoir containing progesterone dispersed in silicone oil. The arms of the "T" were also constructed of PEVA. The drug was released by diffusion over a period of one year (Heilmann, 1978).

A more recent intrauterine system is the Mirena® intrauterine system, which delivers levonorgestrel. The system consists of a T-shaped polyethylene frame. The vertical part of the "T" has a reservoir of a mixture of the drug and polydimethylsiloxane. The reservoir is surrounded by a silicone membrane, and has delivery duration of ≥5 years (Bayer Healthcare Pharmaceuticals, Inc., 2009). Additionally, there are several intrauterine systems that release copper (Benagiano et al., 2008).

Vaginal rings are another insertable contraceptive delivery system. The vaginal mucosa is permeable to a number of substances. The NuvaRing® is constructed of PEVA and delivers two drugs: ethynyl estradiol and etonorgestrol. The outer diameter of the ring is 54 mm, and it has a cross-sectional diameter of 4 mm. The ring is inserted by the user after day 4 of the cycle and removed 21 days later (Benagiano et al., 2008).

Vaginal delivery systems are also being investigated for prevention of sexually-transmitted diseases (Loxley et al., 2010). pH-responsive DDS may be of special utility in this application (Gupta et al., 2007).

THE FUTURE

Some of the most pressing problems of therapeutic drug delivery still have not been addressed adequately. Two major, interrelated problems are patient compliance (which could be solved with appropriate DDS) versus the complexity and expense of developing DDS that control the rate, dose, delivery rate, and duration of delivery to a specific site (e.g., del Valle et al., 2009). Major pharmaceutical companies may not be prepared to absorb the costs of developing a new DDS unless reimbursement is negotiated beforehand. This sometimes results in smaller companies having to accept the risk and expenses incurred during the development and approval process of new DDS.

The key drivers for new DDS applications in the future will be for more cost-effective devices with improved efficacy and patient acceptance. Some DDS may include a diagnostic feature with remote feedback control. Future devices will be smaller, less invasive, more site-specific, and more efficient in drug dosing. Expert opinions on this subject can be found in numerous journal articles (Santini et al., 1999; Telleman, 2001; LaVan et al., 2003; Martin and Grove, 2001; Pizzi et al., 2004; Gardner, 2006; McCoy et al., 2007; Hoffman, 2008; del Valle et al., 2009).

Conflict of Interest Statement. One of the authors, Lothar Kleiner, was affiliated at Abbott Vascular until January 2012, where he was working on fully resorbable drug eluting devices that serve as temporary scaffolds for diseased coronary arteries. The content of the section on drug eluting stents was obtained from peer reviewed references, human clinical trials and conference proceedings. He currently consults in the area of drug delivery systems and medical devices. The other author, Jeremy Wright, currently works at Durect, which has rights to selected DUROS® applications.

ENVIRONMENTALLY-RESPONSIVE SYSTEMS

This section is focused only on "smart" drug delivery systems, and is a companion section to Chapter I.2.11, "Applications of "Smart Polymers" as Biomaterials."

Temperature-Responsive, Phase-Separating Polymer Systems

A well-known polymer that undergoes a sharp, thermally-induced phase separation is poly(*N*-isopropylacrylamide) (PNIPAAm) (Heskins and Guillet, 1968; Schild, 1992). Its transition at 32°C can be shifted to higher or lower temperatures by copolymerization with more hydrophilic or hydrophobic comonomers, respectively. Thus, this material could be of interest in drug delivery applications; however, since acrylamide monomer is toxic, many worry about the potential cell toxicity of NIPAAm monomer, and by extension, of the polymer itself, although this issue has not been thoroughly investigated.

Also of interest as thermally-responsive, nanocarrier drug delivery systems (DDS) are the ABA tri-block copolymers of PEO-PPO-PEO, where either PEG or PEO symbolizes poly(ethylene glycol), and either PPG or PPO symbolizes poly(propylene glycol). These polymers are known as Pluronic® or Poloxamer® polyols. They are discussed further in the sub-section on polymeric micelle drug nanocarriers in Section B above.

One of the more recent trends in thermogelling materials is the development of biodegradable systems suitable as injectable and gelling depot drug delivery systems. Early work on degradable PEO-polyester block copolymers was carried out by Gilding and Reed (1979), with polyethylene terephthalate (PET) as the polyester. Interesting degradable biomaterials can be constructed from ABA triblock copolymers based on poly(ethylene glycol) and poly(lactic-*co*-glycolic acid) copolymers. Sung Wan Kim and co-workers have pioneered with degradable triblock polymers as DDS (Jeong et al., 1997; Shim et al., 2007). The triblock may be designed as PLGA-PEO-PLGA or as PEO-PLGA-PEO, where the former will have a more pronounced thermal gelation capability. PLA and PCL have also been used as the hydrophobic, degradable block segment. When the block lengths and relative amounts are correctly chosen, a material is obtained that is soluble in water at room temperature and forms a firm gel at body temperature (Jeong et al., 1999a; Rohr et al., 2002). Drugs may be dissolved or dispersed, and the resulting mixtures can be injected as a solution or a dispersion having a viscosity not much different from a saline solution. In addition, since only water is used with this material, there are no organic solvent–water interface problems, and protein or nucleic acid drugs can be incorporated without loss of activity. Sometimes these materials are available as dry powders that may be reconstituted prior to use. While the exact mechanism of thermogelling is not known with absolute certainty, it has been postulated that the hydrophobic blocks (PLGA or PLA) of the amphiphilic block copolymers aggregate together to form micelles that are in equilibrium with monomeric polymer chains (Jeong et al., 1999b, 2000). Then, as the temperature is increased, the equilibrium shifts to micelle formation, and above the critical gelation temperature the micelles pack together, resulting in gel formation. Evidence for such a mechanism is provided by ^{13}C NMR studies, dye solubilization studies, and light-scattering studies, which all show an abrupt change in micellar diameter and aggregation at the critical gelation temperature (Jeong et al., 1999b). It has also been postulated that the water content of the gel will determine its degradation rate, and the related release kinetics of the incorporated therapeutic agent (Jeong et al., 1999b).

Kam Leong and Jun Li have developed some very interesting degradable triblock polymer DDS using degradable blocks of poly(hydroxybutyrate) (PHB) as the hydrophobic block in a PEO-PHB-PEO triblock that is further condensed with cyclodextrin (CD) to form a poly(pseudorotaxane) hydrogel DDS (Li et al., 2001, 2003, 2006).

Solvent-Responsive, Phase-Separating Polymer Depot DDS

Another means of developing *in situ* forming drug delivery systems is polymer precipitation in a poor solvent such as aqueous body fluids. Such an injectable delivery

system is prepared from a water-insoluble biodegradable polymer dissolved in a water-miscible, biocompatible solvent. When this system is mixed with a drug and injected into the physiologic environment, water diffuses in to dilute the solvent, which also diffuses out into the surrounding tissues, and the polymer precipitates, forming a solid polymeric implant containing entrapped drug. This method has been used in human (Dunn et al., 1990) and in veterinary applications (Dunn et al., 1995). The polymer that has been most commonly used is a poly(lactic-*co*-glycolic acid) copolymer dissolved in *N*-methylpyrrolidone (NMP). This system is known as Atrigel®. Three formulations of PLGA dissolved in *N*-methyl-pyrrolidone and containing leuprolide acetate, have been used for the treatment of prostate cancer.

There are a number of other similar systems, such as: (1) poly(lactic acid) dissolved in a mixture of benzyl benzoate and benzyl alcohol, known as PLAD (Duenas et al., 2001); (2) poly(lactic-*co*-glycolic acid) copolymer dissolved in glycofurol (Eliaz and Kost, 2001); (3) poly(lactic-*co*-glycolic acid) copolymer dissolved in benzyl benzoate, known as Alzamer®; and (4) sucrose acetate isobutyrate dissolved in NMP or Miglyol, known as SABER™ (Tipton and Holl, 1998).

Temperature- and pH-Responsive Hydrogel DDS

In this smart DDS, drugs are imbibed into lightly cross-linked gels which release the drugs as the gel shrinks in response to changes in temperature or pH. Cross-linked poly(*N*-isopropylacrylamide) or PNIPAAm, is a typical temperature-responsive gel that releases a drug upon collapse at the LCST (lower critical solution temperature) (Hoffman et al., 1986; Dong and Hoffman, 1987; Hoffman, 1987; Okano et al., 1990). Such materials can deliver biological molecules when triggered by temperature changes, but this is not very practical due to the isothermal condition in the body. Furthermore, such systems are not very effective, since the drug may be gradually released by slow diffusion from the hydrogel before the stimulus causes it to release in a burst. However, one unique way to utilize such a thermally-responsive hydrogel in the body was developed by Dong and Hoffman (1991). They prepared a combined pH- and temperature-sensitive hydrogel matrix, based on a random copolymer of NIPAAm and acrylic acid (AAc), and it was shown to release indomethacin, a model NSAID (non-steroidal anti-inflammatory drug), linearly over a four hour period as the pH went from the low, acidic pH found in the gastric region to the physiologic pH in the enteric region of the GI tract. At 37°C body temperature the NIPAAm component was above its LCST, and was trying to maintain the gel in the collapsed state, while as the pH went from acidic (e.g., as it would be in the gastric region) to neutral conditions (e.g., as it would be in the enteric region), the AAc component was becoming ionized,

forcing the gel to gradually swell and slowly release the drug. This is similar to so-called enteric coatings, but in this case the hydrophobic component was thermally-responsive, and the formulation matrix was composed entirely of the copolymer, rather than just being coated.

Temperature-responsive smart polymer hydrogels might also be useful for topical delivery to open wounds, skin, and mucosal surfaces such as the eye or nose. The temperatures of such surfaces may be a few degrees below 37°C, but they are still well above ambient temperature, and that difference could be utilized to deliver a drug from a thermally-sensitive polymer formulated with the drug and applied to the skin or mucosal surface.

F. TRANSDERMAL DDS

Gary Cleary
Corium Inc. Menlo Park, CA, USA

INTRODUCTION

In this section we describe the technologies and materials that are being used in "Passive" and "Active" Transdermal Drug Delivery Systems (TDDS), as well as the biological barriers to drug delivery through the skin. Passive TDDS refers to delivery of drugs by diffusion across the stratum corneum (SC), while Active TDDS includes physical methods that disrupt or bypass the SC for such delivery. From 1980 to 2010 only 20 small drugs, ranging in molecular weight from 62 Da to 359 Da, were approved by the US Food and Drug Administration (FDA) for Passive TDDS.

1. It has been proposed that the upper limit of molecular weight is below 500 Da for reasonable drug diffusion rates through the skin.
2. Thus, Passive TDDS methods are mainly applicable for delivery of small, potent, lipophilic drugs.

> **Passive Transdermal Drug Delivery Systems** are systems that depend on molecular diffusion of drugs across the stratum corneum. These systems are most suitable for transdermal delivery of small, potent, mostly lipophilic drugs from skin patches.
>
> **Active Transdermal Drug Delivery Systems** are systems that utilize some form of mechanical or electromagnetic energy to create micropores or temporary pathways in the stratum corneum for delivery of large biomolecular drugs.

With the advent of molecular biology and biotechnology in the 1980s, it became apparent that the large biomolecular drugs such as proteins, peptides, and nucleic acids would not penetrate intact SC (which is a reflection of the protective behavior of the SC). From the 1990s to the present time, a number of enabling technologies have been developed that use various forms of energy to disrupt the SC and allow passage of larger drugs into the body. These new approaches are called "Active" TDDS, and they can deliver drug molecules greater than 500 Da across the skin (Barry, 2001; Prausnitz et al., 2004; Prausnitz and Langer, 2008).

Skin and the Stratum Corneum (SC)

The top layer of the epidermis (Figure F.1) is the stratum corneum (SC), which is the outermost layer of skin. The SC is packed with dying or dead cells called corneocytes. They have a "brick and mortar-like" structure, and the mortar in the intercellular space is made of lamellar lipid bilayers surrounding the aqueous cores of the dying corneocytes. There are four potential routes through the SC that drug molecules can take as they migrate through the skin and into the systemic circulation. These routes include: (1) molecular diffusion through a tortuous pathway of the intercellular lipophilic space between the corneocytes; (2) electrophoretic transport of charged drugs, which may be drawn through the hair follicles and sweat ducts; (3) various physical methods that can form transient pores in the SC, opening a path directly through the SC for larger biomolecular drugs; and (4) diffusion through holes in the SC, punctured by microneedles (Figure F.2). This section will describe these four methods in more detail below.

The intercellular bilayers in the SC provide alternating regions of interconnected lipid and aqueous layers forming tortuous pathways between the corneocytes. The lipids found in the lipid bilayer domain are free fatty acids, cholesterol, cholesterol sulfate, and ceramides. The corneocyte's outer cell layer of cross-linked protein and intracellular keratin fibers provide a chemical resistant layer and strength as a mechanical barrier to injury. Just below the stratum corneum is the viable epidermis, which is made up of hydrophilic cells called keratinocytes and specialty cells such as langerhans cells (LCs). The LCs play an important role in the immune system, and their location in the viable epidermis is important when vaccines are delivered by microneedles. The outer two layers of skin, the stratum corneum and the viable epidermis, do not contain the sensory nerve endings or the blood vessels that can cause pain and bleeding (Bodde et al., 1989; Barry, 2001;
FIGURE F.1 A schematic of the cross section of the stratum corneum (SC, the main barrier in skin) and the viable epidermis beneath it, showing their major components. (Bodde, Verhoeven and van Driel, 1989.)
FIGURE F.2 The diagram illustrates four potential entry points through the main skin barrier, the stratum corneum: (a) tortuous lipophilic pathways between the corneocytes cells; (b) pathways through and around the hair follicles and sweat ducts; (c) transient pathways created by high electrical voltage pulses (electroporation); and (d) micro-pore pathways through the stratum corneum created by mechanical (micronee-dles) or electromagnetic (thermal ablation) methods. (Prausnitz, Mitragotri and Langer, 2004.)

Prausnitz and Langer, 2008). Below the viable epidermis layers is the dermis, where the capillary blood vessel beds, dendritic cells, and neural cells are located (Bodde et al., 1989; Cleary, 1993; Naik et al., 2000; Menon, 2002). The locations of these cells and the capillary bed are important to consider when delivering vaccines to the lymphatic system, and to minimize or eliminate bleeding and pain when using Active TDDS technologies.

> The **Stratum Corneum** consists of the outer cell layers of skin with a composite of the corneocytes (approximately 10–15 μ thick), with intracellular pathways made of lipid bilayers. The stratum corneum layer is the main barrier to skin permeation.

PASSIVE TRANSDERMAL DELIVERY SYSTEMS (PASSIVE TDDS)

There are various types of topical ointments, lotions, creams, and sprays for applying and delivering drugs passively to the skin. These methods are usually limited to drug molecules with broad therapeutic windows (e.g., testosterone, estradiol). More potent drugs with narrow therapeutic windows are not suitable for such topical applications. With these drugs it is necessary to have a patch with a fixed surface area (footprint), and a controlled release rate.

The challenge with Passive TDDS is to formulate a patch that achieves a therapeutic blood level fairly rapidly, and that also can adhere to the skin without irritation for from one day to a week. Many different components go into a successful TDDS patch, including pressure sensitive adhesives, penetration and diffusion enhancers, solvents to improve drug solubility and partitioning into the SC, barrier membranes, and rate-controlling membranes (Menon, 2002). The patches that have reached the US marketplace are in the form of laminate film structures that consists of layers that adhere to one another within the delivery system, and ultimately adhere to the skin for a day to a week. The drug molecule and other components of this delivery system should not be irritating or cause the patch to fall off from the skin prematurely or impact on drug stability. Selection of biomaterials for Passive TDDS needs to consider the various conditions that the patch will face during manufacturing, storage, and wear by the user for up to several days (Cleary, 1984; Hadgraft and Lane, 2006). The

components must meet several tests for biocompatibility, irritation, sensitization, drug and adhesive stability, human wear time, the amount and duration of drug delivery, and other quality testing required by the regulatory agencies.

Components and Biomaterials used in Passive TDDS Patches

Types and Structures of the Skin Patch. This section will focus on the more predominant structured laminate systems found in the marketed Passive TDDS patches. The typical patch is comprised of 2 or 5 laminated layers with a total thickness from around 100 to 500 μ (not including the release liner), and areas ranging typically from 2 to 40 cm². There are three basic laminate structure designs used in passive transdermal systems, shown in Figure F.3 (Cleary, 1984). Type (a) is a single adhesive plus drug reservoir/skin contact layer design. It has no rate-controlling membrane (RCM), and the SC is the rate-limiting barrier for the diffusing drug. It is often called a matrix or drug-in-adhesive patch. The type (b) design has a backing layer, a viscoelastic or gel-like reservoir, and a middle layer that can serve as a rate-controlling and/or structural membrane, and an adhesive layer. The middle layer is sometimes a non-woven film that serves as a structural support or a very porous structure that can prevent or slow down the adhesive cold flow. The third design, Figure F.3c, is similar to type (b), but it can have a liquid drug reservoir rather than a viscoelastic adhesive reservoir. The liquid reservoir patch is sometimes referred to as a liquid "fill and seal" patch, and may also

be called a "liquid fill patch". Both types (b) and (c) are rate-controlled membrane "reservoir patches" (Cleary, 1984, 1991; Van Buskirk et al., 1997). The reservoir in type (c) is essentially a drug that is formulated as liquid, then sealed between two layers of film, one of which is a rate-controlling membrane. Types (b) and (c) can deliver drug at a rate that is constant (zero order). Each of these three designs utilizes polymeric films that are laminated together by either pressure sensitive adhesives (PSA) or by structural adhesives that make a permanent heat-seal bond by melting the adhesive between two non-adhesive polymer films (Cleary, 1984, 1991; Ventrakaman and Gale, 1998). The drug and excipients are typically formulated together in the drug-adhesive layers in these patches.

> A **Rate-Controlling Membrane** is a membrane (either contiguous or porous) that provides a specific rate of drug diffusion from a device such as a skin patch. It is "rate-controlling" when it controls the rate at a lower rate than that across the stratum corneum, so that the control of drug delivery is built into the patch.

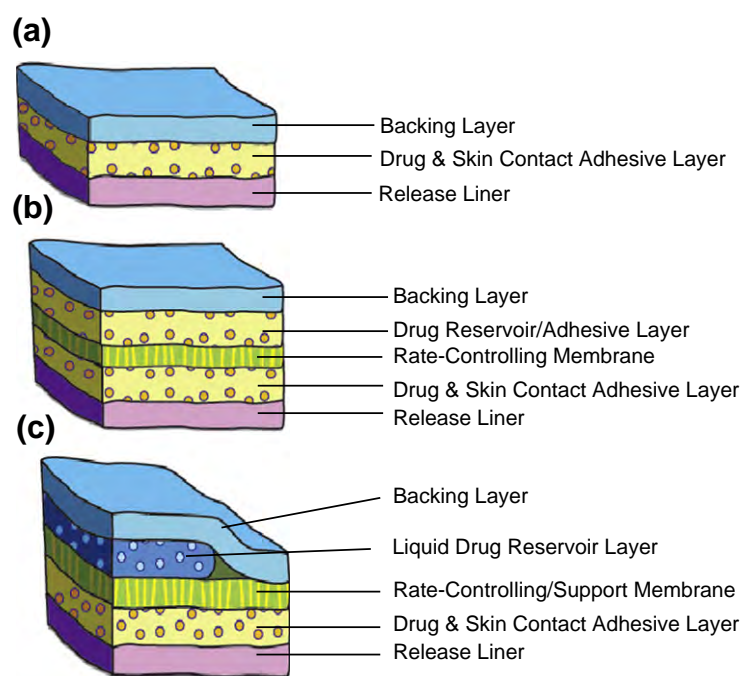
Backing Layer. This layer functions as the primary structural element of the device, it provides the device with much of its flexibility and drape (how the film lays on the curvature of the skin), and skin occlusivity (the degree of breathability of the backing film). Examples of materials useful for the backing layer can be occlusive films such as polyethylene terephthalate (PET), high


FIGURE F.3 Three common passive transdermal drug delivery systems' designs and structures include (a) a three layer patch: backing layer, single adhesive reservoir/skin contact layer, and release liner; (b) a five layer patch: backing layer, adhesive reservoir, a laminate structure as rate-controlling membrane, drug and skin contact adhesive layer, and release liner; (c) a five layer patch: backing layer, a sealed liquid reservoir, a rate-controlling membrane, drug and skin contact adhesive layer, and a release liner. (Van Buskirk et al., 1997; Cleary, 1984, 1991.)

density polyethylene (HDPE), and polypropylene (PP) or more breathable or better drape films, such as polyurethanes (PU) and poly(ether-amide)s (PEA).

Reservoir Layer. In the adhesive reservoir design the reservoir layer is comprised of a polymeric pressure-sensitive adhesive that contains the drug, solubilizers, and enhancers. The liquid reservoir system will have a liquid or hydrogel medium (such as a hydrogel or ethanolic/water gel using carboxymethyl cellulose or hydroxymethyl cellulose) contained in a sealed pouch-like area where one side is an impermeable backing layer, and sealed on the other side is a rate-controlling membrane. This layer may also contain adhesive in order to adhere the rate-controlling layer to the backing layer.

Penetration Enhancers. Penetration enhancers are key components that enable the drug to diffuse from the system and through the skin at higher flux rates. There have been literally thousands of skin permeation enhancers that have been tested and published in the literature and patents. However, there are only a small number of enhancers that have been approved by the regulatory agencies. These enhancers must be non-irritating and non-sensitizing to the skin, and should not interact with other components of the formulation (Bodde et al., 1989; Barry, 2004; Hadgraft and Lane, 2006).

Enhancers make it feasible for a drug molecule to permeate through the SC when the drug by itself does not have ideal physicochemical properties. Barry (2004) suggests that chemical penetration enhancers act through three mechanisms: (1) disruption of the tortuous intercellular lipid pathway between the corneocytes (examples of this type of enhancer are alcohols, glycols, fatty acids, and fatty acid esters); (2) opening up the dense keratin protein structure making it more permeable (examples of these enhancers are ionic surfactants such as decylmethyl sulfoxide and dimethyl sulfoxide); and (3) increasing the partitioning of the drug into the SC (an example of this type of enhancer is ethanol, which increases the SC penetration of nitroglycerin and estradiol) (Barry, 2004; Songkro, 2009).

Skin Contact Adhesive Layer. This layer is adhered to the release liner prior to use. Once the release liner is removed, it adheres to the skin site of application. The skin contact adhesive is responsible for maintaining the system at the same site for anywhere from one to seven days. Pressure-sensitive adhesives are sticky (tacky) to the slight touch of a finger, and have a range of cold-flow characteristics. Usually a very light touch of a finger is sufficient to adhere them to a surface such as skin, while they still may be removed easily from the skin without leaving any residue on its surface. Pressure-sensitive adhesives are based on three families of adhesives – polyacrylates (acrylates), polyisobutylene (PIB) or polydimethylsiloxane (silicone). Drugs usually have low diffusivity in the PIB and acrylate polymers, while silicone has a higher order of magnitude of diffusivity depending on the drug lipophilicity. These effects are related

to the large "free volume" within the adhesive molecular structure of silicones (Cleary, 1984; Ventrakaman and Gale, 1998; Kandavilli et al., 2002).

Release Liner Layer. This layer is a disposable layer which serves only to protect the device prior to application. It is removed prior to application of the device to the skin. The liner should allow easy handling, be user-friendly, and endure the manufacturing processes. The release liner is impermeable to the drug, liquid vehicles or enhancers that could migrate into it while still in the package. Typical examples are films of PET, HDPE, PP, and polycarbonate (PC) ranging in thickness from 50 to 125 microns. Release liners are often coated with a very thin layer of 0.5 nm to several microns of silicone or perfluoroether, to facilitate ease of removal of the liner before applying the patch to the skin.

ACTIVE TRANSDERMAL DELIVERY SYSTEMS (ACTIVE TDDS)

In this section we describe two technologies in depth, microneedle devices and iontophoresis devices. They are examples of mechanical- and electromagnetic-based TDDS. In general, Active TDDS utilize some type of energy to form a transient or a physical micropore through the SC. (One exception is iontophoresis, which utilizes natural, existing skin pores such as hair follicles and sweat glands.) The sources of energy used may be: (1) mechanical, such as with microneedles, microabrasion, solid rods, micro-liquid jets (used at moderate speeds), and micro-solid jets (used at ballistic speeds); (2) electromagnetic, such as with iontophoresis, electroporation, and sonophoresis; and (3) thermal, which uses electric current, radio frequency current or coherent laser light to ablate the SC. Table F.1 describes these eleven different types of Active TDDS technologies. Iontophoresis is the only Active TDDS that has reached the marketplace, while the others are still in different stages of development.

Microneedle Delivery Technology

The concept of microneedle patches was patented nearly 40 years ago (Gerstel and Place, US Patent, 1976). However, technologies that were needed to fabricate microneedles economically were not available until the 1990s. There are a number of different strategies that are being explored today to deliver drugs through the skin using microneedles (Higaki et al., 2003; Cross and Roberts, 2004; Banga, 2009; Cleary, 2009). Figure F.4 illustrates the various compositions and designs of microneedles from the late-1990s to the present day. In the 1990s they were initially made of glass or metals such as stainless steel and titanium (Prausnitz, 2004; Cleary, 2009). In the early 2000s, newer methods of microfabrication, such as heat embossing or microinjection molding, have been used to make polymeric microneedles from polysulfone

TABLE F.1	Active Transdermal Drug Delivery Systems		
Active Transdermal Delivery Systems		**Microporation Mechanisms Through the Stratum Corneum**	**References**
Mechanically-Based Energy	Microneedles	Micropores formed using mechanical force and velocity of an array of microstructures ranging from 100 to 1000 microns long and 40 to 200 microns wide.	Prausnitz, 2004; Gill et al., 2006; Banga, 2009; Cosman et al., 2010; Kalluri and Banga, 2010; Sullivan et al., 2010; Wendorf et al., 2010
	Microabrasion	Removes > several mm^2 of stratum corneum by abrasion, using sand paper or inert sharp-edged microparticles flowing in a gas at a moderate velocity, where skin is masked forming a 200 micron diameter micropore.	Glenn et al., 2007; Gowrishankar et al., 2009
	Solid formulated rod	A solid millimeter-sized rod, formulated with a drug, is inserted into the stratum corneum at a moderate force and velocity.	Bennett and Potter, 2006
	Micro-solid jets	A range of 20 to 100 micron-sized solid particles are inserted into and through the stratum corneum at supersonic speeds using compressed gas from a hand-held delivery device.	Burkoth et al., 1999; Higaki et al., 2003; Cross and Roberts, 2004; Dean and Chen, 2004
	Micro-liquid jets	A large number of pulsed liquid nl-sized droplets are pulsed through the stratum corneum at a velocity greater than 100 m/s.	Arora et al., 2007
Electromagnetically-Based Energy	Iontophoresis	Charged drug molecules migrate through hair follicles and sweat glands along an ion-based pathway using low level $milliamp/mm^2$ electric current density.	Panchagnula and Pillai, 2000; Higaki et al., 2003; Cross and Roberts, 2004; Kalia et al., 2004; Sathyan et al., 2005; Subramony et al., 2006; Power, 2007
	Electroporation	Short microsecond pulses of high voltage AC (>100 V) creates micropores through the stratum corneum.	Higaki et al., 2003; Cross and Roberts, 2004; Denet et al., 2004; Gowrishankar et al., 2009
	Sonophoresis	Ultrasonic energy with frequencies less than 100 kHz initiates cavitation that temporarily disrupts the lipid structure of the stratum corneum, providing increased permeability.	Higaki et al., 2003; Cross and Roberts, 2004; Mitragotri and Kost, 2004
	Electric current	A brief surge of electric current (<60 Hz) occurs with ohmic resistance followed by a rapid increase in heat in microelectrodes. An array of micropores is then created from ablation of the stratum corneum to form micropores.	Badkar et al., 2007; Banga, 2009
	Radio frequency current	Thermal ablation occurs using a high frequency alternating current (~100 kHz) that heats an array of of 100 microelectodes/cm^2 to create micropores.	Sintov et al., 2003; Banga, 2009
	Laser	An erbium:YAG laser emits light at 2.94 μm (H_2O absorption peak) that focuses only on water and not on surrounding tissue. A laser light scanner causes water to vaporize within the stratum corneum to form an array of micropores.	Higaki et al., 2003; Cross and Roberts, 2004; Kalia et al., 2008; Lee et al., 2008; Banga, 2009

(PS), poly(methyl methacrylate) (PMMA), and PC. Figure F.4d shows some newer materials that are biodegradable or dissolvable. Microneedles have been fabricated from degradable biomaterials such as poly(lactic-co-glycolic acid) (PLGA), polyglycolic acid (PGA), and polycaprolactone (PCL) (Figures F.4 and F.5) (Prausnitz, 2004; Cleary, 2009; Kalluri and Banga, 2010; Sullivan et al., 2010).

Solid microneedles can be used or applied to the skin in the following ways: (1) as a pretreatment modality where the microneedles are inserted and removed, with the subsequent application of a drug formulation that diffuses through the pores; (2) by first coating the microneedles with the drug, which dissolves off the microneedle tips as they are inserted (in this case, the patch is applied to the skin with a special applicator device, e.g., Zosano®, 3M); (3) by fabricating the needles from a biodegradable drug-containing polymer (in this case, the patch is inserted in the skin with a separate or integrated
FIGURE F.4 Examples of biomaterials used to make microneedles that are in-plane designs (a) silicon with hollow structure (University of California, Berkeley); and solid out-of-plane designs made of (b) silicon, solid (Georgia Tech); (c) silicon, hollow (University of Twente); (d) titanium, metal, (Zosano); (e) dissolvable and non-degradable polymers, polycarbonate (3M); and (f) biodegradable polymers (Corium). Non-degradable structures (metal, silicon, polycarbonate) are typically coated at the tip of the structure (e) (red tip). A dissolvable microneedle formulation that includes the drug mixed into the dissolving/biodegradable structures (f) – the drug is compounded together with a polymer in the whole structure. (Cleary, 2009; Wendorf et al., 2010.)
FIGURE F.5 (A) Schematic diagram of a degradable polymer microneedle array showing the process of applying the microstructures to the skin: (a) prior to biodegrading; (b) inserted into skin; (c) beginning to degrade, backing is removed; and (d) releasing the drug as they degrade. (B) A side view of the micropore in the skin where a dissolvable maltose microneedle is inserted in the skin using Casein imaging to show presence or absence of the micropore after 24 hours following insertion. Micropores are shown by the arrows pointing towards near vertical white lines: (a) immediately after insertion; (b), (c), and (d) 24 hours later under the following three different conditions: (b) site was kept open (unoccluded); (c) site occluded with water; and (d) site occluded with a plastic film. (Kalluri and Banga, 2010.)

applicator system, e.g., TheraJect®, Corium); or (4) by fabricating the patch with hollow microneedles, which are inserted into the skin, followed by forcing a liquid drug solution through the hollow central bores with a syringe-type applicator, for delivery through the pores (e.g., NanoPass®, 3M) (Prausnitz, 2004; Banga, 2009; Kalluri and Banga, 2010) (Figure F.4).

More recently, the microneedles have been fabricated from solids such as titanium, stainless steel, silicon, and glass, and coated with drug containing soluble polymers. Upon insertion, the coated polymers and their drugs are solubilized by the skin's interstitial fluid, releasing the active ingredients into the body. Figure F.5 provides a side view of the micropore after the microneedle is inserted into the skin. Note that the micropore comes to closure within a few hours when not occluded or kept moist, but persists when the micropores are covered with an impermeable polymer film (Kalluri and Banga, 2010; Sullivan et al., 2010; Wendorf et al., 2010).

Another recent development is that of microneedles entirely made of biodegradable polymers, loaded with the drug (Figure F.6). The microneedles may be designed to dissolve within 15 minutes, releasing soluble drug into the micropore at the same time. With the microneedle and the drug now gone, it becomes easier to dispose of the patch, which is simpler than disposing of a syringe and needle in hazardous waste disposal cans. It also eliminates the possibility of accidental finger sticks.

Microneedles have been used and validated in animal and human clinical studies by determination of therapeutic blood levels, pain sensation, and the time it takes for closure of the micropore (Gill et al., 2006; Kalluri and Banga, 2010). Human clinical studies with

a microneedle patch delivering a polypeptide (parathyroid hormone) have shown pharmacokinetics similar to that of a subcutaneous injection using a syringe and needle. However, the C_{max} may be reached earlier with microneedles compared to a syringe and needle (Cosman et al., 2010). Other human studies have shown that microneedles ranging from 200 to 750 microns in length are painless and bloodless. The micropores created by the microneedles take from 4 to 8 hours to reach closure if they are left without any covering (non-occluded). When they are covered (occluded) it takes about 16 to 22 hours for complete resealing (Kalia et al., 2008; Cosman et al., 2010).

Iontophoresis Technology

Iontophoresis utilizes small electric fields (producing current densities around 0.5 mA/cm^2 or less) to increase the flux of an ionized drug across the intact skin. Iontophoretic delivery is primarily through the appendages: hair follicles, sebaceous glands, sweat glands, and any skin imperfections. These access pores reach into the dermis, and once the water-soluble drug reaches the aqueous viable epidermis and dermis, the drug diffusion continues until it is picked up by the capillary bed in the upper level of the dermis (Kalia et al., 2004; Power, 2007) (Figure F.7).

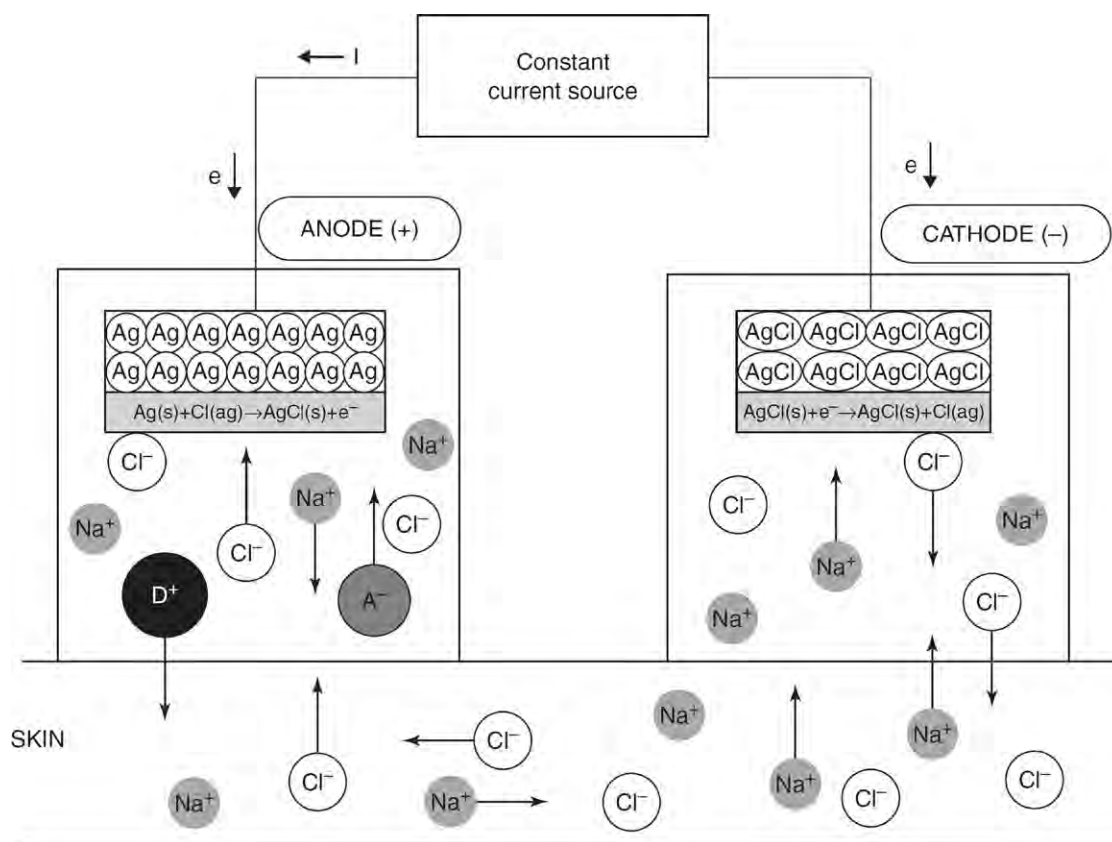
An electrophoresis device has a power source and two electrodes, one positive (the anode) and the other negative (the cathode), typically silver-based, Ag(+) and AgCl(−) respectively. The current flows from the anode to the cathode, and this draws positively-charged drug molecules (D+) through the skin and towards the cathode,
FIGURE F.6 Example of dissolvable microneedles prior to and after they were inserted into skin. These figures show the microneedles at various times: at (a) 0; (b) 1; and (c) 5 minutes after insertion into the skin. (d) View of the microneedle array prior to erosion. (e) Top view of porcine cadaver skin after the microneedles are inserted and dissolved leaving the red Sulforhodamine dye in each hole. (f) Side view of the micropore left by the dissolving microneedles that were inserted into the skin and dissolved in the viable epidermis (Brightfield micrography with H&E staining). (Sullivan et al., 2010.)


FIGURE F.7 This schematic diagram describes the electrode system of an iontophoretic drug delivery device that uses an Ag/AgCl electrode where the current is flowing to the anode (+). There are two electrode compartments: the anode (+) that contains the Drug, D^+A^-, (here the drug D^+ is placed in the reservoir of the same charge, e.g., D is lidocaine or fentanyl) and the cathode (−) or "indifferent" electrode (placed at some other site on the skin). (Kalia et al., 2004; Power, 2007.) See text for more detail on the delivery mechanism.

as the negatively-charged counterion (Cl^-) moves in the opposite direction, toward the anode. There are two reservoirs (or compartments) next to the two electrodes, where one of the reservoirs (the anode) contains the drug of the same charge (in this case, it is +) either as an aqueous liquid or a formulated hydrogel. The total observed flux of the drug from the iontophoretic device is made up of two types of electrokinetic phenomena: electromigration and electro-osmosis. Passive diffusion is considered negligible, particularly for higher molecular weight drug molecules (Kalia et al., 2004).

Iontophoretic devices that have reached the market place are sold either without the drug ("no drug") or come already prefilled with the drug ("with drug") where the physician or paramedic adds the drug solution to a reservoir before treatment. A major advance in the capabilities of iontophoretic systems has come with the availability of microprocessors. Microprocessors allow precise control of drug dosing and delivery profile, and provide increased system safety through monitoring of system functions such as current levels and battery voltage. The ability of microprocessor-controlled iontophoretic systems to offer minimally invasive and controlled administration of medications to patients has spurred an increased interest in the use of iontophoresis for systemic

delivery of drugs, especially those with limited oral bioavailability or those that require a quick onset or cannot be delivered with passive transdermal technology (Kalia et al., 2004; Sathyan et al., 2005; Subramony et al., 2006; Power, 2007) (Figure F.8).

Investigators have used many different types of polymers as "gelling agents," which form hydrogel reservoir films in iontophoretic devices. Examples of such cross-linked gels are agar-agar, gelatin, polyvinyl alcohol (PVA), poly(vinylpyrollidone) (PVP), poly(dimethylaminopropyl acrylamide) (PDAA), cross-linked poly(hydroxyethyl methacrylate) (PHEMA), methylcellulose (MC), and hydroxypropylmethylcellulose (HPMC) (Panchagnula and Pillai, 2000; Peppas et al., 2000; Wang et al., 2005).

Strategies to increase the permeation of large and small drug molecules have combined iontophoresis with other technologies, such as electroporation, sonophoresis or microneedles, or with other materials, such as ion exchange materials that may also serve to improve drug stability and shelf-life. Also, chemical enhancers such as fatty acids, propylene glycol (PG), polyethylene glycol (PEG), oleic acid, terpenes, and surfactants may be added to the formulations for electrophoresis reservoirs. These combination techniques may provide improved delivery of some large drug molecules or poorly water-insoluble

(Power, 2007.)

drug molecules (Panchagnula and Pillai, 2000; Peppas et al., 2000; Wang et al., 2005).

GLOSSARY

EVA is poly(ethylene-co-vinylacetate), a polymer used in Passive TDDS as a non-porous rate-controlling membrane.

FDA is the abbreviation of the US Food and Drug Administration.

HDPE is high density polyethylene, a thermoplastic polymer that is used as a release liner in Passive TDDS.

HPMC is hydroxypropylmethylcellulose, and is used as a hydrogel for the drug reservoir and counterion reservoir in ionotophoresis.

PC is polycarbonate and is melt-extruded to make arrays of microneedle structures; also used as a release liner.

PCL is polycaprolactone, a degradable polymer used to make microneedle structures.

PEA is poly(ether-amide), a polymer with breathable and elastic properties. It has been considered as a backing or rate-controlling membrane in Passive TDDS.

PEG is polyethylene glycol, a biocompatible water soluble polymer that is used as a solubilizer of components in Passive TDDS.

PET is polyethylene terephthalate, a thermoplastic polymer that has been used as a backing and a release liner in Passive TDDS laminate structures.

PG is propylene glycol, which is used as a solubilizer and skin permeation enhancer for drugs.

PGA is polyglycolic acid, a bioerodible polymer used in making bioerodible microneedle structures in Active TDDS.

PHEMA is poly(hydroxylethyl methacrylate), used in hydrogel reservoirs for iontophoresis.

PIB is polyisobutyl rubber, a hydrocarbon-based pressure-sensitive adhesive that is used as an adhesive layer in Passive TDDS.

PLGA is poly(lactic-co-glycolic acid), a bioerodible polymer used in making degradable microneedle structures in Active TDDS.

PMMA is poly(methyl methacrylate), a thermoplastic polymer used to make microneedles.

PP is polypropylene, a semi-crystalline, thermoplastic polymer that has been used as a release liner. It may also be used as a microporous rate-controlling membrane.

PS is polysulfone, it has thermoplastic properties and is a polymer that is used to make microneedles using melt-compression methodologies.

PSA is the abbreviation for pressure sensitive adhesive; PSA polymers are adhesives that bond or adhere to surfaces when pressure is applied. These adhesives have tack (sticky properties when touched), and are used to adhere Active and Passive TDDS to skin and the laminated structures found in TDDS.

PU is polyurethanes, elastomeric polymers that as a film have breathability properties, flexibility, and drape when used as a backing layer.

PVA is polyvinyl alcohol, a water-soluble polymer that is used to make hydrogel reservoirs in iontophoresis drug delivery.

G. ORAL DRUG DELIVERY

Clive G. Wilson
Strathclyde Institute of Pharmacy and Biomedical Sciences, Glasgow, Scotland, UK

Oral drug delivery remains the most popular and most utilized method of patient therapies, although the newest candidate drugs are becoming increasingly difficult to formulate for effective oral delivery. This route of oral delivery represents an important area of innovation in pharmaceutical formulations, where there is a need to maintain the stability of the new biomolecular drugs, increase the solubility and absorption of hydrophobic drugs, and enhance the bioavailability of both types of drugs.

FEATURES OF THE GASTROINTESTINAL TRACT

The arrangement of the human gut – called the GI tract – is illustrated in Figure G.1, showing the esophagus, continuing down into the stomach, and from there into the small intestines through the duodenum, jejunum, and ileum, and then to the ascending, transverse, and descending colon, and rectum. The major area for drug absorption is denoted by shading. Characteristics of the absorption routes through the GI tract are summarised in Table G.1.

pH of the Gastrointestinal (GI) Tract

Drugs used for oral medication are often weak electrolytes and many are salts of bases; thus, the pH change between the stomach and the small intestine will exert important effects on drug absorption. At rest, the stomach pH varies: in one study, the median basal pH for females was 2.79 ± 0.18, and that for males was 2.18 ± 0.18 (Feldman

FIGURE G.1 Schematic diagram of the gastrointestinal (GI) tract.

and Barnett, 1991). In adults, the population of parietal cells decreases, leading to somewhat higher gastric pH in the elderly. Moreover, differences will emerge when considering absorption from the fasted state compared to the fed state. If a medication is taken with water, the pH will be elevated temporarily by dilution, returning to baseline around 20 minutes after imbibing the drug. The change in the pH environment of the upper gastrointestinal tract is very important in oral drug delivery (Table G.2).

Often it is desirable to avoid releasing the drug in the stomach. In this case, the dosage form must remain intact until it reaches the small intestines, so an enteric coating is applied, and it must be insoluble in the gastric fluids. Two types of copolymers are commonly used as enteric coatings: cellulose acetate phthalate (pH range 4.8–7) and methacrylic acid-based copolymers. Control of coating polymer composition and thickness allows the appropriate release location in the small intestine, and the pharmacokinetics to be achieved. If the formulation is designed for colonic delivery, there are two options: coat with a polymer that breaks down by bacterial enzyme attack or use a thick coating of a slowly dissolving polymer.

Gastric Emptying

The duodenum regulates the emptying of the stomach into the small intestine. Fat, high salinity, and highly acid solutions cause the duodenal wall pressure to increase and slow down the exit of the gastric contents. The diameter of the pyloric valve opening varies according to the nature of the gastric contents. When a tablet is taken with water, the time of gastric emptying of the tablet will be highly variable according to posture, volume of fluid taken, and the calorific value of food taken before or with the dosing. If the formulation disintegrates and partially dissolves in the stomach, pulses of material will appear regularly in the small intestine at a rate determined by the meal. As tablets travel down the gut the movement slows, and periods of stasis are common just before the tablet leaves the ileum and enters the large intestine. Eating food later on will cause a gastrocolic reflex, enabling the contents to move from the small intestine to the large bowel.

Pellets and disintegrated dosage forms empty from the stomach as either a series of pulses when fasted or distributed in the meal when fed. The emptying of pellets is much more predictable in the fasted state, but large, intact tablets will stay in the stomach for prolonged and variable periods of time following dosing in the morning. Eating a light meal reduces the variability in emptying. Smaller particulates are emptied in the mass of the food, and the presentation of the dose in a dispersed system is a function of calorific load and mass of the gastric contents (Reilly et al., 1987). If food is eaten throughout the day after dosing with a heavy breakfast, then in some individuals an
TABLE G.1	Absorption Characteristics in the GI Tract		
GI Tract Segment	**Epithelial Type**	**Mucus**	**Absorption Patterns**
Oral Cavity	Stratified Squamous	Dilute	Passive absorption of smaller molecules mol.wt up to around 800 daltons, avoidance of first pass as venous drainage goes to heart directly. Proportion of dose swallowed.
Esophagus	Stratified Squamous	Mainly Salivary	Passive, low surface area. Insignificant contribution to absorption.
Stomach	Secretory Columnar	Thick, Adherent	Uptake of acids into tissue but little escapes into the circulation. Secretion of strong bases from plasma to gastric lumen (follows pH-partition).
Duodenum	Simple columnar	Thin, adherent	Active & Passive absorption over range of polarity up to around 2 kDalton: important route for absorption of drugs released from dose form in stomach.
Jejenum	Simple columnar	Thin, adherent	High Active transport, efflux & metabolism, & passive transport along concentration/ion gradients. Beginning of absorption of moderate lipophiles, lymphatic absorption starts.
Ileum	Simple columnar	Thin, adherent	As jejenum, completion of active absorption, absorption of particulates in Peyers' patches. Transit begins to slow.
Colon & Rectum	Columnar dominated	Thick, increasing	Generally reverts to passive absorption, driven by pH-partition. Absorption of non- by mucus-secreting towards rectum polar drugs in caecum, slowing in transverse ,ceasing as colon contents solidify. Rectal glands route generally DOES NOT avoid first pass (except at anal sphincter). Approximately 1/10TH rate of small intestine.

TABLE G.2	Characteristics of Segments of the Gastrointestinal Tract					
GI Tract Segment	**Approx. Surface Area**	**Approx. Segment Length**	**Approx. Residence Time**	**Approx. pH of Segment**	**Principal Catabolic Activities**	**Bacterial Count* (cfu/ml)**
Oral cavity	100 cm^2	–	Seconds to minutes	6.5	Polysaccharidases	–
Esophagus	200 cm^2	23–25 cm	4–8 seconds**	–	–	–
Stomach	3.5 m^2 (variable)	0.25 m (variable)	90 minutes (variable)	1–2	Proteases, lipases	10^2
Duodenum	1.9 m^2	0.35 m	30–40 minutes	4–5.5	Polysaccharidases, oligosaccharidases, proteases, peptidases, lipases	10^2
Jejunum	184 m^2	2.8 m	1.5–2 hours	5.5–7.0	Oligosaccharidases, peptidases, lipases	10^5
Ileum	276 m^2	4.2 m	5–7 hours	7.0–7.5	Oligosaccharidases, peptidases, lipases	10^7
Colon and rectum	1.3 m^2	1.5 m	1–60 hours (35–38 hours on average)	7.0–7.5	Broad spectrum of bacterial enzymes	10^{12}

enter-coated tablet may remain in the stomach for longer than twelve hours (Wilson et al., 1989).

When drug is ejected from the stomach, it will pass into the duodenum, which is a highly permeable section of the intestine. Thus, the duodenum is a desirable region to deliver drug; however, transit through this region occurs rapidly. Therefore, it is probable that significant duodenal absorption occurs only when the dose is retained in the stomach for a period of time, and slowly exits into the duodenum. This may be accomplished with gastric retention polymers or devices (see below, and Park et al., 2006).

Immediate Release Dosage Forms. Administration of an active compound must be carried out as a unit dosage form; however, once in the body, the work of the formulator must be undone. The formulation usually contains fillers and binders, which aid physical processing during manufacture, including wet and dry granulation, filling into capsules, and formulation into advanced dosage forms. Typical fillers and manufacturing aids include lactose, mannitol, and di-calcium phosphate; binding materials include microcrystalline celluloses and carboxymethylcellulose, starch and gums; fillers include cellulosics such as hydroxypropyl methyl cellulose (HPMC);

and coating materials include enteric copolymers, as described above. To ensure disintegration, the active formulation may contain swelling or fast dissolving agents, and in addition lubricants are added to improve powder flow during manufacture. The usual objective is to produce rapid dissolution in the small intestine. Rapid dissolution is measured as >85% dissolution in 30 minutes in 900 ml media. A compound is classified as highly soluble if it dissolves in 250 ml media.

Lipid Dosage Forms. A solution to the poor aqueous solubility of many drugs is to utilize an alternative solvent, which forms emulsions or supersaturated solutions on dilution with the gut contents. Surfactants may also be incorporated to aid dispersion on release of the drug. The "container" of such formulations is usually soft or hard gelatin capsules, and some formulations may be chewable or enteric-coated, soft gelatin-coated products. Gelatin formulations are often preferred by patients as they are easier to swallow (although if they are buoyant, the reverse may be true, especially in the elderly) (Perkins et al., 1999). The use of gelatin in hard capsule shells is gradually being replaced by HPMC, but in soft capsules highly plasticized gelatin remains prominent.

Gastric Retention Devices. There are regions of the gastrointestinal tract where high absorption occurs, and efforts have been made to design formulations that deliver drugs in those regions. These formulations utilize copolymers that act by several mechanisms, including ligand association and bioadhesion to the local lumen (Park et al., 2006). A few important drugs show an apparent window of absorption, with best permeability in the duodenal segment. Since transit through this region of the gut is very rapid – typically less than 5 minutes – the formulator must attempt to keep the delivery device for a prolonged period of time in the stomach, such that the duodenum is continually bathed in drug. Methods to do this often employ gastric retention devices. A simple test was proposed to test the usefulness of such devices – simply sipping a formulation over a prolonged period to examine a change in the pharmacokinetic parameters (Burke and Wilson, 2006). Other gastro-retention methods have been studied, including use of mucoadhesion, flotation, and obstruction devices, such as superporous hydrogels (Chen et al., 2000; Kim et al., 2004; Park et al., 2006). Floating systems are either effervescent or non-effervescent systems in which gas is either generated or trapped during rapid swelling of a polymeric hydrogel to increase the buoyancy. The control of fluid penetration into the device, and therefore drug dissolution and release, is controlled by the formation of a cross-linked gel barrier on the exterior. A general strategy is to float or to expand due to the liberation of gas into a gelling structure, such as alginate or acrylamide hydrogels, and therefore is most successful if the patient is fed and upright. There are problems if the subject is recumbent and turns onto the left, as the floating layer will empty out of the stomach ahead of the rest of the gastric contents (Jenkins et al., 1983).

Intestinal Transit: How Constant is it?

The primary area of the gut for drug absorption is the small intestine, having an absorptive flux around 10 to 20 times that of the large bowel (Table G.1). The slow absorption associated with compounds of poor solubility or intrinsic slow dissolution still prompts drug formulation scientists to look for methods of increasing small intestinal transit time. Imaging techniques, such as gamma scintigraphy and magnetic moment imaging, show that movement gradually slows as the dosage form moves from the duodenum to the ileum, with periods of stasis and sluggish movement. Sluggish movement in the gastrointestinal tract is often associated with blockages – called "bezoars," due to ingestion of fruit (especially unripe persimmons, phytobezoars), hair (trichobezoars), and mixtures of tablets with an anticholinergic effect (pharmacobezoars).

The opposite extreme – fast transit – is also sometimes evident. In volunteer studies with the drug gefitinib, the pharmacokinetics was shown to be highly variable (Swaisland et al., 2005). Subsequently, it was appreciated that there was a subgroup in the population with consistently faster intestinal transit times (156 minutes for the subgroup versus 204 minutes for the average), resulting in lower drug absorption (Wilson et al., 2009).

> The mechanisms of drug delivery from controlled-release oral dosage forms can be classified into these five main areas: (1) diffusion control; (2) swelling and dissolution control; (3) osmotic pump control; (4) ion exchange control; and (5) bacterial enzyme control.

CONTROLLED RELEASE IN THE GI TRACT

In functional terms, progress in controlled release technology in the GI tract has branched into three main directions: deposition control (control of the site or region of delivery); temporal control (control of the time of delivery, also called chronotherapy or chronopharmaceutics); and barrier control (control of the rate of delivery). Deposition control refers to the coverage of tissue achieved by the device, and its dispersion (spread) and accumulation are the parameters measured. Temporal control refers to devices that delay release of the active component after ingestion, eventually releasing the formulation further down the gut. This will generally result in less dispersion when compared to devices that release in the stomach. Barrier control refers to the construction of devices in which excipients or membranes control the release of the drug. This is especially important for drugs exhibiting a short half-life, and hence requiring three or more doses per day.

The extension of dosing intervals to facilitate increased compliance has been a successful strategy in therapeutics. This relies on the ability to sustain drug delivery for an extended time, using one or more delivery retarding mechanisms of matrix, coating or pump. These mechanisms

may be used in combination, and in a variety of geometries. A slowly dissolving drug will display a flat and variable plasma concentration–time profile, and here the objective may also be first to control the solubility of the drug, and second to modulate its rate of release. This principle has been used to target more distal parts of the gut by controlling the matrix polymer composition and/or the coating polymer composition and thickness. Bimodal distributions of the plasma concentration–time profile (PK) may occur in slowly eroding matrices of conventional tablets, which break up as they go through the ileo-caecal junction (Wilson et al., 1989; Gabacz et al., 2008).

The bacterial enzyme-controlled drug delivery mechanism in the colon depends on the action of the bacteria in the ascending colon to degrade polymer–drug conjugates or polymer matrices or coatings of a tablet as it moves through the colon.

Colon Drug Delivery

Targeted delivery of drugs to the colon, the terminal region of the GI tract, has been employed to achieve one of several major therapeutic objectives: (1) to deliver high local concentrations of a drug for treatment of colonic diseases; (2) to delay delivery of a drug until the colon is reached (where there is a long residence time) in order to treat acute phases of a disease at the appropriate time of day; (3) to utilize sustained delivery to reduce dosing frequency; and (4) to deliver fragile biotherapeutics such as protein drugs, in the hope that the colon is less hostile metabolically to protein-based therapeutics.

> Oral pulsed release systems are generally divided into five major types of systems:
>   Drug delivery systems (DDS) with rupturable coating layers
>   DDS with swellable/erodible layers
>   DDS with increasingly permeable coating layers
>   Capsule-shaped systems with controlled-release plugs
>   Osmotic systems
> (Maroni et al., 2005).

Osmotic Pumps

The osmotic pump has become an important delivery vehicle for oral therapeutics, and is also widely used in pharmacological research. The principle was first demonstrated by Rose and Nelson as a long-term implantable pump that would be of much value in pharmacology; for example for long-term, site-specific delivery to the rat (Rose and Nelson, 1955). A wide variety of osmotic pumps was further famously developed by Alza Corporation scientists, and now there are many different forms, including push-pull, a pulse-release system that works by the generation of sufficient pressure to rupture a controlling membrane. A push-pull system can typically maintain a zero order, constant rate of release for 80% or more of its theoretical content, and was strikingly effective as

a system for delivery of nifedipine (ProCardia XL®). The principle advantage of this type of technology is that the system loads up with water prior to entry into the relatively dry region of the large bowel and, providing transit is prolonged, the delivery of drug can be sustained. The major issue is the variation in normal bowel habit, and all delayed systems run into the problem of the limited amount of water in the colon – at best around 30 mL in the caecum – with a problem of dispersion if the release occurs in the transverse colon and beyond.

> A variety of oral osmotic pump designs and coatings were developed at Alza Corporation in the 1970s and 1980s for controlling the site and rate of release of a drug. Zero order controlled-release kinetics are achievable with these pumps, which are usually ingested as small tablets. Some osmotic pumps are also designed to release two drugs in sequence (Theeuwes and Yum, 1976; Theeuwes, 1983; Theeuwes et al., 1985).

Bacteria and Bacterial Enzymes in the Colon. Biopolymers used for colonic drug delivery are plant-based polysaccharides, which are digestible by the bacterial enzymes of the colon and are almost untouched by mammalian enzymes secreted by the gut wall. As a consequence such materials, particularly those that have pronounced swelling properties, have been investigated as potential excipients in the formulation of controlled-release colonic drug delivery systems. The colonic microflora secretes a number of enzymes that are capable of hydrolytic cleavage of glycosidic bonds. These include β-D-glucosidase, β-D-galactosidase, amylase, pectinase, xylanase, α-D-xylosidase, and dextranases. In addition there are scission reactions catalyzed by azo-reductases that are secreted by the anaerobes that can degrade azo-containing polymers and hydrogels (e.g., Miyata, 2010). Such azo-polymers are also used as prodrugs, e.g., 5-ASA adducts such as balsalazide and olsalazine.

Biodegradable polysaccharides can be incorporated into the formulation matrix or as a coat, alone and in combination with other polymers. Since many of these polysaccharides have limited release-control properties due to their high water solubility, they are used in combination with synthetic non-biodegradable polymers, especially acrylates, or are modified to reduce their solubility (Wilson et al., 2008). Typical polysaccharides include pectin, guar gum, amylose, chitosan, and inulin.

CHAPTER II.5.17 DIAGNOSTIC APPLICATIONS OF BIOMATERIALS

Gonzalo Domingo, Kenneth R. Hawkins, Roger B. Peck, and Bernhard H. Weigl
All authors are affiliated with PATH (www.path.org)

OVERVIEW OF DIAGNOSTICS

Medical diagnostics are devices that aid in the diagnosis of a disease or condition. While there are many different classes of diagnostic devices, ranging from blood pressure cuffs to MRIs, biomaterials are most often used as components of *in vitro* diagnostics (IVDs).

IVDs generally measure the presence, count or concentration of an *analyte* – a chemical or biochemical constituent or bioparticle – in a *sample* such as blood, saliva, urine, other bodily fluids, stool, and sometimes tissues.

Analysis is done *in vitro* (i.e., in a controlled environment outside the body) to minimize noise and potential interferents. This is an important difference from biosensors (see Chapter II.5.13 for a discussion of biosensors). Common analytes include biomarkers for disease presence and progression, components of pathogens themselves, and xenobiotic substances.

The field of medical diagnostics is vast, and this chapter cannot provide an overview of all major classes of diagnostics. Therefore, the authors focus on types of diagnostics that frequently incorporate biomaterials, and especially on devices that are used in lower-throughput, point-of-care (POC) settings.

Requirements of Diagnostics

Diagnostic tests, first and foremost, must provide value to the patient by assisting the healthcare provider in

improving the accuracy of a diagnosis beyond what one could achieve based solely on observable symptoms, epidemiology, and statistics (*syndromic diagnosis*).

Diagnostics, like any other medical intervention, are used within an overall healthcare and economic context. Given infinite resources and patients' willingness to submit to frequent testing, an enormous number of chemical and biological parameters could be measured with current technology to provide information about a patient's current and likely future health. These range from full genomes and time profiles of thousands of known biomarkers to the presence of every foreign organism in or on a patient's body. However, resources are always finite – especially in developing countries that hold the majority of the world's population – and trade-offs always have to be made. The World Health Organization (WHO) has published a list of desirable attributes for diagnostics specifically for global health (*low-resource*) settings. According to the WHO *A.S.S.U.R.E.D.* model, (Mabey et al., 2004) a diagnostic should be:

A = Affordable by those at risk of disease.
S = Sensitive (able to detect the analyte at a clinically significant level).
S = Specific (not responsive to sample constituents other than the analyte).
U = User-friendly (simple to perform with minimal training).
R = Rapid/robust (to enable action at point-of-care).
E = Equipment free (or requiring as little equipment as possible).
D = Deliverable to those who need it (requiring temperature and mechanical stability in transport).

Different healthcare settings value these characteristics according to their priorities. In global health settings, cost, simplicity, and stability of the biomaterials are paramount. In POC settings in developed countries, simplicity is still critical, together with sensitivity and specificity. In laboratory settings, time to result is very important, because a diagnostic parameter may be needed to guide emergency or surgical treatments. In central laboratory settings, a parameter not on the WHO list – throughput – is critical, because a single device may be used to process hundreds of samples daily.

Biomaterials can affect the performance of diagnostics in many of these areas. Affordability is affected by material cost, as well as its stability. The performance of a sensing biomaterials layer will affect both sensitivity and specificity. The response time of a sensing layer (or the resuspension time of a dried reagent layer) affects time to result. A biomaterial that visibly changes in response to contact with a biochemical analyte allows the design of instrument-free diagnostics. The stability of biomaterials determines if a diagnostic can be stored at room temperature, used in hot and humid environments or stored for long enough periods to allow use in remote settings.

The Three Main Aspects of Diagnostics

In general, diagnostic processes all naturally divide into three main aspects: *pre-analytical*; *analytical*; and *interpretation* (Figure II.5.17.1). Each aspect has its own challenges and tools, and can be considered autonomously, although the needs of one will affect the others. Very few diagnostic processes can be performed with a single device from sample collection to output of result. Most often, diagnostic devices perform a pre-analytical, analytical or interpretation function, or some combination thereof. The role of biomaterials in these diagnostic devices varies widely to reflect the huge diversity of *in vitro* diagnostic processes that contain biomaterials.

Case Study 1	**Biomaterials in a Lateral Flow Immunoassay Strip**

The lateral flow immunoassay strip seems to be a simple diagnostic device; however, it requires at least *four distinct biomaterials*, serving seven different functions:

1. In the pre-analytical domain, an *anti-coagulant-coated glass blood collection tube* connected to a puncture device is often used for sample collection.
2. The sample is applied to the *surfactant-impregnated sample pad* of a lateral flow rapid immunoassay test strip where the sample is processed, in this case simply by retaining the majority of red cells, and thus allowing the remaining fraction of the sample to flow along the strip.
3. The sample also interacts with an *immunoreagent attached to a mobile*, *visible particle* in the sample pad. The target analyte molecules are "labeled" with this immunoreagent.
4. In the analytical part of the diagnostic device – the strip – the sample first encounters *strip paper treated with a blocking agent* to prevent nonspecific binding.

5. The sample next encounters a band of *paper-immobilized immunoreagent* that captures the labeled analyte molecules.
6. Shortly thereafter, the sample encounters a second band of *paper-immobilized immunoreagents* (*control line*) as it flows along the strip. The control line captures another generic component of the sample.
7. For interpretation, the bands on the strip paper can be visually observed or inserted into an optical, electrochemical or magnetic reader for machine-aided interpretation. At this phase, the optical properties of the strip paper become important.

With this case study in mind, a more in-depth consideration of the details of each of the three main aspects of diagnostics should implicitly suggest many more ways in which biomaterials can influence the final performance of an IVD device.
FIGURE II.5.17.1 A schematic representation of the three main aspects of any diagnostic process: pre-analytical; analytical; and interpretation. The three phases are linear in nature. Pre-analytical addresses sample collection and preparation; analytical comprises capture and/or detection of the target moiety; and interpretation takes into consideration calibration, comparison, and classification of the results. Each phase interacts with the aspect immediately before or after it. Additionally, each aspect has interactions with samples, patients or users. It is important to note that the users that interface with each aspect may represent very diverse backgrounds with varying levels of training, experience, and expertise.

THE PRE-ANALYTICAL PHASE

The pre-analytical phase of a diagnostic test refers to all of the steps required to deliver the analyte from the sampled environment or patient to the analytical assay. First, the test must sample the matrix in which the target analyte is present. Next, the matrix is processed to perform one or several of the following: (1) concentration of the analyte; (2) purification of the analyte; and (3) conditioning of the analyte for the downstream analytical testing. The performance of a diagnostic test, especially its limit of detection (LOD) and reproducibility, is highly influenced by the pre-analytical phase.

Technologies resolving the pre-analytical phase of the diagnostic test interface with the patient, from whom the specimen is obtained, the user, who utilizes the technology to collect the specimen and process it, and the analytical test, which requires the analyte to be appropriately conditioned. Each of these interfaces must be considered when selecting the appropriate method and biomaterial for the task (Figure II.5.17.2). Different contexts for diagnostics result in different combinations of interfaces (Table II.5.17.1).

Factors Determining Specimen, Specimen Volume, and Specimen Conditioning

In the context of medical diagnostics – and more specifically, infectious disease diagnostics – matrix sampling typically is referred to as *specimen collection*. The major factors contributing to specimen selection are:

- *Analyte abundance in the specimen.* Ideally one would use the specimen in which the highest concentration of the target analyte is found.
- *Clinical relevance of analyte in the specimen.* The presence of a specific analyte in one specimen
FIGURE II.5.17.2 The pre-analytical phase is the first phase of the diagnostic process. In this phase samples are collected from the patient and prepared for the analytical stage. Depending on the level of integration in the diagnostic device, users that may interact with this phase could include the patient, healthcare provider or laboratory technician. Biomaterials may be used to process the sample, but the pre-analytical phase always results in a biomaterial that is appropriate for use in the analytical phase.

may not indicate disease, while in another specimen it will.
- *Ease of specimen collection.* Noninvasive sources of specimens, such as urine, are preferable.
- *Complexity of the specimen.* A less complex specimen simplifies downstream processing.

Specimen collection entails direct interaction with the patient. For POC diagnostics, sample collection minimizes active roles for biomaterials in the host–device interaction, and thus minimizing biocompatibility constraints. Biomaterials are typically restrained to an active role in the specimen receptacle or container and the downstream applications.

The specimen volume or sample size required for a diagnostic test is determined by the analyte concentration in the specimen, the efficiency of analyte purification and/or concentration, the LOD of the analytical phase, and the target LOD for the final diagnostic test. These concepts are illustrated in Case Study 2 at the end of this section.

The pre-analytical phase encompasses purification, enrichment or concentration of the target analyte for downstream analysis. Purification is required to remove substances that inhibit, compete or interfere with the analytical phase; enrichment could be required to improve signal-to-noise ratios; and concentration of the target analyte from large specimen volumes to smaller volumes may be required to meet the appropriate clinical sensitivities. In all of these processes, biomaterials can play a key role.

The downstream analytical assay determines the level and nature of analyte preconditioning that must be performed. For example, for a diagnostic assay using polymerase chain reaction (PCR) as the analytical test, key functions for the pre-analytical phase are release of DNA or RNA from organelles (by sample cell lysis), removal of reverse-transcriptase and polymerase inhibitors and, often, concentration of DNA or RNA into a

TABLE II.5.17.1	Common Specimen Types and Sampling Methods and their Suitability in Various Contexts		
Specimen	Sampling Method	Appropriate for Point of Care	Example Analyte and Comments
<50 µL blood	Finger-prick/heel stick	Yes	Complete blood count (CBC); blood glucose monitoring; bloodborne pathogens, antigens, and nucleic acid; host immune response such as IgM and IgG; xenobiotics
>50 µL blood	Venipuncture	No	Pathogen culture as well as CBC; bloodborne pathogens, antigens, and nucleic acid; host immune response such as IgM and IgG; xenobiotics
Saliva, oral fluid or oral mucosal transudate	Swab or salivette	Yes	Hormones, xenobiotics. Many analytes present only at very low concentration
Sputum	Expectorated	Yes	Lower respiratory tract infections such as tuberculosis
Stool	Self-collected, rectal swab or diaper swab	Yes	Diarrheal infections, fecal occult blood, pathogen culture, nucleic acid, and antigens
Central nervous system	Spinal tap	No	Encephalitis, pathogen culture, nucleic acid, antigen, immune response
Nasal swabs	Swab	No	Upper respiratory infections, pathogen culture, nucleic acid, antigen
Urine	Self-collected	Yes	Hormones, xenobiotics
Urogenital	Provider or self-collected	Yes	Reproductive tract infections

small volume. Purification of the specific target DNA or RNA is not critical, because the PCR reaction itself can be highly specific. In contrast, a diagnostic test based on the nonspecific staining of the entire class of molecules to which the analyte belongs requires a high degree of purification during the pre-analytical phase, because the assay itself has only limited specificity at the analytical phase.

Affinity Capture for Concentration and Purification

One of the most common tools for analyte purification and concentration is affinity capture, whereby physical, chemical or biochemical features of the target analyte are used to capture or exclude the target analyte. In these techniques it is common to immobilize the capture species on a solid support, and then introduce the sample analyte in a liquid or mobile phase.

Charge-based interaction between the phosphate backbone of these biopolymers and silica is used to purifiy DNA and RNA from complex materials (Figure II.5.17.3), whereas specific purification and enrichment of target nucleic acid molecules or subclasses of these molecules can be mediated through complementary strand hybridization. A common example is the use of a poly-T-oligonucleotide immobilized to a surface for the capture of eukaryotic messenger RNA, which is typically polyadenylated.

Case Study 2 | Assay Specifications Drive Biomaterial Choices

A diagnostic test is under development that is specified to detect at least 50 copies/mL of HIV viral RNA in blood plasma. The analytical test is a highly sensitive real-time PCR system with a demonstrated LOD of five copies per reaction. Given the precision of the assay, specimens should be tested in duplicate. The designers would like to use a finger-stick to collect the specimen. Finger-sticks can be expected to yield a maximum of ~500 µL of whole blood, which after spinning down should yield ~275 µL of plasma.

There are two candidate affinity-based biomaterials suitable for the RNA extraction device. The first material is a traditional solid matrix which, due to its kinetic and thermodynamic properties, is capable of extracting 70% of the RNA in the plasma. The second material is a thermally responsive smart polymer system which, due to its ability to change phases in a controlled fashion, is capable of releasing almost all of the RNA it captures, and is therefore 95% efficient. The smart polymer system is far more expensive on a per test basis. The assay designer needs to determine if the extra cost is justified. Performing the unit analysis shows that:

$$\frac{copies}{test} \times \frac{test}{extraction} \times \frac{mL\ plasma}{copies} \times$$

$$\frac{1}{extraction\ efficiency} \times \frac{\mu L}{mL} = \frac{\mu L\ plasma}{extraction}$$

$$\text{For biomaterial \#1}: \frac{5 \times 2 \times 1000}{50 \times 0.7} = \frac{286\ \mu L\ plasma}{extraction}$$

$$\text{For biomaterial \#2}: \frac{5 \times 2 \times 1000}{50 \times 0.95} = \frac{211\ \mu L\ plasma}{extraction}$$

The traditional solid matrix material will not be able to meet the LOD specifications with the volume of plasma expected to be available from a finger-stick. The more efficient smart polymer is required to meet specification; therefore, the additional cost is justified.

Step 1: Lyse sample
Step 2: Adsorb sample to capture matrix
Step 3: Wash contaminants from capture matrix
Step 4: Elute DNA from capture matrix
FIGURE II.5.17.3 Charge-based interaction system for concentration and purification of DNA.

Directed polyclonal or monoclonal antibodies are common tools used for the capture of a wide variety of analytes, ranging from small molecules to proteins, and even whole cells.

Biomaterials can play a key role in optimizing the binding kinetics for effective analyte capture and conditioning. The effective k_{on} rate for a binding event in a complex mixture includes the diffusion rate between the analyte and its cognate receptor. Presentation of the receptors in microfluidic platforms with large surface-to-volume ratios or on nanoparticles that simulate free solution conditions significantly accelerates the overall binding rate and efficiency. Paramagnetic nanoparticles that can be silicanized for nucleic acid capture or conjugated to antibodies for analyte capture offer the benefits of free suspension kinetics during the binding events, and the possibility of analyte concentration through exposure to a magnetic field. A similar concept applies to stimuli-responsive "smart" polymers, which behave as solubilized reagents under a certain pH or temperature, but act as large aggregates when the pH or temperature is modified.

THE ANALYTICAL PHASE

Over the years, many different types of IVD assays have been developed, and new types are being developed daily. To review them all exceeds the scope of this chapter. (A summary of a few of the most common assays and the biomaterials they employ can be found in Table II.5.17.2.) Nevertheless, diagnostic assay design has its lexicon, which concisely describes the general principles that underlie the design. These terms and concepts are briefly reviewed here, and can be used to differentiate the bewildering array of extant assay types. In the sections that follow, the term *sample* will be assumed to mean the output of the pre-analytical processes discussed above.

Technologies resolving the analytical phase of the diagnostic test interface with the pre-analytical phase where the sample is prepared or purified, when the user performs the steps required to conduct the assay, and at interpretation of the results. Each of these interfaces must be considered when selecting the appropriate method and biomaterial for the task (Figure II.5.17.4). Failure to

TABLE II.5.17.2	Several Common Assay Types, Biomaterials Used, and their Suitability in Various Contexts		
Platform	**Types of Tests**	**Biomaterials Utilized**	**Where Used**
PCR	Nucleic acid detection Genetic testing High-sensitivity applications	Nuclease-free lab ware Oligonucleotides Fluorescent labels	Central or reference laboratory
Enzyme-linked immuno-sorbent assay (ELISA)	Protein detection Antibody detection	Coated lab ware Antigens Antibodies Blockers Enzymes/substrate	Central, reference or general laboratory
Flow cytometry	Cell detection and differentiation	Antibodies Fluorescent labels	Central, reference or specialized laboratory
Microscopy	Direct observation Cell differentiation Cell morphology	Slides (surface prep.) Dyes Antibodies	Central, reference or clinic laboratory
Lateral flow strip test	Antibody detection Protein detection Chemistry	Engineered "papers" (strips and pads) Antigens Antibodies Blockers Colormetric labels	POC or near patient (e.g., home use, bedside, doctor's office)
Arrays	Genetic testing Protein detection Complex algorithm	Functionalized glass or plastic substrates Antigens Antibodies Oligonucleotides Fluorescent labels	Central or reference laboratory
FIGURE II.5.17.4 The analytical phase of the diagnostic process receives biomaterial from the pre-analytical phase, and captures and/or detects the target moiety generating a signal or output for interpretation. The user may be a laboratory technician involved in detailed procedures of the test or if the analytical process is integrated into the test, the device user may be detached from the analytical phase. Biomaterials used in the analytical process may include antigens, antibodies, nucleic acid sequences, proteins, and enzymes.

address these interfaces will result in an analytical system that is inadequate.

Any analytical system can be described abstractly as a series of elements that interact to produce the system performance (Figure II.5.17.5). These modules include signal generation, signal modulation, signal transduction, noise filtering, amplification, response extraction, dose response modeling, and others (Christian, 2004; Strobel and Heineman, 1989). The designer manipulates some or all of these elements to achieve the specifications of the assay. There are many different ways to categorize

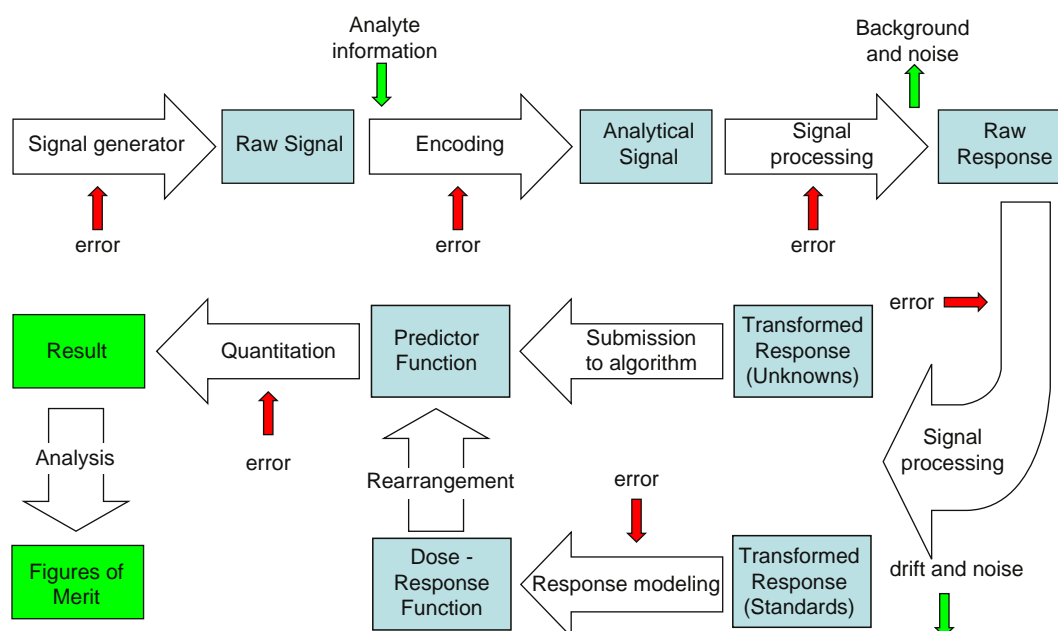
assays. For example, they can be *homogeneous* (all of the steps needed to generate the response occur in the same compartment as the sample) or *heterogeneous* (separation steps isolate the response to a different compartment). They can be *qualitative* (returning a yes or no answer for analyte presence or identity) or *quantitative* (returning a cardinal value for analyte concentration or mass). All of these divisions are useful when discussing assays in particular contexts, but a general treatment should be careful to qualify the specific divisions used as an example.


FIGURE II.5.17.5 A block diagram of the various modules or elements that comprise a generalized diagnostic assay design. The raw signal is encoded with the analyte information in the sample. The analyte response is extracted from the complex analytical signal. Various signal processing steps (amplification, noise filtering, data transformation, background correction, etc.) may be required to achieve a response-to-noise ratio favorable to facile modeling and quantization. Empirical response modeling (calibration) is enabled by the assay of standards. The dose–response function (standard curve) that results is used to determine the predictor function that is used to quantitate unknowns. Error is introduced at each step. Validation is demonstrated by the figures of merit. Predictor functions and validation are considered in the "Interpretation" section of this chapter. *(Reproduced with permission* (Hawkins, 2007)*.)*

Capture and Detection

The most common types of IVDs are heterogeneous. At the heart of most heterogeneous diagnostic technologies is the ability to both *capture* and *detect* a specific analyte from a biological matrix. This is typically done via affinity-binding reactions (as discussed in Box 1 above). As described above, pre-analytical steps will improve analyte availability from the biological matrix. Technologies that eliminate or integrate pre-analytical steps to reduce assay complexity for the end user are increasing – especially in resource-limited locations where high demands are placed on the healthcare provider's time. These demands on the assay performance enhance the importance of analyte capture and detection capabilities, especially because it serves an enrichment and purification step as well.

Capture and detection are the processes that generate the analytical signal in the scheme shown in Figure II.5.17.5. Together they are sometimes referred to as the *assay principle*. (This term can be applied to other types of assays as well, sometimes with a different meaning.) These are the steps that are most visible to the clinician and medical technologist, while signal amplification and processing are frequently "hidden" in instrumentation or analysis software. While capture and detection must work in concert with the analyte of interest, we will first consider them as separate entities, and then examine how they combine to form a fully-functioning assay system.

BOX 1 | **The Kinetics and Thermodynamics of Affinity Capture**

Key aspects to affinity capture and labeling of the analyte are the strength of the interactions between the analyte and the binding molecule defined by the dissociation equilibrium constant (K_d, in M) and the kinetics of binding defined by rate constants for association (k_{on}, in $M^{-1}min^{-1}$) and dissociation (k_{off}, in min^{-1}). For the interaction between a binding molecule B and the analyte A, at equilibrium, $A + B = AB$, $k_{on}[A][B] = k_{off}[AB]$, and $K_D = [A][B]/[AB] = k_{on}/k_{off}$. From these relationships one can infer that small dissociation constants denote strong affinity between A and B, and that the proportion of analyte bound to the capture molecule is related to the available concentrations of analyte and capture molecule. To capture a significant portion of the analyte in purification, the sample must be exposed to an excess of high-affinity binding sites. It is also generally true that a high k_{on} rate (for fast binding) and a low k_{off} rate (so that the complex remains associated) is optimal. If release of the analyte is required, then the capture biomaterial must be selected such that the affinity of the binding reaction can be reduced through a change in properties of the mobile-phase diluent (e.g., a pH or ionic strength change) which elutes the analyte. Consideration must then be given to harmonize the elution conditions to the requirements of the downstream analytical operations. For many of the highest affinity interactions, however, such elution is not possible without damaging the analyte. In these cases, the last step of the pre-analytical process (*concentration/purification*) must coincide with the first step of the analytical process (*analyte capture*). As such, the K_d of the binding molecule can represent a boundary to the LOD of an analytical assay, k_{on} can affect the throughput, and k_{off} can affect the stability of the response once it has been generated.

Most heterogeneous diagnostic platforms have a solid phase and a mobile phase, both of which can be engineered biomaterials. The solid phase is a functionalized material that will capture the analyte of interest. The mobile phase is a solution containing the analyte, other matrix components that may remain after the pre-analytical process, and frequently other biomolecules or biomaterials necessary for the assay principle.

Examples of solid phase materials include the polystyrene plates used in the ELISA, nitrocellulose or nylon membranes used in lateral flow strip tests, and glass surfaces such as slides for microscopy or chips for arrays. Capture of the target analyte can occur via specific binding or nonspecific binding. Nonspecific binding can occur by exploiting the natural properties of the solid phase, such as the ability of nitrocellulose to bind protein or by tethering a reagent that will nonspecifically bind the target analyte to the solid phase. If, for example, one is developing an assay to detect human antibodies directed toward a specific target, the solid phase may consist of a protein, such as protein A or an anti-human immunoglobulin G (IgG), used to nonspecifically capture all IgG in the sample. Specific capture almost exclusively uses a protein or nucleic acid sequence, such as an oligonucleotide or aptamer, to capture the analyte of interest with high-affinity while being relatively insensitive to other species in the sample. Examples include affinity-purified antibodies to the target or a protein that expresses the desired epitope to detect the antibody of interest. These capture biomolecules are tethered to the solid phase in a manner that allows their presentation to the sample in the mobile phase.

Similar to capture, the detector molecule can be either specific or nonspecific in its analyte recognition. Typically, the detector is in the mobile phase. Most detectors also include a signal transduction step (discussed in more detail later in this section). The fundamental assay principle (capture and detection through specific molecular-binding reactions) is transduced into a different type of signal (e.g., fluorescence) by a bifunctional detector molecule (e.g., an antibody labeled with a fluorophore). Assays that are interpreted visually or spectrophotometrically utilize a detector labeled with a dye, colored particle, fluorescent reporter or enzyme. This reporter is tethered to the detector. Linkage to the detector will depend on the chemistry of the reporter and detector. It may be able to occur via ionic bonding or through covalent linkages made possible with a number of chemical cross-linkers.

Assay Formats

A successful assay can combine several of the components mentioned above. As examples, we will describe some of the common heterogeneous immunoassay configurations and examples of the biomaterials used in each. The assay principles illustrated in these formats can be applied to specific recognition molecules other than antibodies. The extension of these formats by using oligonucleotides, aptamers, and molecularly-imprinted polymers is a very active area of research. Signal types may also vary, although colorimetric and fluorometric methods are still the most common.

1. *Antigen detection assays*: These assay formats focus on the detection of a specific antigen in a sample by using its specific cognate antibody. The analyte may be a protein, protein fragment, lipid, carbohydrate or nucleic acid. The analyte may be produced by the host or by an organism infecting the host or it may be indicative of a substance in the host. No matter what the source of the analyte, it must be validated as a marker predictive of the disease, condition or state being assessed. See Figure II.5.17.6.
2. *Serological detection*: Here, *serology* refers specifically to the detection of antibodies in a sample. Antibodies are produced in a host's blood in response to a foreign antigen or infection. Several classes of antibodies are produced, and each has its own half-life relative to the host's state, disease or condition. The most common antibody is IgG, but immunoglobulin A (IgA) and immunoglobulin M (IgM) are also produced, and can be important in diagnostic tests, especially when there is a need to differentiate new infections from previous or latent infections. Since the production of antibodies is a systemic response by the host to what can be a local infection, serology tests are often useful when it is impossible or difficult to test for or collect a sample containing the antigen or nucleic acid. Additionally, serology is useful for determining if a host has been exposed to an antigen or infection after the host has successfully cleared the source of the antigen or infection. See Figure II.5.17.7.

Assay Platforms

It is beyond the scope of this chapter to describe every platform utilized in diagnostic testing. New platforms continue to be developed using the assay formats described in the previous section. Examples of several heterogeneous assay formats include flow-through devices (Figure II.5.17.8), agglutination devices (Figure II.5.17.9), solid-phase devices (Figure II.5.17.10), and lateral flow strip devices (Figure II.5.17.11). Each of these formats have been successfully commercialized and are suitable for use in POC diagnostics. The application of biomaterials in these platforms is extensive and has already been discussed (Table II.5.17.2). Platforms for gold-standard testing in high-resource laboratories tend to use more homogeneous assay principles (although bead-based heterogeneous assays are also common), and are usually focused on very precise, high-throughput

Antigen Detection Assay Formats
FIGURE II.5.17.6 Antigen detection assay formats: (a) Sandwich assay. Step (1) A capture reagent specific to the analyte is immobilized on the solid phase. Step (2) The sample is introduced through the mobile phase. If the analyte is present in the sample, it will bind to the capture reagent on the solid phase through its cognate binding site. Step (3) The detector reagent that is specific to the analyte is introduced through the mobile phase. If the analyte is present in the sample, the detector reagent will specifically bind to it, forming a sandwich and resulting in a signal. If no sample is present, the detector reagent has no place to bind and is washed away. This format works well when the analyte has at least two distinct epitopes or multiple repeats of the same epitope. (b) Competitive assay. Step (1) A capture reagent specific to the analyte is immobilized on the solid phase. Step (2) The sample is introduced through the mobile phase. If the analyte is present in the sample, it will bind to the capture reagent on the solid phase through its cognate binding site. Step (3) The detector reagent is introduced through the mobile phase. In this case, the detector reagent presents an epitope analogous to that of the analyte. If the analyte is present in the sample it will compete with the detector reagent and no signal (or a reduced signal) will be present. If no sample is present, the capture reagent is available to bind the detector reagent, resulting in a maximal signal. Interpretation of this format is somewhat counterintuitive, since the analytical signal is greatest when the analyte is not present in the sample. This format is well-suited for analytes with only one epitope, such as a small protein or xenobiotic. (c) Inhibition assay. Step (1) A capture reagent analogous to that of the analyte is immobilized on the solid phase. Step (2) The detector reagent is specific to the analyte. The sample is premixed with the detector reagent prior to introduction to the solid phase. If the analyte is present in the sample, it will bind to the capture reagent on the solid phase through its cognate binding site. Step (3) If the sample contains the analyte, it will bind to the detector reagent and inhibit its ability to be captured on the solid phase, resulting in no signal or a reduced signal. If no analyte is present in the sample, the detector reagent is available to bind to the capture reagent on the solid phase, resulting in a maximal signal. Similar to the competitive assay, interpretation of this format is somewhat counterintuitive, since the analytical signal is greatest when the analyte is not present in the sample. This format is well-suited for analytes with only one epitope, such as a small protein or xenobiotic.

testing achieved with robotic liquid handling of solutions and parallel processing.

Amplification

For many analytes assayed on conventional assay platforms, the required assay performance dictates that direct labeling and simple detection is inadequate. These analytes require amplification. Amplification can be of two distinct types:

1. *Target or marker amplification* is most frequently found in nucleic acid testing, where a specific nucleic acid sequence is replicated exponentially, thus increasing the amount available for detection and increasing both sensitivity and specificity of the assay. The most widely used nucleic acid amplification is PCR, the details of which can be found in any number of textbooks (McPherson

and Müller, 2000; Meltzer, 1998). This method utilizes specific unique enzymes, primers, reagents, and temperature cycling to amplify the target. PCR is especially sensitive to contaminants and inhibitors; thus, pre-analytical methods are very important. Other isothermal nucleic acid amplification methods recently have been developed that utilize similar principles to specifically increase nucleic acid sequences, but frequently use enzymes that are less susceptible to contamination. Biomaterial designs intended to speed up these processes or localize their products must consider how reactant, heat transport, and enzyme kinetics are altered by reaction geometry and biomaterial chemistry.

2. *Signal amplification* is often done for protein, antibody, and xenobiotic tests.

Some signal amplification is obvious, e.g., electronic gain and optical magnification in a microscope.

Serology Detection Assay Formats
FIGURE II.5.17.7 Serology detection assay formats. (a) Antigen–antibody sandwich assay. Step (1) A capture reagent with the epitope specific to the antibody of interest is immobilized on the solid phase. Step (2) The sample is introduced through the mobile phase. If the specific antibody of interest is present in the sample, it will bind to the capture reagent on the solid phase through its cognate binding site. Nonspecific antibodies present in the sample will not bind to the solid phase and will be washed away. Step (3) Similar to the capture reagent, the detector reagent contains the epitope specific to the antibody of interest. The detector reagent will bind only to the specific antibody of interest, forming a sandwich and resulting in a signal. If the specific antibody is not present, the detector reagent has nothing to bind to and will be washed away, resulting in no signal. (b) Indirect assay. Step (1) A capture reagent with the epitope specific to the antibody of interest is immobilized on the solid phase. Step (2) The sample is introduced through the mobile phase. If the specific antibody of interest is present in the sample, it will bind to the capture reagent on the solid phase through its cognate binding site. Nonspecific antibodies present in the sample will not bind to the solid phase and will be washed away. Step (3) The detector reagent contains an antibody-binding domain that will bind all of the antibodies in the sample – those specific to the epitope of interest and those not directed to the epitope of interest. While the detector binds to all antibodies, due to the specificity of the capture reagent and the wash steps samples with the antibody of interest will generate a signal, while samples without the antibody of interest will have no signal. This assay format can also be reversed, with the specific epitope on the detector and the nonspecific antibody-binding domain immobilized on the solid phase acting as the capture reagent.

However, signal amplification can also be chemical, like the amplification that results when an enzyme is coupled to a detector molecule in a heterogeneous assay. The amount of product produced by the catalytic activity of the enzyme is proportional to the amount of enzyme immobilized by the analyte capture (in the presence of an excess of the enzymes substrate), but can produce a much larger signal.

Enzyme amplification is at the heart of several interesting homogeneous assay principles – the enzyme-multiplied immunoassay technique (EMIT) and competitive enzyme donor immunoassay (CEDIA) – both workhorses in xenobiotic testing. In these techniques, the activity of an enzyme conjugated to an analog of the analyte is changed when bound to a cognate antibody. Competition between analyte in the sample and the analog labeled with enzyme for antibody binding sites serves to modulate the analytical signal.

Regardless of amplification method, signal amplification often amplifies the noise and variation in the analytical signal, as well as the analyte response – sometimes preferentially. Assay contrast is only increased if amplification steps increase the response-to-noise ratio. In cases where the assay principle produces an analytical signal that is inherently difficult to amplify, signal transduction may be desirable.

Signal Transduction

Frequently, the method used to detect the analyte does not generate an analytical signal that is amenable to measurement or amplification, and transduction of the signal into another mode is desirable, especially when simplicity and cost reduction are an end goal. As discussed above, the analyte-specific molecular-binding events that are the core detection principal of an immunoassay or nucleic acid hybridization assay are not easily detected without some linked reporter. Thus, the analyte-modulated chemical-binding signal is converted into a more easily measurable signal with the desired signal-to-noise ratio. Reporters typically used in diagnostics fall under several general categories, including electromagnetic, optical, and physical/mechanical. Several of these modes may be used in series. Signal transduction techniques remain an active area of research, as investigators strive to improve the performance and reduce the complexity or cost of diagnostic devices and methods.

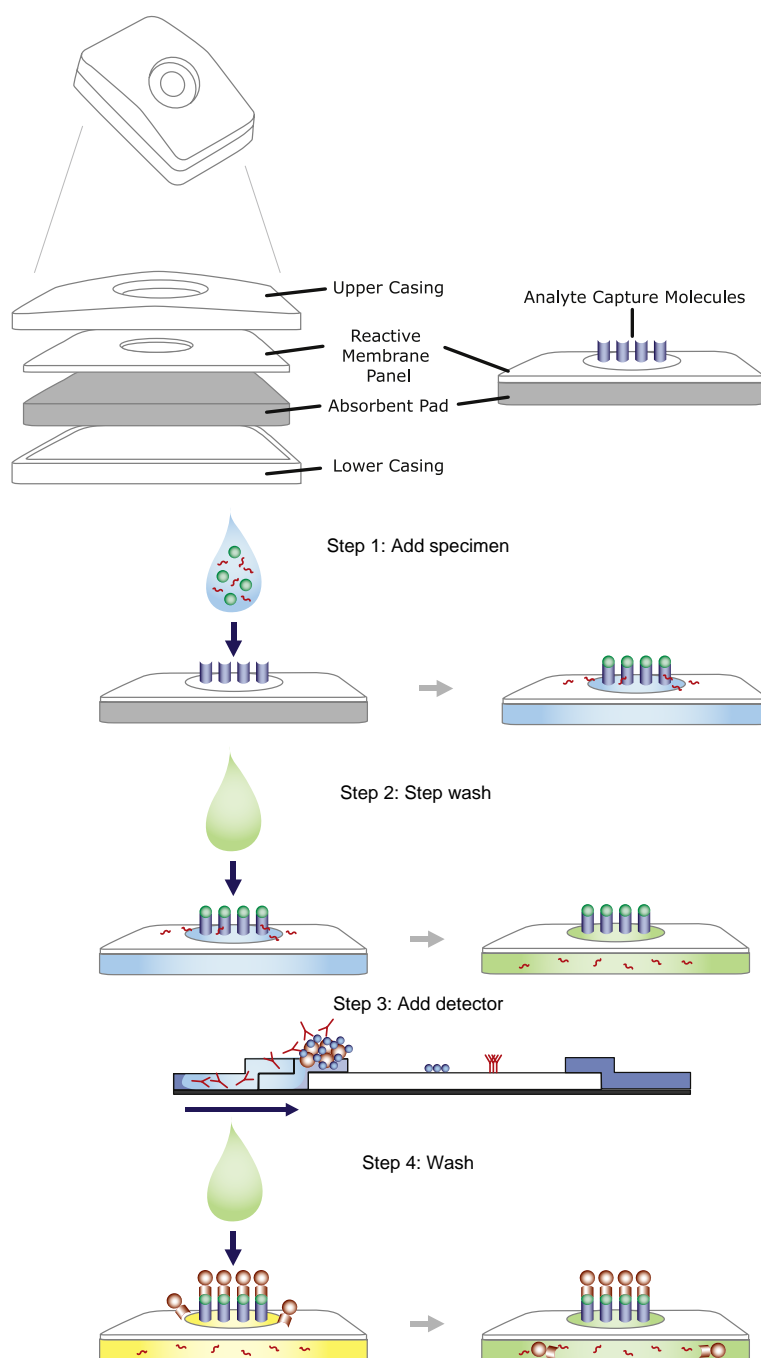
Electromagnetic transduction is attractive, due to the ubiquity of electronic devices and the resulting advanced understanding of electronics. By placing electrodes on either side of a flow cell for liquid reactants or immobilizing specific analyte-capture molecules on an electrode surface, using a biomaterial, potentiometry, amperometry,


FIGURE II.5.17.8 Flow-through devices. Step (1) The specimen is diluted in buffer and dropped on the surface of the membrane. While the liquid flows through the membrane to the absorbent pad, the analyte is captured on the analyte capture molecule. Step (2) The membrane is washed to remove non-specific background binding. The wash buffer flows through the membrane, washing away material that is not bound by the analyte capture molecule. Step (3) A solution containing the detection molecule is dropped onto the membrane. The detection molecule consists of two components: one that binds the analyte specifically and another that facilitates visual detection. In most modern tests, visualization is due to the use of microscopic particles, such as latex beads or colloidal gold, which are visible when they aggregate. Some tests, however, utilize traditional enzyme immunoassay chemistry to provide a precipitate that is visible to the naked eye. As the liquid flows through the membrane into the absorbent pad, the detection molecule binds to the captured analyte. Step (4) The membrane is washed a second time. The wash buffer flows through the membrane, removing detector molecules that are not bound by the analyte capture molecule. A spot is visible on the membrane surface if analyte was present in the specimen.

and cyclic voltammetry can all be modulated by analyte concentration. Native electronic properties of the analyte, charge or spin labels coupled to specifically-binding reporter molecules, and changes in solution electromagnetic properties due to aggregation have all been exploited.

Optical methods have their roots in both microscopy and spectroscopy. Microscopic methods may be as straightforward as traditional examination of a fluorescently stained specimen by a trained pathologist or may involve image capture and analysis through complicated
FIGURE II.5.17.9 Agglutination devices. Step (1) A drop of specimen is placed on a card. The analyte is floating freely in solution. Step (2) A solution that contains an analyte-specific detector molecule attached to a particle is added to the specimen on the card. Analyte and detector molecules initially float free of one another, causing the color and texture of the drop on the card to be uniform throughout. Step (3) The mixture is gently agitated, which causes the analyte and detector molecules to interact. Step (4) The interaction of the analyte and detector molecules forms visibly detectable aggregates. If analyte is not present in the specimen, aggregates do not form, and the color and texture of the mixture remains uniform throughout.
FIGURE II.5.17.10 Solid-phase devices. Step (1) The dipstick is placed in the specimen and incubated to allow analyte (if present) to bind to the analyte capture molecule. Nonspecific binding can occur with molecules other than analyte. Step (2) Nonspecific binding molecules are washed away by incubating the dipstick in wash buffer. Step (3) The dipstick is incubated in a solution containing the detection molecule. The detection molecule consists of two components: one that binds the analyte specifically; and another that facilitates visual detection. In most modern tests, visualization is due to the use of microscopic particles such as latex beads or colloidal gold, which are visible when they aggregate. Some tests, however, utilize traditional enzyme immunoassay chemistry to produce a precipitate that is visible to the naked eye. Some of the analyte detection molecule might stick nonspecifically to the solid substrate. Step (4) Nonspecific binding of detector molecule is washed away by a second incubation in wash buffer. Step (5) The dipstick is removed from the wash solution and read. A spot is visible if analyte is present in the specimen.
FIGURE II.5.17.11 Lateral flow strip devices. Step (1) The sample is placed on the sample pad at one end of the strip. The sample may be used alone, as is commonly done with urine- or serum-compatible tests or it may be mixed with a buffer specific to the test. This buffer may simply be a diluent or running buffer or it may be much more complex. It may have specific components or properties, such as a cell lyses buffer, that are required in order for the strip to perform properly. Step (2) With the addition of the sample, the detector molecules are solubilized. Once dissolved, the detector molecules mix with and bind to analyte present in the sample. Step (3) Capillary action draws the fluid mixture up the sample pad and into the membrane. The sample and detector molecule mix continues to move up the membrane until it reaches the analyte capture molecule. In these lines, a second and sometimes third antibody or antigen, immobilized as a thin stripe in the nitrocellulose, captures the complex if it is positive for the target analyte. The control line should always show as a visible line, otherwise the test is invalid and must be repeated. If the test is positive, a colored (typically pink or purple) line develops along with the control line. Step (4) When the colored line appears, the strip is fully developed. Excess buffer, along with reagents not captured at the test of control line, move into the absorbent pad. This description applies to a gold conjugate detector – a very common detection method. Details for other detectors may vary slightly.

expert system algorithms. A recent trend is to use image analysis for classification and counting of engineered analyte-specific reporters, such as quantum dots and fluorescent barcodes, frequently in a multiplexed assay. Spectroscopic interrogation is most frequent in the visual spectrum (*colorimetry*). Light absorption is modulated by the analyte through a linked chemical reaction or specific reporter (e.g., gold nanoparticles). Much greater analytical sensitivity is achievable through fluorescence spectroscopy (*fluorimetry*), primarily because of the

superior signal-to-noise ratio inherent in properly configured fluorescence optics. However, when *low cost* and *disposable* are design objectives, much of this advantage can be lost. To minimize cost and complexity, simple visual readouts of colored or fluorescent reporters are frequently used, e.g., the indicating line on an immuno-chromatography strip (ICS). Here a chemical signal (*specific antibody-binding*) is transduced into a visual readout by the accumulation and aggregation of absorbing gold nanoparticles at the indicating line.

A number of other diverse transduction techniques are primarily physical or mechanical in nature. The simplest of these is the spatial segregation of the analyte from the rest of the sample through localization of a specific binding event. Spots on a microarray or the accumulation profile of a diffusion immunoassay are examples. More complicated mechanical transduction methods include mass sensing through changes in the resonant frequencies or non-oscillatory bending of piezoelectric structures or microcantilevers. Mechanical methods usually require another transduction step to enable an optical or electronic readout. This readout generally becomes more complex in proportion to the complexity of the mechanical transduction. For example, quartz crystal microbalance mass detection requires complex electronics to generate the oscillations and detect the change in quality factor associated with the specific binding, but it can detect exquisitely small masses of analyte.

Biomaterials play a key role in diagnostic device signal transduction. Polymers are used frequently as inexpensive and rugged diagnostic device materials; however, fluorescence detection methods can be confounded by the photobleaching of highly autofluorescent plastics. Surface immobilized patterned biomolecules can be used to spatially segregate analyte with great specificity. Anisotropic functionalization of a microcantilever enables entropy changes from specific binding to one side to provide the energy to distort the microcantilever. Equally important is the need to create non-fouling surfaces between the specific recognition sites, to ensure that nonspecific adsorption of the analyte to an attractive surface does not erode the desired specificity. (See Box 2 on blockers.) The choice of signal transduction method may hinge on the properties of the biomaterials used. New biomaterials create new methods for signal transduction that have the potential to overcome traditional limits on diagnostic devices and change the face of the field.

Response Algorithms and Noise Filtering

Once the final analytical signal has been generated, the response of the system to the analyte must be abstracted from the complex analytical signal (i.e., separated from noise and background). When this is done "by eye" – with operator discretion – the steps of the algorithm are

The ideal diagnostic test is both highly sensitive and highly specific. Sensitivity and specificity are very closely related to the biomaterials selected for capture and detection of the analyte. Most materials available for diagnostics have characteristics that innately allow nonspecific binding of materials other than the analyte of interest. This is true for the solid phase, capture reagent, and detector reagent. If appropriate cleaning procedures are not identified and followed, the performance of functional devices can be eroded by the deposit of biofilms. In order to minimize nonspecific binding of materials that are not of interest, diagnostic test developers go to great lengths to block these reactions.

Blocking can be grouped into three major categories: protein, surfactant, and chemical modification.

Protein blocking utilizes a protein, protein fragment or peptide to block nonspecific binding. The ultimate goal is to use the blocker protein to mimic the nonspecific binding. Utilizing a blocker that allows the analyte of interest to bind, and is not recognized by the detector, will maximize the analyte available for specific detection.

Surfactant blocking uses a chemical surfactant or detergent to prevent nonspecific binding from occurring. Ionic and nonionic detergents are commonly used. Effective concentrations of surfactant are generally below the critical micelle concentration for the surfactant. The harshness of the surfactant required for a system will generally be dictated by the robustness of the other biomaterials in the system. Surfactant blocking is generally most effective when implemented in the liquid phase.

Chemical modification involves changing the chemical structure of the solid phase, capture or detector molecule surface or surfaces available to the sample, to make them less likely to nonspecifically bind materials that are not of interest. The methods and procedures for chemical modification depend entirely on the chemical structure of the surface to be modified, and how it interacts with and reacts to its environment during the process of running the assay.

A common dose–response model used in immunoassays is the *four-parameter log/logit* equation (Maciel, 1985).

$$R = \frac{R_0 - R_\infty}{1 + \left(\frac{[Ag]}{c}\right)^b} + R_\infty$$

Where R_0 is the response at vanishing analyte concentration, R is the response at infinite analyte concentration, c is the point on the antigen concentration $[Ag]$ axis where the point of inflection is located, and b is the slope of the curve at the point of inflection. In order to empirically determine the standard curve, at least four calibration standards must be assayed: a reagent blank containing no analyte (R_0); a very high $[Ag]$ standard to estimate R ; and two intermediate $[Ag]$ standards to account for the degrees of freedom in b and c. For a full calibration of an immunoassay, six calibrators are typical. A properly chosen set of six calibrators will result in an interpolated function that adequately captures the inherently sigmoid character of the immunoassay dose response. This model can now be fitted easily with the nonlinear regression routines in Excel® or statistical software packages. Its adoption in the days before desktop computing partly arose from the fact that the native variables can be transformed to make the equation linear. By plotting R'_i versus $log\ [Ag]$, where:

$$R'_i = \log \frac{R_0 - R_i}{R_i - R_\infty}$$

the dose response is expected to be linear. If appropriate log/log graph paper is used, a best-fit standard curve can be drawn by eye with a straight edge. The user can use this standard curve to quantify the $[Ag]$ from any response in the dynamic range, simply by noting the point on the curve associated with that ordinate (R'_i), and projecting down to the axis to find the abscissa.

frequently cryptic, uncontrolled, and vary from operator to operator. Operator training can minimize this variation. Analytical instruments are more consistent, and sometimes more sensitive, but instruments must also be "trained" by the judicious application of response abstraction methods. Identifying the best algorithms to maximize the response-to-noise ratio can be one of the most challenging tasks of the diagnostic assay designer. At first, algorithms may not seem of interest to the biomaterial scientist; however, consideration of the nature and type of these algorithms suggests how biomaterials can impact robust calculations.

The response algorithm defines the dose response relationship, i.e., how the analytical signal responds to changes in the amount of analyte, both in terms of magnitude and variation. A good response algorithm yields a dose response that is predictable (low noise) and is modeled by a tractable monotonic mathematical function (*monotonicity* is discussed in the "Interpretation" section below). Molecular binding assays, such as immunoassays and nucleic acid hybridization assays, all have regions where the dose response is not constantly

proportional, due to transport limitations and saturation of binding sites.

Sigmoidal functions, like the log/logit function, can serve as excellent models to describe the dose response of an immunoassay over its entire range. With an appropriate coordinate transformation, they can be fit as a simple line (see Box 3). The response may be fundamentally multivariate. While forcing a multivariate response into a univariate dose response model has advantages for simple interpretation and calculation, a large part of the usable modulation may be discarded.

Noise filtering is advisable at many steps of the response algorithm. The error in a diagnostic device may be systematic (background signal, signal anisotropy) or random (electronic noise, stochastic variation in molecular affinities). Systematic error is generally corrected for by an algorithm suggested by the nature of the error, e.g., in quantitative fluorescence microscopy, material autofluorescence can be removed by subtracting an image of the device before the assay materials are introduced. Random noise can be digitally filtered from the raw data sequence by electronic or digital filters. The right filter

technique for the frequency of the noise can be found in any good text on signal processing.

Care must be taken to apply the noise filtering at the right point in the response algorithm; some transformations can preferentially amplify noise relative to the response.

Very low temporal frequency random noise manifests itself as test-to-test or run-to-run, variation. This type of error is best corrected by some form of analytical signal normalization. In order to normalize, a standard signal must be present. If part of the analytical signal is not affected by the response, it can be used as an internal standard, and all parts of the signal are then rescaled appropriately. Sometimes internal standards are introduced into the analytical signal to enable normalization, e.g., the internal standards used in analytical chromatography to rescale the chromatogram to correct for run-to-run differences in the column and detector response. External standards are also frequently used, both to calibrate and monitor the performance of a diagnostic assay. Calibration and standardization are discussed further in the "Interpretation" section below.

Review of this section suggests how the biomaterials used can be tuned to improve the performance of a diagnostic assay. The goal should be to identify biomaterials that increase the contrast in the assay – that is, steepen the dose–response curve (greater changes in response per unit change in analyte amount). An obvious way to increase contrast is to emphasize the difference between the blank response (no analyte) and the positive analyte case. This can be as simple as using the whitest paper possible for an immunochromatographic assay or finding a polymer for a microfluidic flow cell that has the lowest autofluorescence. Given the many possibilities for response abstraction and noise filtering, however, other methods for increasing contrast are suggested.

Any contribution to the analytical signal by the biomaterial should be easily correctable by being confined to a different domain than the analyte response. For example, if a polymer substrate used for immobilization of capture molecules had a grainy background signal, the spot size of the capture molecules should be made significantly larger than the grain size of the background. This allows a filter to be used to eliminate spatial frequency components of the analytical signal associated with the background, without significantly affecting the response to the analyte at the spots. Similarly, when intense illumination is used for quantitative fluorescence microscopy, some photobleaching of the flow cell is unavoidable. A flow cell material should be chosen that allows significant fluorescence changes to occur more slowly than the time during which the analytical signal is being gathered. In this way, an image subtraction (a simple high-pass filter) is still a valid correction. In the end, the ability to filter the noise will serve to increase the contrast as well, because the response will stand out of the background more prominently.

INTERPRETATION

The interpretation phase involves taking the response from the analytical phase, placing it in context, and assigning meaning to the response. Technologies that resolve the interpretation phase of the diagnostic test interface with the analytical phase, which generated the signal, and the user, who is seeking results of the diagnostic test (Figure II.5.17.12).

Calibration

A common approach in many diagnostics assays is to correct for run-to-run and day-to-day variation with routine recalibration, rather than attempting to eliminate that variation altogether. In a calibration routine, the dose–response curve is redefined using a set of standards (*calibrators*). Pre-existing knowledge about the expected dose–response model is applied to fit a curve to this calibrator set – a *standard curve* – for quantification of unknowns. Thus, the response of unknowns is normalized to the response of the standards. Depending on the form of the model, the magnitude of the variation being corrected for, and the assay dynamic range required, the calibration set may contain one standard or
FIGURE II.5.17.12 Interpretation is the final phase in the diagnostic process. Input is received from the analytical phase. Assay calibration and controls are taken into consideration to classify the diagnostic test results in a manner that is meaningful to the user which may be a laboratory technician, healthcare provider or the patient.

many. Regression is done to fit the model, either in the native coordinate space or using transformed coordinates to simplify fitting of the curve. One of the most exciting recent developments in diagnostics is the engineering of a biomaterial to present calibration data contemporaneously with each unknown as it is assayed. This "instant recalibration" can result in greatly increased accuracy and precision.

In order to use the standard curve to quantify unknowns, the dose versus response standard curve must be rotated in "assay space" to become a response versus dose curve (i.e., the abscissa and ordinate must be reversed). This is usually referred to as a predictor function. The quantification algorithm uses the response of an unknown as an argument, and returns an analyte concentration. We can now see the importance of being able to apply a monotonic function for the dose–response model. Any function with a localized minimum or maximum on the dose versus response space when rotated into response versus dose space will have multiple possible analyte values for a single response – an obviously unacceptable situation. Any tuning of a responsive biomaterial must respect the absolute requirement for a monotonic response.

Readout and Classification

Most of the discussion in the last few sections focuses on quantitative diagnostic assays – assays in which a concentration, mass or count is the result. Many diagnostic assays, particularly those for infectious diseases, can be qualitative in nature. Although classification as positive or negative does not require routine calibration and construction of predictor functions by the end user, the assay designer and developer still need to consider all of the quantitative discussions above. No assay, qualitative or quantitative, can function without some dose–response relationship, and that relationship is usually continuous, not binary. But for qualitative classification, display, and readout purposes, the last step of a response algorithm may include a binary simplification. Even the development of a visible line on a lateral flow strip can be considered a binary simplification of the continuous relationship of analyte concentration and binding equilibrium – with the reader's vision as a threshholding instrument. End users, however, *will* want to be able to relate that classification to a known cut-off value, and still need to understand the limits of detection – both quantitative concepts. The best qualitative assays are good quantitative assays up to the last binary classification step, and it behooves a designer and developer to adopt that attitude.

Controls

Assay controls are an important aspect of diagnostics. Controls assist the user in ensuring that the steps of the assay were conducted, and that the results of the assay are valid and meaningful. A comprehensive discussion of good diagnostic quality control practices is beyond the scope of this chapter; however, this topic is so integral to good diagnostic practice that a summary is needed.

There are two types of controls: internal and external. Internal controls can take two forms:

1. A *procedural control* indicates that certain steps or events in the assay occurred, but does not determine if the assay was run correctly, e.g., a lateral flow strip test that develops a control signal when reagents hydrate with a sample diluent, but cannot differentiate between diluent with or without sample.
2. An *adequacy control* demonstrates that the procedures of the assay were properly conducted, e.g., a lateral flow strip test may have a control line that only develops a signal if the minimum amount of specimen is added to the device.

Of the two types of internal controls, an adequacy control is most meaningful for the device user. As suggested by the examples, engineering of the biomaterials in an assay can be a powerful way to include internal controls in the assay design.

For assays that have multiple channels and can run several samples in parallel, internal controls may not be possible (either due to the nature of the platform or the cost or logistics of running an internal control in each channel). These types of assays are typically best suited for external controls. External controls are generally used to determine the need for recalibration and to assess the proficiency of the system, operator or laboratory. Biomaterials science can contribute greatly to diagnostic technology by creating new ways to include controls and calibration in the assay of every sample.

SUMMARY

Biomolecules are *the* critical components of *in vitro* diagnostics. Ultimately, the interaction of one or more biomolecular species (antibodies, antigens, nucleic acids or enzymes) contained in the diagnostic device with biomolecular species in the sample (analyte) defines the capability, performance, and use conditions of the assay.

In POC assays, where reagents are frequently stored in a disposable container, diagnostic biomolecules are often contained in a biomaterial layer that interacts with a liquid sample. Most POC assays with biomaterial reagent layers that are used in clinical practice are either electrochemical or optical biosensors (e.g., glucometers), rapid strip assays (e.g., pregnancy strips) or slightly more complex cartridge-based assays that can handle assays for multiple targets.

Novel Techniques at Various Stages

POC diagnostics, and the biomaterials that comprise and enable them, are a very active area of research and

development. To date, most POC diagnostics have been based on electrochemical or optical sensors, rapid strip tests or more complex cartridges.

An extremely successful example of a sensor-based test is the now ubiquitous glucose meter for diabetes monitoring (using glucose oxidase or glucose dehydrogenase in a thin-film electrode layer strip), first reported in 1962 (Clark and Lyons, 1962). Novel sensor-based assays continue to be introduced, including assays for cholesterol and cardiac markers. Sensor-based disposable assays are primarily used in home-care applications.

Rapid strip assays (e.g., the lateral flow strip test described in Figure II.5.17.11) also continue to be developed, especially for countries other than the United States, where pregnancy testing remains the primary application. The tests have a wide-range of applications including HIV, troponin T, malaria, fertility, respiratory disease, and drugs of abuse.

Cartridge-based systems, such as the Abbott i-STAT® or the Abaxis Piccolo®, are also electrode-based, but generally comprise multiple reagents in liquid or gel form on a cartridge in addition to the actual electrode layer. Typically, each cartridge can detect multiple analytes in a single drop of blood on panels for blood gases, electrolytes, blood chemistries, coagulation, cardiac markers, and hematology. Cartridge-based systems are used primarily in stat laboratories and in physician's offices.

New assays and cartridges for additional analytes, comprising novel biomarker receptors in biomaterial layers, are developed routinely for the platforms described above. New, even more powerful platforms are being developed for POC applications, especially those that can either increase sensitivity and specificity (e.g., those using nucleic acid amplification techniques), perform very complex assay procedures (e.g., microfluidic cell-based assays) or are highly multiplexed assays (e.g., nanoparticle-based diagnostic platforms).

Disposables

An important discussion in the diagnostic development community centers on the amount of complexity that should reside in a disposable device versus an instrument. There are many extant instruments that use robotics and automated pipetting to transfer liquid reagents and samples, and perform all assay steps in a sequence of reservoirs, tubes, and cuvettes. Such devices require some maintenance and cleaning, but use relatively little in biomaterials or costly custom reagents. On the other hand, almost all reaction steps can be integrated using complex engineered biomaterials and cartridge-based disposables without the need for complex instrumentation. The field of microfluidics has essentially enabled any laboratory process to be performed on a laboratory chip. All that is needed to drive and read them are pumps and electrodes – and in some cases, only fingers and eyeballs.

The question that has emerged is one of trade-offs. Integrated assays are more complex and frequently costlier on a per-test basis than instrument-based assays, but they require a smaller investment for instrumentation and can be used in settings that do not have access to highly trained laboratory personnel.

Biomaterials may help diagnostics achieve the benefits of an integrated disposable without some of the mechanical complexity of microfluidic cartridges. Biomaterials can be engineered in adjacent layers and reagent pads, such that assays requiring multi-step reactions can be performed without externally driven fluid transport and transfer steps. As an example, biomaterials similar to ones used on lateral flow strips can be combined on paper strips to form so-called paper microfluidics assays (Fu et al., 2010; Martinez et al., 2009).

Direction of New Diagnostic Platforms

New diagnostic devices are developed using novel bioengineering and biomaterials-based advances to address many very different requirements, (Jain, 2010; Yager et al., 2008) including: (1) improved sensitivity and specificity to detect analytes at ever lower levels and in ever smaller samples that are less painful to obtain; (2) added biomarkers to address many more disease parameters; (3) improved multiplexing to test for multiple analytes in a single sample; (4) improved throughput to run many different samples in a short period; (5) reduced complexity to allow testing outside of laboratories by personnel with minimal training; (6) reduced cost to allow their use in low-resource settings that cannot afford most laboratory-based technologies common in the developed world; and (7) better communication among platforms, and between platforms and existing databases. This last advance will allow rapid interpretation of individual diagnostic results in the context of the overall health of a patient, and take into account medication and treatment, the epidemiological environment and, in the near future, predictive information such as fully sequenced individual genomes or genetic disease markers.

A few new technologies that usually comprise biomaterials stand out as examples of novel technologies that are currently finding their way into commercial diagnostic devices.

1. *Microfluidics*: Microfluidics deals with the behavior, precise control, and manipulation of fluids that are geometrically constrained to a small (typically submillimeter) scale. Some of the advantages of microfluidic devices include less waste, lower cost of reagents, and smaller sample volumes for diagnostics, faster analysis and response times due to short diffusion distances, fast heating, high surface-to-volume ratios, small heat capacities, and compactness of the systems.

   Over the past 20 years, a variety of microfluidics-based diagnostic devices have been developed by

various research groups. These devices hold promise for miniaturization of analysis equipment, improvement in response times, and simplification of analysis procedures. These systems, a few of which have entered commercial use, typically consist of a small microfluidic chip surrounded by a desktop-sized analysis instrument (Guia and Xu, 2005; Gulliksen et al., 2005; Mcmillan, 2002).

Further integration of electronic and fluidic components will allow additional miniaturization and simplification of the analysis instrument. Another means to further miniaturize instruments and integrate elements of micro total analysis systems (μTAS) is to eliminate as many power-consuming and otherwise complex elements as possible. These elements can be replaced with passive components that operate without external power by manipulating fluids using gravity, air pressure or simple manual actions (Weigl et al., 2008).

Current major barriers against widespread adoption of microfluidics in diagnostic devices include the lack of standardization, and of a large-scale, low-cost manufacturing method for microfluidic disposables.

2. *Micro- and nanoparticle diagnostics*: Biomaterials in the form of small particles have found widespread use in diagnostics as capture and detection tools. Because many different types can be combined in a single assay and individually coded with marker molecules, functionalized particles enable a high degree of multiplexing (i.e., assaying for more than one analyte from a single sample). In addition, the interaction between a biomaterial and analyte molecules contained in a sample volume can be accelerated if the biomaterial is provided in the form of particles rather than a surface – the diffusion distances between the reaction partners are shorter, and more biomaterial surface can be provided. This is especially important if the analytes are large molecules or even bio-particles themselves, such as cells. Biomaterial particles can be magnetic, and thus can be captured and concentrated after interaction with the analyte using a magnet. Different types of particles can also be labeled with different markers (e.g., fluorescent dyes) that allow parallel detection of several analytes in a single sample volume (Sekhon and Kamboj, 2010).

Biomaterial particles are in commercial use in multiplexed diagnostic systems such as the Luminex (Dunbar, 2006), Illumina (Fan et al., 2006), and Nanostring (Geiss et al., 2008; Malkov et al., 2009) platforms.

3. *Microelectrical sensors* (Arruda et al., 2009) utilizing silica nanowire (Cui et al., 2001; Jain, 2007), impedimetric, surface acoustic wave, magnetic nanoparticle, and microantenna technologies are being developed that offer a significant advantage to conventional optical protein assays – the target molecules do not need to be labeled. Their ability to transduce protein-binding events into electrical signals, and their ability

to be easily integrated with microarray, microfluidic, and telemetry technologies, makes them potentially cheaper and easier to use. However, common limitations associated with the microelectrical sensors, including problems with sensor fabrication and sensitivity, must first be resolved.

4. *Nucleic acid amplification assays*: PCR or the more recently developed isothermal amplification methodologies (Gill and Ghaemi, 2008; Morisset et al., 2008) have not traditionally included biomaterials. In recent efforts to develop nucleic acid assays for POC and low-resource diagnostic applications, however, reagents for those assays now frequently are provided as stabilized surface coatings in vials or microfluidic channels. Further, detection of amplified nucleic acid sequences has also been demonstrated with lateral flow strips, some of which are integrated in the cartridges to avoid work area contamination.

5. *Prognostic and predictive biomarkers*: As multiplexing capabilities become more widespread, and genomic- and proteomics-based surveys reveal ever more biomarkers that are associated with a wide variety of diseases, disease states, and genetic predispositions, the field of prognostic and predictive diagnostics is emerging as a significant field of research. While in some cases a single biomarker is predictive, in general most of these assays need to be multiplexed to have predictive value, as the underlying proteomic patterns are usually complex and influenced by many different conditions. IVD for metabolic diseases, as well as cancer and a variety of chronic and aging-related diseases, will soon become possible. Already, existing but expensive platforms such as the biomaterial particles are in commercial use in multiplexed diagnostic systems such as the Luminex (Dunbar, 2006), Illumina (Fan et al., 2006), and Nanostring (Geiss et al., 2008; Malkov et al., 2009) platforms will likely be joined soon by other much more cost-effective, massively multiplexed biomarker assays (Simon, 2010).

6. *Phone-based applications*: Cell phones are emerging as a unifying principle for POC diagnostics (Blobel et al., 2008). Cell phone cameras serve as imaging devices (Braun et al., 2005), and on-chip computing capability can provide some image processing; when additional computing is needed, images can be sent to larger imaging stations wirelessly (McLean et al., 2009). These imaging devices can be coupled to simple microscope attachments (Frean, 2007) that have been shown to be capable of detecting, for example, malaria parasites in erythrocytes (Breslauer et al., 2009) or differentiation between normal and abnormal pap smears. Further, cameras can simply capture and transmit visually readable results from devices such as lateral flow strip tests (Martinez et al., 2008).

Beyond imaging, cell phones can provide a data link for any electronic diagnostic device to a laboratory information system or a telemedicine provider.

Combined with other innovations that allow multiplexing, predictive diagnostics, and simplification of complex assays, they may usher in a new era of telemedicine-enabled, prevention and cost-effectiveness focused and personalized medicine in which most routine diagnostic monitoring happens in people's homes.

Defining the Requirements for New Diagnostics

While diagnostic devices have evolved enormously over the last century, the diagnosis of a disease – and especially the prediction of its course – is still a very inexact science. Even in high-resource medical settings, for most syndromes only a few laboratory parameters are being measured – and those usually only once or twice. From recent work on genomics and proteomics, however, we know that thousands of proteins in many more configurations interact with myriad other biomolecules within and outside of cells. In principle, the presence, concentration, and change in any of these biomolecules can provide diagnostic information (Bolouri, 2010).

The tests developed so far are only scratching the surface of what may be possible in the future. At the moment, most diagnostic tests can detect only a few biomarkers with sufficient sensitivity to be useful. They can measure them only at a single point in time, as a bulk quantity, and in a bodily fluid that is not localized in individual organs or cells. Finally, the tests do not correlate the biomarkers to a patient's individual medical history or genetic make-up very well. Over time, new devices will be developed that can address these issues and provide a much more comprehensive and predictive picture of a person's health (Blair, 2010). Their costs promise to be significant, and barriers to access may be substantial. One hopes that these devices will benefit not only the select few, but patients in all settings, regardless of wealth.

CHAPTER II.5.18 MEDICAL APPLICATIONS OF SILICONES

Jim Curtis[1] and André Colas[2]

[1]Dow Corning Corporation, Midland, MI, USA

[2]Dow Corning Europe S.A., Parc Industriel, Seneffe, Belgium

MEDICAL APPLICATIONS

Silicones, with their unique material properties, have found widespread application in healthcare. Properties attributed to silicone include biocompatibility and biodurability, which can be expressed in terms of other material properties such as hydrophobicity, low surface tension, and chemical and thermal stability. These properties were the basis for the initial use of silicone in the medical field. For example, their hydrophobic (water-repellent) character caused silicones to be considered for blood coagulation prevention in the mid-1940s. Researchers from the Universities of Toronto and Manitoba obtained a methylchlorosilane from the Canadian General Electric Company and coated syringes, needles, and vials with the material. When rinsed with distilled water, the silane hydrolyzed, forming a silicone coating on the substrate. The researchers published results from their clotting time study in 1946, finding that the silicone treatment "on glassware and needles gives a surface which preserves blood from clotting for many hours" (Jaques et al., 1946) (see Chapter II.3.5). Researchers at the Mayo Clinic took notice of the work by their Canadian colleagues, indicating that silicone: "was the most practical of any known [substance] for coating needle, syringe and tube" (Margulies and Barker, 1949). They also demonstrated that leaving blood in silicone-coated syringes had no significant effect on the blood as measured by coagulation time after being dispensed from the syringe. Soon the use of silicone precoating of needles, syringes, and blood collection vials became commonplace. In addition to the blood-preserving quality of silicone, it was soon discovered that silicone-coated needles were less painful (Figure II.5.18.1). Today most hypodermic needles, syringes, and other blood-collecting apparatus are coated or lubricated with silicone.

In addition, silicone materials have found other uses in the medical laboratory. Silicone tubing is used for fluid transport between vessels. Another application is in dentistry, where silicone impression materials have been used since the 1950s (Starke, 1975). Modern silicone impression materials can be obtained using addition or condensation polymerization methods to cure the implants (Ciapetti et al., 1998).

Extracorporeal Equipment

Silicone tubing and membranes found application in numerous extracorporeal machines, due in large part to their hemocompatibility and gas permeability properties. Silicone has been used in kidney dialysis, blood oxygenators, and heart bypass machines. Blood compatibility was also a factor in the application of silicone in several mechanical heart valves (Figure II.5.18.2). The use of silicone in extracorporeal applications continues today. Hemocompatibility testing has suggested that platinum-cured silicone tubing may be superior to poly(vinyl chloride) (PVC) in several respects (Harmand and Briquet, 1999).

FIGURE II.5.18.3 Examples of silicone in catheters, drains, tubes, and cannulae. *(© Dow Corning AV06432)*

Catheters, Drains, and Shunts

The properties of silicone elastomers have also found application in numerous catheters, shunts, drains, and the like (Figure II.5.18.3). These include devices fabricated with silicone extrusions, as well as devices with non-silicone substrates that are silicone-coated to provide less host reaction. For example, although several all-silicone urology catheters are on the market, the Silastic® Foley is a latex catheter whose exterior and interior are coated with silicone elastomer (Figure II.5.18.4).

Figure II.5.18.5 shows the various components of the Cystocath® suprapubic drainage system (Baeham, 1973), which was used for bladder drainage after gynecological surgery that complicated or prevented normal urethral urination. The system included: (A) the catheter, a silicone tube whose non-wetting surface minimized encrustation; (B) the body seal made of flexible silicone elastomer that conformed easily to the body contour and allowed the patient freedom of movement; (C) pressure-sensitive silicone adhesive that adhered well to skin; and (D) the trocar needle used to pierce the bladder and overlying tissue. After vaginal surgery the bladder was inflated and located. Silastic® Medical Adhesive B was applied by brush to the clean abdomen over the bladder and the bottom of the body seal component. The pressure-sensitive adhesive (described in Chapter I.2.2.B) had excellent properties conducive to the application. It provided good adherence to dry or wet skin,

FIGURE II.5.18.5 Cystocath® suprapubic drainage system. (A)–(D): See text details. *(© Dow Corning AV06436)*

without causing irritation or sensitization, and good permeability to oxygen, carbon dioxide, and moisture vapor; it also formed a waterproof and urine-proof seal. After a short wait for the solvent to evaporate, allowing the adhesive to become tacky, the body seal was adhered to the abdomen. The trocar was advanced through the center of the body seal and pierced through the skin and bladder. The stylet was removed and the silicone catheter threaded through the needle and well into the bladder. The needle was withdrawn, leaving the catheter in place. The silicone tube was secured in the retention groove and the distal end attached to a siphon drainage system.

Long-Term Implants

The chemical stability and elastic nature of silicone are beneficial for many applications involving long-term implantation. The first published report of silicone elastomers being implanted in humans was in April 1946,

when Dr. Frank H. Lahey told of his use of these materials for bile duct repair. He obtained the material, called "bouncing clay" at the time, from the experimental laboratory of the General Electric Company (GE). Citing its elastic properties, he reported: "It is flexible, it will stretch, it will bounce like rubber, and it can be cast in any shape" (Lahey, 1946).

In 1948, Dr. DeNicola implanted an artificial urethra fashioned from the same type of GE silicone tubing used previously by Lahey. The first apparently successful replacement of the human male urethra by artificial means was conducted under general anesthesia. The 3¾ inch (9.5 cm) long silicone tube was threaded over a narrow catheter whose distal end was in the bladder. Fourteen months after implantation, the artificial urethra "had been retained with normal genitourinary function. … There is no evidence at this time that the tube is acting as a foreign body irritant…" (DeNicola, 1950).

A particularly notable early silicone implant was the hydrocephalus shunt, which benefitted from the thermal stability of silicone. This application became quite celebrated when tenderly described in *Reader's Digest* (LaFay, 1957). Charles Case "Casey" Holter was born on the seventh of November 1955 with a neural tube defect called lumbosacral myelomeningocele. By December, the baby had contracted meningitis, and surgeons at the Children's Hospital of Philadelphia closed the defect. A few weeks later, hydrocephalus caused young Casey's head to swell as cerebrospinal fluid (CSF) collected in his brain. At the time, there were few treatment options, and this affliction was fatal for most children who contracted it. After infection concerns with the daily venting of CSF through the fontanels (spaces between cranial bones that have not completely fused), Dr. Eugene Spitz implanted a polyethylene shunt catheter in Casey to drain excess CSF from the brain into the atrium of the heart. A valve was needed that would allow the CSF to drain when pressure began to build in the brain, but would close to prevent backflow when the pressure equalized. Spitz did his neurosurgery residency at the University of Pennsylvania in 1952, gaining clinical experience with a ball and spring valve developed by the Johnson Foundation, an arm of Johnson & Johnson. So it was this valve that was first implanted in young Casey. Basically a scaled-down version of an automotive pressure relief valve, it frequently clogged with tissue. Casey's father John, a machinist by profession, asked Spitz about the valve, the CSF, and the pressures involved. Spitz confided in Holter that "a competent one-way valve" that would be stable in the human body was needed (Baru et al., 2001).

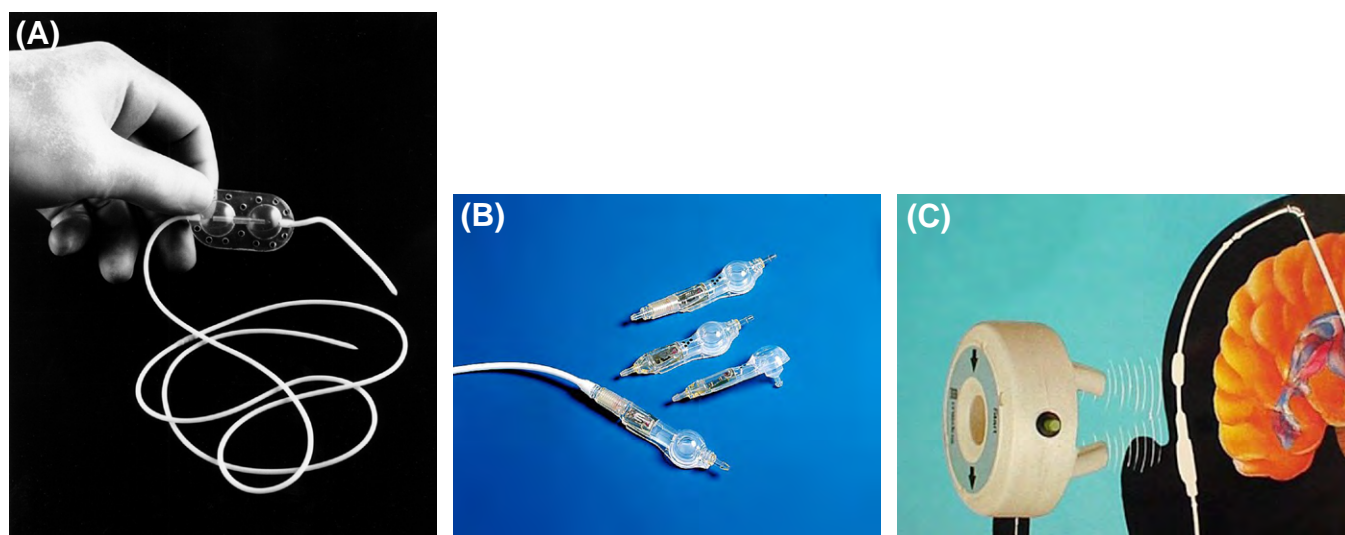
It is said that necessity is the mother of invention, and this is a poignant example. A desperately concerned father went home to his garage workshop that evening and constructed a prototype valve from two rubber condoms and flexible tubing. However, autoclaving caused the material to shrink a bit and the valve to leak. Holter discussed the shrinkage problem with a local rubber company, where the head of


FIGURE II.5.18.6 (A) Original Silastic hydrocephalus shunt. (B, C) Modern Codman Hakim programmable valve shunt. *(Courtesy of Codman, a Johnson & Johnson company).*

research suggested he replace the natural rubber with a thermally stable material known as silicone. Holter obtained Silastic® brand silicone elastomer and tubing free of charge from Dow Corning. In March of 1956, Holter believed the valve that would come to bear his name was ready. At the time, Holter's son was too ill to undergo the surgery; however, Spitz saw promise in the valve design and successfully implanted the ventriculoatrial shunt in another hydrocephalic child. Casey was sufficiently stable for surgery by April, when Spitz implanted him with a Holter valve (Baru et al., 2001). The Holter valve was so successful that its production began that summer, and the valve is still being made in almost unchanged form today (Aschoff et al., 1999) (Figure II.5.18.6).

Early healthcare applications resulted in substantial interest in the emerging silicone materials and their promising properties. The two leading silicone suppliers, General Electric and Dow Corning, began receiving inquiries from the medical field at unprecedented rates. By 1959, Dow Corning was so inundated with requests for materials and information that the Dow Corning Center for Aid to Medical Research was established to act as a clearing house for all information on medical uses of silicone, and to supply medical scientists with research quantities of various silicone materials, all without cost to the researcher. The Center corresponded with more than 35,000 physicians and researchers from all over the world and in numerous areas of healthcare (Braley, 1973).

The upsurge of interest in silicones for healthcare applications continued in the early 1960s. Before the end of the decade, silicone materials were being employed or evaluated in numerous healthcare applications – in orthopedics, catheters, drains and shunts of numerous descriptions, as components in kidney dialysis, blood oxygenators, and heart bypass machines, heart valves, and aesthetic implants, to name just a few.

Silicone materials continue to find application in various parts of the body today. Including orthopedic applications, silicone implants are literally found from head to toe. In the eye, silicone foam and elastomer scleral bands and bucklers, silicone vitreous fluid replacement, and elastomer intraocular lenses help restore vision after retinal reattachment or cataract surgery. In addition, the incorporation of siloxane into soft contact lens material resulted in the development of the silicone hydrogel contact lens. First launched in 1999, this innovative lens material greatly increases the amount of oxygen that reaches the cornea, allowing the lenses to be worn for as long as one month of continuous wear. The use of these lenses has resulted in fewer complications, and much improvement in patient symptoms of dryness and discomfort compared with the previous soft lenses (Dillehay, 2007).

In the ear, examples include silicone elastomer tubes for otological ventilation, as well as electronic cochlear implants that are encapsulated and insulated with silicone. Silicone elastomers are used in voice prostheses placed in the throat between the trachea and esophagus after laryngectomy. This is a particularly challenging location for any elastomeric material, as yeast and bacterial biofilm colonization often develop with long-term use (Delank and Scheuermann, 2008).

Silicone elastomers find application in many devices implanted in the thoracic cavity. A key example is the cardiac pacemaker, where silicone is used to encapsulate and insulate. Two interesting examples involving the stomach are the popular gastric band implant (Lap-Band®) for weight loss, and the Angelchik antireflux device for management of gastro-esophageal reflux or hiatal hernia which have not been resolved by more conservative treatments (Timoney, et al. 1990). The latter has the distinction of being the first medical

device containing silicone gel to be approved by the US Food and Drug Administration (FDA) (FDA approval P790006, 1979).

Silicone Orthopedic Implants

The most significant orthopedic applications of silicone are hand and foot joint implants. Dr. Alfred Swanson, with assistance from Dow Corning, developed silicone finger joint implants such as those shown in Figure II.5.18.7 (Swanson, 1968). Similar implants were developed for the other small joints of the foot and hand. In addition to double-stemmed finger joint implants in each of the metacarpophalangeal joints (large arrow), Figure II.5.18.7D also shows a single-stemmed Silastic ulnar head implant at the distal terminus of the ulna (small arrow). Nearly four decades later, silicone remains the most prevalent type of small joint implant.

Cement restrictors made of silicone elastomer with added barium sulfate for radiopacity (Figure II.5.18.8A) are used in joint replacement surgery involving cement. For example, one of these implants, also known as a bone plug, is inserted deeply into the prepared intramedullary canal of the femur during hip replacement surgery (Figure II.5.18.8B). It fits securely to restrict distal migration of poly(methyl)methacrylate bone cement intra- and postoperatively.

Another early orthopedic application of silicone was in 1969, when the French GUEPAR (Groupe d'Utilisation et d'Étude des Prothèses ARticulaires) posterior-offset hinged total knee implant was introduced. This design was constructed of the metal Vitallium, with a shock-absorbing silicone bumper that prevented impact of the anterior portions of the tibial and femoral components during knee extension (Mazas and GUEPAR, 1973).

Aesthetic Implants

Silicones have been used extensively in aesthetic and reconstructive plastic surgery for over 40 years. Silicone elastomer is used in implanted prosthetics of numerous descriptions. Silicone implants are widely used in the breast, scrotum, chin, nose, cheek, calf, and buttocks. Some of these devices may also employ a softer-feeling substance known as silicone gel. The gel is a lightly cross-linked silicone elastomer, without silica or other reinforcing filler, that is swollen with polydimethylsiloxane fluid. The gel is contained within a silicone elastomer shell in breast, testicular, and chin implants. Surgeons implant these medical devices for aesthetic reasons, to correct congenital deformity or during reconstructive surgery after trauma or cancer treatment.

With silicone materials and prototypes supplied free of charge from Dow Corning, Doctors Cronin and Gerow developed and tested their silicone gel-filled breast implant in 1961. They implanted the first pair in a woman in 1962 (Cronin and Gerow, 1963). Word of

The most prominent of these aesthetic implants is the silicone breast implant. Breast enlargement by surgical means has been practiced for over a century. In 1895, Czerny reported transplanting a lipoma to a breast in order to correct a defect resulting from the removal of a fibroadenoma (Czerny, 1895). The insertion of glass balls into the breasts was described by Schwartzmann in 1930, and again by Thorek in 1942. The Ivalon sponge, introduced by Pangman in 1951, was the first augmentation prosthesis to be retained fairly consistently. This surgical sponge, formulated of poly(vinyl alcohol) cross-linked with formaldehyde, was at first hand-trimmed to the desired shape by the implanting surgeon, and later preformed by Clay Adams, Inc. There was some early recognition of the tendency for tissue growth into the open-cell foam, and in 1958 Pangman patented the concept of encapsulating the foam with an alloplastic (manmade) envelope. His patent also contemplated the use of other fill materials, such as silicone, in place of foam. The Polystan and Etheron polyurethane sponge implants began to be used as breast implants in 1959 and 1960, respectively. These sponge implants became popular in the early 1960s, later being supplanted by the Cronin-type silicone gel-filled breast implants.

their success and the superiority of these silicone implants to the existing foam type led to the popularity of the silicone gel breast implant (Gerow, 1976).

Figure II.5.18.9 shows the appearance of these implants in 1964. The shells of Cronin-type implants were vacuum-molded with anterior and posterior elastomer pieces sealed together creating a seam around the perimeter of the base. The posterior shell had exposed loops of Dacron® mesh attached. The surgeons believed that prosthesis fixation to the chest wall was necessary to prevent implant migration.

Since this early 1964 design, Dow Corning and the numerous other companies that manufactured silicone breast implants made prosthesis design improvements, including elimination of the seam and realization that fixation is frequently unnecessary.

In the early 1990s, these popular devices became the subject of a torrent of contentious allegations regarding their safety. The controversy in the 1990s initially involved breast cancer, then evolved to autoimmune connective tissue disease, and continued to evolve to the frequency of local or surgical complications such as rupture, infection or capsular contracture. Epidemiology studies have consistently found no association between breast implants and breast cancer (McLaughlin et al., 1998, 2007; Park et al., 1998; Brinton et al., 2000; Mellemkjær et al., 2000). In fact, some studies suggest that women with implants may have decreased risk of breast cancer (Brinton et al., 1996; Deapen et al., 1997). Reports of cancer at sites other than the breast are inconsistent or attributed to lifestyle factors (Herdman and Fahey, 2001). The epidemiologic research on autoimmune or connective-tissue disease has also been remarkably uniform, and

FIGURE II.5.18.9 Silastic mammary prosthesis, 1964. *(© Dow Corning, AV06444.)*

FIGURE II.5.18.10 Silicone testicular implants. *(© Dow Corning, AV06437.)*

concludes there is no causal association between breast implants and connective-tissue disease (Gabriel et al., 1994; Sánchez-Guerrero et al., 1995; Hennekens et al., 1996; Edworthy et al., 1998; Nyrén et al., 1998; Kjøller et al., 2001; McLaughlin et al., 2007).

Numerous systematic reviews (UK IEAG, 1993; France ANDEM, 1996; US IOM, 1996; Australia TDEC, 1997; Germany BgVV, 1998; UK IRG, 1998; EU EQUAM, 2000; US NSP/MDL926, 2001; Spain/EU STOA, 2003) commissioned by various governments have repeatedly and consistently borne out that the evidence fails to support a cause-and-effect relationship between silicone breast implants and systemic diseases. Following FDA approval action on 17 November 2006 making silicone gel breast implants widely available in the United States again, the controversy has diminished.

Largely without any specific safety concern or allegation critical of it, another silicone gel-filled implant was swept up in the breast implant controversy. At the time, most testicular implants were constructed of the same materials as silicone gel breast implants. Silicone

artificial testicles had been used nearly as long as the breast implants. Dow Corning, one of several companies that manufactured these implants, was producing them as early as 1964. These devices served to ameliorate psychological stress associated with testicle loss due to cancer, traumatic injury or those absent at birth. The Teflon® strips seen in Figure II.5.18.10 shield each implant shell during suturing through an elastomer loop at the superior pole to achieve fixation for proper anatomical orientation in the scrotum.

BIOCOMPATIBILITY

There has been much discussion regarding the various definitions of the term *biocompatibility*. We now take it to mean "the ability of a material to perform with an appropriate host response in a specific situation" (Black, 1992; Remes and Williams, 1992). Historically it has been tacitly understood that silicone materials are intrinsically biocompatible, since they have been used successfully in so many healthcare applications. However, given the modern definition of the term, no material can be assumed to be universally biocompatible, since this

implies that it is suitable for every conceivable healthcare application involving contact with the host patient.

Numerous silicone materials have undergone biocompatibility testing. Many have passed every bioqualification test; however, others have not. Several factors can affect the results of such testing, including the composition of the material. As described in Chapter I.2.2.B, the basic polydimethylsiloxane (PDMS) polymer can be modified to replace methyl with other functional groups. In some cases, those groups may be responsible for untoward host response. There may be by-products from the preparation of silicone materials that might trigger tissue reaction. For example, these could come from the use of a peroxide initiator under inappropriate temperature and processing conditions.

Purity is another factor that can affect biotest results. Medical silicone materials, including fluids, gels, elastomers, and adhesives, are manufactured by several companies today. Some of these firms manufacture these medical materials following good manufacturing practice (GMP) principles in dedicated, registered, and inspected facilities. Others sell materials generated on their industrial production line into the healthcare market.

Selection of appropriate preclinical material bioqualification tests for their application is the responsibility of the medical device or pharmaceutical manufacturer. Several national, international, and governmental agencies have provided guidance or regulation. Several silicone manufacturers offer special grades of materials that have met these specific requirements. The buyer should carefully investigate the supplier's definition, since there are no universal special grade definitions. At Dow Corning, Silastic BioMedical Grade materials have been qualified to meet or exceed the requirements of ISO 10993-1, USP (*United States Pharmacopeia*) Class V Plastics tests (acute systemic toxicity and intracutaneous reactivity), hemolysis, cell culture, skin sensitization, mutagenicity, pyrogenicity, and 90 day implant testing. Other physio-chemical qualification tests have been conducted, such as certain tests from the *European Pharmacopoeia*. Specific information regarding material biotesting can be found in other chapters of this text. Testing of the device in finished form should follow material bioqualification tests such as those described above.

BIODURABILITY

Traditionally we have thought of *biocompatibility* as the situation in which the biomaterial has minimal adverse impact on the host. Conversely, *biodurability* is where the host has a minimal adverse effect on the biomaterial (see Chapter II.4.2). The material properties of silicone, such as hydrophobicity, have been related to biocompatibility properties such as hemolytic potential, and the relative purity, and high molecular weight polymeric

nature and chemical structure of the material, provide a theoretical basis for its lack of toxicity. The biodurability of silicone in medical applications is probably related to its exceptional thermal and chemical stability properties.

Silicones are used in numerous applications requiring high temperature resistance (Noll, 1968; Stark et al., 1982). During thermogravimetric analysis and in the absence of impurities, poly-dimethylsiloxane degradation starts only at around 400°C. Thus, silicones remain essentially unaffected by repeated sterilization by autoclaving, and they can usually also be dry-heat sterilized. Other sterilization methods can be used, such as ethylene oxide exposure and gamma and e-beam irradiation – although care must be taken to ensure complete sterilant outgassing in the former, and that dosage does not affect performance properties in the latter.

Although silicones can be chemically degraded, particularly at elevated temperatures, by substances capable of acting as depolymerization catalysts (Stark et al., 1982), their hydrophobic nature limits the extent of their contact with many aqueous solutions. Typically, the biologic milieu does not present a particularly hostile chemical environment for silicone. A notable exception, however, is the stomach, which excretes large amounts of hydrochloric acid, capable of attacking PDMS if it remains there too long. Based on silicone elastomer performance in long-term implantation applications, its biodurability is generally considered excellent (Table II.5.18.1).

The chemical stability associated with silicones became so well-established that it has been formulated into other biomaterials, such as polyurethane, to enhance their biodurability (Pinchuk et al., 1988; Ward, 2000; Christenson et al., 2002; Ward et al., 2006a,b).

Notwithstanding the chemical stability of silicone, certain factors have been shown to affect its durability in terms of long-term *in vivo* performance. The hydrophobic elastomer is somewhat lipophilic, and can be swollen by lipids or other nonpolar agents. Early experience with *in vivo* failure of silicone-containing heart valves was traced to elastomer absorption of lipids from the blood that resulted in significant dimensional swelling (McHenry et al., 1970). In most cases the absorption was low and failures did not occur, but in a small percentage of cases, the silicone was absorbing quantities sufficient to render the valves variant. Researchers speculated that variations in silicone poppet manufacture, such as cure, might have been a factor (Carmen and Mutha, 1972). Absorption of lipids was a variable reported by Swanson and LeBeau (1974) and Langley and Swanson (1976). The work of Brandon et al. (2002, 2003) has shown that the shells of silicone gel-filled breast implants also absorb silicone fluid (from the gel), causing a minor diminution in mechanical properties, one that is reversed after extraction of the elastomer.

TABLE II.5.18.1	Biodurability Studies of Silicone Elastomer and Medical Implants

Year	Researcher	Synopsis
1960	Ames	Explant examination of a clinical silicone ventriculocisternostomy shunt used in the treatment of hydrocephalus showed "the silicone rubber tubing was unchanged by three years implantation in the tissues of the brain and in the cervical subarachnoid space." Similarly, after over three years' implantation of silicone tubing in the peritoneal cavity of dogs, Ames wrote: "The physical properties of the tubing itself are apparently unchanged by prolonged contact with tissues."
1963	Sanislow and Zuidema	Silastic® T-tubes were placed in the common ducts of dogs and explanted nine months later. They were found to be free of bile-salt precipitation and completely patent. Four were tested for tensile strength and compared with a control sample from the same lot of elastomer. "These tests suggested that little physical change occurred in the Silastic as a result of prolonged contact with animal bile." The tensile strength after nine months was reported as 1130 psi (7.8 MPa), the same value as reported for the non-implanted control.
1964	Leininger et al.	The Battelle Memorial Institute examined the biodurability of five plastics by implanting films in dogs for 17 months' duration. The materials tensile strength and elongation were measured and compared with non-implanted controls. Although sizeable changes were seen in the tensile properties of polyethylene, Teflon®, and nylon, the results for Mylar and Silastic® remained essentially the same.
1974	Swanson and LeBeau	"Dog-bone"-shaped specimens of medical grade silicone rubber were implanted subcutaneously in dogs. Tensile properties and lipid content were measured at six months and two years postimplantation. A slight, but statistically significant, decrease in measured ultimate tensile strength and elongation were observed, as well as a small weight increase attributed to lipid absorption.
1976	Langley and Swanson	Mechanical test specimens were implanted in dogs for two years. Tensile strength, elongation, and tear resistance showed no statistically significant changes. Lipid absorption into the elastomer ranged from 1.4 to 2.6%.
2000	Curtis et al.	Six silicone breast implants surgically excised after 13.8 to 19.3 years, and 10 similar non-implanted units were tested to determine shell tensile properties and molecular weight of silicone gel extracts. The "study observed only minor changes (less than the explant or implant lot-to-lot variation range) in the tensile strength of Dow Corning silicone breast implants after nearly 20 years of human implantation." The gel extract molecular weight was either unchanged by implantation or increased slightly.
2003	Brandon et al.	In the most comprehensive study of breast implant biodurability heretofore published, the authors reported their results of tensile, cross-link density, and percent extractable measurements made on 42 explants and 51 controls. The study included some of the oldest explants, with human implantation durations up to 32 years. The researchers also performed a literature search, and plotted all published explant tensile modulus data against implantation duration, finding no temporal relationship. Neither was a relationship with implant time seen for the cross-link density results, supporting the biodurability of the silicone elastomer utilized in the implant shells. The researchers concluded, "There was little or no degradation of the base polydimethylsiloxane during *in vivo* aging in any of the implants we examined."
2008	Taylor et al.	Silicone biodurability after long-term implantation was examined by a highly sensitive NMR spectroscopy technique, as well as NMR relaxometry measurements of explanted gel breast implants and matched non-implanted controls. No evidence of chemical degradation of the cross-linked silicone matrix was observed in specimens explanted after as many as 32 years *in vivo*, underscoring the biostability of the cross-linked silicone shell and gel.

CONCLUSION

A variety of silicone materials have been prepared, many possessing excellent properties including chemical and thermal stability, low surface tension, hydrophobicity, and gas permeability. These characteristics helped originate the use of silicones in the medical field and are key to the materials' reported biocompatibility and biodurability. Since the 1960s, silicones have enjoyed expanded medical application and today are one of the most thoroughly tested and important biomaterials.

Applications of Biomaterials in Functional Tissue Engineering

CHAPTER II.6.1 INTRODUCTION: REBUILDING HUMANS USING BIOLOGY AND BIOMATERIALS

Frederick J. Schoen

Professor of Pathology and Health Sciences and Technology (HST), Harvard Medical School, Executive Vice Chairman, Department of Pathology, Brigham and Women's Hospital, Boston, MA, USA

Contemporary biomaterials investigation and development of important applications has been stimulated and informed by advances in materials science and engineering, an understanding of the interactions of materials with the physiological environment, and a logical evolution of the concepts and tools of cell and molecular biology. These developments have permitted the progression of concepts of and approaches to controlling tissue–biomaterials interactions, often exquisitely. In *tissue engineering* (also sometimes called regenerative therapeutics), the logical and rapidly developing extension of this technology, engineered surfaces, and architectures (at the bulk, micro-, and nanoscale) are intended to stimulate the replacement of dysfunctional or lacking tissue or stimulate other (patho)physiological interactions through highly precise reactions with proteins and cells at the molecular level. Biomaterials play a key role in tissue engineering and regenerative therapeutics.

Tissue engineering uses a set of tools at the interface of the biomedical and engineering sciences to support the growth of living cells or attract endogenous cells to aid tissue formation or regeneration to produce therapeutic or diagnostic benefit. In the most frequent paradigm, cells are seeded on a scaffold composed of synthetic polymer or natural material (collagen or chemically-treated tissue), a tissue is matured *in vitro*, and the construct is implanted in the appropriate anatomic location as a prosthesis (Langer and Vacanti, 1993). A typical scaffold is a bioresorbable polymer in a porous configuration in the desired geometry for the engineered tissue, often modified to be adhesive for cells, in some cases selective for a specific circulating cell population. Application-specific and differentiated or undifferentiated (stem) cells are used (Stocum, 2005; see Chapters II.1.7 and II.6.4).

Recent emphasis is on micro- and nanoscale control of scaffold–cell interactions (Wheeldon et al., 2011).

The first phase is the *in vitro* formation of a tissue *construct*, by placing the chosen cells and scaffold in a metabolically and mechanically supportive environment with growth media (in a *bioreactor*), in which the cells proliferate and elaborate extracellular matrix. In the second phase, the construct is implanted in the appropriate anatomic location, where remodeling *in vivo* is intended to recapitulate the normal functional architecture of an organ or tissue (Orlando et al., 2011). The key processes occurring during the *in vitro* and *in vivo* phases of tissue formation and maturation are: (1) cell proliferation, sorting and differentiation; (2) extracellular matrix production and organization; (3) degradation of the scaffold; and (4) remodeling and potentially growth of the tissue. The general paradigm of tissue engineering is illustrated in Figure II.6.1.1. Biological and engineering challenges in tissue engineering are focused on the three principal components that comprise the "cell–scaffold–bioreactor system." Control of the various parameters in device fabrication (Table II.6.1.1) may have major impact on the ultimate result. Exciting new possibilities are opened by advances in stem cell technology, and the recent evidence that some multipotential cells possibly capable of tissue regeneration are released by the bone marrow and circulate systemically (Lakshmipathy and Verfaillie, 2005), while others may be resident in organs such as heart and the central nervous system formerly not considered capable of regeneration (Leri et al., 2011). Indeed, it may be possible to use the context of the *in vivo* physiological environment as a bioreactor, and thereby bypass the *in vitro* phase of initial tissue formation (Stevens et al., 2005; Mendelson and Schoen, 2006). The importance of developmental biological and biomimetic principles in tissue engineering is being realized (Gerecht-Nir et al., 2006; Ingber, 2010a,b), since a scaffold can contain specific chemical and structural information that controls tissue formation, in a manner analogous to cell–cell communication and patterning during embryological development.

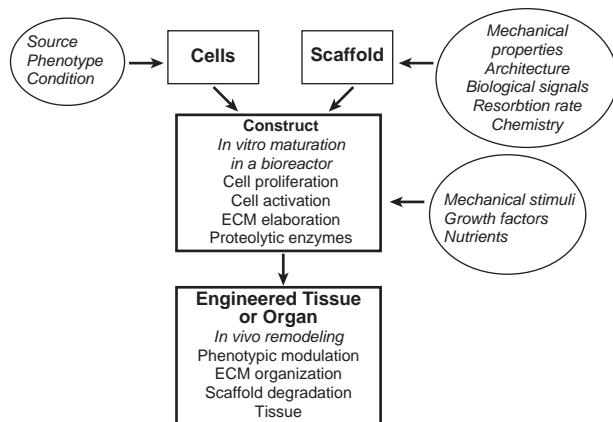
In addition to the goal of developing implantable medical devices that use living cells (normal or genetically-manipulated), together with extracellular components


FIGURE II.6.1.1 Tissue engineering paradigm. In the first step of the typical tissue engineering approach, differentiated or undifferentiated *cells* are seeded on a bioresorbable *scaffold* and then the *construct* matured *in vitro* in a bioreactor. During maturation, the cells proliferate and elaborate extracellular matrix (ECM) to form a "new" tissue. In the second step, the construct is implanted in the appropriate anatomical position, where remodeling *in vivo* is intended to recapitulate the normal tissue/organ structure and function. The key variables in the principal components – cells, scaffold, and bioreactor – are indicated. (By permission from Rabkin, E. & Schoen, F. J. (2002). Cardiovascular tissue engineering. *Cardiovasc. Pathol.*, **11**, 305.)

Modified from Rabkin, E. & Schoen, F. J. (2002). Cardiovascular tissue engineering. *Cardiovasc. Pathol.,* **11**, 305.

(either natural or synthetic), *tissue engineering* also seeks to: (1) understand structure–function relationships in normal and pathological tissues (particularly those related to embryological development and healing; Ballachandran et al., 2011); (2) to create models for human tissue that can be used for detection of toxins or infectious agents or for high-throughput drug testing (Khetani and Bhatia, 2008); and (3) to control cell and tissue responses to injury, physical stimuli, and biomaterials surfaces through chemical, pharmacological, mechanical, immunological, and genetic manipulation (Hubbell et al., 2009; Huebsch and Mooney, 2009; Lutolf et al., 2009; Reilly and Engler, 2010; Edalat et al., 2011). A key challenge in tissue engineering is to understand quantitatively how cells respond to molecular signals and integrate multiple inputs to generate a given response, so that cell responses specifically follow desired receptor–ligand interactions.

This section summarizes the major concepts and recent progress in translational tissue engineering. Sarkar et al (Chapter II.6.2) describes the essential overview concepts in the field, followed by chapters on tissue engineering scaffolds (Singh, Kasper and Mikos, Chapter II.6.3), cell sources (Caplan, Chapter II.6.4), micromechanical design criteria (Ghosh, Thodeti and Ingber, Chapter II.6.5), and bioreactors (Tandon et al., Chapter II.6.6). These general chapters are followed by descriptions of the major areas of progress and challenges for engineering tissues for specific applications, including bone (Brown, Kumbar and Laurencin et al., Chapter II.6.7), cartilage and ligament (Kuo, Li and Tuan, Chapter II.6.8), blood vessels, (Schutte and Nerem, Chapter II.6.9), heart valves (Schoen and Hoerstrup, Chapter II.6.10), cardiac muscle (Godier and Vunjak-Novakovic, Chapter II.6.11), skin (Mansbridge, Chapter II.6.12), esophageal and gastrointestinal tissue (Ratner, Chapter II.6.13), neuronal regeneration (Bellamkonda, Clements and Munson, Chapter II.6.14), immunoisolation (Rainbow and Lysaght, Chapter II.6.15), and engineering with decellularized tissues (Badylak, Brown and Gilbert, Chapter II.6.16).

The early phase of translation of tissue engineering technology to the clinic has begun. Tissue-engineered products for skin replacement are in clinical use (MacNeil, 2007). Further examples of previous and ongoing tissue engineering approaches used clinically include cartilage regeneration using autologous chondrocyte transplantation (Brittberg et al., 1994), a replacement thumb with bone composed of autologous periosteal cells and natural coral (hydroxyapatite) (Vacanti et al., 2001), bladder replacement (Atala et al., 2006), and blood vessels (McAllister et al., 2009). Biohybrid extracorporeal artificial organs using functional cells (Humes and Szcypka, 2004), tissue-engineered heart valves (Vesely, 2005; Sacks et al., 2009), blood vessels (Quint et al., 2012), ligaments (Laurencin and Freeman, 2005), and bone (Khan et al., 2008), are in active preclinical studies. Complex organs such as lung and heart (myocardium) are under development (Nichols et al., 2009; Badylak et al., 2011;

Vunjak-Novakovic et al., 2011). General problem areas include: (1) development of new cell lines and biomaterials; (2) evaluation of the optimal implant configuration, including a functional vasculature for three-dimensional tissues; (3) development of testing methodology appropriate to validate the concept; and (4) the reproducible manufacture and preservation of bioartificial devices until ready for use. A particularly interesting approach is the decellularization followed by recellularization of a complex organ (Badylak et al., 2011).

Cell-compatible biomaterial microarrays that allow rapid, microscale testing of biomaterial interactions with cells have recently been described, and may be extremely helpful in this regard (Anderson et al., 2005; Khademhosseini et al., 2006). Exquisite control of scaffold architecture and overall and regional surface chemistry is now also possible; these features may precisely regulate cell behavior (Lutolf et al., 2009). Another approach is *biomimetics*, in which natural structures and processes (e.g., development, wound healing) are mimicked. Modified native extracellular matrix (ECM) may have particularly advantageous properties in this regard (Badylak et al., 2009).

Future directions in biomaterials, tissue engineering, and regenerative therapeutics are indeed exciting, and priorities are under active discussion (Hacker and Mikos, 2006; Goldberg et al., 2007; Hellman and Nerem, 2007; Johnson et al., 2007; Daley and Scadden, 2008; Kohane and Langer, 2008).

GENERAL INTRODUCTION

History of Tissue Engineering

The term "tissue engineering" as recognized today was first introduced at a panel meeting of the National Science Foundation in 1987, which led to the first tissue engineering meeting in early 1988 (Nerem, 2006; Vacanti, 2006). However, tissue engineering strategies date back to the seventies and eighties for developing skin substitutes (Vacanti, 2006). Despite these early approaches for replacement, repair, and regeneration of failing organs, the true emergence of tissue engineering as a medical field started in the early nineties when tissue engineering was defined as an interdisciplinary field that applies the principles of engineering and life sciences toward the development of biological substitutes that restore, maintain or improve tissue function (Langer and Vacanti, 1993). The field has since rapidly progressed worldwide, with nearly $4 billion invested in the field in the 1990s resulting in over 70 companies and several products on the market by the end of the millennium (Lysaght and Reyes, 2001). As of mid-2007, approximately 50 firms or business units with over 3000 employees offered commercial tissue-regenerative products or services with generally profitable annual sales in excess of $1.3 billion (Lysaght et al., 2008). Well over a million patients have been treated with these products. In addition, 110 development-stage companies with over 55 products in US Food and Drug Administration (FDA)-level clinical trials and other preclinical stages employed ~2500 scientists or support personnel, and spent $850 million development dollars in 2007. While early success has been challenging, technological advances alongside biological discoveries continue to propel the field of tissue engineering into exciting new frontiers.

GOALS OF TISSUE ENGINEERING AND CLASSIFICATION

Goals of Tissue Engineering

Tissue engineering aims to restore tissue and organ function by employing biological and engineering strategies to clinical problems. The functional failure of tissues and organs is a severe and costly healthcare problem, as their replacement is limited by the availability of compatible donors (Langer and Vacanti, 1993, 1999).

Artificial prostheses and mechanical devices save and improve the lives of millions of patients, but are not ideal since they are subject to mechanical failure upon long-term implantation. Furthermore, mechanical devices rarely integrate with host tissues, and can trigger a host immune response damaging healthy tissue around the implant. In addition, surgical reconstruction of organs and tissues are attempted where the organs or tissues are moved from their original location to replace a damaged tissue, e.g., saphenous vein as bypass graft, patella tendon for anterior cruciate ligament (ACL) repair. However, often this strategy fails to replace all the functions of the original tissue. Additionally, development of malignant tumors, surgical complications, and morbidity at the donor sites are major problems in surgical reconstruction of tissues. Thus, tissue engineering has emerged as another alternative for tissue or organ transplantation. The primary goal of tissue engineering is to provide a biological substitute to treat tissue/organ loss or failure by integrating multiple aspects of engineering, biology, and medicine. By recapitulating the normal tissue development process, tissue engineering represents a strategy to restore, maintain, and improve tissue

function, which ultimately aims toward complete organ replacement.

Classification of Tissue Engineering Approaches

Traditional Tissue Engineering Approaches. Tissue engineering includes two main strategies: (1) transplantation of a tissue grown *in vitro* consisting of an artificial matrix with cells and growth factors; and (2) *in situ* regeneration of tissue utilizing a combination of an artificial matrix and growth factors as a guiding template to induce host cell regeneration of the tissue *in vivo* (Figure II.6.2.1).

In addition to traditional tissue engineering approaches, other methods used for tissue regeneration include local and systemic cell injection without a scaffold, and closed looped systems used as implantable or extracorporeal devices. While classically these methods are not regarded as tissue engineering, they have contributed significantly to tissue regeneration and are therefore briefly introduced here.

Cell Therapy. Cell therapy involves delivery of cells through systemic injection into the bloodstream or through direct transplantation into a local tissue (Mooney and Vandenburgh, 2008; Karp and Leng Teo, 2009). The major requirement for this strategy is to harvest the cells and grow them in large numbers for *in vivo* transplantation.

Direct injection of cells to a local site is a common strategy attempted to promote tissue regeneration. However, the survival of the delivered cells is typically low, often due to a lack of a rich nutrient and oxygen supply (Muschler et al., 2004). Alternatively, cells can be administrated via systemic injection, which relies on cells traveling through circulation to engraft in the target site. Cell transplants from bone marrow, peripheral blood or umbilical cord have been used to treat several blood-related diseases including leukemia, multiple myeloma, and immune deficiencies. The main goal of these strategies is to deliver hematopoietic (blood) stem cells to treat blood-related diseases (Thomas, 1987). Recently, mesenchymal stem cells, connective tissue progenitor cells, which repair or regenerate non-hematopoetic tissues, have been systemically injected to treat diseases including myocardial infarction (Barbash et al., 2003), bone diseases (Horwitz et al., 1999), and brain injury (Mahmood et al., 2003) in clinical trials. The main challenges for cell transplantation are: growing large number of cells without bacterial contamination; preservation of cell phenotype; and preventing accumulation of genetic mutations during culture expansion. Although cells have been successfully delivered to the heart to treat ischemic tissue following myocardial infarction, and into the joint to treat arthritis, irrespective of the delivery route, cell therapies face challenges due to widespread death of the transplanted cells, poor engraftment, and loss of control over the fate of the transplanted cells.

Closed Loop Methods. A variety of closed loop systems are used as extracorporeal or implantable devices which house the transplanted cells in a semipermeable membrane (Murua et al., 2008). The membrane permits diffusion of nutrients and excreted products, but prevents the movement of antibodies, pathogens or immunocompetent cells. There are several types of designs for such devices. Vascular type design uses a conduit structure around which the cells are transplanted in a chamber.

(A) In vitro tissue engineering followed by transplantation

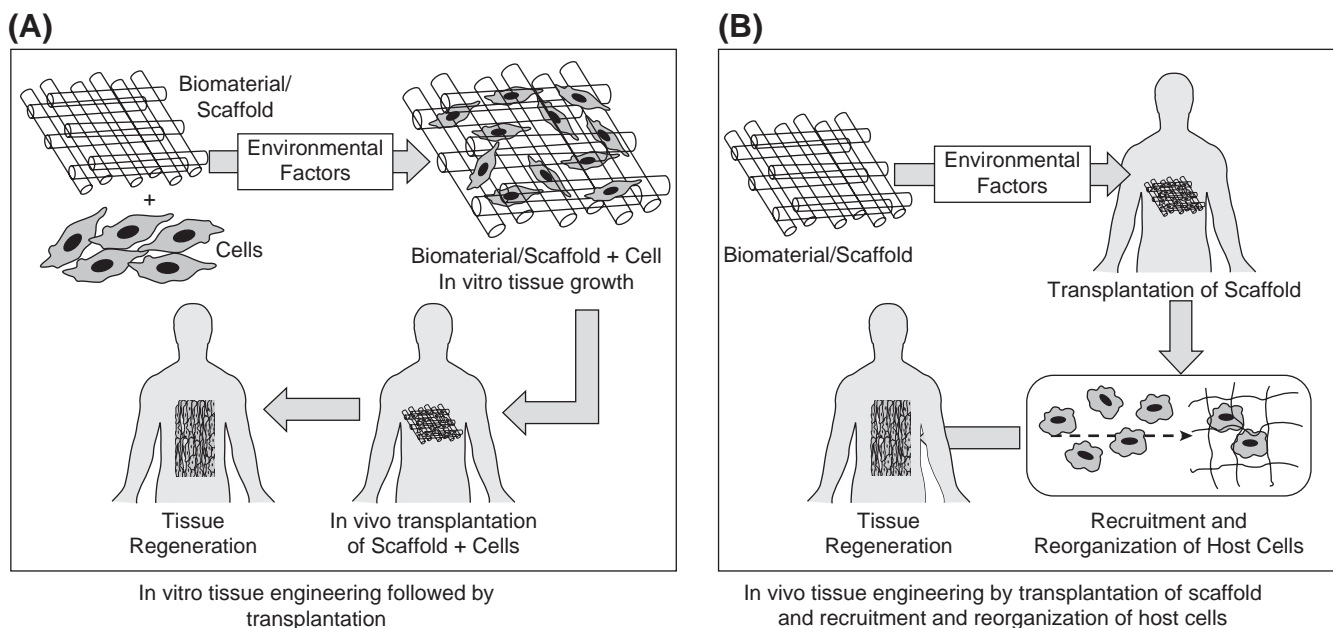
(B) In vivo tissue engineering by transplantation of scaffold and recruitment and reorganization of host cells


FIGURE II.6.2.1 Tissue engineering approaches may be classified into two categories: (A) transplantation of *in vitro* grown tissues; and (B) promotion of tissue regeneration *in situ*. In both approaches the scaffolds or artificial matrices, often biodegradable polymers, are integrated with microenvironmental factors (such as cytokines, growth factors, mechanical forces, physico-chemical factors, spatial and temporal signals, and extracellular matrix molecules).

As blood flows through the conduit it provides nutrients to the transplanted cells, while cell-secreted substances diffuse into the bloodstream (Langer and Vacanti, 1993; Patzer, 2001). Additionally, micro/macrocapsule-based systems have been used as closed loop systems (Aebischer et al., 1991; Winn et al., 1991) where cells are encapsulated within hydrogel droplets. The encapsulated cells can then be cultured *in vitro* or transplanted *in vivo*, either to repopulate a defect site or to produce growth factors or other molecules that will have an effect on the targeted cell population. Closed loop extracorporeal devices have been used for the treatment of liver, pancreas, and kidney pathologies. Major problems associated with these types of devices include fouling, fibrous tissue overgrowth, restricted and hindered diffusion, and immunogenic response (Wiegand et al., 1993).

COMPONENTS OF TISSUE ENGINEERING

Tissue engineering strategies typically involve multiple components including cells, a physical template, and a combination of growth cues that promote tissue regeneration and integration of the construct into a functional and organized tissue.

The Cell

Cell Source. Cells are the building blocks of tissues, and play a critical role in promoting tissue healing and regeneration. Within tissue engineering strategies, cells may be a component of the *in vitro* construct or may be recruited *in vivo* with the aid of immobilized or soluble signals. Cell types utilized for tissue engineering are selected from a variety of sources which include autologous cells from the patient, allogeneic cells from another human, and xenogeneic cells from a different species. However, allogeneic and xenogeneic cells often suffer from immune rejection.
Cell Type. Common cell types include stem cells (capable of self-renewal and differentiation into multiple lineages), differentiated mature cells, or a mixture of differentiated cells. Stem cells (see also Chapter II.1.7 "Stem Cells: Key Concepts" and II.6.4 "Cell Sources for Tissue Engineering: Mesenchymal Stem Cells") may include embryonic stem cells and adult stem cells, such as mesenchymal stem cells and hematopoietic stem cells. Embryonic stem cells are an attractive cell source for tissue engineering as these cells can self-renew without differentiation, can be culture expanded, and most importantly can differentiate into any cell type. Since embryonic stem cells are isolated from an embryonic stage, they can develop into any of the three germ layers: endoderm (interior stomach lining, gastrointestinal tract, the lungs); mesoderm (muscle, bone, blood, urogential); or ectoderm (epidermal tissues and nervous system). Successful reprogramming of differentiated human somatic cells into pluripotent cells has led to the creation of induced pluripotent stem (iPS) cells (Takahashi and Yamanaka, 2006). These cells are

functionally similar to embryonic stem cells, but do not require the destruction of an embryo and can be created from a patient's own cells, eliminating the risk of host rejection (Takahashi et al., 2007). Adult stem cells include, for example, mesenchymal (Pittenger et al., 1999), hematopoietic (Baum et al., 1992), neural (Snyder et al., 1997), and hepatic (Petersen et al., 1999) stem cells. In particular, hematopoietic stem cells have been used in clinics for a few decades for treating blood diseases (i.e., bone marrow transplantation). Mesenchymal stem cells (MSCs), which can be transplanted as an allogenic cell source to another patient without immunosuppressive drugs, are capable of differentiation into multiple lineages that may produce tissues including bone, cartilage, and muscle, and have been approved for use in multiple systems to treat bone defects. Mesenchymal stem cells can also modulate the host immune response through paracrine or endocrine mechanisms, and are currently being applied in clinical trials for treatment of immune diseases. Nevertheless, adult stem cells are rare, challenging to isolate and expand without altering cell phenotype, and limited in their differentiation potential.

Further investigation is needed to identify the best source of stem cells for each tissue engineering application. In the near future, it will be necessary to compare the performance of the different stem cell populations under the same testing conditions. Multiple variables should be addressed in the selection of the best stem cell population, including: (1) stem cell accessibility (e.g., the isolation of neural stem cells is invasive and relatively difficult compared to other stem cells); (2) number; (3) proliferation capacity; (4) differentiation profile; and (5) ethical issues.

In addition to stem cell populations, committed and/or differentiated cell types are also frequently used in tissue engineering approaches. For example, culture expanded chondrocytes have been used for over 15 years to treat cartilage defects (Brittberg et al., 1994). However, the potential of differentiated adult cells is often limited due to their low proliferation capability, loss of phenotype, and dedifferentiation in culture.

In addition to primary cells, the intrinsic biological potential and performance of a cell can be modified by transient or permanent alteration of specific genes (Hannallah et al., 2003). The introduction of new or altered genes is often accomplished with vectors created by modifying naturally-occurring viruses such as retrovirus, lentivirus, adenovirus or adeno-associated virus. There are several concerns for these approaches, such as transformation efficiency, safety of virus transfection, vector stability, and optimal function of the inserted genes. Non-viral transfection techniques have been developed to circumvent some of these issues; however, the long-term fate of these genetically modified cells still presents a potential risk.

The cell phenotype can also be regulated through manipulation of isolation and culture conditions. Although

this may expand the available tools to manipulate cell characteristics, it can create more hurdles for consistently manufacturing high quality cells. In particular, care must be taken during the cell isolation process to maintain cell phenotype, purity, and differentiation state. It is critical to achieve a high purity of cells defined by rigorous characterization. In addition, it is important to consider that cell culture may "activate" cells, altering their phenotype from those found *in situ*. There are many decisions that must be made, often without suitable premise, such as the ideal number of cells to be transplanted, the maximum number of times cells can be passaged, the maximum length of time cells should be maintained in culture, the ideal differentiated state of the cells to produce a therapeutic effect, and the ideal storage conditions for the cells. These factors can significantly alter the outcome of a regenerative approach, and often need to be optimized on a case-by-case basis for specific animal models (Bueno et al., 2007).

MATERIALS

Biomaterials are used to develop scaffolds, which provide a template for cells to organize and restore structure and function to damaged or dysfunctional tissues. Guidance can be achieved through biophysical and biochemical cues that direct cell behavior, morphology, adhesion, and motility (Hubbell, 1995; Langer and Tirrell, 2004). Biomaterials can, at the same time, be used to supply nutrients, drugs, and bioactive factors that direct specific tissue growth. Accordingly, the material should be non-toxic and degradable within a clinically useful range into fully biocompatible products. Ideally, the material should also possess physico-mechanical and engineering properties suitable for the intended application, and be compatible for further functionalization with bioactive molecules. Biomaterial scaffolds for tissue engineering are discussed in more detail in Chapter II.6.3 "Tissue Engineering Scaffolds."

To accommodate these material requirements, the field of tissue engineering has witnessed tremendous development of new biomaterials over the past few decades. These materials are derived from both natural and synthetic sources, and possess a broad spectrum of structural and functional properties that make them suitable for many clinical applications.

Natural Materials

A wide range of natural-origin polymers, including proteins and polysaccharides, are used as carriers for cells and bioactive molecules (Malafaya et al., 2007). Natural materials are advantageous due to their inherent biological recognition through receptor–ligand interactions, cell-mediated proteolysis and remodeling, and low toxicity.

Protein-based natural polymers include collagen, gelatin, silk fibroin, fibrin, elastin, and soybean. Collagen is a major component of the extracellular matrix, the natural cell scaffold, which interacts with cells in all tissues, providing essential signals for the regulation of cell anchorage, migration, proliferation, differentiation, and survival (Yang et al., 2004). As a result, collagen has been studied for engineering artificial skin (collagen IV), bone (collagen I), and cartilage (collagen II), resulting in several tissue engineering products. Bilayered collagen gels seeded with human fibroblast and keratinocytes are used as a bioengineered artificial skin by Organogenesis, Inc. under the name of Apligraf®. Gelatin is a natural polymer derived from collagen that has significantly lower antigenicity in contrast to collagen and has been used for engineering bone, cartilage, and skin. Gelatin is also well-suited to serve as a carrier for bioactive molecules, including fibroblast growth factor and transforming growth factor (Ito et al., 2003). Silk fibroin has received significant attention as a versatile natural polymer due to its high strength-to-weight ratio and slow degradation (Sofia et al., 2001). Another commonly used natural material is fibrin, the structural component of blood clots that provides a transitory matrix for cell migration during wound healing. Fibrin has been used as a matrix for studying the regeneration of bone, cartilage, skin, nerve, and spinal cord (Ahmed et al., 2008).

Another class of natural polymers is polysaccharides that contain monomers (monosaccharides) linked together by O-glycosidic bonds to form linear and branched polymers (Malafaya et al., 2007). Several polysaccharides, including chitosan and alginates, have been studied for tissue engineering applications. Chitosan, the fully or partially deacetylated form of chitin found particularly in the shell of crustaceans, has attracted significant attention, due to its biocompatible properties, for regeneration of skin, bone, cartilage, and vascular grafts (Park et al., 2000; Mi et al., 2001; Kim et al., 2003). Alginates in the form of hydrogels, beads, and scaffolds are a widely utilized polysaccharide polymer used to promote angiogenesis and regenerate bone and cartilage (Marijnissen et al., 2002; Simmons et al., 2004; Tilakaratne et al., 2007). Other commonly employed polysaccharides include starch, hyaluronan, chrondoitin sulphate, cellulose, dextran, and polyhydroxyalkanoates.

Unfortunately, there are several limitations of natural materials which include purification, cost, immunogenic responses, and lack of mechanical properties and processability. Although some of these disadvantages have been avoided through recombinant protein expression technologies (Rodriguez-Cabello et al., 2005), synthetic biomaterials (see below) present a paradigm shift that overcomes many of these challenges while opening the door for custom-designed biomaterials.

Synthetic Materials

Many synthetic polymers have been designed and fabricated for tissue engineering purposes. Biodegradable synthetic polymers offer a number of advantages compared

to natural materials, such as controlled mechanical properties and degradation kinetics, easy processability into custom shapes and structures, and easy modification of the material for specific applications.

The vast majority of synthetic biomaterial-based polymers belong to the polyester family which includes poly(glycolic acid), poly(lactic acid) and their copolymer poly(lactide-*co*-glycolide) (PLGA) (Shalaby, 1988). Polyesters have long been used in the clinic in the form of degradable sutures, and have more recently been studied to promote regeneration of bone, cartilage, bladder, skin, and vasculature. In particular, PLGA and its constituent polymers are used in a vast array of applications due to their ease of degradation by hydrolysis of ester bonds, controllable degradation rate, and minimal inflammatory response. Another class of polyester used in tissue engineering is polylactones, such as poly(caprolactone) (PCL), which are less crystalline than PLGA and degrade at a much slower rate. Interestingly, caprolactone-based materials have an added advantage given their shape memory properties which enables the polymer to change their shape after an increase in temperature (Lendlein et al., 2001). Other classes of polyesters that have been explored include poly(ortho esters) and poly(propylene fumarate) (Kharas et al., 1997). Recent development of elastomeric polyesters has shown significant promise as tissue engineering biomaterials that mimic the mechanical properties of soft tissues due to their elasticity compared to other polyesters, e.g., poly(glycerol sebacate) and poly(diol citrate) (Yang et al., 2006; Nijst et al., 2007).

Poly(anhydrides) are another class of synthetic polymers developed from the condensation of diacids or a mixture of diacids. These polymers are biocompatible and have well-defined degradation characteristics. Several poly (anhydride) homopolymers and copolymers have been synthesized to control their degradation rate and mechanical properties (Domb, 1987). Amino acid-based polymers, e.g., L-tyrosine based poly(carbonate), poly(imminocarbonate), and poly(phosphate) (Pulapura and Kohn, 1992; Gupta and Lopina, 2004) have been developed as a substitute for poly amino acids where the peptide linkages are partially replaced with non-peptide links. Biodegradable polyurethane elastomers have also been developed as synthetic biomaterials for regeneration of heart, cartilage, and skin (Guan et al., 2005). Polyurethanes with degradable linkages and biocompatible components have been developed from amino acids and peptides with a wide range of mechanical properties and degradation kinetics (Skarja and Woodhouse, 2001; Sarkar et al., 2009). Synthetic polymers with photopolymerizable groups are based on poly(ethylene glycol) and poly(acrylates). Upon exposure to ultraviolet radiation and cross-linking agents, these polymers can cross-link to form three-dimensional networks.

Due to complexities in the design and synthesis of biomaterials, recent techniques in combinatorial approaches to develop and screen synthetic biomaterials are rapidly gaining interest in this field (Anderson et al., 2004; Kohn, 2004; Yang et al., 2008). Such techniques can be used to rapidly synthesize a library of polymers by altering the structure and composition of polymers and to characterize their interactions with cells in a high-throughput manner.

Semi-Synthetic Materials

Combinations of natural and synthetic polymers have particular advantages compared to pure natural or synthetic counterparts for some applications. These biosynthetic hybrids are usually designed by incorporation of biologically active macromolecules onto the backbone of synthetic polymers to optimize both structure and function (Seliktar, 2005). From a tissue engineering perspective, the objective of using a biosynthetic hybrid material is to reproduce the intricate extracellular stimulation of the native cellular environment, yet exhibit enhanced control over the material properties (compared to purely natural materials). For example, semi-synthetic PEG(polyethylene glycol)-fibrinogen hydrogel has been developed to control cell migration and tissue regeneration where the synthetic PEG component controls density, stiffness, and biodegradability, and the fibrinogen component presents biofunctional domains for cell-mediated remodeling (Dikovsky et al., 2006).

SCAFFOLD DESIGN

Scaffolds act as the synthetic analog of the natural extracellular matrix. The role of scaffolds is to recapitulate the normal tissue development process by allowing cells to formulate their own microenvironment (Lee et al., 2008). The scaffold provides the necessary support for cells to attach, proliferate, and maintain their differentiated function and subsequent regeneration of new tissues. Ideally, a scaffold should have the following characteristics: (1) three-dimensional highly porous structure with an interconnected pore network to facilitate cell/tissue growth and diffusion of nutrients, metabolic waste, and paracrine factors; (2) biodegradable or bioresorbable with controllable degradation and resorption rates to match cell/tissue growth *in vitro* and *in vivo*; (3) suitable surface chemistry for cell attachment, proliferation, and differentiation; (4) mechanical properties to match those of the tissues at the site of implantation; and (5) be easily processed to form a variety of shapes and sizes.

Conventional Fabrication Methods

The formation of a porous structure is the main goal of scaffold fabrication. Most methods for fabricating porous scaffolds, including particulate leaching, freeze drying, gas infusion, and phase separation, create isotopically distributed interconnected pores. Porous structures are developed by introducing particles or bubbles

when the scaffold is solidified, which are later removed leaving behind an interconnected network of pores. Although these techniques are relatively simple for developing a three-dimensional structure, they are limited by uncontrolled pore size and connectivity, poor mechanical strength, and residual solvent/porogens (Yang et al., 2001). Hydrocarbon templating is a combination of two distinct foam processes where water-insoluble hydrocarbon particulates are leached with the precipitation of the polymers. This process has several advantages, including control over scaffold thickness and pore structure, although use of organic solvents is typically a disadvantage for biological applications as it is difficult to remove completely.

Fiber-Based Scaffolds

Fibrous scaffold structures may be developed by electrospinning of polymers to generate continuous micro- or nanoscale diameter fibers. Additionally, the orientation of fibers can be controlled during electrospinning to develop random or aligned fibers. Electrospun scaffolds are advantageous due to their high surface-to-volume ratio and structural similarity to natural extracellular matrix. However, it is difficult to control the distance between fibers, an important factor that influences the migration of cells. Self-assembly of biopolymers, e.g., peptides and nucleic acids, using noncovalent interactions including H-bonding, hydrophobic, electrostatic interactions, and van der Waals forces into three-dimensional structures has also been used for scaffold development. The main advantage of such biopolymers is that their self-assembly relies on specific biorecognitions (e.g., DNA hybridization) which therefore make the formation of scaffold highly predictable and programmable.

Solid-Free-Form Methods

To enhance control over the three-dimensional organization of porous scaffolds, rapid prototyping techniques borrowed from electrical and mechanical engineering can be used. These techniques involve computer-assisted methods with solid-free-form (SFF) fabrication techniques (Hollister, 2005). Specifically, they involve acquiring a two-dimensional image of a target specimen by nondestructive imaging, then developing macroscale three-dimensional architecture with software, and finally fabrication of the three-dimensional matrix with highly precise and automated layer-by-layer SFF processes. There are several SFF processes, including laser-based, ink-jet type printing-based, and nozzle-based approaches. These methods offer precise control of the three-dimensional structure of the scaffolds; however, they are associated with higher costs and require more complex equipment compared to conventional salt leaching or gas foaming processes.

Hydrogel-Based Scaffold

Hydrogels are typically cross-linked networks swollen in water to suspend cells in three dimensions. Photocross-linkable hydrogels are frequently used to encapsulate cells (Ferreira et al., 2007a). Polymers with photocross-linkable moieties are polymerized into three-dimensional networks in the presence of cross-linkers under UV radiation. By controlling the structure with defined cross-linking density, mechanical properties, mass transport, and degradation characteristics, the gels can be tuned for a range of applications. Hydrogels are an appealing three-dimensional scaffold because they are structurally similar to the extracellular matrix of many tissues, can often be processed under relatively mild conditions, and may be delivered in a minimally invasive manner (Drury and Mooney, 2003). In addition, hydrogels are advantageous due to high water content, facile transport properties, and controlled degradation kinetics (Nuttelman et al., 2008). Furthermore, hydrogels can be chemically modified to improve the adhesion and proliferation of the cells on the gel matrices through inclusion of adhesion peptides, i.e., RGD(Arg-Gly-Asp tripeptide). In order to achieve more control over the cell placement within the hydrogels, three-dimensional patterned hydrogels are used. However, major problems with using hydrogels include structural instability and overall inferior mechanical properties for placement within dynamic environments.

DEVELOPMENT OF TISSUE ENGINEERING CONSTRUCTS

Strategies for Tissue Engineering

As outlined above, there are two main strategies to develop a tissue engineering construct. To facilitate tissue growth, scaffolds can be transplanted with or without cells. Each strategy's success largely depends on effective integration of different factors including cells, scaffolds, and environmental cues (e.g., growth factors, biological molecules).

Cells with Scaffold Transplantation. Scaffolds provide a substrate upon which cells attach, proliferate, and produce extracellular matrix within a predefined three-dimensional orientation. However, the main challenges for this strategy include: generating a complete functional tissue; preserving cell viability and function during transplantation; biological and mechanical integration with the surrounding tissue; and supplying oxygen and nutrients to the transplanted cells (Muschler et al., 2004). The transplanted cells within the core of large defects often die before contributing to the healing process. Moreover, the scaffolds are often filled with blood clots which present a harsh environment for the transplanted cells. Regardless, this strategy can be useful for transplantation of thin tissue grafts, such as corneal and skin grafts, where an immediate connection to the vascular system is not essential.

Scaffold-Only Transplantation. Another strategy involves *in situ* tissue regeneration by providing an instructive scaffold that can guide and control the regeneration process *in vivo* (Zhao and Karp, 2009). This process uses an artificial scaffold matrix that, once implanted, recruits host cells and relies on the body's innate regenerative ability. The scaffold recruits such cells through signal presentation (Richardson et al., 2001; Simmons et al., 2004; Lee et al., 2008). For example, transplantation of PEG-collagen matrices with enzyme cleavable matrix metalloproteinase (MMP) links that release bone morphogenic protein-2 (BMP2) can promote regeneration of critical size bone defects effectively through invasion of the host cells (Lutolf et al., 2003a). The absence of MMP sensitive linkages and/or BMP-2 hindered the regeneration process, indicating that transplantation of scaffolds with appropriate soluble and insoluble signals is critical. Thus, the success of scaffold transplantation-based approaches largely depends on the appropriate presentation of signals to mediate host cell mobilization and coordination of the subsequent behavior of the cells, e.g., adherence, migration, and proliferation.

Biological Factors in Tissue Growth

Type of Biological Factors. Biological factors including hormones, cytokines, growth factors, extracellular matrix molecules, cell surface molecules, and nucleic acids can significantly influence the function and behavior of cells in the scaffold. The temporal and spatial coordination of cellular processes is orchestrated by these signals from the extracellular environment. A large number of biomolecules have been explored to induce tissue regeneration, but the majority of these molecules can be categorized as follows: (1) small molecules, e.g., corticosteroids, hormones, are used for intercellular and intracellular signaling by binding to specific protein receptors; (2) proteins and peptides act on the cells as mitogens, morphogens, growth factors, and cytokines; and (3) oligonucleotides, either DNA or RNA, can either affect gene transcription and/or translation or can be incorporated into the cell's genome.

Delivery and Presentation of Biological Factors. The challenges and strategies to deliver these factors vary due to the differences in their physical and chemical properties. Presentation of factors as soluble cues is an important strategy to control the interaction of cells and their microenvironment. Strategies to embed factors within scaffold matrices or encapsulate them within micro- and nanoparticles have been used to control the release of the agents. Presentation of a single or multiple factors has been achieved by release of factors from polymeric scaffolds with controlled degradation characteristics or diffusion of the factors out of the scaffold. This allows delivery of multiple soluble cues to cells at distinct rates. This strategy has been demonstrated to release vascular endothelial growth factor (VEGF) and platelet derived growth factor (PDGF) in a PLGA scaffold to promote the growth of blood vessels *in situ* (Richardson et al., 2001). A similar strategy has been employed to regenerate bone with transplanted stromal cells in alginate scaffolds through dual delivery of BMP2 and transforming growth factor-β3 (TGF-β3) (Simmons et al., 2004). Additionally, presentation of factors in a spatio-temporally controlled manner is important for the development of spatially complex tissues. In particular, scaffolds developed by layer-by-layer deposition can control the releases of different growth factors and proteins. For example, by controlling spatial gradients of nerve growth factor (NGF) within the scaffold, axonal outgrowth can be achieved (Moore et al., 2006).

In addition to presenting growth factors in a soluble form, an alternative strategy is to bind factors to a surface, in either random or specific orientations. Non-covalent association of the matrix components, e.g., glycosaminoglycans (GAGs), can slowly release and potentiate binding to the cell membrane receptors (Sakiyama-Elbert and Hubbell, 2000). Alternatively, covalently bound growth factors can also influence cell behavior, i.e., covalently conjugated epidermal growth factor (EGF) enhances the survival of mesenchymal stem cells in a Matrigel™-based scaffold (Fan et al., 2007). The presence of protease sensitive peptide sequences within such growth factor proteins allows these molecules to be released on demand (Zisch et al., 2003). In addition, the adhesion of cells, which is a crucial step for cell survival and is mediated by cell-surface receptors with cell adhesion proteins, on the scaffold matrices can also be controlled by presentation of specific peptides and carbohydrates. In particular, a prototypical three amino acid sequence arginine-glycine-aspartic acid (RGD) is frequently found in many adhesion proteins and binds to many integrin receptors on cells. RGD peptide sequences have therefore been covalently immobilized on a synthetic material surface at a defined density and orientation to guide cell adhesion (Silva et al., 2008). To note, the graft density of RGD is essential to balance cell adhesion versus migration (Gobin and West, 2002). Finally, the covalent immobilization of protease sensitive cleavable linkages (i.e., MMP sensitive links) on synthetic matrices mimics the native extracellular matrix which can be used, in addition to soluble growth factors and other chemotactic cues, to guide migration of cells (Gobin and West, 2002; Lutolf et al., 2003b).

Mechano-Chemical Factors in Tissue Growth

In addition to soluble and immobilized biological factors, the physical and/or chemical nature of the scaffold is also known to play an important role in regulating cell fate. For example, recent studies suggest surface chemistries can regulate the differentiation of MSCs (Benoit et al., 2008). Similarly, the structure of scaffold can also

influence the shape of stem cells, which impacts other cell functions such as differentiation. For instance, MSCs cultured in highly cross-linked hydrogels exhibit round morphology, but can be induced to spread by reducing the cross-linking density via photodegradation (Kloxin et al., 2009). Moreover, nanoscale geometry and matrix size can also influence cell adhesion, proliferation, and migration. By altering surface topography, cytoskeletal organization can be altered which directly influences molecular and biomechanical signals. Furthermore, mechanical forces exerted by scaffold matrix and the elasticity of the material also influence the cell fate. For instance, matrix stiffness can control the differentiation of MSCs (Engler et al., 2006; Winer et al., 2009). In conclusion, the physical environment, consisting of geometry, time-varying stress, strain, fluid flow, pressure, and potentially other biophysical parameters, e.g., osmotic pressure and electrical field, can regulate cell phenotype and tissue structure in a three-dimensional environment.

Integration of Multiple Factors

Successful integration of the appropriate cells, scaffolds, soluble cues, and mechano-chemical factors is a key in regulating cell fate and ultimately regenerating a functional tissue. Hence, combinatorial approaches in which the effect of different factors in combination is examined are useful (Flaim et al., 2005). Thus, an engineered "niche" or microenvironment is a useful approach for critical understanding of biology, as well as for engineering tissue regeneration (Lutolf and Blau, 2009). Static *in vitro* tissue engineering systems often fail to take into account the multiple factors that contribute to the healing and regeneration process. Thus, it is critical to understand the system as a whole through dynamic *in vitro* systems, such as bioreactors and relevant *in vivo* models.

MODELS FOR TISSUE ENGINEERING

Bioreactors

Importance of Bioreactors. The traditional tissue engineering approach of growing tissues on two-dimensional surfaces (i.e., petri dishes) or in three-dimensional scaffolds is limited by mass transfer, since the diffusion of metabolites, oxygen, and carbon dioxide under static conditions can only support a certain thickness of tissue (Lees et al., 1981). Consequently, cartilaginous tissue grown in petri dishes has been reported to reach only a maximum height of 0.5 mm (Martin et al., 1998). Multicellular spheroids also develop large, central necrotic regions with increasing diameter (Sutherland et al., 1986). Bioreactors can hence provide an enhanced environment for tissue growth. Their higher rates of mass transfer provide improved oxygen influx and waste disposal. Various cell seeding strategies (i.e., traditional static seeding through gravity, dynamic seeding which

takes place in an agitated environment or seeding in a perfusion system) allows for desirable cell density and homogeneity, and mechanical conditioning (Martin and Vermette, 2005). By designing bioreactors it is possible to provide the desired conditions, i.e., mechanical signals, temperature, flow rate, oxygen, and carbon dioxide concentrations for simulating the *in vivo* environment required for regeneration of functional tissues (Burg et al., 2000; Freed et al., 2006). Bioreactors are discussed in more detail in Chapter II.6.6 "Bioreactors for Tissue Engineering."

Types of Bioreactors. Traditional industrial reactors such as the continuous stirred-tank reactor (CSTR) have been adapted as bioreactors in tissue engineering. In particular, the stirred-flask reactor improves reactor performance by agitating the media used for seeding scaffolds (Vunjak-Novakovic et al., 1996). Another system is the rotating-wall vessel, which aims to minimize the shear stress and turbulence of previous approaches. This system was developed for cell culture experiments in space, and thus is often referred to as a microgravity reactor (Unsworth and Lelkes, 1998). Another interesting bioreactor is the hollow fiber reactor that permits the cultivation of highly sensitive cells such as hepatocytes. Cells can either be situated on the exterior or in the lumen of the fibers. These reactors can also introduce two different solutions to the tissue culture system that are optimized to either provide metabolites or remove waste products. Bioartificial liver systems based on this reactor type are in clinical trials to treat patients with hepatic failure (Gerlach et al., 2008).

Another method of seeding and culturing cells is the direct perfusion reactor that can perform continuous perfusion of a cell suspension through a scaffold. This system can increase the efficiency and uniformity of cell seeding (Wendt et al., 2003). There are several other bioreactors designed to grow tissues that primarily serve a biomechanical function. Mechanical constraints can be induced through bioreactors for the successful regeneration of functional tissue, as demonstrated by the *in vitro* generation of a tissue-engineered heart valve (Karim et al., 2006) and a trachea (Martin et al., 2004; Macchiarini et al., 2008).

Limitations and Challenges. While bioreactors have been shown to enhance uniformity of cell seeding and perfusion of three-dimensional cultures, reactor conditions such as mass transfer properties, cell seeding, mechanical environment, and hydrodynamics must be uniquely optimized for each tissue. Fortunately, mathematical modeling (Mehta and Linderman, 2006) and computational fluid dynamics are available to help understand the complex interactions of these factors (Hutmacher and Singh, 2008). However, even within the best designed bioreactor, one limitation remains, i.e., the transport of nutrients inside the tissue. To overcome this barrier, controlled vascularization of the tissue must be fully understood and applied.

Role of *In Vivo* Models

While *in vitro* development of tissues is the starting point of a tissue-engineered product, an appropriate *in vivo* model is crucial to validate the tissues' function. Several factors cannot be assessed *in vitro*, for example the role of angiogenesis in a newly created tissue, host immune reactions to the graft, as well as functional considerations, such as rheological properties of engineered vessels and innervation of the graft (Fabian Schmidt, 2008). These factors must be tested to understand the efficacy of an engineered tissue or organ. Different animal models are used to investigate different tissue products, as all models have limitations that make them appropriate to assess some features but not others. For example, an immune-compromised mouse system is appropriate for initially evaluating graft integration with host tissue, but is not appropriate for evaluating host rejection. Thus, for any tissue-engineered product it is critical to analyze the outcomes of an *in vivo* study in the context of the model and its efficacy.

APPLICATIONS OF TISSUE ENGINEERING

The main goal of tissue engineering is to regenerate and replace human tissues and organs through a combination of biological, clinical, and engineering approaches.

Replacing/Regenerating Target Organs

Investigators have attempted to engineer almost every mammalian tissue. The following section describes some key developments in the field for several tissues:

- *Skin*: Tissue-engineered skin aims to restore barrier function to patients for whom this has been severely compromised, e.g., burn patients. Skin is a widely explored engineered tissue, and several commercial skin products are available, e.g., Epicel® by Genzyme is a product based on autologous cells grown to cover a wound; Apligraf® by Organogenesis is a dual layer skin equivalent with keratinocytes and fibroblasts on collagen gel; Dermagraft® by Advanced Tissue Science uses a similar approach with dermal fibroblast on resorbable polymer, among many others (MacNeil, 2007). These products treat burns, ulcers, deep wounds, and other injuries. Collagen, fibrin, hyaluronic acid, and poly(lactic glycolic acid) are mainly used in skin substitute matrices. Keratinocytes, melanocytes, and fibroblasts compose the majority of cells in skin tissue, thus expanding and transplanting these cells within biocompatible matrices is key to successful skin regeneration (Priya et al., 2008). Additionally, to achieve effective healing, tissue-engineered skin must attach to the wound bed and avoid rejection by the immune system. Despite great success in engineering skin tissue, pitfalls include scar tissue formation, wound contraction, incomplete healing of deep wounds, lack of full recovery of skin function, and imperfect regeneration of skin components such as glands and hair follicles (MacNeil, 2007). Thus, incorporating our understanding of the requirements of skin regeneration into new three-dimensional model systems is important to develop a fully functional skin replacement.

- *Liver*: Liver transplantation is end-stage treatment for many liver diseases. Several factors including drug use, alcohol abuse, and viruses like Hepatitis can cause acute liver failure. It is important to completely replace the damaged liver or support the patients that wait for donor organs or suffer from chronic liver diseases with tissue-engineered livers (Kulig and Vacanti, 2004). Intense efforts exist to develop a bridging device that can support a patient's liver function until a donor is available, e.g., dialysis, charcoal hemoperfusion, immobilized enzymes or exchange transfusion. Several extracorporeal systems use patients' own cells in a hollow-fiber, spouted-bed or flat-bed device, which reduce the chance of immune rejection. Tissue engineering approaches to transplant hepatocytes consist of several critical steps: culture and expansion of hepatocytes in a three-dimensional polymer substrate, maintaining the viability and differentiated state of the cells, engrafting a sufficient number of hepatocytes with vascularization for survival of the graft, and attaining the complex structural geometry of liver. Several bioartificial livers (BAL) have been developed and designed to flow patient's plasma through a bioreactor that houses/maintains hepatocytes sandwiched between artificial plates or capillaries. These BAL devices have different hepatocyte sources, treatment, and perfusate (i.e., blood or plasma). The liver tissue engineering field has developed two main strategies: (1) transplantation of suspended hepatocytes with extracellular matrix components; (2) use of biodegradable scaffolds to provide a platform for hepatocyte attachment. Recent advancement of microfabrication techniques has improved the three-dimensional design of artificial livers with microcapillary beds to mimic physiological conditions (Powers et al., 2002). However, challenges remain in liver tissue engineering due to the complex vascularized architecture of the liver, relatively high volumetric oxygen consumption rate of the tissue, and need for long-term culture for applications such as the evaluation of toxicity, efficacy, and infection (Griffith and Swartz, 2006).

- *Pancreas*: Diabetes is the fifth highest cause of death in the US, and diabetes-related expenses were estimated at more than $100 billion in 2007 (American Diabetes Association, 2008). One type of diabetes is type 1 diabetes mellitus (T1DM), an autoimmune disease which destroys the insulin-secreting cells of the pancreas. T1DM is relevant to tissue engineering, since

it can be treated by replacing the destroyed pancreatic islet cells. Techniques for pancreatic tissue engineering aim to release insulin from transplanted islets into the blood to restore normal blood glucose levels. Three main approaches are used: a tubular membrane that encapsulates islets and connects to blood vessels; hollow fibers containing islets embedded in a polymer matrix; and encapsulation of islets in microcapsules (Lacy et al., 1991; Sullivan et al., 1991; Lanza et al., 1995). The membranes used in the perfusion devices and coatings in microcapsules are developed from biocompatible polymers that allow insulin to diffuse into the bloodstream, while protecting the cells from destruction by immune cells. An insufficient source of islet cells presents a challenge, but recent advances with stem cells may overcome this.

- *Heart*: Cardiovascular disease is the leading cause of death in the US. Many patients are left with damaged or malfunctioning cardiac tissue that lead to arrythmias and diminished cardiac output. Tissue engineering is actively pursing treatments for myocardial infarction, congenital heart defects, and stenotic valves through regenerating cardiac tissues. Heart valves are developed by transplanting autologous cells onto a scaffold, growing and maturing the cell-seeded scaffold, and finally transplanting the valves into the patient. Scaffolds can be made from biomaterials, but decellularized heart valves from donors or animal and biomaterials are also used (Wilson et al., 1995). Decellularized heart valves consist of extracellular matrix which is repopulated with host cells, but they can potentially produce severe immune response (Simon et al., 2003). Alternatively, biomaterial-based heart valves are designed from various natural materials, e.g., collagen, fibrin, and synthetic polymers, e.g., PLGA, poly(hydroxy butyrate) (Hoerstrup et al., 2000). Biomaterial-based heart valves have advantageous characteristics, including malleability and improved mechanical strength. Cells for cardiovascular applications are usually obtained from donor tissues, e.g, peripheral arteries with mixed populations of myofibroblasts and endothelial cells, as well as established cell lines of myofibroblasts and endothelial cells. There are several successful applications of tissue-engineered heart valves for both *in vitro* and *in vivo* models. Additionally, efforts have been made to regenerate myocardium by scaffold-based approaches with natural and synthetic materials (Kofidis et al., 2002; Shimizu et al., 2003). Furthermore, recent devlopments have shown stem cells to be promising tools for the field of cardiovascular tissue engineering (Caspi et al., 2007). However, the complex metabolic, electrical, and mechanical nature of heart tissues continues to present a significant challenge to engineering myocardial tissues (Parker and Ingber, 2007).

- *Blood vessels*: Poly(tetrafluoro ethylene) PTFE and Dacron® grafts have traditionally been used as vascular grafts, particularly for large diameter vessels. However, these grafts are largely unsuccessful for small diameter blood vessels, due to thrombogenicity and compliance mismatch (Edelman, 1999). Tissue engineering strategies therefore provide great opportunities for development of blood vessels. Decellularized arteries with well-preserved extra cellular proteins have been repopulated with cells both *in vitro* and *in vivo* to generate blood vessels (Bader et al., 2000; Kaushal et al., 2001). Polymer-based scaffolds are often used as a template to guide the regeneration of blood vessels. By generating sufficient extracellular matrix and adequate mechanical responsiveness, scaffold guided blood vessels have shown significant promise (Niklason et al., 1999). Also, recently developed microfluidic and microfabrication techniques allow the complex architecture of a blood vessel with defined microstructures to be realized (Fidkowski et al., 2005). In an alternative approach, sheets of smooth muscle cells and extracellular matrix are generated under flow conditions in the absence of scaffold, and are subsequently rolled over a support to mature into a vessel structure (L'Heureux et al., 1998). An emerging approach focuses on combining endothelial cells with mesenchymal stem cells or smooth muscle cells to help stabilize the blood vessel and help aid in the vessel pruning process (Ferreira et al., 2007b). It is important to note that formation of new blood vessels is critical for engineering any tissue to supply nutrients and oxygen to cells. Unfortunately, vascularization of large organs is still a challenge for tissue engineering. Several approaches, including delivery of one or more growth factors from scaffold, have been used to stimulate angiogenesis in engineered tissues (Richardson et al., 2001).

- *Nervous system*: Generation of nerve tissues is a major focus in tissue engineering (Schmidt and Leach, 2003; Zhang et al., 2005). Injuries in the central nervous system (CNS) are often accompanied by permanent functional impairment, unlike peripheral nervous system (PNS) damage where the axons are able to re-extend and re-innervate, leading to functional recovery (Belkas et al., 2004). This is because the environment of the damaged site in CNS blocks the regeneration of neurons. Peripheral nerve grafts that include synthetic or biological substrates have been developed to act as a bridge to guide the nerve regeneration process. To restore the structures lost in the disorganization of axons during injury it is critical to build a bridge that spans the lesion gap with all the morphological, chemical, and biological cues that mimic normal tissue. Both natural and synthetic polymer bridges and conduits have been shown to aid nerve regeneration, and these graft materials may be

seeded with Schwann cells, for example, which aid the regeneration process (Bellamkonda and Aebischer, 1994; Zhang et al., 2005). Studies have also shown that controlled release of neurotrophic factors, neuronal adhesion molecules, and growth factors induces a local sprouting response, stimulates reinnervation, and remodels the growing axons (Schnell et al., 1994; Kapur and Shoichet, 2004; Slack et al., 2004). These methods of delivering cells and factors might also treat neurodegenerative disorders *in vivo* (i.e., encapsulated dopamine producing cells for treating Parkinson's disease) (Lindvall et al., 1990).

- *Bone*: There are numerous clinical applications that can benefit from bone regeneration therapies including spinal fusion to alleviate back pain, temporomandibular joint reconstruction to alleviate jaw pain, and restoration of contour and shape within reconstructed craniofacial bone. Significant progress in the development of bone regeneration therapies has been achieved, yet large critical-sized defects which do not heal remain a significant clinical challenge. Although several inorganic-, polymeric-, and hybrid-based scaffolds have been examined to engineer bone, it has been difficult to develop a material that displays optimal mechanical properties and degradation kinetics for bone repair (Muschler et al., 2004). It is clear that the scaffolds for bone regeneration should have an interconnected macroporosity to allow three-dimensional bone growth throughout the scaffold (Gao et al., 2001; Karp et al., 2003, 2004). Implantation of empty macroporous scaffolds that are devoid of cells typically do not improve the healing response (Grande et al., 1999; Louisia et al., 1999; Petite et al., 2000). Although combining biodegradable scaffolds with cells is a commonly explored strategy (Goshima et al., 1991; Holy et al., 2000; Ma et al., 2001; Hutmacher and Sittinger, 2003) these strategies have low success rates, as many of the cells may die due to a lack of vascularization (Petite et al., 2000). Since most tissue engineering scaffolds have heterogeneous pore sizes, and since the amount of blood that fills a scaffold depends on the geometry of the scaffold pores (Whang et al., 1999), it is likely that there is a high variability in the amount of blood that fills these scaffolds; a critical phenomena that is often neglected. It is important to consider that the diverse compositions of scaffolds with respect to materials, porosity, surface chemistry, morphology, degradation rate, pore sizes, and mechanical properties, employed in the field of bone engineering makes it challenging to compare results between studies, and this limits what can be learned and applied by others. Controlled systematic studies and increased understanding of the osteogenic microenvironment is required to provide rational design criteria for the next generation of bone engineering approaches.

In addition to the tissues described above, there are many other tissues which have been targeted for regeneration by tissue engineering strategies. These include cartilage, muscle, kidney, blood, cornea, gastrointestinal tissues, vocal chord, and many others.

Other Applications of Tissue Engineering

There are several non-traditional, yet useful and important applications of tissue engineering strategies (Griffith and Naughton 2002; Ingber et al., 2006). In particular, the field of drug screening is in need of advanced *in vitro* methods for the assessment of the activity and toxicity of drugs before clinical studies are initiated (Saltzman and Olbricht, 2002). Since most drugs are metabolized in the liver, microscale hepatocyte systems may allow high-throughput screening for liver toxicity (Bhadriraju and Chen, 2002; Khetani and Bhatia, 2008). Furthermore, humans or animals "on a chip" are in development. These chips are essentially several reactors with different cell types connected in series which can simulate the pathway of a chemical substance through several parts of the body, such as the liver, brain, and fat (Viravaidya et al., 2004; Khamsi, 2005). In the future, tissue engineering-based drug testing and toxicity assays can provide an alternate strategy to reduce the use of *in vivo* animal testing. Moreover, an artificially engineered tissue-engineered system can provide enhanced control of tissue microenvironments, both in physiological and pathological conditions (e.g., cancer tumor), contributing to the understanding of complex tissues and organs (Ali et al., 2009).

CURRENT CHALLENGES AND FUTURE DIRECTIONS

The past two decades have seen a dramatic increase in the exploration of tissue engineering as a promising approach to restore, maintain, and enhance tissues and organs. Tissue engineering concepts based on the application of a scaffold/cell construct have significant potential in the healthcare industry. Indeed, a number of engineered tissues have been approved by the FDA, and are used in the clinic for treatment of patients worldwide. Some examples of tissue engineering products and programs are included in Table II.6.2.1.

Challenges

Despite the excitement and early success, there are many hurdles to be addressed before tissue engineering reaches its eventual goal to treat millions of patients (Griffith and Naughton, 2002). In addition to efficacy, potential for facile scale-up, reliability, established regulatory routes, and societal acceptance issues, there are many technical

TABLE II.6.2.1	Tissue Engineering Products and Programs for Replacement or Restoration of Human Tissue Function	
Application	**Product (approved for application) and Program (currently under development)**	**Company**
Skin	Apligraf®	Organogenesis
	TransCyte®, Dermagraft®	Advanced Tissue Sciences
	Epicel®	Genzyme
Cartilage	Carticel®	Genzyme
	Menaflex™	ReGen Biologics
	NeoCart®, VeriCart™	Histogenics
Bone	Osteocel®	Osiris Therapeutics
	Pura-matrix™	3DM
	OsteoScaf™	Tissue Regeneration Therapeutics
Bladder, Kidney	Neo-bladder	Tengion
	FortaPerm®	Organogenesis
Blood vessels	Lifeline™	Cytograft Tissue Engineering
	Omniflow® II	Bionova
Cardiac	Anginera™	Theregen
	CardioWrap®, CryoValve®,	Cryolife
Retinal	ECT Implant	Neurotech

challenges to overcome. Some of the major challenges are discussed below.

Cell Source

A cell source is one of the key aspects for an effective tissue engineering strategy. It is critical to access reliable cell sources that are adequate to repair the damaged tissue, and to understand at the molecular level how cells function. Specifically, it is important to comprehend how cells respond to molecular signals and integrate multiple inputs to generate a predictable response. Additionally, although local transplantation or injection of cells represents a potential approach, locally administered cells often die before significantly contributing to the healing response, due to diffusion limitations of nutrients and oxygen (Muschler et al., 2004). Cells need to be within ~200 µm of the nearest blood vessel, and it may take many weeks or months for vascularization to reach the cells, leading to cell and tissue death. This significantly reduces the capacity for an exogenous cell source to contribute to the regenerative process. In addition to issues with cell delivery, embryonic stem cells are fraught with several ethical concerns, but recent federal approval to expand research with these stem cells has invigorated the field of tissue engineering. More importantly, the recent development of iPS cells may replace embryo-derived embryonic stem cells, as iPS cells avoid the destruction

of embryos, providing a cell source for drug screening, *in vitro* models, and future clinical applications. However, currently many existing techniques for creating iPS cells utilize viral transfection techniques that produce a very low yield. Consequently, there is currently a plethora of research ongoing to develop non-viral and highly efficient iPS cell techniques.

Vascularization

Vascularization, the growth of blood vessels, is a major engineering hurdle to overcome in creating artificial organs, particularly large-scale three-dimensional tissues (Soker et al., 2000). It is critical to have effective transport of oxygen, nutrients, and removal of cell-secreted waste for the survival of cells. This is the major reason why most successful engineered organs are restricted to tissues, such as skin, cartilage, and ligament. For these tissues, thin layers of cells (e.g., 1–2 cell layers in skin tissue) that are well-accessible to the blood vessels are sufficient and a proximal blood supply is not essential for survival (Rouwkema et al., 2008). For other tissues and organs, several potential strategies exist to address the issue of vascularization. Recent tissue studies have focused on prevascularizing the tissue constructs prior to implantation or delivering angiogenic growth factors. Although these methods have shown promising results, more critical issues remain as to methods of developing the complex vascular network using scalable technology and integrating the systems with host vasculature.

Material Design

It is a challenge to develop an ideal instructive biomaterial that can effectively induce the growth of tissues. In spite of significant progress in biomaterial development, it is not fully understood how the scaffold should be used to control cell–matrix interactions (Place et al., 2009). The type of signals and the mode of their presentation (e.g., density and organization of adhesion ligands, delivery of growth factors and cytokines) as soluble or insoluble cues can dramatically impact the functionality of the scaffold. Thus, it is critical to develop large-scale screening systems that can thoroughly and systematically analyze these effects. Specifically, new materials that control and manipulate transcription factors for regulating development and morphogen expression can be useful to control the formation of new tissues. It is important to consider how a cell acts at the molecular level, i.e., the cell's biochemical pathways and how these pathways are affected. Thus, the design of such materials is extremely important to understand the concerted effect of all the factors on the cell functions which are guided by their supporting scaffold, growth factor and cytokine profiles, and biomechanical forces. Additionally, immune rejection of engineered tissues and organs presents a serious problem

(Chan and Mooney, 2008). Strategies to evade the host immune system are clearly needed; particularly technologies that can alter or reduce the inflammatory response to increase tolerance will help to overcome this problem.

FUTURE PERSPECTIVES

Multiple challenges remain for translation of tissue-engineered products to the clinic. Cell type, source, and manipulation are critical parameters that need to be further studied and defined, in order to achieve the best clinical outcomes. Many approaches are too complex for scale-up to industrial level manufacture. Ideally, tissue-engineered products involving cells should be amenable to cryopreservation (Griffith and Naughton, 2002; Pancrazio et al., 2007). It is also critical to consider that *in vivo* animal models may not adequately represent the human condition. Furthermore, it is still not clear how the FDA will regulate combination products. This significantly increases the risk for new companies to develop multi-component systems.

Recent developments in the field of gene microarray analysis and imaging (e.g., magnetic resonance imaging (MRI)) provide valuable tools and strategies for advancing the field (Yamada et al., 2006; Pancrazio et al., 2007). More quantitative approaches such as computational modeling and systems biology will be useful to understand the mechanism of tissue development and regenerative processes. Although significant advances have been accomplished, most regenerative therapies are still in the developmental phase. Understanding the fundamental biology associated with normal tissue development is critical for the creation of highly integrated approaches to achieve controlled cell differentiation and tissue formation.

CHAPTER II.6.3 TISSUE ENGINEERING SCAFFOLDS

Milind Singh, F. Kurtis Kasper, and Antonios G. Mikos
Department of Bioengineering, Rice University, Houston, TX, USA

In the search for alternatives to conventional treatment strategies for the repair or replacement of missing or malfunctioning human tissues and organs, promising solutions have been explored through tissue engineering approaches (Langer and Vacanti, 1993). Biomaterials-based scaffolds have played a pivotal role in this quest. The fundamental purpose of a tissue engineering scaffold is to act as a three-dimensional template that may provide mechanical stability, deliver therapeutic agents, and facilitate processes critical in tissue repair, such as tissue induction, cell proliferation and differentiation, and/or guided tissue growth. To date, a wide variety of biomaterials have been explored for application as tissue engineering scaffolds, including metal-based implants, purified extracellular matrix (ECM) xenografts, ceramics, and natural and synthetic polymers. Bioresorbable synthetic polymers are particularly attractive for two main reasons. First, they degrade into products that can be safely metabolized and/or excreted, potentially leaving no residual foreign materials in the recipient, and second they are highly versatile with regard to the control over their physicochemical properties and ease of processability, allowing them to be tailored in an application-specific manner. This chapter provides an overview of bioresorbable synthetic polymeric scaffolds for tissue engineering applications.

SCAFFOLD DESIGN

When designing a polymeric scaffold, a combination of biological and engineering requisites is considered in an application-specific manner. One of the most essential design elements is the biocompatibility of the scaffolds, implying that the scaffold should not demonstrate immunogenicity or elicit an adverse inflammatory response (Babensee et al., 2000). In this regard, the bioresorbable scaffolds should also be sterilizable, and should degrade without significant cytotoxic, inflammatory or immunogenic degradation components. In addition, scaffold design considerations include suitable bulk properties, and the presentation of microenvironments to regulate cell adhesion, spreading, motility, survival, and differentiation.

For anchorage-dependent cells, cell-to-scaffold interactions need to be optimized. Cell-to-scaffold interactions have a direct impact on cell adhesion and morphology, which may in turn affect various cellular processes. These interactions are directly or indirectly influenced by physicochemical characteristics of the polymer surface, including features such as wettability (hydrophilicity), roughness, crystallinity, charge, and functionality (for reviews, see Ruardy et al., 1997; Singh et al., 2008a).

Synthetic polymer surfaces are usually devoid of specific ligands that cell surface receptors recognize, so modification with extracellular matrix (ECM) molecules is often applied to improve cell-to-scaffold interactions (Kraehenbuehl et al., 2008; Weber and Anseth, 2008). The ECM molecules are known to play important roles in integrin-mediated signaling and associated cellular functions (Howe et al., 1998). For this purpose, the presence of pendant functional groups on polymer chains is desirable, because these may be used to conjugate proteins or peptides. In some cases, specific surface functionalities may directly influence the desired cellular activity and function, precluding the need for ECM molecules. For example, it was recently shown that small molecules of specific functionalities (charged phosphate group and hydrophobic t-butyl group) tethered to a poly(ethylene glycol) (PEG) hydrogel can induce osteogenesis and adipogenesis of human mesenchymal stem cells in the absence of any cytokine (Benoit et al., 2008).

Substrate rigidity is another important factor that determines cell cytoskeletal shape and associated cellular function (see review by Discher et al., 2005). In general, increased cell adhesion and spreading leads to cell proliferation, while moderate cell adhesion and a rounded cell morphology corresponds to differentiated cellular function (Mooney et al., 1992), and substrate stiffness is known to affect the extent of cell spreading. For example, fibroblasts cultured on soft two-dimensional polyacrylamide substrates (substrate stiffness 14 kPa) display a rounded morphology compared to the cells cultured on stiffer substrates (substrate stiffness 30 kPa), which adopt a flat morphology (Lo et al., 2000). Usually, substrate stiffness similar to the native tissue yields a cellular phenotype similar to that tissue. Another polymer property that impacts cell–scaffold interactions is dimensionality and overall architecture. When compared to two-dimensional environments, a three-dimensional environment has been shown to lead to reduced cell adhesion to the substrate (Cukierman et al., 2001). In addition to impacting individual cell behavior, a three-dimensional environment also facilitates formation of a larger number of cell–cell contacts, allowing for cellular interactions that are often vital in tissue remodeling processes. A three-dimensional scaffold of the shape of native tissue is also desired, to define and guide the ultimate shape of the regenerated tissue.

Porosity, pore size, and interconnectivity of pores are morphological characteristics of scaffolds that have a direct influence on the cell-to-cell interactions, the surface area-to-volume ratio, and mass transport processes critical for cell survival. A high porosity is desirable to maximize the possible accommodation of cell mass and vascular infiltration; however, high porosity values often compromise the mechanical properties of the scaffold (Karageorgiou and Kaplan, 2005). Pore size is another important factor to consider, because it is known to influence the cellular infiltration, cell-to-cell interaction,

and transport of nutrients and metabolites (Mikos et al., 1993c). For a given porosity, smaller pore sizes lead to an increased surface area-to-volume ratio, resulting in a larger area available for cell attachment. The minimum pore size that will allow cellular infiltration, either during initial seeding or through cellular proliferation and migration, is dependent on cell size (roughly 10 μm); however, optimal pore sizes are almost always larger, and are dependent on the topological features of the scaffold. Moreover, pore sizes can also be controlled in order to facilitate the process of vascularization, and to reduce fibrotic tissue formation (Ratner, 2007). Recently, it was shown that monodisperse pore sizes of ~35 μm in poly(2-hydroxyethyl methacrylate) (PHEMA) scaffolds resulted in an improvement of the vascularization of the implants and a reduction in fibrotic tissue formation compared to ~20 μm or ~70 μm pore sizes for soft tissue regeneration (Marshall et al., 2004a,b). In addition to optimization of pore size and porosity, the geometry of the pore network must also be considered. An interconnected pore network is desired in order to minimize inaccessible pore volume, and the tortuosity of this network is an important determinant of mass transport rates. Pore geometries may also critically affect cellular organization in the scaffolds (Ma and Zhang, 2001; Zmora et al., 2002). For example, pores in the form of tubular guidance channels have been widely utilized to promote directed neurite growth.

One of the major engineering considerations in tissue regeneration is the mechanical stability of bioresorbable scaffolds. Usually, the mechanical properties of the scaffolds are required to be similar to the native tissue. A weak structure may not be able to withstand the biomechanical forces encountered *in vivo*, whereas a stiffer scaffold may lead to stress shielding, a phenomenon where transfer of physical load to the scaffold leads to insufficient mechanical stimulation of tissues surrounding the implant. In addition, due to the degradation of bioresorbable polymeric scaffolds, their mechanical properties change as a function of time, so control over the degradation of tissue engineering scaffolds is a highly desired feature. Degradation of polymeric scaffolds is dependent on several parameters, as listed in Table II.6.3.1 (also see Chapters I.2.6 and II.4.3). Polymers also differ in the mechanism through which they degrade, e.g., surface erosion, bulk erosion, enzymatic action. Ideally, the tissue–polymer construct should provide sufficient mechanical stability consistently throughout the process of reconstruction. In addition, the degradation rate determines the available space for tissue growth and implant integration with the host tissue. In an optimal scenario, the degradation rate of the scaffolds and the rate of tissue formation should be matched to provide consistent structural and mechanical stability to the transplant.

Another important consideration when designing a scaffold for any tissue engineering application is the selection of a suitable material with desired characteristics, which is discussed in the following section.

TABLE II.6.3.1	Important Factors that Influence Scaffold Degradation
Polymer characteristics	
Polymer composition	Polydispersity index
Chemical structure and functionality	Hydrophilicity
Morphology	Chain motility and orientation
Molecular weight	Charge density
Crystallinity	Presence of additives or impurities
Scaffold architecture	
Pore size	Mass
Porosity	Density
Surface area-to-volume ratio	Shape
Surface roughness	Size
Processing effects (if any)	Sterilization (γ-irradiation)
***In vitro* factors**	
Medium composition	Incubation temperature
Medium refreshment frequency	Mechanical loads
pH	Cell type and density
Ionic strength	Enzyme concentrations
***In vivo* factors**	
Site of implantation	Tissue modeling and remodeling
Nutrient diffusion	Mechanical loads
Access to vasculature	Metabolism of degraded products
Dynamic pH	Enzyme concentrations

SCAFFOLD MATERIALS

Material selection for tissue engineering applications is based on several important factors including biocompatibility, surface characteristics, degradability, processability, and mechanical properties (see review by Thomson et al., 1995a). Synthetic bioresorbable polymers constitute a set of polymers that provide extreme versatility with regard to control over their physicochemical properties, and are generally easy to process into tissue engineering scaffolds. Synthesis of these polymers can be tailored to yield a specific molecular weight, chemical structure, end group chemistry, and composition (homopolymers, copolymers, and polymer blends).

A range of bioresorbable polymers have been explored for potential application in tissue engineering (for reviews, see Babensee et al., 1998; Gunatillake and Adhikari, 2003; Martina and Hutmacher, 2007) (Table II.6.3.2) (Chapter I.2.6). Among these, polyesters have been most widely investigated. Poly(α-hydroxy esters) (such as poly(lactic acid) (PLA), poly(glycolic acid) (PGA), and poly(lactic-co-glycolic acid) (PLGA)) have attracted extensive attention for a variety of biomedical applications. The ease of processability of these polymers into various shapes is a major advantage. However, there is a known concern that their degradation products may lead to a drop in local pH, creating an acidic environment that may harm cells and tissues. Moreover, the degradation products may also catalyze the degradation of these polymers, resulting in different

degradation rates depending on the removal of these products (Li et al., 1990). Copolymers that combine poly(α-hydroxy esters) with amino acids, such as block copolymers of poly(lysine-co-lactic acid), have been produced that allow the addition of cell adhesion peptides to lysine groups (Cook et al., 1997). Another important class of polyesters are polylactones, among which

TABLE II.6.3.2	Scaffold Materials, and Example Applications[a]
Materials	**Example Areas of Applications**
Polyesters	
Poly(glycolic acid) (PGA)	Bone, cartilage, liver, tendon, urothelium, and intestinal tissue engineering
Poly(L-lactic acid) (PLLA)	Bone, cartilage, ligament, and neural tissue engineering
Poly(D,L-lactic-co-glycolic acid) (PLGA)	Bone, cartilage, urothelium, and neural tissue engineering
Poly(lysine-co-lactic acid)	Bone, cartilage, and neural tissue engineering

[a]Partially adapted and reproduced with permisson from Gunatillake and Adhikari (2003), and Martina and Hutmacher (2007).

poly(ε-caprolactone) (PCL) has been the most utilized as a tissue engineering scaffold. Blends and block copolymers of PCL with other poly(α-hydroxy esters) (such as poly(L-lactic acid-co-ε-caprolactone) (PLLACL) or poly(D,L-lactic acid-co-ε-caprolactone) (PDLLACL)) have been used to produce polymers with tailored properties, such as degradation rate. Polydioxanone is a bioresorbable poly(ether-ester), which has been used in fiber forms for fixation and other applications (Boland et al., 2005; Smith et al., 2008). Poly(propylene fumarate) (PPF), an unsaturated linear polyester based upon fumaric acid, has also been explored as part of an injectable formulation in tissue engineering applications (Timmer et al., 2003a,b). Cross-linking agents and initiation mechanisms (photoinitiation or thermal initiation) can be altered to form PPF networks of desired properties (Peter et al., 1999; He et al., 2000; Fisher et al., 2002a). Several composites and copolymers of PPF have been developed and investigated, mainly for bone tissue engineering and drug delivery applications.

To increase wettability, biocompatibility, and/or softness of bioresorbable polymers, blends and copolymers with non-degradable poly(ethylene glycol) (PEG) have been developed, such as block copolymers of PEG with PLLA, PLGA, and PCL (for reviews, see Hoffman, 2002; Baroli, 2007). Injectable, *in situ* forming hydrogels based on PEG, such as oligo[poly(ethylene glycol) fumarate] (OPF), have also been developed and investigated. An OPF-based hydrogel is biodegradable and demonstrates a high degree of swelling (Jo et al., 2001; Temenoff et al., 2002, 2003). These hydrogels have been recently investigated for bone, cartilage, and osteochondral tissue engineering applications (Shin et al., 2003; Holland et al., 2005; Kasper et al., 2006; Guo et al., 2009).

In addition to those derived from polyesters, a number of bioresorbable materials have been developed from various other polymer families. Many amorphous and soluble pseudo-poly(amino acids) (amino acids linked by both amide and non-amide bonds) have been processed into tissue engineering scaffolds, such as polycarbonates and polyacrylates. Polyanhydrides and poly(anhydrides-co-imides) have been vastly studied for drug delivery, and for use as hard tissue substitutes (Gunatillake and Adhikari, 2003). Degradable polyurethanes and their copolymers have been investigated for skin and other soft tissue engineering and replacement applications (Bruin et al., 1990; Spaans et al., 2000). Polyorthoesters have been used in bone tissue engineering and drug delivery (Andriano et al., 1999; Wang et al., 2004; Nguyen et al., 2008), and lastly, polyphosphates and polyphosphazenes have been mainly used in scaffolds for bone tissue engineering applications (Brown et al., 2008a; Nukavarapu et al., 2008; Deng et al., 2010).

To summarize, a wide variety of synthetic bioresorbable polymers have been investigated for their potential application in tissue engineering. Material selection is a critical factor of the scaffold design for an intended tissue

engineering application. The following section briefly discusses a few established strategies for scaffold-assisted tissue regeneration.

APPLICATIONS OF SCAFFOLDS

Tissue Induction

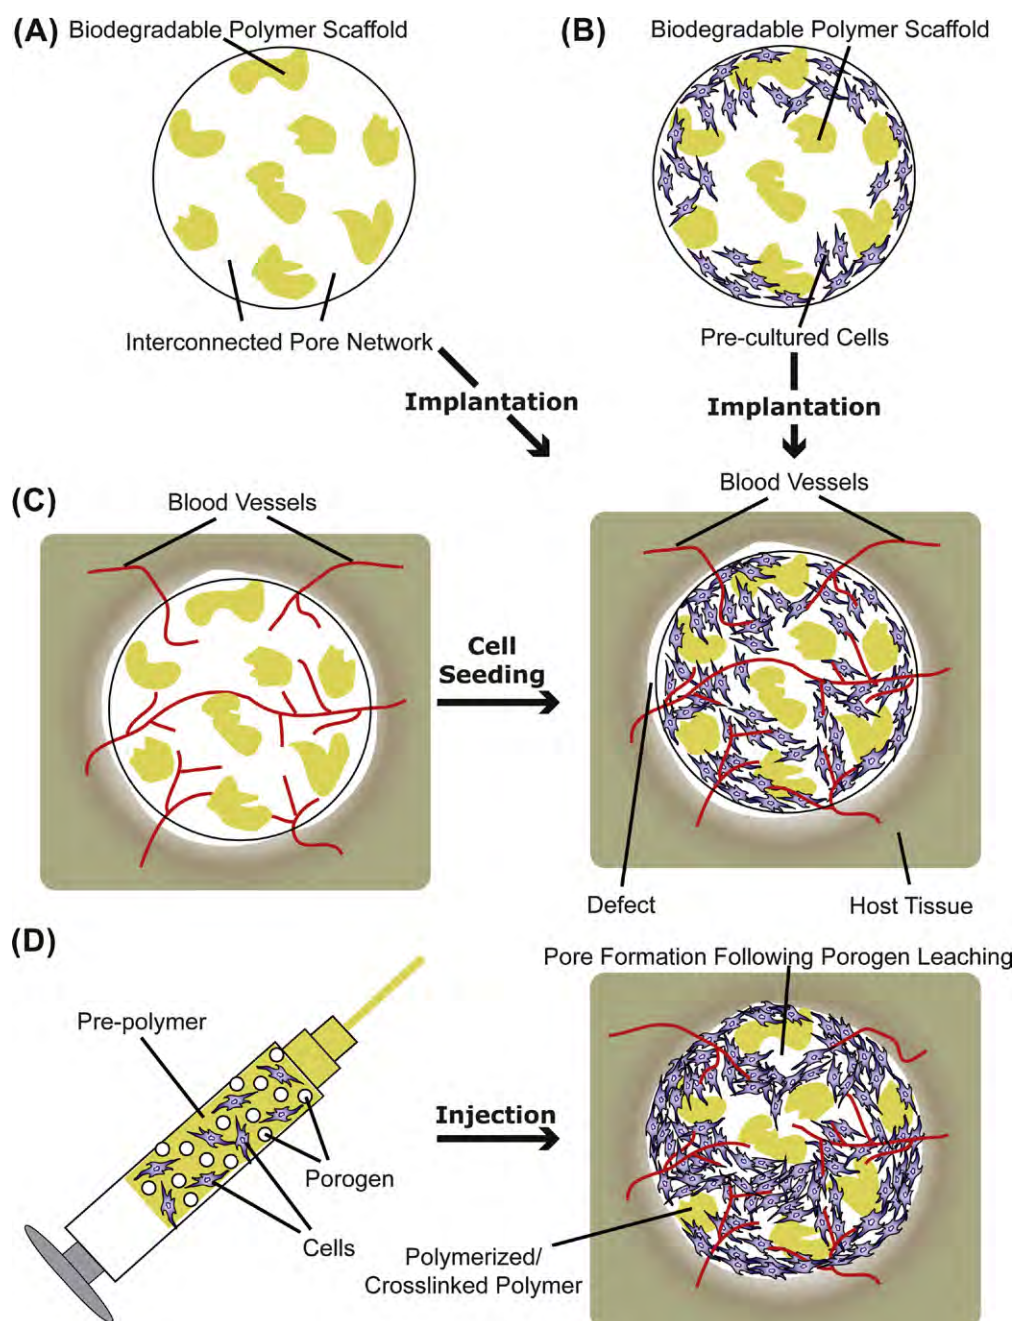
After implantation, a porous acellular three-dimensional scaffold can act as a substrate to allow infiltration and ingrowth of the surrounding host tissue, a process known as tissue induction (Figure II.6.3.1A). For instance, an osteoinductive material has the property of promoting pre-osteoblast infiltration and bone induction. Tissue induction is commonly marked by events of host cell migration, proliferation, and differentiation, as well as vascularization. This scaffold-based approach has the potential of offering an "off-the-shelf" solution for defect repair in the form of implantable acellular devices. The selection of a material and scaffold design (such as pore size and porosity), however, are important factors that can affect the selectivity and extent of tissue induction. Regeneration of various tissues including skin, bone, ligament, and nerve has been investigated using this approach.


FIGURE II.6.3.1 Polymeric scaffolds in tissue engineering applied in prefabricated (A–C) or injectable form (D). Specific applications of prefabricated scaffolds: (A) tissue induction; (B) cell transplantation; and (C) prevascularization.

Cell Transplantation

Cell transplantation is a sub-class of cell-based therapies, where cells placed on a two-dimensional or in a three-dimensional polymeric scaffold facilitate the repair or regeneration of damaged tissue. In this approach, cells obtained from a donor site in a patient are harvested, expanded in culture, seeded onto an appropriate scaffold, and then transplanted to the defect site (Cima et al., 1991; Bancroft and Mikos, 2002) (Figure II.6.3.1B). In most practices, the cells are allowed to attach to the construct, and are cultured for a period of time to allow them to proliferate and/or differentiate before implantation. When using cell transplantation, an appropriate choice of material that favors the attachment and growth of seeded cells and integration of the transplant with the host tissue is critical. Using this approach, transplantation of a variety of differentiated cell types including osteoblasts, chondrocytes, fibroblasts, hepatocytes, and smooth muscle cells has been pursued. Due to the donor site morbidity often associated with the harvest of differentiated cells, transplantation of undifferentiated or pre-differentiated autologous adult stem cells (such as mesenchymal stem cells) has also been investigated. When engineering heterogeneous interfacial structures, a cell transplantation approach can be used to design multiphasic scaffolds containing more than one cell type regionalized spatially into the different phases of the scaffold along its axis (Cao et al., 2003; Schek et al., 2004; Chen et al., 2006; Spalazzi et al., 2008). Recently, a multilayered scaffold design has also been applied for pancreatic islet encapsulation in PEG-based hydrogels, where an additional outer layer serves as an immunoprotective barrier to minimize graft–host interaction (Weber et al., 2008). By using genetically modified cells that are programmed to produce desired bioactive factors at the site of interest, this approach also offers the possibility of simultaneous *in situ* delivery of cells and bioactive factors that may enhance the tissue regeneration process (Gilbert et al., 1993; Blum et al., 2003).

Prevascularization

Nutrient diffusion in a scaffold is generally restricted to a few hundred micrometers from the scaffold edge, which imposes one of the major challenges for the regeneration of large three-dimensional organs, such as the liver (Mooney and Mikos, 1999). Development of bioreactor technology has imparted the ability to grow large constructs *in vitro*, as discussed later. However, most of the cultured cells do not survive when implanted *in vivo* without their own blood vessels to supply nutrients and oxygen (Mooney and Mikos, 1999). Post-implantation scaffold vascularization may take place, but the rate may not be sufficient to prevent cell death and tissue necrosis, especially in the core of the scaffold. Bioactive factor delivery strategies (discussed later) have been utilized

to expedite the vascularization process in polymeric scaffolds via the delivery of angiogenic factors such as vascular endothelial growth factor (VEGF) and basic fibroblast growth factor (bFGF) (Lee et al., 2002; Peattie et al., 2006; Patel et al., 2008), or by delivering gene expression vectors (e.g., plasmid DNA) that may allow the cells to produce such angiogenic factors *in situ* (Geiger et al., 2005). Co-culture of endothelial or progenitor cells with the cells of interest is another avenue of research to induce vascularization in the engineered tissue *in vitro* (see review by Lovett et al., 2009), which may help in the generation of a vascular network early after implantation. To promote sufficient vascularization of the implants, an alternate and effective strategy is to prevascularize a porous scaffold by first implanting it in a highly vascular site where the ingrowth of fibrovascular tissue or vascular tissue may take place by tissue infiltration. These prevascularized implants can then be seeded with cells and transplanted to the site of interest (Figure II.6.3.1C). Scaffold properties (such as pore size and morphology) are important factors that influence the extent of prevascularization, and determine the availability of space for cell seeding and tissue infiltration in the prevascularized implant (Mikos et al., 1993c). Apart from the regeneration of large organs, this strategy has also been applied for the treatment of critical-sized osseous defects. Prevascularized bone flaps were fabricated via ectopic bone formation by suturing an open chamber containing a mixture of a bioresorbable polymer and osteoinductive morcellized bone graft onto the cambium layer of the periosteum at a location remote from the defect site (Thomson et al., 1999), which may then be transplanted to the defect site and anastomosed to the host vasculature via microsurgery. An associated limitation of the prevascularization approach is that it requires multiple surgical procedures.

Injectable Systems for Minimally Invasive Tissue Engineering

In situ cross-linking biomaterials consist of space-filling injectable precursors, which solidify by cross-linking in the defect site (Figure II.6.3.1D). One method of classifying *in situ* cross-linking materials is based on the initiation mechanism of cross-linking, e.g., thermal initiation (such as PPF and OPF), photoinitiation (such as PEG-diacrylate (PEG-DA) or PPF), and ionic interaction (such as alginate or charged PLGA nanoparticulates) (for reviews see Hou et al., 2004; Kretlow et al., 2007; Van Tomme et al., 2008). Thermogelling polymers also fall under the category of injectable polymers; however, they undergo gelation by virtue of physical transition upon a sufficient temperature change (such as copolymers of poly(*N*-isopropylacrylamide) or poly(ethylene oxide-*b*-propylene oxide-*b*-ethylene oxide)) (Ruel-Gariepy and Leroux, 2004). One of the major advantages of *in situ* cross-linking materials is that they can be administered

in a minimally invasive manner. Moreover, they also lend themselves to drug and cell delivery purposes, which can be achieved, under proper conditions of solidification, by simple mixing of cells and/or bioactive factors in the precursor solution (Kretlow et al., 2007). However, there are several additional design criteria that must be met, such as cytocompatibility of all the constituents, suitable rheological properties of the precursor solution, curing time, and polymerization conditions (e.g., temperature, pH, duration of exposure to the initiating wavelength of light, and heat release) that do not negatively impact the implanted cells and the surrounding tissue (Hou et al., 2004).

To facilitate cellular infiltration and guided tissue growth, an *in situ* cross-linking three-dimensional scaffold can be made highly porous via several methods, including particulate leaching or gas foaming (discussed later) (Peter et al., 1998; Behravesh et al., 2002). Since increased porosities usually lead to a reduction in mechanical properties, the mechanical properties of such materials can be tailored in an application-specific manner by either inclusion of micro- or nanophase materials that provide mechanical reinforcement or by varying the cross-linking mechanism, cross-linking agent, and/or cross-linking density (Timmer et al., 2003b; Shi et al., 2006). However, changes in the precursors or reaction/gelation conditions must be made so as to avoid any adverse reaction on the implanted cells or surrounding tissue. For example, an excessive concentration of the porogen salts, leachable components or cross-linking agents may not be suitable for implanted cells or surrounding host cells. In such cases, an alternate strategy of cell transplantation has been developed, where cells are encapsulated in a cytocompatible environment (in this case, gelatin microspheres) that is then included in the precursor solution to form a composite material (Payne et al., 2002a,b). Similar strategies have been widely applied for the delivery of bioactive factors, where bioresorbable micro- or nanoparticles loaded with bioactive agents can be included in the precursor solution to support sustained temporal release, as discussed in the following section.

Delivery of Bioactive Molecules

Bioactive molecules comprise many soluble molecules, including growth factors, angiogenic factors, cytokines, hormones, DNA, siRNA, and immunosuppressant drugs, which interact with and modulate the activity of a cell (Holland and Mikos, 2003; Kasper and Mikos, 2004). For instance, early in embryonic development, the fate of the uncommitted cells towards the formation of tissue patterns is governed by the spatiotemporal expression of specific signaling molecules, referred to as morphogens (Gurdon and Bourillot, 2001). Delivery of bioactive molecules is often desirable to induce tissue formation and/or selectively modulate various cellular activities, such as cell proliferation, differentiation or ECM production. For example, bone morphogenetic proteins (BMPs) constitute a family of proteins that have been exploited to enhance osteogenesis by bone cells (Cheng et al., 2003). *In vitro*, these bioactive factors are usually delivered in their soluble forms via the cell culture media. However, to administer such tissue inducing factors *in vivo* locally in a controlled manner, the concept of incorporating these factors into tissue engineering scaffolds has evolved. One approach is to deliver the bioactive factors directly from the supporting matrix (Figure II.6.3.2A). Another approach is to bind these molecules to the substrate surface at the time of scaffold processing (Figure II.6.3.2B). One of the most widely used examples is the use of cell adhesion molecules (such as RGD and YIGSR peptide sequences) covalently linked to the scaffold that provide attachment sites for anchorage dependent cells (see review by Hersel et al., 2003). Similarly, many growth and differentiation factors lead to an increase in desired cellular responses when they are linked covalently to the polymer substrate, as compared to the soluble forms (Hubbell, 2007). For example, recently it was shown that survival of mesenchymal stromal cells (MSCs), osteogenic colony formation of human bone marrow aspirates, and osteogenic differentiation of MSCs were all enhanced in the presence of epidermal growth factor
FIGURE II.6.3.2 Localized delivery of bioactive factors. (A) Bioactive factors released directly from a scaffold. (B) Bioactive factors chemically conjugated to the surface of a scaffold. (C) Localized production of bioactive agents by genetically modified cells seeded in a scaffold. (D) Controlled delivery of bioactive factors from a carrier (such as microparticles or nanoparticles) dispersed within the porosity of a scaffold.

(EGF) covalently attached to the substrate, as compared to the soluble EGF (Fan et al., 2007; Marcantonio et al., 2009; Platt et al., 2009). Alternatively, bioactive factors can be produced *in situ* using genetically modified cells seeded in the scaffold matrix that produce bioactive factors locally at the site of interest (Gilbert et al., 1993; Blum et al., 2003; Macdonald et al., 2007) (Figure II.6.3.2C). To achieve temporal control over the release of the bioactive factors (e.g., a sustained release over a desired period) in the scaffold, these molecules can be loaded in a carrier, such as bioresorbable micro- or nanoparticles (Figure II.6.3.2D) (Hedberg et al., 2002; Panyam and Labhasetwar, 2003; Kasper et al., 2005). More recently, lipid-based microtubular devices have also been explored as carriers for the delivery of plasmid DNA and growth factors (Meilander et al., 2003; Jain et al., 2006; Johnson et al., 2009). The release of bioactive factors from the carrier *in vivo* can be a function of many factors, such as molecular diffusion, degradation rate, and local enzyme concentration and activity (for polymers such as gelatin, a naturally derived polymer that degrades through enzymatic action) (Hedberg et al., 2002; Johnson et al., 2009). Depending on the application, the aforementioned delivery strategies also lend themselves to the delivery of multiple growth factors with desired release profiles (Richardson et al., 2001). For example, to explore the synergistic effects of simultaneous delivery of angiogenic and osteogenic proteins, dual growth factor delivery of VEGF and BMP-2 via a scaffold was achieved using acidic and basic gelatin microspheres as carriers, respectively (Patel et al., 2008). Spatial control over the expression of bioactive factors within a scaffold is desirable for the engineering of heterogeneous tissue structures (such as osteochondral tissue). For such applications, spatial patterning of bioactive factors at the time of scaffold processing is possible (Holland et al., 2005, 2007; Guo et al., 2009). Many such heterogeneous scaffold designs with biphasic, multiphasic or graded distribution of bioactive agents are currently under investigation, with the intention of controlling the spatiotemporal release of single or multiple growth factors.

In summary, the basic function of a tissue engineering scaffold is to provide a three-dimensional environment for tissue growth. Addition of other features to a scaffold (e.g., drug carrying ability or injectibility) imparts another degree of functionality to the scaffold that makes it more suitable for certain applications. In the following section, an overview of general scaffold fabrication techniques is provided.

SCAFFOLD PROCESSING TECHNIQUES

Various manufacturing methodologies have been developed to form porous three-dimensional substrates. In each of these techniques, one or more bioresorbable polymers of desired characteristics are processed uniquely to produce porous three-dimensional structures of particular shapes and morphologies (Hutmacher, 2000) (Table II.6.3.3). Polymer processing steps usually involve: (1) heat-assisted fusion/melting of the polymers above their glass transition or melting temperatures; (2) dissolution in organic solvents; (3) treatment with gases or supercritical fluids under high pressure; and/or (4) porogen (such as salt crystals, soluble microspheres or wax) leaching. Scaffold shape and morphology, mechanical

TABLE II.6.3.3	**Fabrication Techniques for Three-Dimensional Scaffold Production, Required Polymer Characteristics, Geometry Produced, and Example Materials Processed[a]**		
Processing Technique	**Required Polymer Characteristics**	**Structures**	**Examples**
Fiber bonding	Thermoplastic or soluble	Thin foams or membranes	PGA fibers, PLA/PLGA coated PGA fibers
Solvent casting and particulate leaching	Soluble	Thin foams/mold-specific	PLA, PLGA, PPF foams
Superstructure engineering	Thermoplastic or soluble	Three-dimensional structures	PLA and PLGA membranes, sintered PLGA microspheres
Compression molding	Thermoplastic	Mold-specific	PLA, PLGA foams
Extrusion	Thermoplastic	Fixed cross-sectional profile	PLA, PLGA conduits
Freeze-drying	Soluble	Mold-specific	PLGA, PLGA/PPF foams
High internal phase emulsion templating	Soluble[b]	Mold-specific	PPF, poly(lactic acid-*co*-styrene), poly(ε-caprolactone-*co*-styrene)
Phase separation	Soluble	Mold-specific	PLA, PLGA foams
Gas foaming at near-critical conditions	Amorphous	Mold-specific	PLGA foams
Supercritical fluid processing	Amorphous	Mold-specific	PLA, PLGA foams
Solid freeform fabrication	Thermoplastic or soluble	Shape-specific	Complex three-dimensional structures of PLA, PLGA
Electrospinning	Soluble	Aligned or random fibers	PLA, PGA, PLGA, PCL fiber-based sheets and conduits

properties, and biocompatibility are greatly influenced by the choice of scaffold processing technique. A majority of these techniques allow for the incorporation of bioactive molecules into the polymer matrix. However, due to exposure to harsh chemical and thermal environments, retention of the bioactivity for sustained drug release has been a significant challenge. In the following sections, some established scaffold fabrication techniques are presented.

Fiber Bonding

Fiber-based technologies for scaffold fabrication have been very appealing, due to the large surface area-to-volume ratio that they provide, their early commercial availability, and the ease of fabrication of the fibers by industrial processes (such as hot drawing) (Freed et al., 1994). PGA fiber-based tassels and felts were some of the earliest constructs produced for organ regeneration purposes (Vacanti et al., 1991). However, the mechanical instability of such structures imposed a limitation on their *in vivo* application. To address this issue, a method was developed to fabricate bonded fiber networks of high porosities (up to 81%) (Mikos et al., 1993a). With this method, a non-bonded PGA fiber mesh is immersed in a PLA solution in methylene chloride. Following the evaporation of the organic solvent, the PLA–PGA composite is heated above the melting temperature of PGA. PGA fibers melt and bond with other PGA fibers at their contact points, while the molten PLA provides a structural casing around the fibers that prevents them from collapsing. PLA is finally removed by selective dissolution in methylene chloride, leaving the PGA fibers in an interlocked structure. Due to the specificity of the fiber bonding method with regard to the two polymers selected (they must be immiscible with appropriate relative melting temperatures) and to the solvent, the general use of this technique is precluded.

An alternate method of fiber bonding has also been developed, where PGA fibers are bonded by spray casting an atomized solution of PLA or PLGA in chloroform over the PGA fiber mesh placed on a rotating Teflon® mold (Mooney et al., 1996b). The PGA fibers are coated with a thin layer of sprayed polymer, which bonds the fibers at their cross-points. Solvent evaporation results in the formation of a thin tubular conduit made of bonded fibers. Such conduits were shown to support fibrovascular tissue in-growth following implantation (Mooney et al., 1996b). This fabrication technique, although useful for the preparation of thin fiber matrices, does not generally allow for the creation of complex three-dimensional structures. With the advent of computerized scaffold fabrication methodologies, complex fiber-based structures have now been created using solid freeform fabrication techniques, such as fused deposition modeling, as discussed later.

Solvent Casting/Particulate Leaching

Some of the drawbacks of fiber bonding techniques were addressed by the development of a new method, a solvent casting and particulate leaching (SC/PL) technique, which provides desired control over the porosity, pore size, surface area-to-volume ratio, and crystallinity of the prepared porous scaffolds (Mikos et al., 1994b). In an example of this method, sieved salt particles are dispersed in a solution of PLA dissolved in chloroform, which is used to cast a membrane on a platform (such as a glass petri dish). Following solvent evaporation, the dry polymer–salt composite is heated above the melting point of the polymer, then annealed or quenched at controlled cooling rates to produce a semicrystalline or amorphous polymer composite. The composites are then placed in water to leach out the salt particles, and subsequent drying yields polymer membranes that are highly porous. Regulation of the porogen-to-polymer weight ratio, porogen size, and cooling rate during the annealing/quenching step provides independent control over the production of scaffolds with desired porosity, pore sizes, and crystallinity, respectively. For example, PLA membranes fabricated using the SC/PL technique demonstrated porosities up to 93%, and median pore diameters up to 500 μm (Mikos et al., 1994b). Scaffolds produced using the SC/PL technique have been shown to support cell attachment and growth *in vitro*, as well as *in vivo* (Ishaug-Riley et al., 1997, 1998).

While the SC/PL technique is simple and inexpensive, extensive use of organic solvents during fabrication limits the possibility of using these matrices as carriers of specific bioactive agents. Moreover, the method is restricted to producing brittle thin membranes (up to 3 mm) (Wake et al., 1996). In one variation, blending of PEG with PLGA for the SC/PL technique resulted in an improvement in the pliability of the resulting membranes (Wake et al., 1996). In another method, thick scaffolds were constructed using particulate hydrocarbon wax as a porogen (Shastri et al., 2000). In this case, a mixture of viscous polymer solution and porogen is placed in a Teflon® mold. A hydrocarbon solvent (such as pentane or hexane) treatment is then used for selective extraction of the porogen from the mold, leaving a porous polymer foam matrix. PLA- and PLGA-based scaffolds fabricated using this method demonstrated porosities up to 87% and pore sizes above 100 μm, and this process supports the construction of thick shape-specific scaffolds.

In general, the SC/PL technique can be extended to any bioresorbable polymer that is soluble in an appropriate solvent (e.g., methylene chloride or chloroform), such as PLA or PLGA. In addition, a modified method of thermal cross-linking/particulate leaching has also been applied for cross-linkable polymers such as PPF. For example, by cross-linking the PPF in the presence of salt particles that are eventually leached in water, PPF

scaffolds with porosities up to 75% and pore sizes in the range of 300–800 µm were prepared (Fisher et al., 2003). These scaffolds can be processed to allow for the incorporation of bioactive factors, and have been investigated for *in vivo* use in soft and hard tissue replacements (Fisher et al., 2002b; Hedberg et al., 2002, 2005). In addition, by incorporating another material phase (such as β-tricalcium phosphate or single-walled carbon nanotubes) in the scaffold design, reinforced porous PPF-based composite scaffolds can also be constructed to yield improved mechanical characteristics (Peter et al., 1997; Shi et al., 2005).

Superstructure Engineering

Superstructure refers to a three-dimensional structure made of superimposed two-dimensional structural elements such as fibers, pores or microspheres, which are ordered in a periodic, stochastic or fractal pattern (Wintermantel et al., 1996). Both individual elements and the pattern of organization determine the characteristics of the scaffold. Stable superstructures can be created from reproducible individual elements, the coherence of which determines the anisotropic structural behavior of the constructs (Wintermantel et al., 1996). An example of a superstructure is a three-dimensional structure produced by multiple stacked membranes fabricated using a membrane lamination process (Mikos et al., 1993b). In this method, individual membranes prepared by a SC/PL method are bonded together using chloroform on their contact surface to yield a shape-specific three-dimensional structure. Periodic arrangement of polymer microspheres is another simple example of a superstructure made of microspheres as the structural element. Recently, a variety of methods have been employed to produce polymer microsphere-based scaffolds by sintering the microspheres packed in a mold (Borden et al., 2004; Brown et al., 2008a; Jaklenec et al., 2008; Singh et al., 2008b, 2010). Here, the size of the microspheres and their packing configuration determines the coherence of the structure. For example, monodisperse microspheres in a cubic lattice yield a stable isotropic structure.

Compression Molding

Compression molding is a scaffold fabrication technique used with thermoplastic polymers. In an example of the compression molding technique, PLGA powder is mixed with gelatin microparticles and loaded in a Teflon® mold (Thomson et al., 1995b). The mixture is heated above the glass transition temperature of the amorphous polymer, while being compressed under a constant force. The composite is then removed from the mold, and the embedded gelatin is leached out in water. Porosity and pore sizes of the PLGA scaffolds thus produced can be varied selectively by altering the initial gelatin loading and gelatin microsphere size, respectively. This method

avoids the use of any organic solvents, and may allow for the incorporation of bioactive factors in the polymer or porogen phase when performed at relatively low temperatures. By changing the mold geometry, it is also possible to prepare shape-specific scaffolds.

Several variations of compression molding exist. To extend the application of this process to bioresorbable semicrystalline polymers, such as PLA or PGA, a similar compression molding method has been use in which the mixture of polymer and porogen is heated above the melting temperature of the polymer. Melt-based compression molding has also been widely applied to create blends of polymers. Retention of the biological activity of bioactive factors at such elevated temperatures, however, is difficult. In another variation, compression molding can be applied together with the SC/PL technique to fabricate porous three-dimensional foams. In this method, solid pieces of polymer–salt composites are obtained by drying the cast polymer–salt solution or by coagulating it in an anti-solvent (Widmer et al., 1998; Hou et al., 2003). Particulate polymer–salt composites (<5 mm edge length) can then be compression molded, and subsequent salt leaching results in an open-cell foamed three-dimensional porous scaffold. This method has been shown to result in a relatively homogeneous pore morphology compared to the SC/PL method. Compared to the compression molding method, the SC/compression molding/PL method also offers the possibility of fabricating composites with another solid phase homogeneously distributed in the foamed three-dimensional structure. Using this method, foamed three-dimensional scaffolds reinforced homogeneously with osteoconductive hydroxyapatite microfibers were produced, and these demonstrated superior compressive strength compared to non-reinforced scaffolds of the same porosity within a certain range of polymer-to-fiber ratios (Thomson et al., 1998). Such a variation in scaffold fabrication is favorable for bone tissue engineering applications, because both incorporation of osteoconductive elements and improvement in mechanical properties are desired characteristics.

Extrusion

Extrusion is a well-known process applied to form objects of a predefined fixed cross-section; it has been used to process thermoplastic bioresorbable polymers for three-dimensional scaffold fabrication with macroscale cross-sectional areas (>1 mm). Processing of polymers using various extrusion methods, such as solid-state extrusion (die drawing), cylinder-piston (ram) extrusion or hydrostatic extrusion, generally changes the polymer chain orientation, leading to increases in their strength and modulus of elasticity (Ferguson et al., 1996). Using a mixture of polymer powders, extrusion methods can be readily applied to create solid blends of polymers. To create porous scaffolds, an SC/melt–extrusion/PL

technique has been developed (Widmer et al., 1998). Dry polymer–salt composites produced by SC are cut into pieces (<5 mm edge length) and placed in a custom piston extrusion tool connected to a hydraulic press. The polymer is heated to the desired processing temperatures and equilibrated, then extruded by applying pressure using the hydraulic press to produce tubular constructs. Constructs of desired length are cut from the tube, and are then placed in water for salt leaching. Porous tubular conduits thus produced have been used for guided tissue engineering applications, including peripheral nerve regeneration (Evans et al., 2002). As with the SC/PL techniques, porogen-to-polymer weight ratio and porogen size can be selectively altered to produce scaffolds of desired porosity and pore sizes, respectively. In addition, processing temperature is another important variable that influences the pressure required for extrusion, and can influence the scaffold morphology and thermal degradation of the scaffold.

Freeze-Drying

Freeze-drying is a simple approach for polymer foam fabrication. The polymer is dissolved in a solvent such as benzene or glacial acetic acid, then frozen and lyophilized under high vacuum to remove the dispersed solvent (Hsu et al., 1997). Depending on the polymer–solvent system used, the resulting scaffolds demonstrate leaflet or capillary-like microfeatures. Several materials, including PLA, PLGA, and PLGA/PPF, have been used to fabricate polymer foam scaffolds using this method (Hsu et al., 1997). These scaffolds usually have a random pore structure and network. Due to their low density and pore connectivity, further processing, such as grinding and extrusion, is usually required to fabricate matrices useful for application.

An emulsion freeze-drying method is very similar to the freeze-drying approach; however, it involves the formation of an emulsion (Whang et al., 1995). The polymer is first dissolved in a solvent; then water is added to form a water-in-oil emulsion. The polymer is subsequently quenched in liquid nitrogen and freeze-dried to remove the dispersed water and solvent. Important process parameters include the polymer–solvent system, molecular weight of the polymer, polymer solution-to-water ratio, and emulsion viscosity. Using this technique, PLGA (methylene chloride as solvent) and PLA (dioxane as solvent) scaffolds with porosities greater than 90% have been prepared (Whang et al., 1995; Hu et al., 2002). Compared to the SC/PL technique, the emulsion freeze-drying method produces foams with a lower median pore diameter and higher specific pore surface area.

Another class of emulsion-derived porous polymeric foams known as polyHIPEs (Barby and Haq, 1982) are formed by a high internal phase emulsion templating method (see review by Cameron, 2005). A high internal phase emulsion (HIPE) consists of a monomer (external)

phase and a droplet (internal) phase, and is defined by a characteristic internal phase volume fraction of at least 0.74 (Lissant, 1974). In this method, the continuous macromer phase is first polymerized around a template of the droplet phase, and subsequent removal of the droplet phase results in the formation of a porous polyHIPE. Many polyHIPEs have been recently investigated for their tissue engineering applications, including polyHIPEs based on PPF, poly(lactic acid-*co*-styrene), and poly(ε-caprolactone-*co*-styrene) (Busby et al., 2001, 2002; Christenson et al., 2007). Factors that govern pore size, pore interconnectivity, and porosity of the polyHIPEs include composition of the HIPE (e.g., composition and viscosity of the two phases, volume fraction of the droplet phase), the droplet radius, molecular weight of the macromer, and cross-linker density.

Phase Separation

In the thermally-induced liquid–liquid phase separation technique, the polymer is first dissolved in a solvent that has a low melting point and that can be easily sublimed (such as molten phenol, naphthalene or dioxane) (Lo et al., 1995; Nam and Park, 1999a,b). Lowering the solution temperature below the melting point of the solvent leads to liquid–liquid phase separation, and later quenching of the phase-separated solution creates a two-phase solid. Subsequent removal of the solvent via freeze-drying for several days results in a porous polymeric scaffold. There are several process variables that can affect the morphology of the scaffolds, including the polymer–solvent system, polymer concentration, molecular weight, and cooling rate. For example, this technique was used to prepare polymer foams with porosities greater than 90% and pore sizes close to 100 μm (Nam and Park, 1999a). This process also allows the incorporation of bioactive factors, which can be homogeneously mixed in the polymer solution before inducing phase separation (Nam and Park, 1999a). Depending on the choice of solvent, however, the bioactive factors may become denatured and lose some of their activity (Lo et al., 1995). More recently, phase separation has also been utilized to produce interconnected nanostructured networks (Chen and Ma, 2004; Yang et al., 2004). Using tetrahydrofuran as a solvent, PLA nanofibrous scaffolds were produced via phase separation with fibers in the range of 50–300 nm, and were shown to support neural stem cell differentiation and neurite outgrowth (Yang et al., 2004). It is, however, difficult to control the orientation of the fibers produced in such nanostructured networks (Murugan and Ramakrishna, 2007).

Gas Foaming and Supercritical Fluid Processing

Processing of many bioresorbable amorphous polymers with gases at ambient temperature and high (critical,

near-critical or sub-critical) pressures has offered an alternative method for porous scaffold fabrication. Specifically, carbon dioxide (CO_2) has been most widely used, as it is inexpensive, non-toxic, non-flammable, recoverable, and reusable. The polymer is first saturated with CO_2 at high pressures in a vessel, which is followed by depressurization to ambient levels that results in nucleation of the gas, forming pores in the material. The amount of dissolved CO_2, the rate and type of gas nucleation, and the rate of gas diffusion to the pore nuclei are factors that primarily determine the pore structure and porosity of the resulting scaffold. Application of gas foaming (GF) at near-critical pressures (5.5 MPa) has been shown to produce highly porous scaffolds (>90% porosity and around 100 μm pore size) from pre-processed solid PLGA discs (Mooney et al., 1996a), and the technique has also been shown to allow the retention and delivery of active growth factors (Sheridan et al., 2000). In contrast to gas foaming at near-critical conditions, supercritical CO_2 (T_c = 304.1 K, P_c = 73.8 bar) absorbs into and liquifies many materials by lowering their glass transition temperatures (Jung and Perrut, 2001), and a supercritical fluid processing method has been used to incorporate bioactive factors and/or cells at the time of scaffold fabrication in a single step (Howdle et al., 2001; Ginty et al., 2006). Although these foaming techniques are advantageous over temperature-regulated or organic solvent-assisted scaffold fabrication for the incorporation of bioactive factors, an inherent limitation is the closed-cell structure and lack of pore interconnectivity. This problem was addressed by a modified technique of gas foaming/particulate leaching (GF/PL), where porogens (NaCl) included at the time of processing were leached out following gas foaming, resulting in an open pore structure of macropores (effected by porogen leaching), along with a non-interconnected microporous network (Harris et al., 1998; Murphy et al., 2000). The matrices produced demonstrate a relatively homogeneous pore structure, and higher mechanical strength than those fabricated with SC/PL.

In lieu of direct processing of polymers with CO_2, on-site production of CO_2 and foaming can be achieved using effervescent salts (Nam et al., 2000). For example, a combination of ascorbic acid, ammonium persulfate, and sodium bicarbonate was used to form highly porous hydrogels for bone tissue engineering (Behravesh et al., 2002), and these foams demonstrated excellent compatibility for marrow stromal cell differentiation and production of bone matrix *in vitro* (Behravesh and Mikos, 2003).

Solid Freeform Fabrication

Solid freeform fabrication (SFF), also known as rapid prototyping (RP), refers to a set of automated computer-assisted fabrication technologies, which have been utilized to produce porous three-dimensional scaffolds using bioresorbable materials. Examples of SFF techniques include three-dimensional printing (3DP), stereolithography, fused deposition modeling, selective laser sintering (SLS), and ballistic particle manufacturing. The underlying principle is analogous to a bottom-to-top approach, where mold-less creation of complex scaffolds is achieved by addition of materials to form cross-sectional levels in a layer-by-layer manner (obtained by computer-assisted design (CAD)), followed by layer fusion to yield a three-dimensional structure. These methods provide selective and precise spatial control over the scaffold morphology, including material composition, pore size, porosity, and microstructure. In addition, some technologies also offer the ability to pattern cells or bioactive molecules during the scaffold fabrication process.

SLS involves computerized laser scanning for the creation of patterned objects (Bartels et al., 1993). In SLS, a layer of polymer powder is first spread over a building platform. A desired two-dimensional profile is created by selectively scanning the polymer powder by an x–y controlled laser beam, which heats the polymer surface to or above its glass transition temperature. Upon cooling, the polymer particulates transition from a rubber to a glassy state, and fuse with the surrounding particulates. The layered scanning process is repeated with a fresh layer of polymer powder until the desired scaffold dimensions are met. Using this method, many bioresorbable materials have been processed into scaffolds, including PLLA, PCL, and PLGA, with or without a bioceramic component (Tan et al., 2003; Williams et al., 2005; Wiria et al., 2007; Simpson et al., 2008).

In stereolithography, computer-controlled movement of an ultraviolet laser is used to photopolymerize a liquid precursor solution in desired three-dimensional shapes. For example, a diethyl fumarate/PPF resin was used as a liquid base material in a custom-design stereolithography apparatus (Cooke et al., 2003). In a bottom-to-top manner, desired two-dimensional patterns of a fixed thickness (in this case, 100 μm) were created in the surface layer of the liquid resin over a building platform placed in a resin-filled tank. Sequential layers of 100 μm thickness were produced by lowering the stage in the tank by a fixed step-size of one layer, allowing the resin to cover the finished layer, and then exposing the fresh surface layer to UV. Both dimensions of the laser and resolution of the movement in the z-direction determine the overall resolution of the fabricated scaffolds. Using PEG-based photopolymerizable precursor solutions with cytocompatible photoinitiators, stereolithography has also been utilized to create fibroblast and Chinese hamster ovary (CHO) cell-loaded three-dimensional hydrogel constructs (Dhariwala et al., 2004; Arcaute et al., 2006). In some variations of the stereolithography technique, photopatterning of a precursor can be performed by selective exposure to UV via a designed photomask, which can also allow precise pore or cell positioning within the fabricated constructs (Albrecht et al., 2005; Bryant et al., 2007).

The 3DP technique is an automated inkjet printing-based technology (Sachs et al., 1993). In 3DP technique, a layer of polymer powder is first spread over a building platform. Using the print head of an inkjet printer, a desired two-dimensional profile is created by depositing a binder material (e.g., an organic solvent) over this layer to selectively join the polymer powder. The building platform is lowered and the process is repeated with a fresh layer of powder placed over the last finished layer until the desired part is obtained. The unbound powder is finally removed to yield the desired three-dimensional scaffold. Spatial resolution of this technique (~50–250 μm) is dependent on several factors, such as the size of the polymer particulate/powder being used, the size of the printed droplet, and the resolution of the printhead movement. 3DP is performed at ambient temperature, and allows the integration of controlled release features (Wu et al., 1996). Various direct and modified 3DP techniques have been utilized to create composite scaffolds for bone tissue engineering applications (Taboas et al., 2003; Lee et al., 2006; Ge et al., 2009).

Controlled dispensing methodologies have also been developed, where a polymer is deposited over a building platform in a layered fashion. The fused deposition modeling process is one such example, which involves controlled deposition of a melted/cast material through a computer-controlled nozzle in an automated layer-by-layer manner (Crump, 1992; Cao et al., 2003; Taboas et al., 2003).

In general, SFF techniques allow fabrication of precise complex shapes. In specific applications, some SFF techniques can also be used in combination with conventional scaffold fabrication techniques. For example, incorporation of porogens in the polymer powder for 3DP can be performed to introduce additional microfeatures in the scaffolds, which can improve the available surface area for cell attachment and mass transport, and enhance guided tissue regeneration (Kim et al., 1998b).

One limitation of the discussed techniques, with rare exceptions, is their inability to incorporate and pattern cells during the scaffold fabrication in a cytocompatible manner. Recently, development of new techniques that allow printing of cells during scaffold fabrication has been an area of great interest, the so-called organ printing or bioprinting technologies. In the automated process of bioprinting, controlled deposition of cell suspensions or cellular aggregates ("spheroids") is applied to create three-dimensional cellular constructs of desired geometries (see review by Mironov et al., 2008). Direct inkjet printing of cells on hydrogels has been used to produce two-dimensional or multi-layered structures (Boland et al., 2003; Wilson and Boland, 2003; Xu et al., 2005; Lee et al., 2009). Using modified controlled dispensing methodologies, direct printing of cells loaded in cross-linkable viscous hydrogel precursors has been accomplished via extrusion, microstereolithography or inkjet printing (Smith et al., 2004; Cohen et al., 2006; Lu et al., 2006; Wang et al.,

2006; Smith et al., 2007; Moon et al., 2010). In addition, self-assembly of multicellular structures has also been investigated, where controlled dispensing of cellular aggregates is performed directly into a hydrogel (Mironov et al., 2009). The bioprinting techniques show promise to alleviate some major challenges associated with the traditional approaches, including cell seeding at high densities, user-defined positioning of multiple cell types, and creation of vascular beds within large three-dimensional structures (Boland et al., 2006; Mironov et al., 2009).

Electrospinning

Electrospinning is a versatile process with high production capability that has been used to form non-woven micro- and/or nanofibrous scaffolds using synthetic bioresorbable polymers (for reviews see Pham et al., 2006a; Murugan and Ramakrishna, 2007) (Figure II.6.3.3I). In a simple set-up, a dissolved solution of polymer is passed through a needle at a controlled rate. An electric field applied using a high voltage source across the needle and a grounded collector charges the surface of the polymer droplet held at the needle tip. When the forces of electrostatic repulsion within the solution overcome the surface tension, a thin polymer jet forms. Solvent evaporation occurs as the jet travels from the needle tip to the collector where polymer fibers are formed and deposited on the collector. Anisotropically distributed polymer fibers can be produced using a rotating mandrel or patterned electrodes, and these have been shown to influence the polarity of the cells (Figure II.6.3.3II) (Li et al., 2003; Yang et al., 2005). There are several variables (e.g., solution viscosity, polymer charge density, polymer molecular weight, surface tension, electric field strength, tip-to-collector distance, needle design, and the composition and design of the collector) that influence the process of electrospinning, and each can be varied selectively to obtain the desired fiber and scaffold morphology (Pham et al., 2006a). For example, by adjusting these variables, poly(ε-caprolactone) microfibers with a range of selected fiber diameters were produced (Figure II.6.3.3 III) (Pham et al., 2006b). In electrospun matrices, fiber size is the primary factor that defines the pore sizes and porosity of the scaffold. Recently, nanofibrous scaffolds have received special attention in tissue engineering, as the scaffolds are highly porous (>90% porosity) with a fiber architecture that resembles closely the nanofeatures of native ECM (Li et al., 2002). Due to the presence of nanofibers, a multi-layered PCL nanofiber/microfiber scaffold was shown to enhance cell attachment and spreading of rat marrow stromal cells, compared to scaffolds containing microfibers alone (Pham et al., 2006b). The electrospinning process also allows the possibility of controlled delivery of single or multiple bioactive factors. For example, using a coaxial needle design, core shell fibers with PEG as the core and PCL as the shell were produced that can be used for the controlled release

(I, II) Schematic representations of electrospinning set-ups commonly used for the production of a non-woven fiber mesh (I), and an annulus of oriented fibers (II). (III) Scanning electron micrographs of electrospun non-woven poly(ε-caprolactone) microfibers of different fiber diameters: (A) 2 μm; (B) 3 μm; (C) 4 μm; (D) 5 μm; (E) 6 μm; (F) 7 μm; (G) 8 μm; and (H) 10 μm. (Scale bar: 10 μm) (Reproduced with permission from Pham et al., 2006a.)

of dual bioactive factors (Saraf et al., 2009, 2010). An issue that must often be addressed is that the nanodimensioned fibers have nanodimensioned interstices between them, hindering cell entry into the porous structure.

In summary, manufacturing methodologies described herein have been widely applied to process bioresorbable synthetic materials into porous three-dimensional scaffolds. The selection of the technique depends both on the envisioned application, and on the material under consideration. Post-fabrication, the attributes of the processed scaffolds are usually determined by characterizing the scaffolds, as discussed in the following section.

CHARACTERIZATION OF PROCESSED SCAFFOLDS

A number of techniques are available for the characterization of scaffolds (Table II.6.3.4). Surface chemistry of polymers (Chapter I.1.5) can be characterized by electron spectroscopy for chemical analysis (ESCA) and secondary ion mass spectroscopy (SIMS), among other techniques. Polarized infrared (IR) and near-edge X-ray absorption fine structure (NEXAFS) are employed to determine the orientation of the functional groups. Contact angle measurements provide information about the surface energy and wettability (hydrophilicity) of the polymer surface. Surface texture and roughness can be qualitatively or quantitatively assessed using scanning electron microscopy (SEM), scanning probe microscopy (SPM) or atomic force microscopy (AFM). AFM may also be employed to determine the surface rigidity.

TABLE II.6.3.4	Bioresorbable Polymeric Scaffold Characterization Techniques
Properties	**Characterization Technique**
Surface Characterization	
Chemistry	ESCA, SIMS
Texture	SEM, SPM, AFM
Orientation of functional groups	Polarized IR, NEXAFS
Surface energy and wettability	Contact angle measurement
Chemical Characterization	
Composition, sequence distribution of copolymers and crystal structure	NMR, XRD, FTIR, FTR
Mechanical Characterization	
Strength, stiffness, yield strength, etc.	Mechanical testing (compression, tension, shear, torsion)
Thermal Characterization	
Thermal properties (T_g, T_m, X_c)	DSC
Physical Characterization	
Molecular weight and distribution	GPC
Degradation	*In vitro, in vivo*
Mass loss	Gravimetry
Morphology	SEM, confocal microscopy
Pore-size and porosity	Mercury intrusion porosimetry, μ-CT
Interconnectivity	μ-CT

To determine the bulk properties (such as information regarding polymer composition, sequence distribution of co-polymers, and crystal structure), chemical characterization of the polymers can be performed using nuclear

magnetic resonance (NMR) spectroscopy, Fourier transform IR (FTIR) spectroscopy, FT-Raman (FTR) spectroscopy, and X-ray diffraction (XRD). Bulk mechanical properties are usually characterized by uniaxial mechanical testing under different modes of loading (e.g., compression, tension, shear, and torsion), and provide valuable data regarding mechanical characteristics (such as strength and modulus). Thermal properties (glass transition temperature (T_g), melting temperature (T_m) and degree of crystallinity (X_c)) are determined by differential scanning calorimetry (DSC). Molecular weight and distribution are commonly determined by size exclusion chromatography methods, such as gel permeation chromatography (GPC). SEM and confocal microscopy can be employed to determine the microscopic structure and pore morphology qualitatively, while mercury intrusion porosimetry and μ-computed tomography (μ-CT) are useful techniques to determine the porosity and/or pore interconnectivity of the scaffolds quantitatively. Additionally, mass loss from the scaffold can be characterized by simple gravimetric evaluations. To characterize the *in vitro* degradation of the scaffolds, a combination of physical, chemical, and mechanical properties can be assessed as a function of time on scaffold samples placed under simulated physiological conditions. *In vivo* assessment is usually required, however, to assess "true" degradation rates, which are ideally coupled with the rate of tissue regeneration. Like *in vitro* degradation assessment, the *in vitro* release profile of any impregnated biomolecule from the scaffold can be quantitatively determined by using various techniques, such as radioactivity measurements of radiolabelled biomolecules.

CELL SEEDING AND CULTURE IN THREE-DIMENSIONAL SCAFFOLDS

Engineering of large tissues and organs *ex vivo* generally requires culture of cells seeded at high densities in bioresorbable scaffolds in a controlled culture environment. However, there are many practical challenges that need to be overcome, such as uniform cell seeding, sufficient nutrient supply, and waste removal. In addition, control over the culture environment, including temperature, oxygen tension, pH, biochemical and mechanical stimulation (such as compression and shear stress), is desired (Vunjak-Novakovic, 2003 and Chapter II.6.6). To gain control over the physicochemical and hydrodynamic environment in culture conditions, various strategies have been developed that are used for cell seeding and culture of polymer constructs, some of which are described here.

Static Seeding and Culture

Static conditions represent the simplest form of cell seeding and culture. A cell suspension is allowed to adsorb onto a porous polymeric scaffold, cells are permitted to attach, and the constructs are then cultured in the presence of culture media (Figure II.6.3.4A). A major drawback of this method is that the penetration of a majority of cells in the scaffolds is generally limited to depths of approximately a few hundred microns (Ishaug et al., 1997), leading to undesired heterogeneous tissue growth. To improve cell penetration, several variations of seeding techniques exist, such as cell seeding by injection, centrifugation, and application of vacuum (van Wachem et al., 1990; Mikos et al., 1994a; Kim et al., 1998a; Godbey et al., 2004; Roh et al., 2007), which have all been shown to improve the cell distribution. To improve the cell seeding density in hydrophobic polymeric materials, various methods have been developed. Pre-wetting a hydrophobic polymeric scaffold with ethanol and water helps to increase the available volume for cell penetration by the displacement of air from the pores (Mikos et al., 1994a). Similarly, hydrolysis of the polymer surface or infiltration with hydrophilic polymers has been shown to increase the cellularity of the constructs (Mooney et al., 1995; Gao et al., 1998). As molecular diffusion is the primary driving force for nutrient supply and waste removal under static conditions, poor cell survival in the central parts of the scaffold is usually seen due to the gradients of nutrients and metabolites generated across the scaffold (Goldstein et al., 2001; Vunjak-Novakovic, 2003). To gain uniform cellularity and continuous convection-driven mass
FIGURE II.6.3.4 Dynamic cell seeding and culture techniques used *in vitro*. (A) Static culture in a well plate. (B) Rotary vessel. (C) Spinner flask. (D) Flow perfusion system.

transport, various bioreactor devices have been built that are more suitable for the culture of large constructs and allow the possibility of multiple scaffold processing and scale-up, discussed next.

Spinner Flask Culture

In spinner flask culture, fluid flow driven by a magnetic stir bar creates a well-mixed cell suspension for dynamic seeding and culture of the scaffolds that are fixed inside the flask on needles or wires (Figure II.6.3.4B) (Sikavitsas et al., 2002). This technique has been applied to culture a variety of cells, including chondrocytes, hepatocytes, MSCs, and umbilical cord matrix stem cells (Yamada et al., 1998; Sikavitsas et al., 2002; Bailey et al., 2007). Optimization of stirring speed is usually desired, as turbulence and eddies generated at high speeds may improve cell penetration and mass transfer; however, these high speeds can also result in cell damage or ECM loss. Due to the velocity field created by the vortex of the stir bar and eddies generated on the rough surfaces of the scaffolds, convection is almost always higher at the exterior of the scaffold than in the interior (Goldstein et al., 2001; Vunjak-Novakovic, 2003). As a result, matrix formation in peripheral scaffold areas has been reported to be more prominent than in areas near the center (Vunjak-Novakovic et al., 2002; Meinel et al., 2004).

Rotary Vessel Culture

Rotary vessel culture usually involves the use of a rotating-wall cylindrical vessel (RWV) or two concentric vessels with the purpose of creating a microgravity environment for the constructs placed inside the vessel (Figure II.6.3.4C) (Freed and Vunjak-Novakovic, 1997). Centrifugal forces generated due to the rotation of the cylinder counterbalance the gravitational pull on the scaffolds, suspending the scaffolds in the culture medium in a low-shear laminar flow-dominated environment. By controlling the rotational speed, penetration of nutrients and oxygen into the scaffold can be adjusted. Rotary vessel culture is especially useful for applications where enhanced mass transport is needed in low shear environments. Rotary vessel culture has been applied for the engineering of musculoskeletal tissues (Freed et al., 1997; Goldstein et al., 2001; Sikavitsas et al., 2002; Detamore and Athanasiou, 2005), among other tissues.

Perfusion Culture

Direct flow perfusion culture systems have been developed for the *in vitro* reconstruction of large three-dimensional tissues and organs (Figure II.6.3.4D) (Griffith et al., 1997; Kim et al., 1998b; Bancroft et al., 2002; Grayson et al., 2008). In general, the culture medium continually circulates through the cell–polymer constructs. With a continuous flow of culture

media through the porous structure of a scaffold, most mass transfer limitations are mitigated. In addition, flow-induced shear stresses can be modulated to upregulate desired cellular processes (such as cell differentiation or ECM production) in specific applications. For instance, increasing the shear stress resulted in an increased matrix deposition by MSCs cultured on three-dimensional scaffolds in a perfusion bioreactor (Sikavitsas et al., 2003). In another study, shear stress generated by direct perfusion was found to induce osteogenic differentiation of MSCs, even in the absence of other biochemical factors (Holtorf et al., 2005). Flow perfusion culture has also been shown to significantly outperform static culture, resulting in increased cellular proliferation, differentiation, and ECM deposition (van den Dolder et al., 2003; Datta et al., 2006). In addition to direct flow perfusion culture, other complex designs of perfusion bioreactors have also been developed, such as oscillatory flow perfusion bioreactors or pulsatile flow perfusion bioreactors (Brown et al., 2008b; Du et al., 2009).

Culture in Mechanically Stimulated Conditions

Mechanotransduction plays a key role in tissue development and maintenance (see reviews by Goodman and Aspenberg, 1993; Duncan and Turner, 1995; Sikavitsas et al., 2001; Ingber, 2006) (also see Chapter II.1.6). With the hypothesis that culture of cells in conditions that mimic the *in vivo* environment can optimize tissue regeneration *in vitro*, effects of biophysical forces on tissue growth *in vitro* have been widely studied, particularly for musculoskeletal and cardiovascular tissue engineering. The selection of mode of loading depends on the particular tissue engineering application, e.g., compression or shear for cartilage and bone tissue engineering, or tension for tendon tissue engineering. Level, loading profile (e.g., constant or cyclic), duration and frequency of mechanical stimulation are some of the variables that can influence cellular function.

Other Culture Conditions

As some cells respond to other particular biophysical cues, such as an electrical field (cardiac cells) or light intensity (retinal cells), inclusion of these as additional stimuli during the culture have also been studied (Hughes and Maffei, 1966; Radisic et al., 2004). Co-culture of different cell types is sometimes preferential to induce endogenous mutual signaling between the selected cell types, which has been used to facilitate *in vitro* organogenesis. Transwell culture systems have been used to selectively expose the apical and basal sides of the constructs to different media, desired in certain applications such as epithelial cell culture. Gradients of

physical and chemical cues, which are known to influence cell motility, function, and survival, may also be introduced in the culture (Singh et al., 2008a). For instance, concentration gradients of growth factors have been widely applied for guided neurite growth in peripheral nerve regeneration. Moreover, the substrate on which cells are expanded in two dimensions is also important for specific applications. For example, engineering of continuous two-dimensional epithelial cell sheets is desired for corneal epithelial replacements (Hayashi et al., 2010). For this purpose, use of surfaces coated with temperature-responsive thermoreversible polymers (such as poly(*N*-isopropylacrylamide)) has been applied to engineer organized sheets of epithelial cells (Okano et al., 1995; Yamato et al., 2001) (Chapter I.2.11). The polymer is designed to support cell attachment at 37°C, whereas a reduction in temperature below its lower critical solution temperature swells the polymer, causing the cells to detach while remaining attached to their extracellular matrix and each other (Okano et al., 1995).

CONCLUSIONS

Continuous progress is being made towards the long-term goal of engineering human tissues and organs. As highlighted throughout the chapter, many challenges still remain that limit clinical success for several tissues. The integration of advances in biological sciences with modern material science will not only produce designed scaffolds, but will also generate new technologies for regenerative medicine applications.

CHAPTER II.6.4 CELL SOURCES FOR TISSUE ENGINEERING: MESENCHYMAL STEM CELLS

Arnold I. Caplan
Professor of Biology, Director Skeletal Research Center, Case Western Reserve University, Cleveland, OH, USA

INTRODUCTION

Highly specialized, differentiated cells fabricate tissues and further differentiate to maintain these tissues. These specialized cells are derived from progenitor cells that are available to replace and regenerate the cells which expire or become injured. For example, during embryonic development, osteogenic progenitor cells give rise to osteoblasts in a multi-step, lineage sequence (Bruder and Caplan, 1990a). The osteoblasts fabricate osteoid that becomes calcified into bone; the osteoblasts organize as a monolayer sheet of electrically and functionally connected cells that are driven by vasculature at their backs to produce oriented sheets of collagen (osteoid) from their front surfaces (Caplan and Pechak, 1987). Some few osteoblasts further differentiate into osteocytes as they become encased in bone, and function to maintain bone (Bruder and Caplan, 1990b). Osteoblasts have 8–10 day half-lives in humans and the expired cells are replaced by cells derived from resident progenitors. Thus, to tissue engineer bone, the delivery of osteoblasts or their progenitors in a suitable delivery vehicle or scaffold would be required (Ohgushi and Caplan, 1999). Osteoblasts or their progenitors have been isolated from bone or from bone marrow, and this experience forms the basis for the logics involved in skeletal tissue engineering.

MESENCHYMAL STEM CELLS

The osteogenic potential of whole bone marrow has been known since the days of Roman or Greek medicine. More recently Friedenstein, Owen and their colleagues showed that osteoprogenitor cells could be isolated from marrow (Friedenstein et al., 1974; Friedenstein, 1980; Owen and Friedenstein, 1988). In the late 1980s, my colleagues and I formalized a protocol for isolating a class of progenitors from adult human and animal marrow that we called Mesenchymal Stem Cells, MSCs (Arias et al., 1991; Majumdar et al., 1998; Wakitani et al., 1995; Yoo et al., 1998; Young et al., 1998).

These marrow-derived MSCs are capable of differentiation into bone (Arias et al., 1991), cartilage (Yoo et al., 1998), muscle (Wakitani et al., 1995), marrow stroma (Majumdar et al., 1998), tendon/ligament (Young et al., 1998), fat and other connective tissue, as shown in Figure II.6.4.1. These MSCs could be culture expanded and their progeny shown to form cartilage, bone, tendon or fat in various preclinical animal models or in *in vitro* or *in vivo* test situations (Arias et al., 1991; Dennis et al., 1992; Majumdar et al., 1998; Wakitani et al., 1995, 1998; Yoo et al., 1998; Young et al., 1998; Solchaga et al., 1999). Indeed, MSCs could be attached to a scaffold and induced into a differentiation pathway in culture, and subsequently implanted into tissue defects in order to "jump-start" the cells to fabricate a specific tissue, such as bone (Kotobuki et al., 2004) or cartilage (Solchaga et al., 2006), in the *in vitro* setting.

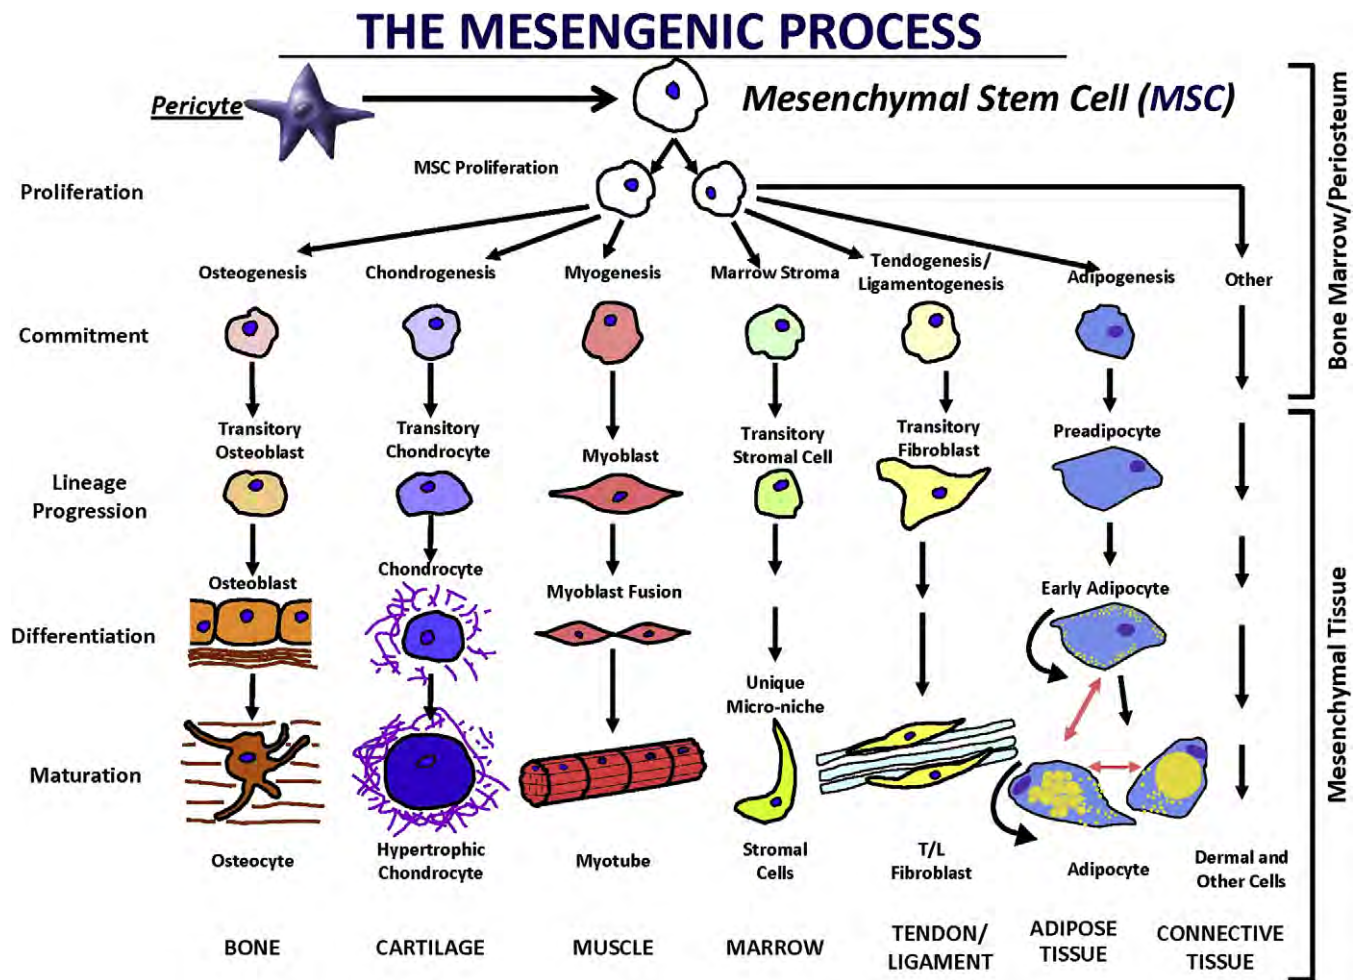
It is now clear that conditions for the *in vitro* expansion and differentiation of human marrow-derived MSCs have been optimized (Lennon et al., 1969). Several laboratories have published details of such optimization, and a few have used autologous human MSCs in tissue-engineered implants in humans to regenerate bone (Augello et al., 2007) and human autologous chondrocytes for osteochondral defects in the knee (Brittberg et al., 1994; Dell'Accio et al., 2001; Pavesio et al., 2003; Saris et al., 2008). In these clinical circumstances, many millions of MSCs or chondrocytes have been obtained from culture expansion of adherent cells from marrow or cartilage biopsies. Importantly, the titers of MSCs in marrow sharply drops off as a function of age, as seen in the crude colony-forming assays depicted in Figure II.6.4.2.


FIGURE II.6.4.1 The Mesengenic Pathway of differentiation lineages for adult marrow-derived Mesenchymal Stem Cells (MSCs).
FIGURE II.6.4.2 Estimate of MSCs as CFU-f in whole marrow from individuals of different ages.

Although there are no precise quantitative assays for MSCs, the CFU-f assay has long been used as an estimate for progenitor cell titers from marrow (Friedenstein et al., 1974, 1980). Certainly, 5-, 50-, and 90-year-olds show dramatically different capacities to repair bone and cartilage, and this must be reflective of their MSC titers in the marrow.

MSC-NICHE

Recently, the earlier assertions that perivascular cells had osteochondrogenic potential (Brighton et al., 1992; Diaz-Flores et al., 1992) have been verified (Crisan et al., 2008) and stimulated me to suggest that "all" MSCs are pericytes (Caplan, 2008). The converse is not correct (i.e., some pericytes are not MSCs). Thus, Figure II.6.4.2 can be thought of as a plot of vascular density, and this decreased frequency of blood vessels would be expected to have a clear effect on the rate of healing of various tissues.

OTHER SOURCES OF MSCs

Several reports now clearly document that multipotent, mesenchymal progenitors can be isolated and expanded in culture from muscle, fat, skin, liver, brain, etc. (Gronthos et al., 2001; Nuk et al., 2001; Campagnoli et al., 2004; Gotherstrom et al., 2005; Kimelman et al., 2007).

Retrospectively, this makes good sense if "all" MSCs are pericytes, since all of these tissues have vasculature. In addition, it is now clear that differentiated mesenchymal cells are plastic in their phenotypic characteristics (i.e., capable of transdifferentiation) (Herzog et al., 2003). Thus, we can take a pure population of human adipocytes and induce them with dexamethasone to become osteoblasts. This plasticity infers that the transdifferentiation pathways depicted in Figure II.6.4.3 are the result of transcriptive accessibility of promoters for the genes prominent in the newly-differentiated phenotypes. Conversely, the promoters for non-mesenchymal macromolecules are not accessible, unless other inductive or derepressive agents are introduced into the cells. The exact mechanism and fundamental details for mesenchymal plasticity have yet to be fully described. In addition, the basic unresolved issue is whether such *in vitro* plasticity has relevance to *in vivo* events. Indeed, the relative ease of such transdifferentiation challenges the use of such *in vitro* assays as definitions of MSCs, since a culture of human adipocytes and a culture of MSCs would both exhibit osteogenic progression when exposed to dexamethasone and ascorbate.

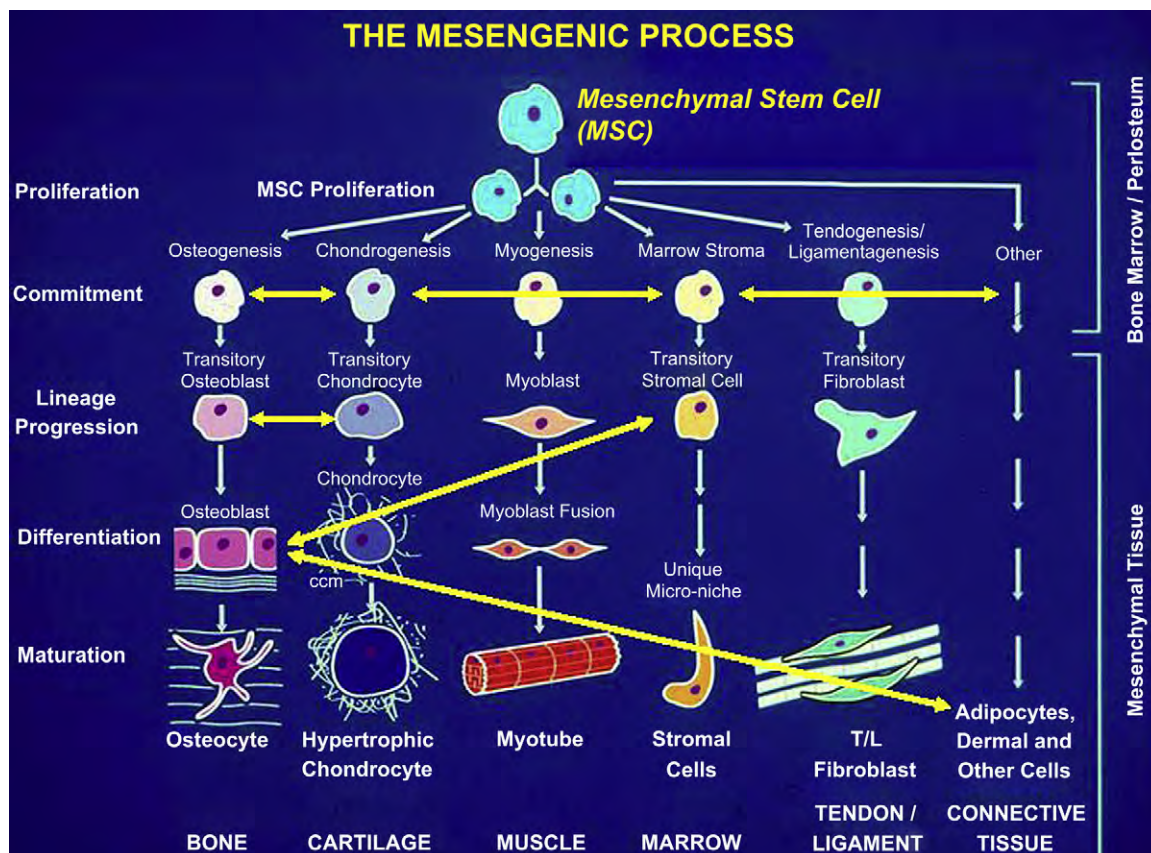
Multipotent mesenchymal progenitor cells have been isolated from a number of vascularized tissues. Indeed, a recent publication documented that if cell surface markers are used to sort out pericytes from several different


FIGURE II.6.4.3 The original Mesengenic Pathway diagram with non-vertical lines depicting the plasticity of MSCs and their descendents.

tissues; these cells also have MSC markers and are multipotent for several mesenchymal phenotypes (Crisan et al., 2008). Likewise, when cells are sorted for MSC markers, the sorted cells exhibit pericyte markers. We have recently shown that when labeled marrow-derived MSCs are added to cultures in which human vascular endothelial cells are forming capillary-like tubes in a human dermal fibroblast-produced extracellular matrix, the labeled human MSCs take up pericyte locations around the endothelial tubes (Sorrell et al., 2008). These same MSC preparations were multipotent in both *in vivo* and *in vitro* assays.

It is important to stress that the *in vitro* and *in vivo* conditions that are optimal for marrow-derived MSCs are not optimal for MSCs isolated from other tissues. Thus, the fetal calf serum used in the culture expansion of the adherent MSCs must be screened for each tissue source used to obtain those MSCs (Lennon et al., 1969). Furthermore, when optimally expanded MSCs from marrow and, for example, fat are tested for multi-potency, the test conditions must be separately optimized for each tissue-specific MSC. For example, as we have shown when human marrow MSCs are pelleted and the growth medium replaced with a defined medium containing TGF-β, the cells will differentiate into chondrocytes (Yoo et al., 1998). For this to occur for human fat-derived MSCs, BMP-6 must be added, in addition to TGF-β (Estes et al., 2006). This observation may be interpreted to show that both marrow- and fat-derived MSCs are chondrogenic, but that they are quite different in their response to TGF-β alone. Likewise, human marrow MSCs form osteogenic cells in culture when exposed to dexamethasone, while mouse marrow MSCs form adipocytes under these culture dexamethasone-supplemented conditions. Both mouse and human MSCs are multipotent, but optimal conditions must be separately used to isolate, expand, and assay them when derived from various different tissue sources. It follows that different scaffolds may prove to be necessary for MSCs from different tissue sources, and for different anatomic implantation sites.

It is important to stress that mature cell types can be used for tissue engineering applications. As mentioned above, autologous chondrocytes are culture expanded and used in specific scaffolds or in special surgical applications to repair both chondral and osteochondral defects (Brittberg et al., 1994; Dell'Accio et al., 2001; Pavesio et al., 2003; Saris et al., 2008). Likewise, endothelial cells can be isolated from autologous fat to be used in tissue-engineered vascular grafts (Arts et al., 2001). Last, both autologous and allogeneic tissue-engineered skin equivalents have been used in human clinical situations such as for burns or skin ulcers for more than 20 years (Supp and Boyce, 2002; Nakagawa et al., 2005). In all of these cases, optimal scaffolds and culture conditions for cell expansion have been developed for each cell type, and for each medical circumstance.

A NEW ERA OF MSC-BASED THERAPIES

Although not directly germane to materials science and tissue engineering, it is important to note that new information is available about the functioning of human MSCs that has resulted in their use for various clinical conditions as systematically introduced allogeneic MSCs (da Silva Meirelles et al., 2008). In brief, MSCs intrinsically secrete large amounts of bioactive molecules (Hyanesworth et al., 1996) that are immune-modulatory (Maitra et al., 2004; Beyth et al., 2005), are trophic (Caplan and Dennis, 2006), and support local tissue regeneration. The immuno-modulatory functions locally to inhibit T-cells, and to a lesser extent B-cells. Thus, allo-MSCs are not "seen" by the host's immune system. Indeed, human marrow-derived MSCs have dramatic effects in modulating the immune systems in rodents (Mahmood et al., 2003; Bai et al., 2007) and other animals. Clinically, rather spectacular clinical improvements of graft-versus-host-disease and Crohn's disease have been reported (see website: Osiris Therapeutics, Inc., www.osiris.com). Whether allo-MSCs can be used in tissue engineering constructs is yet to be thoroughly tested.

Allo-MSCs also have powerful trophic effects (Caplan and Dennis, 2006). These effects have been documented in animal models, and in some clinical trials of acute myocardial infarct, stroke, inflammatory bowel disease, acute kidney failure, tendonitis, spinal cord injury, and meniscus regeneration (Mahmood et al., 2003; Murphy et al., 2003; Maitra et al., 2004; Pittenger and Martin, 2004; Beyth et al., 2005; Lange et al., 2005; Caplan and Dennis, 2006; Bai et al., 2007; Brooke et al., 2007; Harman et al., 2007). These trophic effects involve four discrete activities: (1) anti-apoptosis especially in areas of ischemia; (2) anti-scarring; (3) angiogenesis; and (4) mitosis of tissue-intrinsic progenitors. In all cases, the allo-MSCs were delivered systemically, and they seem to home to sites of tissue injury. These newly discovered capacities of marrow MSCs have stimulated a new era of cell-based therapies. The use of the immuno-modulatory and trophic capacities of MSCs from other tissue sources is untested. From clinical trials (Brooke et al., 2007 and www.osiris.com), it is clear that systemically delivered marrow-derived human allo-MSCs will come to the healthcare marketplace long before tissue-engineered products.

LONG-TERM GOALS

Tissue engineering and cell-based therapies can be used to provide tissues that the body cannot naturally provide in cases of massive injury, disease, old age or surgical intervention. These technologies will allow us to better understand the complex dynamics of tissue repair and regeneration to overcome medically relevant deficiencies. Long-term, however, our goal must be to determine how to better manage the body's own intrinsic repair

and regeneration potential so that less intrusive, more natural, protocols can be developed. The clearest example of this logic is distraction osteogenesis (Aronson, 1994; Rhee and Buchman, 2003) where broken or cut bones can be lengthened by mechanically manipulating the repair callus spanning the bone-break site. Although crude and time-inefficient, distraction osteogenesis manages the natural regenerative capacity to bring about a medically relevant solution. Other logics like this, including the targeting of systemically delivered MSCs, will change the course of healthcare delivery.

SYNOPSIS

The use of mature cell types or their progenitors to engineer tissue repair and/or tissue replacement strategies requires that adequate sources of cells be identified. Additionally, these cells are often expanded in number in plate cultures or bioreactors prior to the implantation of a cell-scaffold composite. Adult mesenchymal stem cells (MSCs) are the putative progenitors for a number of different skeletal and mesenchymal tissues. It appears that most or all MSCs reside as perivascular cells (i.e., pericytes) surrounding various blood vessels. Best-studied are the MSCs from bone marrow, but several other sources have been described, including fat and muscle. The optimization of isolation and *in vitro* expansion and assay parameters are essential for each tissue source, and for each species that serve as the source and recipient for cell-based therapies. New information about the intrinsic functioning of MSCs has changed the emphasis of their clinical delivery and utility.

INTRODUCTION

The field of tissue engineering emerged from work striving to construct artificial tissues and organs *in vitro* by integrating the principles of cell biology, polymer chemistry, and materials science (Langer and Vacanti, 1993). In this approach, cells isolated from whole organs (e.g., liver, kidney) or multi-potential stem cells are cultured within three-dimensional scaffolding materials, which can be designed in myriad forms to provide the necessary structural and chemical cues to induce cell growth and tissue differentiation. This cell–scaffold construct is then implanted *in vivo* with the aim of promoting new tissue formation following injury or disease.

Skin was the first to be artificially constructed using natural scaffold materials in combination with patient-derived skin cells (Bell et al., 1981). Development of tissue-engineered skin is less challenging than constructing artificial internal organs, such as whole liver or kidney, because the relatively thin skin constructs can be implanted directly onto a pre-existing vascularized wound bed. In contrast, cells within larger three-dimensional cell–scaffold constructs from many solid organs (e.g., liver) die rapidly when implanted *in vivo* without prior vascularization, due to insufficient delivery of oxygen and nutrients. Interestingly, despite their simplicity, artificial skin grafts have not made a significant impact on the market. This is, in part, due to their failure to maintain optimal cell viability; however, the major difficulty has arisen from the tough regulatory and cost challenges involved in the development of medical products containing living cells. These limitations highlight the importance of exploring alternative materials-based tissue engineering approaches that rely on development of more sophisticated biomimetic scaffolds to promote angiogenesis, and induce recruitment and reprogramming of endogenous multipotent progenitor cells (e.g., either resident within remaining tissues or bone marrow-derived cells that circulate in the blood) when implanted *in vivo*. To do this effectively, however, we must fully-understand and recapitulate the dynamic and reciprocal interactions that occur within the cell–ECM microenvironment during normal tissue formation.

Biomaterials used in tissue engineering were initially viewed as inert carriers for cell delivery. However, modern strategies for regenerative medicine now employ methods to manipulate their biochemical and biophysical properties, in order to best promote orderly tissue growth and restore normal function. Materials that more closely mimic the inductive environment of normal developing tissues have been fabricated using natural ECM proteins (e.g., collagen, fibrin, hyaluronan, etc.), as well as synthetic polymers (PLGA, PEG, PVA, etc.) (Lutolf and Hubbell, 2005). To enhance cell adhesion, these polymeric scaffolds have also been covalently derivatized with proteins or peptides found within natural ECMs (Ghosh et al., 2006). The RGD (arginine-glycine-asparatic acid) tripeptide sequence is the most commonly used cell adhesion moiety (Hersel et al., 2003; Shu et al., 2004); however, other peptides such as the YIGSR and IKVAV peptides of laminin and VPGIG sequence of elastin have also been explored (Ranieri et al., 1995; Panitch et al., 1999; Lin et al., 2006). Importantly, these ECM-mimicking biomaterials support key cell functions, including cell spreading, migration, growth, and differentiation *in vitro*, as well as tissue repair *in vivo* (Shin et al., 2003; Lutolf and Hubbell, 2005).

To better mimic the fibrillar microarchitecture and anisotropy (alignment) of native ECMs, specialized fabrication techniques have been developed, such as electrospinning and three-dimensional weaving that produce fibrous biomaterial scaffolds with varying pore size and volume, ranging from macro- to nanoscale dimensions (Yang et al., 2001; Muschler et al., 2004; Tsang and Bhatia, 2007). These scaffolds may be rendered stable to hydrolytic or proteolytic degradation via inter- or intramolecular cross-linking, and cell recognition moieties can be chemically tethered to their polymer backbone to promote cell adhesion. To engineer mechanically active tissues that bear continuous cyclical hemodynamic and compressive loading (e.g., heart valve and cartilage, respectively), cell–biomaterial constructs are preconditioned prior to *in vivo* implantation by being cultured in specialized bioreactors that simulate the physical environment of native tissues (Waldman et al., 2003; McCulloch et al., 2004; Fehrenbacher et al., 2006; Isenberg et al., 2006). This mechanical force regimen significantly alters ECM structure, as well as cellular growth and function.

Despite efforts to mimic the properties of natural ECMs through various chemical and mechanical modifications, most tissue-engineered constructs fail to completely restore normal tissue form and function when implanted *in vivo*. Our inability to produce ideal tissue substitutes may be due to the failure to address the role of micromechanical forces in guiding cell and tissue development. These microscale forces result from the tension (contractility) generated in the cell cytoskeleton, which is exerted on the cells' adhesions to ECM and to neighboring cells. Cells sense these forces through transmembrane integrin and cadherin receptors that mediate cell–ECM anchorage and cell–cell adhesion, respectively (Chen et al., 2004). Mechanical stresses acting on these

cell surface receptors are transmitted across the cell surface, and to internal cytoskeletal and nuclear scaffolds via specialized membrane adhesion complexes (e.g., focal adhesions, adherens junctions) (Wang et al., 2009). Mechanotransduction – the process by which mechanical signals are transduced into changes in cellular biochemistry and gene expression – can occur in these adhesion complexes or at many other locations along loadbearing structural elements in the cell where force induces molecular distortion (Ingber, 2006; Vogel and Sheetz, 2006). Importantly, these cell-generated forces influence various cell behaviors critical for developmental control, including growth, movement, differentiation, apoptosis, and stem cell fate switching (Chen et al., 1997; Engler et al., 2006; Ghosh et al., 2007).

In this chapter, we describe how micromechanical interactions between cells and ECM govern normal tissue morphogenesis and control cell fate switching. We also review various microscale design approaches to biomaterial fabrication that leverage this critical developmental paradigm. Finally, we explore how our growing knowledge of micromechanical control of cell function and biomaterials science can be integrated to develop improved biomimetic microenvironments for *in situ* tissue repair and regeneration.

MICROMECHANICAL CONTROL OF TISSUE FORM AND FUNCTION

Tissues and organs arise during embryogenesis from coordinated self assembly of large populations of cells that organize themselves into precise three-dimensional spatial patterns. Multicellular self-organization is facilitated by molecular self assembly of cell-derived proteins (e.g., collagen, laminin, fibronectin) into fibrous multimolecular ECM scaffolds that function as physical templates for orderly cell attachment and renewal (Vracko, 1974; Leivo, 1983). Cells attach to this anchoring ECM scaffold through transmembrane integrin receptors (Ruoslahti, 1991; Hynes, 1992), and they exert cytoskeleton-generated traction forces on these cell–ECM adhesions, as well as on their attachments to neighboring cells (Ingber, 1991; Chicurel et al., 1998a; Galbraith and Sheetz, 1998; Geiger et al., 2001; Ingber, 2003c). The resistance produced by cell–ECM and cell–cell linkages to cytoskeletal forces maintains the cell in a state of isometric tension or prestress that stabilizes cell and tissue form through a tensegrity mechanism (Ingber and Jamieson, 1985; Ingber, 1993, 2003b; Stamenovic and Ingber, 2009). The importance of ECM-dependent micromechanical forces in regulating tissue form is evident from observations of new epithelium formation in the early embryo and in specialized organs (e.g., kidney), which is always accompanied by concomitant formation of planar ECM scaffolds or "basement membranes," that promote consistent cell orientation and generation of epithelial form (Leivo, 1983; Yurchenco and Ruben, 1988).

ECM is also centrally involved in the morphogenetic patterning that occurs during embryonic organogenesis. For example, formation of lobular epithelial glands in salivary gland and lung, as well as branching capillary networks, appear to require establishment of local differentials in ECM remodeling (Bernfield and Banerjee, 1978; Moore et al., 2005). In general, regions of highest ECM turnover, which lead to basement membrane thinning, exhibit the highest rate of cell growth and tissue expansion, while cells in the neighboring areas (only several microns away) that experience increased ECM accumulation (due to low degradation relative to synthesis) remain quiescent. These microscale differentials in cell growth and ECM density drive the budding, folding, and branching of many epithelial and endothelial tissues (Ausprunk and Folkman, 1977; Bernfield and Banerjee, 1978).

These observations have formed the basis of a micromechanical model of tissue development (Figure II.6.5.1), which postulates that morphogenetic events such as epithelial budding and branching are controlled by local micromechanical variations that lead to spatial differentials in the cellular force balance (Ingber and Jamieson, 1985; Huang and Ingber, 1999). In this model, local enzymatic degradation of the prestressed (tensed) basement membrane causes it to stretch and thin in regions of high turnover, with concomitant distortion of the adherent epithelial cells. These stretched cells become more responsive to soluble mitogens and undergo proliferation (Singhvi et al., 1994; Chen et al., 1997; Folkman and Moscona, 1978) compared to their neighboring counterparts that remain quiescent in regions experiencing basement membrane accumulation. Reiteration of this micromechanical control scheme that couples ECM stretching and cell growth could then produce the complex fractal-like tissue patterns that characterize development of virtually all organs (Huang and Ingber, 1999; Moore et al., 2005). Stable tissue forms finally emerge when the stabilizing tissue prestress is restored by accumulating thickened ECMs and strengthened cell–cell adhesions that fully balance cell-generated tensional forces (Ingber and Jamieson, 1985; Hardin and Keller, 1988).

This micromechanical model of tissue morphogenesis is supported by the finding that changing the cell–ECM force balance within embryonic mouse lung rudiments alters branching morphogenesis (Figure II.6.5.1) (Moore et al., 2005). Specifically, suppressing cytoskeletal tension generation inhibits regional thinning of the basement membrane at the tips of expanding buds and interferes with epitheliogenesis, while increasing tension accelerates epithelial branching morphogenesis (Moore et al., 2005). These treatments also had similar stimulatory and inhibitory effects on formation of neighboring capillary networks, as well as on the growth of the entire organ. Importantly, this force-dependent spatial patterning was not mediated by alterations in the overall rate of
FIGURE II.6.5.1 Micromechanical control of tissue morphogenesis. (Left) Schematic diagrams of a micromechanical model of epithelial morphogenesis (Huang, S. & Ingber, D. (1999). Nat Cell Biol) showing progressive development of a simple planar epithelium into complex branching patterns (top to bottom). Local increases in basement membrane degradation (green), coupled with traction generated by overlying adherent cells (white arrows), result in local thinning and stretching of the basement membrane, as well as the overlying adherent epithelium (red), whereas neighboring cells only microns away remain quiescent (white). Cell distortion enhances cell sensitivity to soluble growth factors, which results in increased cell proliferation in regions of highest ECM turnover. Spreading and growing cells simultaneously deposit new ECM, which causes local basement extension and new bud formation. Reiteration of this process over time and space leads to the development of complex tissue architecture, with characteristic fractal-like patterns. (Center) Photomicrographs of individual epithelial buds in developing mouse lung epithelium corresponding to the stages shown at left (Moore, K. et al., (2005). Dev Dyn). (Right) Theoretical mechanical strain distributions within the basement membrane of the developing mouse lung epithelium at corresponding times during branching morphogenesis. Increased spacing between the strain field lines indicates regions where the basement membrane thins and experiences greatest mechanical strain (distortion). These regions of increased strain correlate precisely with regions of epithelial expansion and new bud formation (Moore, K. et al. (2005). Dev Dyn). (Reproduced from Ghosh, K. & Ingber, D., (2007). Adv. Drug Deliver. Rev. 59: 1306–1318, with permission from Elsevier ©2007).

cell proliferation within the mesenchyme and epithelium, but rather by establishment of local growth differentials within the forming gland (Moore et al., 2005). Thus, although tissue development is driven by soluble

cytokines and changes in gene expression, it is also a highly mechanical process that is significantly influenced at the microscale by alterations in the mechanical force balance between cells and their surrounding adhesions to

ECM and neighboring cells. The tissue architecture generated by this mechanical patterning mechanism also feeds back to alter gradients of soluble developmental cues (Nelson et al., 2006), thereby establishing a vital feedback mechanism that further integrates changes in tissue form and function.

MICROSCALE DESIGN OF BIOMIMETIC SCAFFOLDS FOR TISSUE RECONSTRUCTION

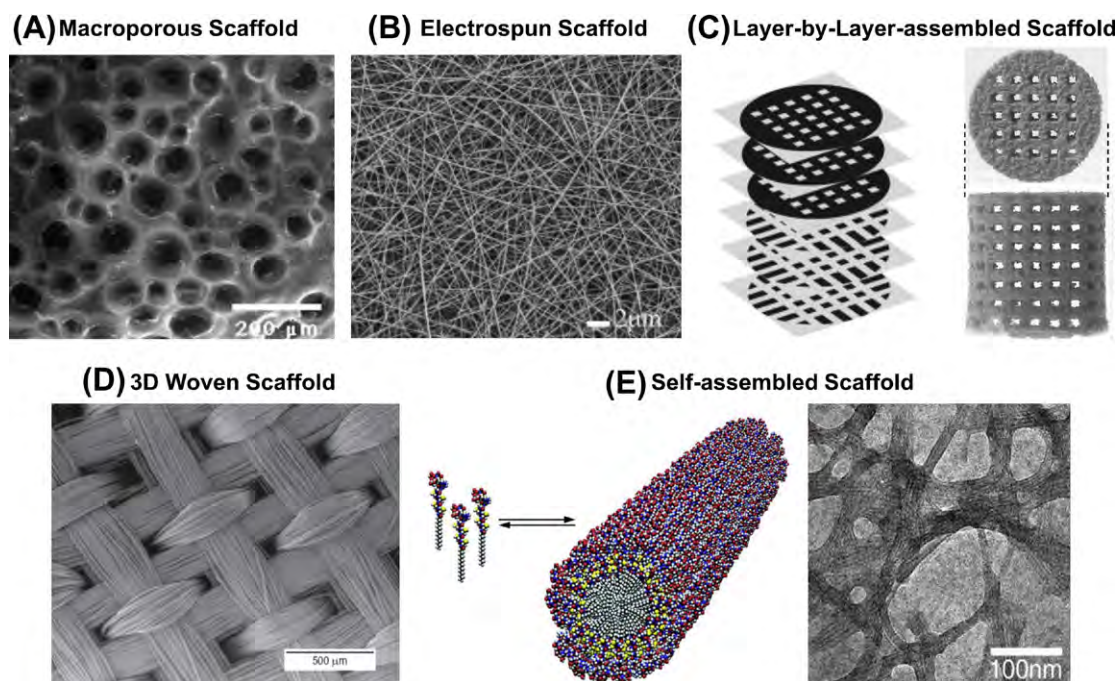
Given the critical role of external physical cues and cell-generated forces in regulating tissue form and function, it is paramount that these factors be considered in the design of rational tissue engineering approaches aimed at restoring the normal structure and functionality of damaged tissues and organs. Tissue engineering scaffolds have been developed using various types of polymeric materials (natural, synthetic, and semi-synthetic) and techniques (gas foaming, phase separation, etc.) (Figure II.6.5.2A) (Agrawal and Ray, 2001; Lutolf and Hubbell, 2005). The design challenges focused on in the past lay largely in achieving appropriate macroscopic features, such as bulk stiffness and suitable degradation rate (to facilitate integration with host tissue), porosity (to promote nutrient exchange and tissue ingrowth), and adhesiveness (for cell adhesion and function). But more recent studies have shown that cell function within such bulk scaffolds can be more tightly regulated by introducing precise micro- or nanoscale structural features. For instance, microporous biopolymer scaffolds (pore size ~100–500 μm) induce cells to exhibit a flattened cell morphology similar to that seen when they are cultured on a two-dimensional tissue culture substrate, while nanofibrous scaffolds (Figure II.6.5.2B) (fiber diameter ~50–100 nm; pore size ~0.5–5 μm) cause these cells to assume a dendritic morphology similar to that seen in native tissues (Grinnell, 2003; Stevens and George, 2005; Ji et al., 2006). Further, creating nanoscale features within an otherwise microporous scaffold alone can markedly enhance cell spreading, growth, and expression of tissue-specific ECM components (Pattison et al., 2005). Such apparent differences in cell morphology likely arise from the differential ability of these topographies to induce distinct membrane protrusions (e.g., lamellipodia formation on flatter surfaces while filopodia form on more fibrous ones) (Cukierman et al., 2001; Curtis et al., 2004).


FIGURE II.6.5.2 Microscale design of biomimetic scaffolds for tissue reconstruction. Increasing knowledge of the influence of microscale ECM material properties on cell and tissue development has led to novel physical design strategies for tissue engineering biomaterials. (A) Initial attempts to engineer three-dimensional tissues used macroporous scaffolds. Their large surface area allows greater cell spreading, while the large pore size facilitates sufficient metabolic exchange (Eiselt, P. et al. (2000). Biomaterials 21: 1921–1927). (B) Electrospun scaffolds that better mimic the fibrous architecture of natural ECM are being increasingly used nowadays. Cells cultured on these scaffolds assume dendritic morphology similar to that exhibited by cells within native tissues (Ji, Y. et al. (2006). Biomaterials). (Reproduced with permission from Elsevier ©2006. (C) More sophisticated design strategies involving automated CAD/CAM programs with solid free-form fabrication approaches allow a bottom-up approach to scaffold construction, where the microscale material properties can be controlled in a precise spatiotemporal manner (Seitz, H. et al. (2005). J Biomed Mater Res). (D) Three-dimensional weaving technology has been recently used to produce fibrous scaffolds that mimic the anisotropy, porosity, and bulk mechanical properties of native ECM (Moutos, F. et al. (2007). Nat Mater). (E) Self-assembling molecules have been engineered that can spontaneously organize into complex three-dimensional structures in a manner reminiscent of the bottom-up molecular assembly of natural ECM materials (Hartgerink, J. et al. (2001). Science). (Reproduced with permission from AAAS ©2001.)

Because local variations in ECM structure and elasticity can trigger differential cell responses required for tissue morphogenesis and development (as seen during lung development), it would be desirable to engineer biomaterial scaffolds that exhibit such structural and mechanical variations across small length scales. One way to address this challenge is to use solid free-form fabrication (SFF) techniques (e.g., three-dimensional microprinting, soft lithography, etc.) that enable the development of biomaterials with complex three-dimensional microscale features using computer-assisted design and manufacturing (CAD/CAM) platforms (Figure II.6.5.2C). In this bottom-up approach, thin sequential layers of polymer are deposited one-at-a-time, with each layer having a prescribed physical structure and composition (Giordano et al., 1996; Seitz et al., 2005). By depositing polymer solutions at precise predetermined locations, and by varying the type and concentration of polymers used, the architecture and mechanical properties (stiffness, degradation rate, etc.) of the scaffold can be tightly controlled with microscale resolution. Such an approach can produce anisotropic scaffolds that better recapitulate the physical complexity of loadbearing tissues such as cartilage, which is composed of distinct tiers of cell and ECM organization. If so, this may lead to significant improvement in both scaffold integration at the defect site and tissue function. Such biomaterials have, in fact, been fabricated using a novel microscale three-dimensional weaving technology where the resultant porous scaffold closely resembles native cartilage, not only in terms of bulk (compressive, shear, and tensile) moduli, but also with respect to its physical anisotropy (tension-compression nonlinearity) (Figure II.6.5.2D) (Moutos et al., 2007). Specifically, small-pore scaffolds (pore dimensions 390 μm × 320 μm × 104 μm) produced by designing a biased woven structure that contained a higher fiber volume fraction in the weft direction than in the warp direction exhibited ~35% higher ultimate tensile stress when tested in the weft direction than in the warp direction, which is reminiscent of the mechanical anisotropy seen in native articular cartilage.

Native ECM is produced through complex self assembly reactions involving various natural biopolymers, such as collagen, elastin, and hyaluronic acid, among others. Due to this systematic bottom-up approach, the ECM displays a remarkable level of hierarchical organization that spans from nano- to mesoscale. Artificially replicating this self-assembly process may produce scaffolds that better mimic both the material and biological properties of native ECM. To this end, novel polypeptide systems have been developed that spontaneously self-assemble in physiological solvents to produce nanoscale, branched fibrous networks analogous to those seen in native ECM (Ryadnov and Woolfson, 2003). Peptides have also been modified to contain alternating hydrophilic and hydrophobic groups that enable them to interact with their complementary moieties to form β-sheet membranes, which further self-assemble to form higher-order structures (Zhang, 2003). Hydrogel scaffolds developed using such techniques can successfully encapsulate cells, as well as enhance cell viability and expression of tissue-specific ECM components (Kisiday et al., 2002). In another novel, and potentially valuable, application of this self-assembly process, amphiphilic molecules have been precisely engineered such that each nanofiber presents a template for hydroxyapatite mineralization, as well as osteoblast adhesion, which together enhance bone regeneration (Hartgerink et al., 2001) (Figure II.6.5.2E). An interesting feature of this technique is the ability of nanofibers to direct alignment of hydroxyapatite crystallization, which mimics the collagen fiber-induced hydroxyapatite alignment seen in native bone.

The apparent effects of scaffold structure on cell form and function may be due to differences in membrane receptor clustering and binding that result from alterations in the physical context in which adhesive cues are presented to cells. Varying the nanoscale (~50 nm) distribution of the integrin-binding RGD tripeptide on an otherwise non-adhesive two-dimensional surface reveals that cell spreading and motility on lower ligand density surfaces (~10^3–10^4 RGD molecules/μm²) occur best when RGD is presented in clusters of nine ligands per cluster (Maheshwari et al., 2000). Notably, this influence of RGD clustering on cell function is markedly weakened when RGD is presented either at saturated levels (10^5 molecules/μm²) or as individual peptides (Maheshwari et al., 2000). This functional difference correlates with the ability of RGD clusters to induce actin stress fiber formation (Maheshwari et al., 2000), confirming that adhesive ligands influence cell behavior by promoting optimal traction-mediated cell spreading and simultaneously activating integrin-dependent biochemical signaling inside the cell (Ingber, 2003c). Achieving this precise nanoscale control over adhesive signaling is desirable in biomaterial scaffolds, as that will allow the creation of well-defined three-dimensional cellular niches. To this end, poly(ethylene) glycol scaffolds containing separate RGD and PHSRN peptide sequences spaced precisely 4 nm apart have been developed that promote osteoblast growth and metabolism, while inhibiting ECM deposition, whereas different RGD-PHSRN spacings are less effective (Benoit and Anseth, 2005).

CELL AND ECM MECHANICS AS KEY REGULATORS OF TISSUE DEVELOPMENT

The mechanism of control of tissue development and related tissue engineering approaches described above are based on the concept that local changes in ECM structure and mechanics result in physical distortion of adjacent adherent cells. Cell distortion alters the level of cell prestress and deforms the cytoskeleton, which changes the cell's ability to respond to soluble growth factors and morphogens. To directly test this concept that cell shape

distortion is critical for functional control, we applied microfabrication techniques first developed to make microchips for the computer industry to microengineer adhesive ECM islands with controlled size, shape, and position on the micrometer scale (Whitesides et al., 2001). Using this approach, cell shape can be controlled independently of the nature and density of immobilized ECM molecules or the presence or absence of soluble growth factors. Specifically, we created single cell-sized adhesive islands coated with a saturating density of ECM molecules (e.g., fibronectin) that were surrounded by non-adhesive regions. Cells spread by adhering to immobilized ECM ligands and exerting traction forces on these adhesions. Thus, these microengineered adhesive islands provided a simple method to control cell shape distortion, because cell spreading was limited only to the area of the ECM island (Singhvi et al., 1994; Chen et al., 1997).

When single capillary endothelial cells or primary hepatocytes were plated on each island, they spread and flattened, eventually taking on the precise size and shape (e.g., circle, square, hexagon, etc.) of the adhesive island. Most importantly, in the presence of optimal soluble mitogens, cells that distorted (spread) exhibited the highest growth rates (Singhvi et al., 1994; Chen et al., 1997), whereas round endothelial cells adherent to the same ECM coating underwent apoptosis (Figure II.6.5.3). Interestingly, cells that were cultured on intermediate size islands exhibited enhanced cytodifferentiation (secretion of blood proteins by liver epithelial cells) as well as histodifferentiation (e.g., tube formation by capillary cells) (Singhvi et al., 1994; Dike et al., 1999).

In addition, when cells cultured on square-shaped ECM islands were stimulated with motility factors (e.g., PDGF, FGF), they preferentially extended lamellipodia at their corners, which are also the sites of maximal cytoskeletal tension and focal adhesion density (Parker et al., 2002).

Subsequent studies revealed that this form of cell shape-dependent developmental control results from cytoskeletal distortion and alterations in the level of cytoskeletal tension within the cell. For example, the Rho family GTPase, RhoA, mediates cell shape-dependent growth regulation by altering the balance of activities between its downstream effector proteins mDia1 and ROCK that are involved primarily in cytoskeletal remodeling (Mammoto et al., 2004). Dissipation of cytoskeletal tension using pharmacological or genetic methods inhibits cell distortion-dependent cell cycle progression, stimulates apoptosis, and suppresses lamellipodia formation (Parker et al., 2002; Numaguchi et al., 2003).

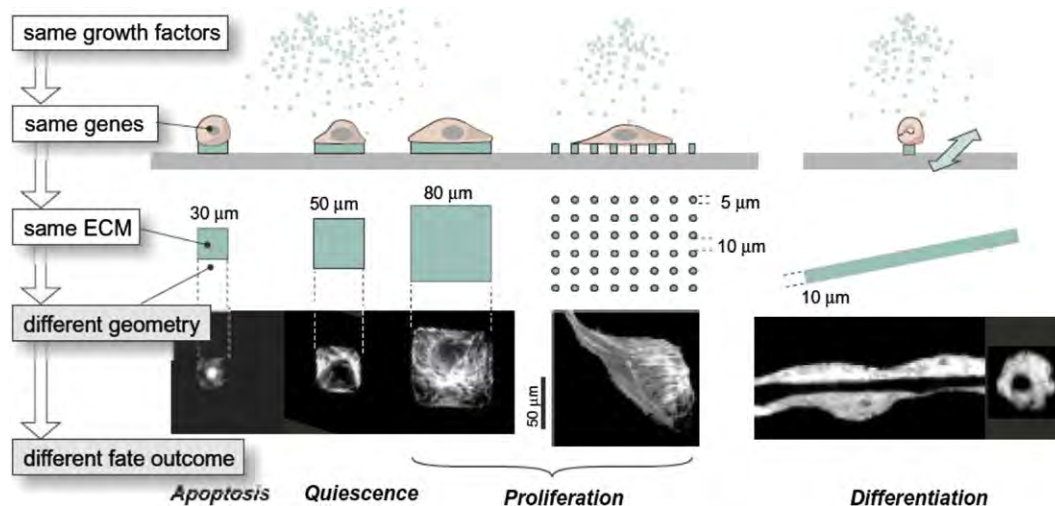
The mechanical properties of the ECM can also regulate cell shape, as well as these same behaviors including cell growth, motility, and differentiation, and again these effects are mediated at least in part through modulation of cytoskeletal tension. For example, cells plated on rigid ECM substrates generate higher levels of tension and proliferation, whereas softer substrates reverse this phenotype (Wang et al., 2000; Ghosh et al., 2007). ECM rigidity can also influence tissue-specific differentiation (Engler et al., 2004, 2006), as well as guide directional cell motility (durotaxis) by regulating cell-substrate mechanical interactions that lead to spatial differentials in cell traction forces and focal adhesion dynamics


FIGURE II.6.5.3 ECM-mediated geometric control of cell shape regulates key developmental programs. Shown here is a schematic summary of experiments where microfabricated fibronectin islands (solid green) of desired shape and size were used to control cell shape and spreading. Under the influence of the same growth factors (light green dots) and ECM composition, round cells die (apoptosis) and spread cells proliferate, while those partially spread become quiescence (Huang, S. & Ingber, D. (1999). Nat Cell Biol; Chen, C. et al. (1997). Science). Note that cells plated on the small 5 μm dots in the center are in contact with approximately the same absolute amount of fibronectin as on the small 30 μm islands, yet they proliferate because they are allowed to extend over the ECM dots. The first four panels in the bottom row show fluorescence micrographs of phalloidin-stained actin "stress fibers." Allowing endothelial cells to extend on 10 μm-wide linear ECM arrays (right panel) stimulates tube formation, a manifestation of endothelial cell differentiation, as verified using confocal fluorescence microscopy of cytoplasm-stained cells (Dike, L. et al. (1999). In Vitro Cell Dev Biol Anim). (Reproduced from Huang, S. & Ingber, D. (2006). Breast Disease, 27–54, with permission from IOS Press ©2006, 2007.)

(Pelham and Wang, 1997; Lo et al., 2000). Importantly, matrix stiffness alone can control three-dimensional tissue morphogenesis, as normal mammary gland development commonly seen in compliant three-dimensional gels is disrupted when the gel stiffness is raised from 170 Pa to 1200 Pa (Paszek et al., 2005). Likewise, varying ECM elasticity from 700 Pa to 900 Pa can significantly alter three-dimensional endothelial capillary formation *in vivo*, with the intermediate stiffness (800 Pa) promoting the highest VEGF receptor expression and capillary ingrowth (Mammoto et al., 2009). Thus, it is critical to take into account the importance of mechanical features of the tissue microenvironment in future studies focused on engineering artificial inductive scaffolds.

BIOMATERIALS FOR STEM CELL DEVELOPMENT AND TISSUE REGENERATION

Engineered biomaterials that aim to promote complete regeneration of diseased or injured tissues and organs must recapitulate the developmental programs that drive endogenous tissue formation and function. This goal can be accomplished by developing biomimetic scaffolds that leverage the regenerative potential of stem and multipotent progenitor cells – the primitive cells that retain an ability to differentiate into mature cells of various tissue types. Since cell and ECM mechanics alone can regulate the development and function of mature tissue cells, it is conceivable that stem cell differentiation and functionality similarly depend on its physical microenvironment. Indeed, stem cells implanted in the absence of proper mechanostructural cues form teratomas (Wakitani et al., 2003; Hentze et al., 2007), which result from stem cells growing and differentiating into multiple different lineages in the absence of higher-order pattern controls. Thus, a major challenge in regenerative medicine will be to develop biomaterials that can provide appropriate physical cues required to precisely drive stem cell differentiation along a specific lineage, and stimulate regeneration in damaged tissues and organs.

In this regard, it is important to note that mechanical cues such as ECM topography and stiffness alone have been shown to direct mesenchymal stem cell (MSC) lineage specification. When human MSCs are grown on single cell-sized microfabricated ECM islands and exposed to a cocktail of soluble differentiation-inducing factors, adipogenic differentiation is favored on smaller (~1000 μm^2) ECM islands, while osteogenesis is induced in cells spread on larger (~10,000 μm^2) islands (McBeath et al., 2004). Notably, this shape-dependent lineage specification is mediated by cytoskeletal organization and tensile prestress as disruption of Rho activity and actin assembly favors adipogenic differentiation while inhibiting osteogenesis; moreover, overexpressing Rho has an opposite effect. Even more striking is the finding that this Rho-mediated lineage switching occurs independently of the

appropriate differentiation-inducing medium (McBeath et al., 2004), suggesting that cell shape and tension alone can govern which cues are necessary and sufficient for stem cell commitment.

The nanotopography of biomaterial surfaces can similarly regulate stem cell differentiation. When human MSCs are cultured on titanium oxide (TiO_2) nanotubes, they adhere strongly but fail to differentiate when the nanotubes are small in size (~30 nm diameter), whereas they differentiate into bone on larger nanotubes (~70–100 nm diameter) that promote cytoskeletal stress-dependent changes in cell form and function (Oh et al., 2009). MSCs grown on ECM-coated flexible substrates can also be directed towards different lineages by tuning the substrate stiffness to match the elasticity of the whole living tissue. For example, neurogenesis is induced on softer substrates (0.1–1 kPa) that mimic brain's elasticity; stiffer substrates (8–17 kPa) that mimic muscle mechanical properties promote myogenic differentiation; and bone induction is observed on the stiffest substrates (25–40 kPa) that matched bone elasticity (Engler et al., 2006). Again, this elasticity-driven lineage switching is dependent on cytoskeletal tension, as disrupting non-muscle myosin II activity abolishes this effect (Engler et al., 2006) in a manner reminiscent of Rho-mediated cytoskeletal control of shape-dependent lineage specification (McBeath et al., 2004). Neural stem cell (NSC) differentiation can similarly be controlled in an ECM stiffness-dependent manner; compliant substrates (~100–500 Pa) favor neuron formation, whereas stiffer hydrogels drive glial cell formation (Saha et al., 2008). Thus, biomaterials developed for tissue engineering and regeneration must be tailored to provide the correct mechanostructural cues that promote desired tissue functionality while suppressing undesirable responses.

Embryonic stem (ES) cells, the pluripotent cells that can give rise to derivatives of all three embryonic germ layers (i.e., endoderm, mesoderm, and ectoderm), possess greater regenerative potential when compared with MSCs and, as such, they are being increasingly explored for cell-based therapies. Notably, human ES (hES) cell self-renewal and differentiation are remarkably sensitive to the physical dimensions of the culture microenvironment. Cell colonies generated from single hES cells initially cultured on micropatterned ECM islands of varying sizes revealed that smaller (200 μm diameter) hES cell colonies preferentially undergo endodermal differentiation, while larger (1200 μm) colonies differentiate into mesoderm (Bauwens et al., 2008; Lee et al., 2009). However, high mesodermal and cardiac induction is observed when the smaller endodermal-biased hES cell colonies are grown into embryoid bodies of large sizes, suggesting that the size of both the cell colony and embryoid body regulate hES cell fate determination (Bauwens et al., 2008). Taken together, these findings suggest that mechanical interactions at the cell–cell and cell–ECM interface guide tissue development not only by

facilitating morphogenetic shape changes (as seen during lung branching), but also through precise spatiotemporal control of stem cell fate commitment.

To be effective, tissue and organ regeneration strategies must simultaneously promote the formation of a robust vascular network to maintain optimal oxygen delivery and metabolic exchange. But, despite years of research, achieving this single functionality still poses a huge challenge for tissue engineers. Past *in vitro* studies have shown that heterotypic interactions between endothelial cells and mesenchymal precursor cells, mediated by specific growth factors such as TGF-β and PDGF, cause significant enhancement in vessel stabilization through mesenchymal differentiation into mural cells (pericytes or smooth muscle cells) that are ultimately recruited to the perivascular niche (Hirschi et al., 1998; Ding et al., 2004). Indeed, when such co-cultures are grown in three-dimensional ECM gels and implanted in animals, long-lasting and robust vessels form that remain stable up to one year (Koike et al., 2004). hES cell-derived endothelial cells have also been co-cultured with mouse myoblasts and embryonic fibroblasts within three-dimensional porous polymeric scaffolds to obtain prevascularized tissue constructs *in vitro*, with improved vascular network and blood perfusion *in vivo* (Levenberg et al., 2005).

However, given the complexity of culturing multiple cell types in a controlled and reproducible manner, alternate approaches have been developed that use biomaterial scaffolds to release single or multiple angiogenic growth factors (e.g., VEGF, PDGF) in a spatiotemporally controlled manner to induce new vessel formation. These materials stimulate rapid and robust capillary ingrowth and maturation, as well as increased blood perfusion and improved tissue functionality (Richardson et al., 2001; Nillesen et al., 2007). More recent studies show that in addition to soluble cues (e.g., VEGF) scaffold elasticity can exert a significant effect on three-dimensional capillary formation by endothelial cells *in vivo* via transcriptional control of VEGF-receptor expression. In this study, ECMs with intermediate stiffness (800 Pa) promoted the highest VEGF-receptor expression and capillary ingrowth, compared with both softer (700 Pa) and stiffer (900 Pa) scaffolds *in vivo* (Mammoto et al., 2009). In addition to vascular density, the three-dimensional spatial patterning of the newly formed endothelial capillaries can also be controlled by providing appropriate mechanical cues. For instance, application of exogenous cyclic stretch to endothelial cell-seeded polymeric scaffolds results in three-dimensional sprouting in a direction perpendicular to the stretch axis (Matsumoto et al., 2007). Thus, formation of a robust vasculature within engineered tissues will benefit from the use of instructive biomimetic scaffolds that can effectively integrate and present both soluble and physical cues in a precisely controlled manner.

In addition to their pivotal role in cell-based regenerative approaches, biomaterials are also crucial for targeted delivery of therapeutic drugs and genes that, in turn, has direct implications for regenerative medicine. The physical properties of biomaterials are as important for optimizing drug and gene delivery, as they are for control of tissue development (Mitragotri and Lahann, 2009). Cellular uptake of injected microparticles, for instance, is greatly influenced by particle shape, where rod-like particles with an intermediate aspect ratio of 3 are preferably internalized relative to their spherical counterparts (Decuzzi and Ferrari, 2008; Gratton et al., 2008). Subsequent theoretical modeling and experimental work have revealed that particle internalization is greatly favored with increasing contact angle between the particle and the cell surface (which is high for cylindrical particles and low for spherical ones), which influences the development of a complex actin structure within the cell required for particle internalization (Champion and Mitragotri, 2006). Oblate particles are also expected to adhere more strongly to the vascular endothelium than spherical particles of the same volume (Decuzzi and Ferrari, 2006; Muro et al., 2008), a feature that has important implications for drug delivery to blood vessels. In addition, the degree of internalization depends on particle elasticity, as softer particles are less likely to be phagocytosed by macrophages, and thus have a longer lifetime in the circulation (Beningo and Wang, 2002; Geng et al., 2007). The efficiency of gene delivery to cells similarly depends on the elasticity of cell adhesive hydrogels, and the uptake and expression of plasmid DNA were shown to be higher on stiffer substrates (Kong et al., 2005).

MOLECULAR MECHANISMS OF CELLULAR MECHANOTRANSDUCTION

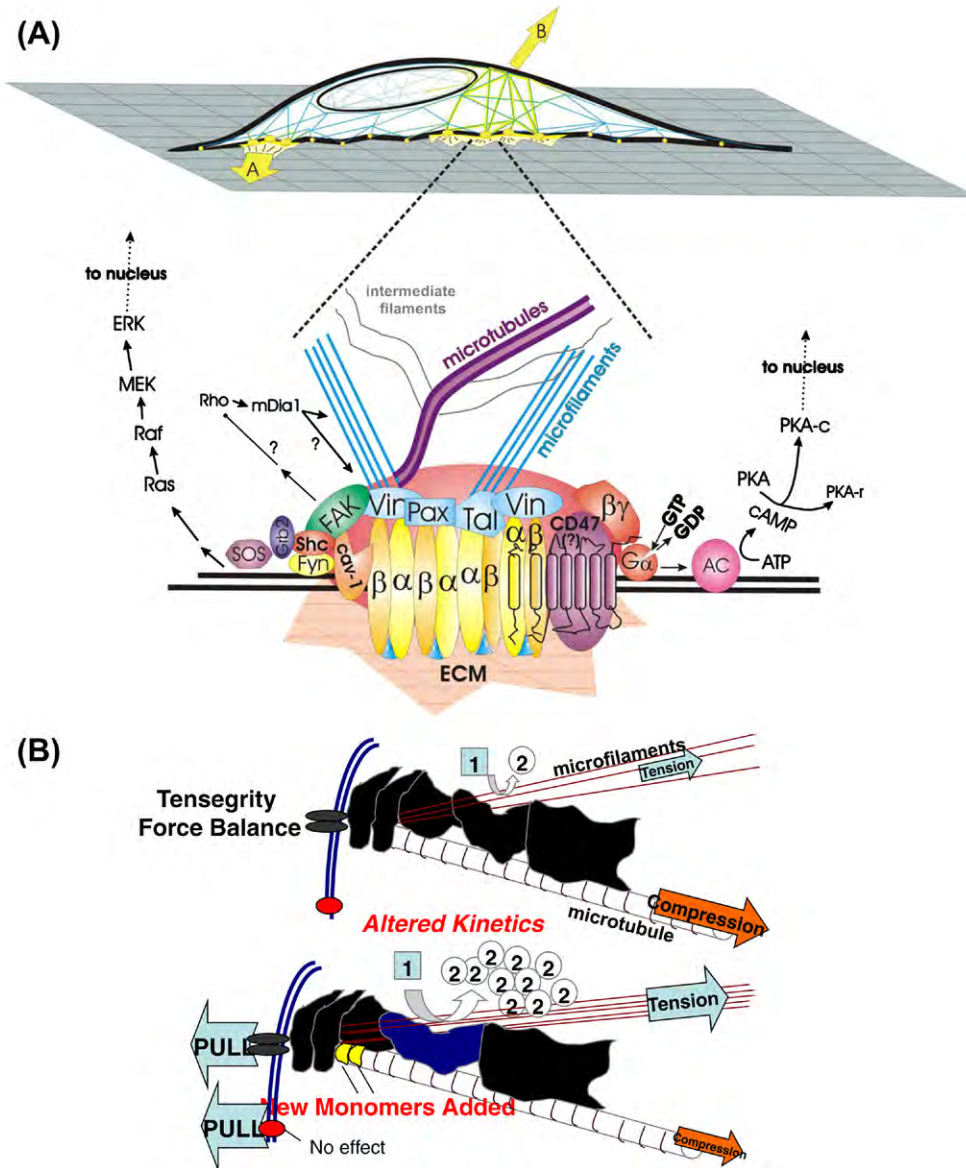
It is now clear that cells can actively sense and respond to physical cues from the ECM by modulating their level of contractility, which further alters ECM mechanics, thereby establishing a feedback loop that ultimately controls cell fate and function. This dynamic reciprocity of cell–ECM mechanical interactions is mediated by transmembrane integrin receptors that transmit mechanical forces across the cell surface and facilitate mechanochemical transduction events that control cell function and govern cell fate (Alenghat and Ingber, 2002). Integrins refer to a family of heterodimeric transmembrane proteins that bind various ECM molecules on the external surface of the cell (Hynes, 2002) and interact with actin-binding proteins (e.g., vinculin, paxillin, and zyxin) within focal adhesion anchoring complexes inside the cell (Zamir and Geiger, 2001; Ingber, 2003c) (Figure II.6.5.4A). Focal adhesions play a central role in mechanochemical transduction, because in addition to physically coupling the ECM to actin cytoskeleton and bearing high mechanical loads focused through integrins, they also contain many signaling molecules that alter their activity when mechanically stressed (Chicurel et al., 1998b; Alenghat and Ingber, 2002).


FIGURE II.6.5.4 (A) Integrin-associated focal adhesions mediate cellular mechanotransduction. Forces applied to cells via their basal ECM adhesions are transmitted across cell surface integrin receptors to their cytoplasmic domains down to the underlying focal adhesion scaffolds that link to the cytoskeleton. Forces such as fluid shear stresses, which act on the apical cell surface and produce generalized distortion can also result in increased tension on the cell's basal focal adhesions that are stiffened relative to the remainder of the cell and cytoskeleton. Internally-generated tension (contractility) and forces transmitted via intercellular junctions similarly reach focal adhesions through the cytoskeleton. Forces concentrated within the focal adhesion can stimulate clustering of dimeric (α,β) integrin-receptors, and induce recruitment of focal adhesion proteins (e.g., Vinculin (Vin), Paxillin (Pax), Talin (Tal)) that connect directly to actin microfilaments and indirectly to microtubules and intermediate filaments. Forces applied to this specialized focal adhesion complex activate various integrin-associated signaling cascades, including focal adhesion kinase (FAK), extracellular signal-regulated protein kinase (ERK), Rho, mDia1, heterotrimeric G-proteins, and protein kinase A (PKA), among others, which ultimately regulate gene expression and thereby cell behavior (Ingber, D. (2003c). J Cell Sci). (B) Tensegrity model as the architectural basis of cellular mechanotransduction. (Top) A schematic diagram of the tensegrity-based complementary force balance between tensed microfilaments, compressed microtubules, and transmembrane integrin-receptors (gray oval dimer) in living cells (intermediate filaments are not shown for simplicity). Black forms indicate regulatory proteins and enzymes that are physically immobilized on load-bearing cytoskeletal filaments; red oval represents a transmembrane protein that does not link to the internal cytoskeletal lattice. (Bottom) When force is applied to integrins, thermodynamic and kinetic parameters change locally for cytoskeleton-associated molecules that physically experience the mechanical load; when force is applied to non-adhesion receptors that do not link to the cytoskeleton, stress dissipates locally at the cell surface, and the biochemical response is muted. In this schematic, new tubulin monomers add onto the end of a microtubule (yellow symbols) when tension is applied to integrins, and the microtubule is decompressed as a result of a change in the critical concentration of tubulin. The blue form indicates a molecule that is physically distorted by stress transferred from integrins to the cytoskeleton and, as a result, changes its kinetics (increases its rate constant for chemical conversion of substrate 1 into product 2). In this manner, both cytoskeletal structure (architecture) and prestress (tension) in the cytoskeleton may modulate the cellular response to mechanical stress. (Ingber, D. (2003c). J Cell Sci; Stamenovic, D. & Ingber, D. E. (2009). Soft Matter 5: 1137–1145.)

Integrin-mediated force transfers occurs bidirectionally. In addition to sensing external mechanical forces, cells also exert cytoskeleton-generated contractile forces on these same integrin-ECM linkages (Ingber, 1997; Alenghat and Ingber, 2002; Ingber, 2006; Lele et al., 2006; Parker and Ingber, 2007). Moreover, since ECM is relatively rigid compared to the cell, differences in the ability of the ECM to physically resist cell-generated traction forces directly modify cytoskeletal prestress in a manner that is consistent with the "cellular tensegrity" hypothesis (Ingber et al., 1985; Ingber, 2006; Stamenovic and Ingber, 2009). In this model of cell structure, mechanical stability of the cell and cytoskeletal network results from inward-directed tensional forces borne by actin microfilaments and intermediate filaments that are balanced by microtubule struts and cell surface adhesions to ECM and neighboring cells (Stamenovic and Coughlin, 1999; Wang et al., 2001; Ingber, 2003b) (Figure II.6.5.4B). In addition to stabilizing cell shape and structure, the cytoskeletal tension-mediated cell–ECM force balance regulates cell sensitivity to external mechanical and chemical cues, thereby exerting a significant impact on overall cell function (Ingber, 2003b, 2006; Ghosh et al., 2008; Mammoto et al., 2009). Thus, although mechanical forces applied to integrins initiate a local response at the site of focal adhesion (Chicurel et al., 1998b; Geiger et al., 2001), the cell integrates this intracellular transduction response with other external cues in a tensegrity-dependent manner to elicit a global behavioral response (Ingber, 2003a).

IMPLICATIONS FOR FUTURE MATERIALS DESIGN FOR *IN SITU* TISSUE ENGINEERING

The availability of artificially-engineered skin and cartilage as commercial products serves as a testament to the significant progress that has been made in the field of tissue engineering over the past two decades. However, it must be noted that the success in artificially engineering these tissues is, to a large extent, due to the relative simplicity of their structure and composition, and the low vascularity of the cartilage matrix and skin epidermis. Yet, producing these "living" tissue constructs in a large-scale and reproducible manner has proved challenging, primarily owing to high cost and stringent quality control measures. Thus, to achieve the ultimate goal of regenerating more complex tissues and whole organs, we will need to develop novel *in situ* engineering approaches that can address these limitations by harnessing endogenous tissue and stem cells.

One way to accomplish this goal would be to design strategies for "targeted" delivery of biomaterials to specific injury or diseased sites in the body (Figure II.6.5.5). These injectable delivery systems could be used to target therapeutic agents (drugs, genes) or soluble factors

to these critical locations, where they can then recruit endogenous tissue cells or bone marrow-derived stem cells required for tissue repair and regeneration. Peptides that selectively home to the vasculature of specific organs have been identified (Rajotte et al., 1998), and biomaterials derivatized with such targeting moieties could be used for tissue-specific therapies. These injectable, homing biomaterials will need to be programmed such that, upon reaching their target site, they self-assemble into stable, higher-order structures that integrate into the host tissue, and provide the correct adhesive and morphogenetic cues essential for orderly tissue ingrowth and development. Various approaches that facilitate self-assembly of nanoscale materials into supramolecular structures have already been developed. For instance, ampiphilic peptides have been engineered that can self-assemble into a three-dimensional hydrogel *in situ* and promote local tissue repair (Zhang, 2003). Self-assembled, tensegrity-based three-dimensional nanostructures have also been built using DNA that can potentially be used as templates for *in situ* cell and tissue engineering (Douglas et al., 2009).

Regardless of the chemical strategies, it will be advantageous to tune the microscale chemical and mechanical properties of three-dimensional scaffolds *in situ* and in real-time, in order to dynamically regulate the cellular microenvironment, as seen during different stages of endogenous tissue development. This concept has recently been explored using photosensitive PEGDA-based hydrogels, where three-dimensional chemical and mechanical micropatterns were created *in situ* by exposing cell-seeded hydrogels to light in a spatiotemporally defined manner (Hahn et al., 2006; Kloxin et al., 2009). Such variations in local scaffold properties produce distinct microenvironmental niches that permit precise spatiotemporal control over MSC differentiation (Kloxin et al., 2009). It may be possible to use similar approaches to pattern three-dimensional scaffolds in a way that can simultaneously establish differentials in cell growth and apoptosis, as seen during tissue morphogenesis. Such "smart" biomaterials offer great promise as scaffolds that can induce tissue and organ regeneration through recapitulation of the complex morphogenetic and differentiation events that underlie endogenous developmental processes.

CONCLUSION

Today, biomaterials are an indispensable tool in our efforts to repair and regenerate injured or diseased tissues and organs. They are no longer viewed as inert carriers for cell delivery; instead, biomaterials are now designed to actively interact with cells and promote tissue development, as well as restore its function. As cells adhere and spread on a substrate, they exert traction forces at their adhesion points that are balanced by the resistance (stiffness or elasticity) of the substrate. This
FIGURE II.6.5.5 Biomaterial design strategies for *in situ* tissue engineering. The schematic diagram depicts an example of how smarter approaches that leverage targeting nanomaterials and endogenous stem cells might be used to treat a diseased organ; myocardial infarction is used as an example. The first challenge will be to identify moieties (e.g., peptides, aptamers) that bind to site-specific ligands with high affinity. Nanomaterials derivatized with these targeting moieties (top) can be injected intravenously (middle left) and delivered selectively to sites of tissue damage (bottom left). These materials will need to be programmed to self-assemble into a three-dimensional scaffold that integrates into the host tissue (bottom center), but only when they reach to their target site. Once this occurs, they will be designed to release potent soluble bioactive factors that can increase expansion of critical stem cell populations within bone marrow (middle right), mobilize them into the circulation and recruit them to the infarct site (bottom left). Either the newly formed scaffold materials will need to release different factors over time that stimulate proliferation and differentiation of recruited stem cells and endothelial progenitor cells, or other materials with these inducing properties may be injected and targeted to these same sites at later times. In this manner, formation of vascular networks that can provide continued supplies of oxygen and nutrients will be stimulated in parallel with development of functional tissue structures (e.g., muscle bundles, nerves, connective tissue) (bottom right). This type of *in situ* tissue engineering approach may potentially lead to development of more effective and more cost-effective therapeutics for tissue and organ regeneration.

mechanical force balance drives cytoskeleton-dependent changes in cell shape, which can switch cells between different fates (e.g., growth versus differentiation) in both mature tissue cells and in various types of stem cells. Analysis of embryonic development reveals that micromechanical interactions between cells and the ECM are also critical for tissue morphogenesis, thus suggesting the existence of an overarching micromechanical control point for developmental control. However, the mechanical and structural features of developing tissues vary over space and time on the micrometer scale. Thus, biomaterials that allow precise spatiotemporal regulation of adhesive and micromechanical cues might have tremendous regenerative potential if they can better recapitulate the dynamic cellular microenvironment characteristic of endogenous developmental processes. The ultimate challenge, however, will be to promote tissue repair and regeneration *in situ* at the local site of tissue defect. This goal could be accomplished by developing injectable biomimetic nanomaterials that specifically home to injury or diseased sites, where they self-assemble into higher-order structures that provide

the correct developmental and morphogenetic cues required for orderly tissue renewal.

CHAPTER II.6.6 BIOREACTORS FOR TISSUE ENGINEERING

Nina Tandon, Elisa Cimetta, Sarindr Bhumiratana, Amandine Godier-Furnemont, Robert Maidhof, and Gordana Vunjak-Novakovic

Department of Biomedical Engineering, Columbia University, New York, USA

INTRODUCTION

This chapter is a review of the principles of bioreactor design for tissue engineering. We describe the design and operation of tissue engineering bioreactors developed to direct the differentiation and functional assembly of cells cultured on three-dimensional biomaterial scaffolds. We first discuss the general design requirements for tissue engineering bioreactors, with a focus on mass transport considerations associated with environmental control, and biophysical signals necessary to modulate cell differentiation and the formation of engineered tissues. Next, we discuss the specifics of bioreactor design and operation using six examples of distinctly different tissue engineering systems: (1) cartilage tissue engineering with mechanical loading; (2) tissue engineering of anatomically shaped human bone; (3) cardiac tissue engineering with mechanical stretch; (4) cardiac tissue engineering with electrical stimulation and medium perfusion; (5) tissue engineering of heart valves with mechanical stimulation and perfusion; and (6) tissue engineering of blood vessels with pulsatile

medium flow. Lastly, we address challenges in bioreactor design and operation in biological research, and translation into animal models and clinical treatment modalities.

BIOREACTOR DESIGN CONSIDERATIONS

Cells are the key architects of tissues and organs. The cells both respond to and remodel their microenvironment by taking specific differentiation paths, interacting with the neighboring cells, extracellular matrix, molecular and physical signals, and assembling functional tissue units (Kaplan et al., 2005). Both *in vivo* (during development/regeneration) and *in vitro* (in tissue engineering settings), the cues with which cells are presented are the principal determinants of the phenotypic nature of the resultant tissues. Notably, the same factors that determine cell fate and function *in vivo* also determine the progression of cell differentiation *in vitro*. Hence, for tissue engineering applications, major efforts have been invested into characterizing the native tissue environments, and describing these environments by parameters that may be recapitulated experimentally (Kirouac and Zandstra, 2008).

Cell function and the progression of tissue assembly depend on the entire context of cell environment: the availability of a scaffold for cell attachment and tissue formation; the maintenance of physiological conditions in the cell–tissue environment; the supply of nutrients, oxygen, metabolites, and growth factors; and the presence of physical regulatory factors. The regulatory factors of cell differentiation and tissue assembly can be utilized *in vitro* to engineer functional tissues by an integrated use of cells, scaffolds, and bioreactors, as depicted in Figure II.6.6.1. Bioreactors are the primary tools for mimicking the native environments, and providing tissue engineered constructs with physiologically relevant stimuli that can orchestrate the conversion of a "collection of cells" into a specific tissue (Freed and Vunjak-Novakovic, 1998; Bilodeau and Mantovani, 2006; Freed et al., 2006; Kretlow and Mikos, 2008).

Key Components

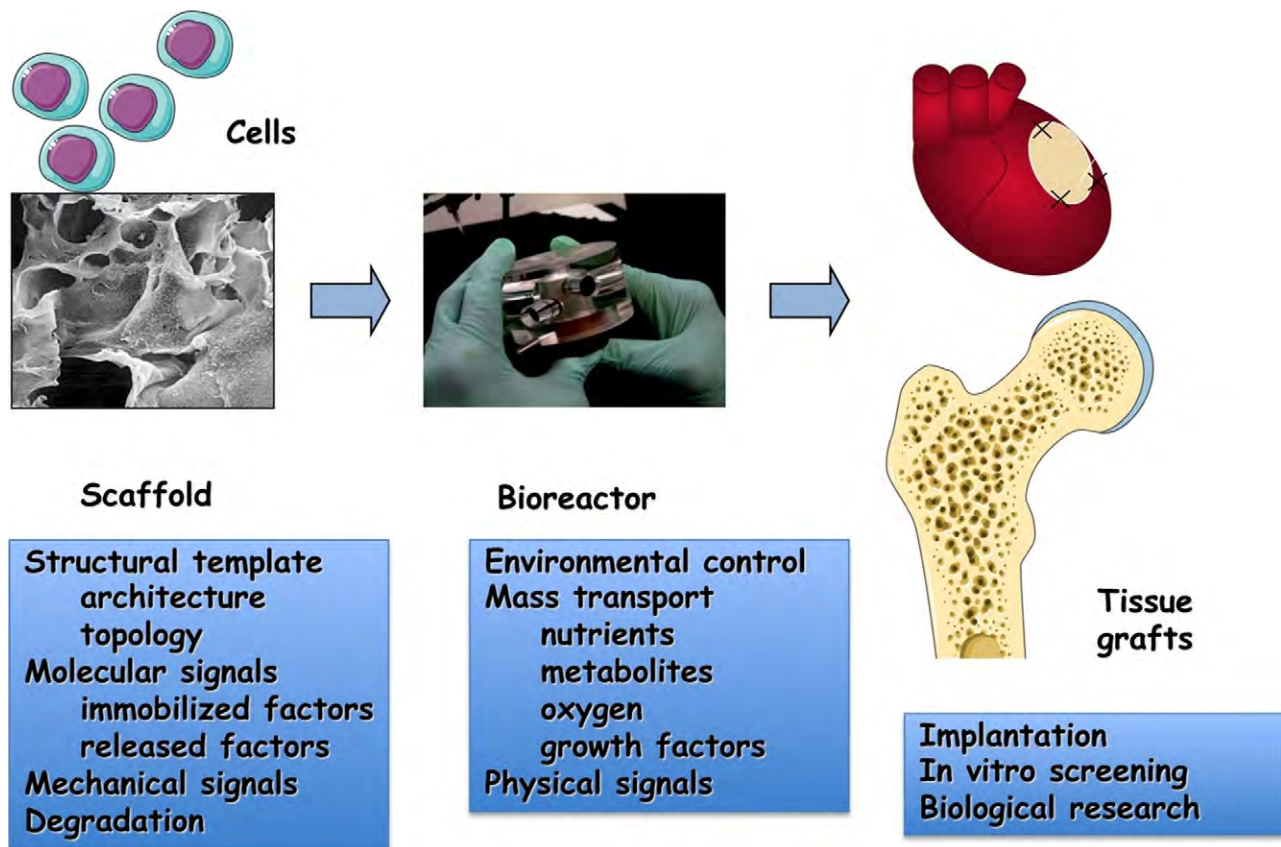
Bioreactors are composed of several building blocks: the culture chamber; medium reservoir; gas and medium exchange system; and instrumentation for monitoring and control (in many cases operated by computer


FIGURE II.6.6.1 The tissue engineering paradigm. The living cells (either differentiated or progenitor/stem cells) are seeded onto a biomaterial scaffold, and cultured in a bioreactor to carry out the process of tissue formation. The *scaffold* provides a template for cell attachment and tissue formation through its structural properties (overall architecture, surface properties), molecular factors (immobilized and released molecules and cell-receptor ligands), mechanical properties (stiffness and elasticity), and it degrades in parallel with the deposition of new tissue matrix. The *bioreactor* provides the entire milieu of environmental conditions necessary for regulating cell differentiation and functional assembly, through the control of cell environment (temperature, pH, medium composition) and application of physical stimuli (hydrodynamic shear, mechanical stretch, compression, electrical stimulation).

software). These building blocks are either modular (so that they can be used within several different tissue engineering setups) or integrated into a single device. In most cases, the bioreactor design is customized to meet the need of a specific application, although some of the components (as for example the gas exchange system) can be used within various bioreactor systems.

Technical Requirements

As described in the following sections, there is a great diversity in bioreactor designs that mirrors the range of environmental and regulatory signals that need to be provided to the cells to direct their differentiation into various lineages and assembly into engineered tissues. The environments needed to engineer bone or muscle or blood vessels are quite different from each other, in many respects. However, there are some universal requirements that need to be met by all tissue engineering bioreactors.

An essential prerequisite for all bioreactor components that come in contact with the cells and culture medium is their *biocompatibility*. In contrast to biomaterials used for clinical applications, which are typically designed to be bioactive in some way, all materials used for the bioreactor chamber, gas and medium exchange, and in-line sensors need to be as inert and neutral as possible, so that the cells and molecular factors in culture medium are not affected.

The bioreactor components need to be sterilizable (ideally by autoclaving, ethylene oxide or UV irradiation), and the *sterility* and *sterile containment* must be maintained during the entire culture period. This requirement extends to sampling of tissue constructs and culture medium (during which time the sterile envelope may be broken), imaging of the growing tissues or application of external stimuli (such as mechanical loading). The case studies discussed below show some examples of how this requirement is addressed for specific bioreactor designs.

Biomaterial Scaffold

An engineered tissue is, in most cases, formed by cell cultured on biomaterial scaffolds. In general, tissue engineering scaffolds are biodegradable. To this end, it is important that the scaffold degrades at a rate comparable to that of the tissue formation. Fast degradation not only disrupts the initial structure of the cell-biomaterial construct, but can also result in environmental changes (e.g., a decrease in pH associated with hydrolysis of polyesther scaffolds such as polyglycolic acid (PGA) and polylactic acid (PLA)), while slow degradation leaves too much scaffold material in the way of new tissue formation.

A scaffold serves as a structural template for cell attachment and tissue formation, and it is designed to define the shape, size, and structural properties of the forming tissues. The scaffold is also an informational template, by virtue of its mechanical properties, immobilized and released bioactive factors and cell receptor ligands, and overall architecture (including surface properties, pore size and connectiveness, orientation, and alignment). To mimic the anisotropy of native tissues (such as bone or heart), scaffolds are also made of materials that have different structural and mechanical properties in different directions (Peppas and Langer, 1994; Hubbel 1995; Langer and Tirrell, 2004). In all cases, the cells receive important regulatory signals – molecular, topological, and mechanical – from the scaffold. Hence, the bioreactor designs are largely determined by the specific scaffold properties, and the bioreactor chamber accommodating a flexible tubular scaffold used to engineer a blood vessel is distinctly different from the bioreactor chamber that accommodates an anatomically-shaped engineered bone construct.

Gas Exchange

A gas exchange unit is necessary to ensure the maintenance of physiological levels of gases inside the culture chambers: carbon dioxide to regulate the pH of the culture medium; and oxygen to ensure the correct metabolic activity of cells. In most cases, the bioreactor is placed into an incubator, and this function is provided by mass transport between the incubator gas and the culture medium circulating through a coil of silicone tubing or across a silicone membrane. The efficiency of gas exchange depends on the permeability coefficients of each gas through the materials used, the geometry of the system, temperature, composition of the gas atmosphere, and the flow rate that determines the residence time of the fluids during gas exchange. In general, thin silicone tubing and membranes are selected for gas exchange systems because of their high permeability for oxygen and carbon dioxide, high biocompatibility, and possibility for reuse as these materials can be autoclave-sterilized.

Environmental Control

One of the key functions of a bioreactor is to control, maintain, and modulate as necessary the environmental parameters such as temperature, pH, oxygen tension, and medium composition. Bioreactors allow the establishment of steady-state conditions thus maintaining, by definition, all parameters of interest at constant levels. On the contrary, standard culture systems such as Petri dishes can be considered batch bioreactors, where the environmental conditions are precisely defined only at time zero, and then continuously vary with time between two medium exchanges, often with diffusion-limited and unpredictable kinetics. It is important that bioreactors can be designed to introduce tightly controlled perturbations into the system (such as an episode of hypoxia), and investigate the dynamics of the resulting biological responses.

Mass Transport

Nutrients, oxygen, and regulatory molecules have to be efficiently transported from the bulk culture medium to the tissue surfaces (external mass transfer), and then through the tissue to the cells (internal mass transfer) to maintain the viability and metabolism of cells within tissue engineered constructs. At the same time, metabolites and CO_2 need to be removed from the cells, through the tissue matrix, and into the bulk medium. External mass transfer is determined by the flow conditions at construct surfaces, while the internal mass transport depends on molecular diffusion and convection, and the internal construct structure.

Transport of oxygen to the cells is by far the most critical among all molecules of interest, due to extremely low oxygen solubility in aqueous media. Fully oxygenated culture medium contains only 220 μM of oxygen at physiologic temperature. Oxygen concentration in blood plasma is even lower – only 130 μM. However, the total concentration of oxygen in oxyhemoglobin can reach 8600 μM, through reversible binding of oxygen to hemoglobin. Oxygen transport becomes critically inadequate in large non-perfused constructs (Muschler et al., 2004; Martin and Vermette, 2005), because the diffusional penetration depth of oxygen within native tissues is only 100–200 μm.

Transport phenomena occurring in bioreactors can be subjected to theoretical analysis and precise control once the geometries of the system, the transport distances, and fluid flow rates have been determined. The relative importance of the convective versus the diffusive component to the global mass transport can be calculated and analyzed in conjunction with the kinetics of uptake and release by the cultured cells.

Physical Signals

Tissues and organs in the body are subjected to complex biomechanical environments with dynamic stresses and strains, fluid flow, and electrical signals. Biophysical signals that play a role in cell physiology *in vivo* can also modulate the activity of cells within engineered tissues cultured *in vitro*. Innovative bioreactors have been developed to apply one or more regimes of controlled physical and/or electrical stimuli to three-dimensional engineered constructs, in an attempt to improve or accelerate the generation of a functional tissue (Freshney et al., 2007). *Shear stress* from the tangential forces applied to a surface (typically where cells reside) is important because of the profound effects of flow environment in biological systems (Wang et al., 2005). *Mechanical forces* play fundamental roles in determining the correct development and function of a multiplicity of organs and systems. The application of *mechanical stimulation* (compression, tension, torsion) can improve the engineering of tissues that normally provide mechanical

function in the body (bone, muscle tissue, cartilage, tendon) (Stolberg and McCloskey, 2009). Likewise, *electrical stimulation* can improve the physiologic characteristics of tissues that are electrically excitable, such as myocardium (Tandon et al., 2009).

Scale

Tissue engineering bioreactors can have volumes ranging from hundreds of milliliters down to a few milliliters or in some cases only a few microliters. In recent years, micro-bioreactors with volumes of the order of micro- or even nano-liters are helping open new perspectives in studying cell biology and physiology, (Chang et al., 2007; Toner and Irimia, 2005) as they allow experiments conducted at the characteristic time and length scales of biological phenomena (Figallo et al., 2007). While macroscale observations of averaged cell–tissue properties are critical for engineering clinical-size grafts, they cannot be reliable in defining the cell-scale phenomena in biological systems, and should thus be supported by more precise microscale observations (Cimetta et al., 2009). In microscale systems, flow is always laminar (Reynolds numbers Re <1000), and transport is dominated by molecular diffusion or by convective regimes with defined hydrodynamic profiles. Reducing the characteristic dimensions to a microscale level allows working with very short transport distances, which are in turn associated with short time constants. As a result, biological responses are not limited any more by the slow kinetics of physical phenomena. Microscale systems also allow easier decoupling of the effects of mass transport phenomena (such as the generation of specific concentration patterns) from physical phenomena (such as the application of shear forces).

CARTILAGE TISSUE ENGINEERING WITH MECHANICAL LOADING

The avascular nature of articular cartilage predisposes it to a limited ability to regenerate once injured. Articular cartilage is a loadbearing tissue, and is exposed to cyclical stress, which induces fluid pressurization within the tissue and resultant fluid shear. In a 2000 paper, Hung, Ateshian, and colleagues (Mauck et al., 2000) developed a dynamic loading bioreactor to induce pressurization of the interstitial media within agarose scaffolds seeded with bovine articular chondrocytes. Agarose was selected as a scaffold material because of its open lattice structure that minimizes diffusional distances, while maintaining the three-dimensional structure necessary for the fixation of cells. Agarose is a clear polysaccharide hydrogel that has been used extensively for long-term chondrocyte culture, as it permits the application of deformational loading immediately upon cell encapsulation, and is suitable for the preparation of anatomically correct constructs. The spatial uniformity of cells after seeding (compared
FIGURE II.6.6.2 Bioreactor with mechanical loading for tissue engineering of cartilage. Custom designed bioreactor demonstrating how scaffolds experience loading under sterile conditions. The culture well is fitted with a custom designed loading lid imposed by the cam follower system. (Reproduced by permission from Mauck et al., 2000.)

to seeded fibrous scaffolds) is considered an additional advantage. Cell encapsulation in agarose, combined with the staged application of growth factors, resulted in engineering of functional articular cartilage with mechanical properties far exceeding those achieved using culture systems without mechanical loading.

Hung, Ateshian, and colleagues developed a custom loading system with a cylindrical loading platen, designed to subject a set of cell-seeded agarose discs that were cultured under sterile conditions in a simple Petri dish covered with a lid to dynamic loading (Figure II.6.6.2). Impermeable platens were used for unconfined compression. The loading platen was connected to an eccentric circular cam driven by a motor. Optimal parameters were determined through empirical testing, using biomechanical properties of tissue constructs as the main readout. Following tare load and tare equilibrium, cyclical displacements were applied to agarose discs, with a saw tooth wave to determine lift-off limits, and recovery of the samples after each loading cycle. Dynamic axial compression was applied as a sinusoidal wave with 10% peak-to-peak compressive strain amplitude, at 1 Hz frequency, to mimic physiologic joint loading.

After four weeks of culture, with loading applied five days per week, with three "one-hour-on-one-hour-off" cycles per day, significant differences in mechanical properties of the engineered articular cartilage were observed as compared to free swelling controls. Specifically, the equilibrium aggregate modulus in the loaded group increased 21-fold over the time of cultivation, and reached a value that was 6-fold higher compared to the free swelling controls. As expected, the improved biomechanical properties correlated with increased amounts of cartilage proteoglycans (Mauck et al., 2000).

The increased nutrient supply interacted synergistically with the mechanical signals to advance tissue growth, as shown by combining dynamic deformational loading and the supplementation of TGF-β1 to the chondrocyte-laden agarose constructs. A particularly interesting result is that dynamic deformational loading applied in sequence with TGF-β (two weeks of growth factor supplementation followed by mechanical loading) yielded significantly increased overall mechanical properties. The equilibrium modulus reached 1306 ± 79 kPa and glycosaminoglycan levels reached 8.7 ± 1.6 % w.w. during the eight-week period of cultivation, and both of these values are similar to host cartilage (994 ± 280 kPa, 6.3 ± 0.9 % w.w.) (Lima et al., 2007).

TISSUE ENGINEERING OF ANATOMICALLY-SHAPED HUMAN BONE

Success of bone reconstructions is uniquely dependent on the viability, mechanical function, and precise geometry of the bone grafts. Traditionally, autologous or allogenic tissues are harvested, reshaped, and implanted, leading to suboptimal geometries, tissue quality, and morbidity. Tissue engineering offers the possibility of generating personalized tissues, tailored to the unique geometrical requirements of each patient and the defect being repaired, by using autologous or allogeneic cells, customized biomaterial scaffolds, and customized bioreactors. Critical to bone development are sufficient access to nutrients, regulated by mass transport, and exposure to shear that results from fluid flow and dynamic mechanical compression. Tissue engineering of bone requires the cultivation of spatially uniform seeded cells on mechanically strong scaffolds, with interstitial flow of culture

medium to provide mass transport and hydrodynamic shear at levels necessary for proper bone formation.

The combined anatomical, biological, and functional requirements are probably most stringent for bones of the head and face. Craniofacial bone grafts with clinical utility require mechanical functionality, viability, capacity for integration with blood supply, and precise geometry, furthering the need for new methods to engineer anatomically correct yet functional tissues. Grayson et al. (2009) developed a bioreactor capable of meeting some of the above requirements. The group demonstrated the

feasibility of engineering "designer bone grafts," in their report of engineered anatomically accurate temporomandibular joint (TMJ) condular bone (Figure II.6.6.3A–C), one of the most complex joints in the human body.

The group selected fully decellularized bone in the exact geometry of the TMJ (Figure II.6.6.3D) as the scaffold material. This way, the cells were cultured in a scaffold that had the structural, biochemical, and mechanical properties of native bone (through the use of fully decellularized bone), and the actual geometry of the final graft (through image-guided fabrication). The void volume of

decellularized bone was >80%, as determined by micro-computer tomography (µCT), and the pore sizes were approximately 1 mm, as determined by scanning elec-tron microscopy (SEM) and histological analysis.

The exact shape of the patient's TMJ was recreated from µCT images, and the resulting three-dimensional images were used to shape the scaffold using a computer-driven machine. Human mesenchymal stem cells (hMSCs) were seeded into the scaffold at a physiological density, and cultured in an "anatomical bioreactor" in which bone differentiation and bone formation were induced. The bio-reactor itself provided controllable interstitial flow through the scaffold, by adjusting the input and output flow rates throughout the entire scaffold, based on the measurements and mathematical modeling of medium flow.

The bioreactor consisted of an external chamber machined from plastics (acrylic and polyetherimide) (Figure II.6.6.3F). The outer chamber housed a polydimethylsiloxane (PDMS) mold, which in turn held the scaffold. The PDMS mold was created in two steps: digital computer tomography images of a patient's TMJ condyle were used to generate a three-dimensional copo-lymer in the exact shape of the TMJ; and PDMS was poured over the model and cured to generate the mold. Once placed inside the mold, the scaffold was further compressed by the acrylic external chamber, which served to ensure perfusion through the scaffold rather than peripheral flow around the scaffold (Figure II.6.6.3G, H). Six ports were built into the acrylic chamber – three inlets and three outlets. A peristaltic pump was used to drive the medium through a common inlet, which inter-faced to the three inlet ports (Figure II.6.6.3I). The exit-ing medium was recirculated through the scaffold via a medium reservoir (Figure II.6.6.3E), which also served as a bubble trap.

Modeling of interstitial flow through the bioreactor revealed flow patterns through the cell-seeded scaffold. The model incorporated physical properties of the scaf-fold, including its porosity. The fluid was assumed as incompressible and passing through a porous medium, with no-slip boundary conditions at scaffold boundaries. The inlet flow was assumed as fully developed, to achieve laminar flow with minimal shear at construct surfaces. The experimental flow results from the bioreactor sub-stantiated the model. After seeding with hMSCs, tissue constructs were cultured in osteogenic medium for a total of five weeks, at a medium flow rate of 1.8 mL/min. Rapid, spatially uniform proliferation of hMSCs was facilitated by the high porosity and large pore sizes in decellularized bone scaffolds. Enhanced bone forma-tion and mineralization were achieved, resulting in tissue constructs with physiological cell density, and bone-like architecture. The resulting bone grafts were centimeters in size, fully viable, with physiological cell density and the formation of mineralized bone matrix.

The use of this "anatomical" bioreactor system showed, for the first time, the feasibility of engineering anatomically correct pieces of three-dimensional human bone, with the ultimate aim of generating patient-specific bone grafts. Notably, the bioreactor system is modular, and can be readily modified to accommodate the culti-vation of bone grafts with different shapes, by simply changing the PDMS mold and adjusting inlet port posi-tions to ensure fluid will perfuse the entire scaffold. Over-all, the system has significant potential for bone tissue engineering, in a domain where graft geometry, viability, and function define the success of bone repair.

CARDIAC TISSUE ENGINEERING WITH MECHANICAL STRETCH

Motivated by the positive results obtained using neona-tal rat hearts to reconstitute tissue-like structures within an elastic scaffold, it was hypothesized that the applica-tion of passive and cyclic mechanical stretch within bio-reactors would improve cell alignment and differentiation of cardiac cells (Zimmermann et al., 2002, 2006). Over the course of ten years, the Eschenhagen–Zimmermann group has established an effective approach to cardiac tis-sue engineering by cultivation of neonatal rat heart cells in collagen gel with the application of mechanical stretch. The addition of Matrigel (extracellular matrix from Engel-brecht Swarm tumors) has been essential for the differen-tiation and functional assembly of cardiac myocyte. This effect is most likely due to the high growth factor content in Matrigel, and was never reproduced using other scaf-fold materials. Interestingly, mixed populations of heart cells (myocytes, endothelial cells, and fibroblasts) could be cultured in type I collagen gels, but the contractile force developed by the engineered tissue and its respon-siveness to calcium and isoprenaline of engineered cardiac constructs were markedly better if Matrigel was included.

In the first version of this approach, neonatal rat ven-tricular myocytes were suspended in a gel consisting of collagen type I and Matrigel that was cast into rectangu-lar wells (11 × 17 × 4 mm) holding Velcro-coated silicone tubes (7 mm length, 3 mm outer, 2 mm inner diameter) kept at a fixed distance with a metal wire spacer (Figure II.6.6.4A1) (Fink et al., 2000). The mixture was allowed to gel before culture medium was added to the dish, and the resulting gel–cell constructs were cultured for four days before being exposed to unidirectional stretch, using a motorized device for six days (Figure II.6.6.4A2). In this device, tissues were connected at both ends to stretch-ing bars, which pulled the matrix apart with a constant frequency of 1.5 Hz and +20% of original length. The entire arrangement was held in a CO_2 incubator at 37°C, and the culture medium was changed every other day. These early studies showed that the stretch improved organization of cardiac myocytes, increased the mito-chondrial density, the length of myofilaments, and the force of contraction generated by the tissue construct.

In the next version of the approach, they strove to improve upon certain shortcomings, including the simplification of
FIGURE II.6.6.4 Bioreactors for cardiac tissue engineering with mechanical stimulation. (A) Bioreactor for initial studies for stretching of rectangular engineered cardiac tissues. complicated casting techniques and improvement of inhomogeneous cell distribution. In the next generation set-up, neonatal rat cardiac cells were suspended in the collagen–Matrigel mix, and cast around cylindrical molds (Zimmermann et al., 2002). After seven days of culture, the rings of cardiac tissue were placed around two rods of a mechanical stretcher, and subjected to unidirectional cyclic stretch at 10% strain and 2 Hz (Figure II.6.6.4B1–3). With this approach, the level of structural and functional organization of the dissociated cells in hydrogel that was achieved within a relatively short time period was quite remarkable. Cells reconstituted cardiac-like tissue with interconnected, oriented cells displaying sarcomeres, adherens junctions, gap junctions, and desmosomes. Ultrastructurally, cardiac

myocytes displayed a predominant orientation of sarcomeres along the longitudinal axis of the cell, and were composed of Z, I, A, and H bands, with the occasional presence of M bands. Importantly, capillary structures positive for CD31 were also noted. Functionally, the constructs exhibited contractile properties with a high ratio of twitch to resting tension, strong β-adrenegenic response, and action potentials characteristic of rat ventricular myocytes.

The size, homogeneity, and relative strength of the engineered tissues consisting of cardiac cells in hydrogel were further improved by fusing engineered cardiac tissue together (Zimmermann et al., 2006). A new bioreactor could accommodate five loop-shaped constructs as they fused to form a single synchronously contracting multi-loop

construct ~15 mm in diameter and 1–4 mm thick (Figure II.6.6.4C 1–3). When these constructs were investigated for their ability to support or improve the contractile function of infarcted hearts in an immunosupressed rat model of cardiac ischemia (Figure II.6.6.4C4), grafted hearts were able to develop a greater active force than ungrafted, indicative of the engineered constructs playing a significant role in the regeneration of contractile activity in the infarcted hearts. Although the implants did not reverse the problems associated with infarction, they did significantly improve the diastolic and systolic heart function.

This elegant and effective approach has shown, in a rigorous and convincing way, that immature cardiac cell populations have a remarkable ability to assemble into cardiac constructs, if subjected to mechanical signals during cultivation. The loop-shaped constructs, assembled into larger structures, could not only slow down the progression of heart disease in an animal model of chronic infarction, but could also yield some functional improvements. The use of a hydrogel scaffold that contained growth factors necessary for cell differentiation, enabled encapsulation of the cells, and the application of mechanical stretch was critical for cell assembly and development of mechanical force.

CARDIAC TISSUE ENGINEERING WITH ELECTRICAL STIMULATION AND MEDIUM PERFUSION

In native heart, mechanical stretch is induced by electrical signals, and the orderly coupling between electrical pacing signals and mechanical contractions is crucial for the development and function of native myocardium. In an attempt to direct the differentiation and functional assembly of cardiac cells by factors guiding native development and function of the heart, the Vunjak-Novakovic group (Radisic et al., (2008); Radisic et al., (2004); Tandon (2009); Maidhof et al., (2010); Maidhof et al., (2011)) developed a "biomimetic" approach to cardiac tissue engineering. They engineered compact, synchronously contracting cardiac tissue constructs, by providing an environment combining two critical functions: (1) convective–diffusive oxygen transport (critical for cell survival and function) via perfusion bioreactors; and (2) excitation–contraction coupling (critical for cell differentiation and assembly) by using bioreactors with perfusion (interstitial flow) of culture medium and electrical stimulation.

Oxygen Supply by Perfusion

In native heart muscle, a capillary bed provides efficient exchange of oxygen, nutrients, and metabolites between the blood and tissue cells, while shielding cardiomyocytes from direct exposure to hydrodynamic shear. Therefore, the design of cardiac tissue engineering scaffolds and bioreactors should be based on the provision of efficient mass transport of nutrients (and most critically oxygen), along with the control of hydrodynamic shear. Both the

transport rates and hydrodynamic shear increase with the increase in flow rate of culture medium; while low values of shear stress may induce phenotypic changes in cardiac cells, including elongation, higher values (e.g., >2.4 dyne cm^2) cause cell dedifferentiation, apoptosis, and death.

The group developed scaffolds and bioreactors that allow: (1) rapid cell inoculation into scaffolds using forward–reverse flow (Radisic et al., 2008); and (2) interstitial flow of culture medium through inoculated scaffolds. Cardiac cell populations isolated from neonatal rat heart ventricles and enriched for cardiac myocytes were suspended in Matrigel at concentrations of approximately 10^8 cells/mL (corresponding to physiological cell density in native myocardium), and loaded into a porous collagen scaffold (Ultrafoam™). By thermal gelation, cells were locked in place inside collagen scaffolds, and the perfusion of culture medium could be established. In these hybrid scaffolds, the gel phase provided cell encapsulation and growth factor supply, and the collagen scaffold provided the porous structure and biomechanical properties that supported the formation of contractile cardiac grafts.

The first-generation bioreactor consisted of perfusion loops comprised of tubing and cartridges (outfitted with silicone gaskets made from silicone tubing to hold scaffolds in place) that were maintained inside a cell culture incubator and connected to a peristaltic pump (Figure II.6.6.5A). During cell inoculation, forward–reverse flow was applied to increase the spatial uniformity of cell seeding, critical for engineering thick constructs with high and spatially uniform densities of viable cells. After cell seeding, the volume of culture medium was increased as required for longer-term cell culture, and the pump was switched to unidirectional flow.

Notably, the final cell viability in perfused constructs cultured for eight days was indistinguishable from the viability of the freshly isolated cells, and markedly higher than the cell viability in dish-grown constructs. Cells expressing cardiac markers (sarcomeric α-actin, sarcomeric tropomyosin, cardiac troponin I) were present throughout the perfused constructs. In response to electrical stimulation, perfused constructs contracted synchronously, had lower excitation thresholds, and readily recovered their baseline function levels after treatment with a gap junction blocker. However, most cells in perfused constructs were round and mononucleated, a situation that was likely due to the exposure of cardiac myocytes to hydrodynamic shear, in contrast to the native heart muscle where blood is confined within the capillary bed and is not in direct contact with cardiac myocytes.

Convective–Diffusive Oxygen Supply in Perfused Channeled Scaffolds

The observed effects of hydrodynamic shear on cardiomyocytes motivated the design of scaffolds with an
FIGURE II.6.6.5 Bioreactors for cardiac tissue engineering with perfusion and electrical stimulation. (Reproduced by permission from Maidhof et al., 2011.)

array of channels that provide a separate compartment for medium flow. In order to reduce the exposure of cardiac myocytes to hydrodynamic shear, the Vunjak-Novakovic group has designed porous elastomer scaffolds of poly(glycerol sebacate) with an array of parallel channels providing a separate compartment for medium flow (Maidhof et al., 2010, 2011). The developed a technique for spatial uniform seeding of these channel's scaffolds by stacking scaffolds two at a time, with channels not aligned to each other, so as to block medium flow through channels during seeding, and force the flow of cell suspension through the bulk phase of the scaffold. Following seeding, the scaffolds were separated (to reveal channels) and cultured individually. When cultured under these conditions, constructs were observed to contract synchronously in response to electrical stimulation after only three days of culture, while channels remained open. Improved construct properties were correlated with the enhanced supply of oxygen to the cells.

Electrical Stimulation of Contractile Constructs

In order to deliver electrical signals that can induce synchronous contractions of cultured constructs, the Vunjak-Novakovic group designed a custom bioreactor delivering signals mimicking those in native heart (Tandon et al., 2009). This bioreactor has several unique features, including the maintenance of a constant position of the scaffolds with respect to direction of the electrical field gradient, while neither restricting the contractions of cells, nor the ability to observe the constructs under a microscope. The bioreactor is fitted with a pair of parallel carbon rod electrodes that were held in place by silicone adhesive (Figure II.6.6.5B). The spacing between the electrodes accommodates the width of the constructs between them.

When neonatal rat cardiomyocytes suspended in Matrigel onto collagen sponges were cultured for three days subjected to trains of monophasic electrical pulses (5V/cm, 1 Hz, 2 ms duration) for an additional five days, they progressively developed into conductive and contractile cardiac constructs (Radisic et al., 2004). On a molecular level, electrical stimulation increased the expression of myosin heavy chain, Cx-43, creatine kinase-MM, and cardiac troponin-I. Morphologically, cells in stimulated constructs were more aligned and elongated, and contained abundant mitochondria, in addition to cells with clearly visible M and Z lines, and H, I, and A bands closely resembling those in native myocardium.

The effects of electrical stimulation depended strongly on the time of its initiation, indicating that cells required some time to reassemble their excitation–contraction coupling machinery before electrical stimulation could provide any reinforcement of its positive effects on cellular differentiation. Functionally, electrical field stimulation also induced cell alignment and coupling, increased the amplitude of synchronous contractions, and resulted in a remarkable level of ultrastructural organization of engineered myocardium, over only eight days of cultivation.

Bioreactors with Perfusion and Electrical Stimulation

Most recently, the group developed a bioreactor that simultaneously applies two conditioning stimuli – medium perfusion and electrical stimulation (Figure II.6.6.5C1–3) to scaffolds seeded using the perfusion loops (Figure II.6.6.5A) (Maidhof et al., 2011). The perfusion-stimulation bioreactor was machined from alternating layers of Teflon™, silicone, and plastic (polyetherimide), forming a "Y" shaped channel that routes culture medium through two constructs and into a single perfusion outlet. Constructs may freely contract, and are only loosely kept in place between silicone spacers and carbon rods (which also served as electrodes for stimulation) over an array of perforated holes through which culture medium was drawn. The upper bioreactor pieces form a medium bath

above the constructs that serves for both gas exchange and as a trap for any bubbles generated during perfusion flow. A silicone tubing loop connects the bioreactor inlet and outlet and a peristaltic pump is used to flow culture medium through the system at a rate of 18 μL/minute.

The bioreactor was characterized by mathematical modeling, and in dye flow studies to show that the electrical field stimulus was linear, and that the flow was restricted to cultured tissues. Cardiac constructs were formed by seeding neonatal rat heart myocytes into highly porous poly(glycerol sebacate) scaffolds with an array of parallel channels (250 μm diameter, 500 μm wall-to-wall spacing) and subject to simultaneous perfusion and electrical stimulation (3 V/cm, 3 Hz, 2 ms duration monophasic square waves) for a period of eight days (three days of pre-culture and five days of stimulation).

> ### Electrical Versus Mechanical Stimulation
>
> Because of the high degree of electro-mechanical coupling, it is difficult to decipher whether there are indeed roles for the application of separate mechanical and/or electrical stimulation for engineering cardiac constructs. In constructs prevented from contracting by supplementation of verapamil, electrical stimulation maintained the gap junction protein connexin-43 (Cx-43) at levels comparable with stimulated drug-free controls, suggesting that electrical stimulation, even without contractile activity, aids in the establishment of functional gap junctions (Radisic et al., 2004). Similarly, mechanical stimulation resulted in functional coupling of cardiac cells (Zimmermann et al., 2002). Mechanical stretch and electrical stimulation each appeared to greatly enhance the differentiation of cardiomyocytes, and it may be speculated that a method incorporating the application of both factors could outperform a regime applying just one.

Constructs grown with simultaneous perfusion and electrical stimulation exhibited improved functional properties, including a significant increase in contraction amplitude, greater DNA content and a more uniform cell distribution throughout the scaffold thickness. Simultaneous perfusion and electrical stimulation also enhanced cell morphology, tissue organization, and cardiac protein expression, as shown by immunostaining and Western blot analysis. This novel bioreactor that enables the simultaneous application of culture medium perfusion and electrical conditioning may be appropriate for generating cardiac constructs with clinical size and organization, and may pave the way for further studies incorporating the delivery of combinations of biophysical forces in tissue engineering applications.

TISSUE ENGINEERING OF HEART VALVES WITH MECHANICAL STIMULATION AND PERFUSION

To repair heart valve defects, especially in children, it has been proposed to engineer replacement valves consisting of viable cells that could grow in sync with the

developing heart. An autologous cell source offers the best chances of graft compatibility, but the method of obtaining differentiated heart valve cells (i.e., smooth muscle and endothelial cells) requires an invasive procedure. Therefore, research has been directed towards obtaining stem cells from less invasive sources (i.e., bone marrow-derived mesenchymal stem cells), and differentiating these cells during culture *in vitro*.

In the body the biophysical forces the heart valve cells are exposed to include: (1) mechanical stretch as the valves are forced open and closed; and (2) hydrodynamic shear as the blood flows over the valve surface. Each of these forces was independently shown to enhance the differentiation, organization, and mechanical properties of engineered heart tissue valves in *in vitro* bioreactor cultures. Therefore, it was proposed that a combination of these conditioning regimes applied during culture could yield further improvement of the engineered tissues.

To test this hypothesis, a flex-stretch-flow (FSF) bioreactor was developed to simultaneously apply mechanical stimulation and hydrodynamic shear to

engineered heart valves (Figure II.6.6.6) (Engelmayr et al., 2008). The bioreactor consists of two stationary posts to which tissue specimens can be affixed, and cyclic flexure is applied by a third post attached to a linear actuator. Parameters for the amount of flexure of the engineered valves, and the flow rate for hydrodynamic shear, were selected based on measurements of typical valve opening and closing distances in the heart, and estimations of shear stress in the native heart. Culture medium is recirculated within the FSF bioreactor chamber by a magnetically coupled paddle-wheel driven by an immersible magnetic stirrer. The entire FSF bioreactor is constructed from sterilizable parts, and may be operated in an incubator for several weeks of culture.

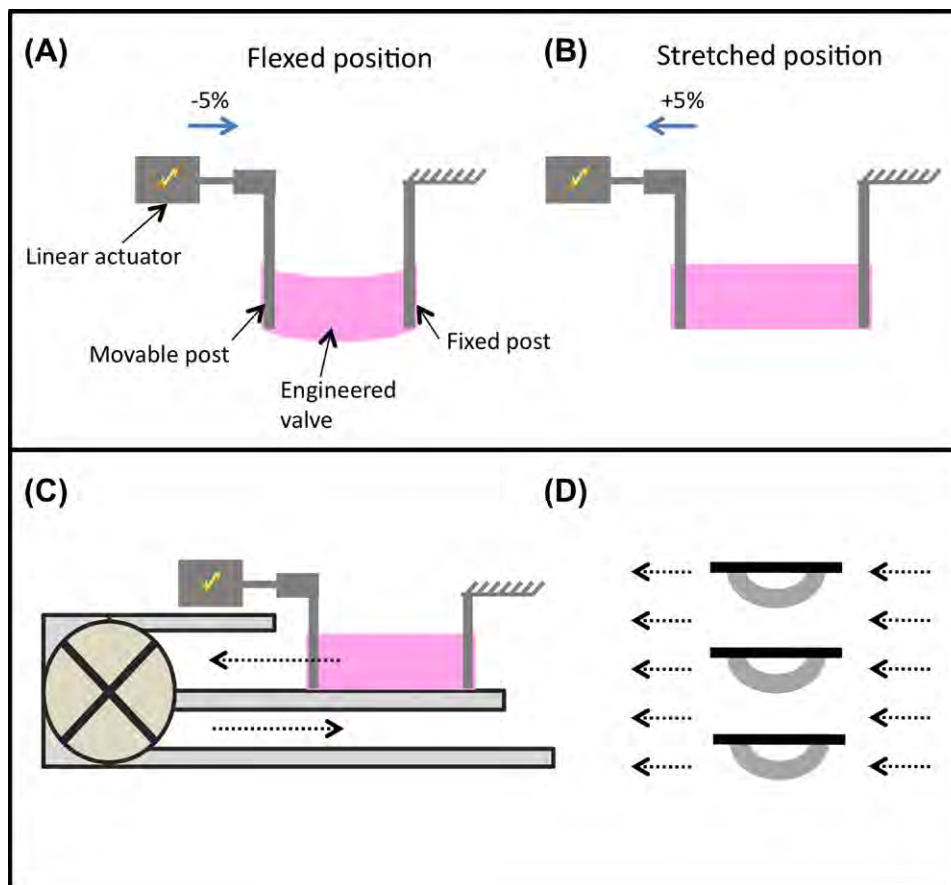
Mesenchymal stem cells (MSCs) derived from sheep bone marrow aspirates were cultured on sheets of non-woven scaffold containing 50% fibers of polyglycolic acid and 50% fibers of poly-L-lactic acid that were assembled into a valved conduit by manual and machine needle punching, and cultured in the bioreactor. The combined application of mechanical stimulation and


FIGURE II.6.6.6 Flex-stretch-flow bioreactor for engineering a heart valve. (A) Each scaffold is attached to a movable post coupled to a linear actuator and a stationary post. (Reproduced by permission from Engelmayr et al., 2008.) The scaffolds are then flexed (A) or stretched (B) via activation of the linear actuator along the direction of the blue arrow. Culture medium can be recirculated (C, dashed black arrows) within the bioreactor chamber via a magnetically coupled paddle-wheel to provide laminar flow and associated fluid shear stresses to scaffold specimens. In the no flex groups, scaffold specimens are maintained in the straight, undeformed configuration (solid black bars) with or without flow (D). In the flex groups, scaffold specimens are cycled at 1 Hz between the undeformed and flexed configurations (curved gray bars), with or without medium flow.

hydrodynamic shear resulted in increased collagen content and effective stiffness of engineered valves after three weeks of culture. In control groups that excluded either one or both of these conditions, collagen content and mechanical properties were lower. By the end of three weeks the combination of mechanical stimulation and hydrodynamic shear resulted in engineered valves with a modulus comparable to those generated starting from smooth-muscle cells in previous studies. Thus, the FSF bioreactor can be used to provide cyclic flexure and laminar flow, and can synergistically accelerate bone MSC-mediated tissue formation in engineered heart valves.

TISSUE ENGINEERING OF BLOOD VESSELS WITH PULSATILE MEDIUM FLOW

Atherosclerotic vascular disease is a major cause of mortality in the US. A commonly used treatment modality is bypass grafting with autologous veins or arteries, but adequate tissue for bypass vessels is lacking in many patients. Engineered blood vessel grafts could make up for this tissue shortage; however, issues including insufficient mechanical properties of the engineered vessels, and lack of a differentiated cell population, have limited clinical implementation. To help overcome these shortcomings, the design of a pulsatile perfusion bioreactor was proposed over a decade ago (Niklason et al., 1999).

During vasculogenesis and throughout life, vascular cells (endothelial and smooth muscle cells) are exposed to pulsatile physical forces generated with each heartbeat. Studies have shown that mechanical stretch is an important factor in extracellular protein synthesis and expression; specifically, cyclic stretch upregulates collagen and other extracellular matrix protein production in vascular cells. A biomimetic system to culture engineered vessels should replicate this cyclic stretch, with culture medium serving as the "blood" and a pulsatile pump providing the "heart beat."

A suspension of smooth muscle cells (SMCs) isolated from the medial layer of bovine aorta and expanded in culture was seeded onto tubular scaffolds made of fibrous polyglycolic acid (PGA). The surface of the PGA scaffolds was chemically modified with sodium hydroxide to cause ester hydrolysis on the surface of the fibers, and enhance hydrophilicity, adsorption of serum proteins, and cell attachment. The seeded scaffolds were fitted with silicone tubing, placed into the vessel lumen, and transferred into bioreactors and cultured with the application of pulsatile flow for eight weeks. At the end of cultivation, the silicone tubing was removed, a suspension of bovine endothelial cells was introduced, and the cells were allowed to adhere for three days to the lumen surfaces.

The bioreactor was designed to support the cultivation of tubular scaffolds seeded with cells and attached to a perfusion loop, so that culture medium was forced
FIGURE II.6.6.7 Pulsatile flow bioreactor for engineering blood vessels. A pulsatile pump is used to flow culture medium through the lumen of an engineered blood vessel causing cyclic stretch of the tissue during culture. After exiting the vessel the medium is returned to a reservoir that provides oxygenation and allows for medium exchange throughout the culture period. (Niklason et al., 1999.)

to flow through the lumen (Figure II.6.6.7). A pulsatile pump was used to vary the medium pressure inside the vessel over each cycle, causing the vessel to cyclically stretch in the radial direction. The cultivation conditions were designed to mimic those found during fetal development (~165 beats per minute and 5% radial distension of the vessel).

After eight weeks of culture, the gross appearance of the engineered vessels was similar to that of native arteries. Bioreactor-cultured vessels developed significantly greater mechanical properties (rupture strength, suture retention) than those cultured without pulsatile flow, and matched and correlated with the increased collagen content. Upon implantation into the right saphenous vein of a miniature pig, vessels subjected to cyclic stretch remained open to blood flow for up to four weeks, whereas non-stretched vessels developed thrombosis after only three weeks. Taken together, these results indicate that a bioreactor that subjects engineered vessels to cyclic mechanical stretch can improve the differentiation of engineered vascular grafts prior to implantation.

CHALLENGES IN BIOREACTOR DESIGN

Part of the motivation behind bioreactor development has been to create greater correlation between *in vitro* studies and *in vivo* outcomes. The thought has been that advanced tissue culture platforms, recapitulating the *in vivo* environment in a controllable manner, would aid

in the transition from cell studies to animal models, and eventually to human clinical trials and even the clinic. These engineered "biomimetic" environments allow cells to be measured and physically manipulated in unprecedented ways, and they are now replacing the simple but deficient environment of culture dishes. However, several important challenges remain to be resolved to establish conditions that are predictive of cell behavior *in vivo*, and provide bioreactors beyond the laboratory bench.

Producing Conditions More Predictive of Cell Behavior *In Vivo*

In terms of providing bioreactors that will better recapitulate the actual cell–tissue environment, and be more predictive of cellular responses *in vivo*, the main challenge is the difficulty of identifying and optimizing necessary biophysical and molecular cues. Although bioreactors outperform standard culture systems in their ability to provide matrix, molecular, and biophysical factors, current systems still lag behind nature's ability to deliver the highly coordinated sequences of spatial and temporal gradients of regulatory factors at the level of the cell which are necessary to regulate cell function in a developing and adult organism. This performance gap is likely responsible for at least some of tissue engineering's limited success in delivering on the promise of a "one stop shop" of engineered tissues for the entire body.

For reasons that are still little understood, certain tissues (such as cardiac and osteochondral) are more conducive to tissue assembly within bioreactors than others (such as pancreatic and hepatic). Perhaps some bioreactor limitations will be ameliorated through future research in developmental biology, which may shed more light on how tissues emerge from coordinated sequences of cell proliferation, differentiation, and functional assembly that are orchestrated by factors originating from the surrounding cells, matrix, and the external environment. Likewise, future research on regeneration of adult tissues may shed more light on how cells respond to the entire milieu of injury or disease, and help incorporate the most critical biophysical and/or molecular cues into the repertoire of current bioreactors. Some known biophysical cues, such as molecular gradients, although relatively facile to apply in microfluidic conditions, are difficult to produce in the larger-scale three-dimensional culture settings of the bioreactor, without applying significant shear stresses or using excessive amounts of expensive culture medium.

Furthermore, the large cell-number and media requirements for most bioreactors still preclude the performance of screening studies, which are key to optimizing culture conditions, let alone transitioning results from animal models to human stem cells. Overcoming this challenge may indeed involve the development of high-throughput microbioreactors that are equipped to provide certain well-known biophysical cues (e.g., transport, mechanical stimulation, electrical stimulation).

Providing Bioreactors Beyond the Laboratory Bench

In the current tissue engineering paradigm, a common approach is to culture cells on a biomaterial scaffold and regulate the environmental conditions via bioreactors toward reconstructing a functional tissue. With this approach, one can attempt to manipulate the cells' responses in predictable ways, by utilizing the same complex factors known to direct development and remodeling *in vivo*, with the eventual goal of producing a tissue with enough fidelity for implantation. Several challenges related to current bioreactor fabrication economics and logistics remain, before tissue engineering may deliver on this promise.

A bioreactor should ideally provide a native-like cell environment, and address the specific requirements for the tissue of interest. Therefore, bioreactors are often custom-designed to recapitulate the specific mechanisms of nutrient transfer and specific biophysical signals in each type of tissue. These custom-designed systems require an understanding not only of general cell culture principles, but also of the specific mechanisms of relevance to the tissue at hand. As cells are highly sensitive to changes in their environment, even minute changes in molecular and biophysical cues may have implications on the reproducibility of a bioreactor's regulation of cell survival, behavior, and differentiation capacity. Therefore, quality control and implementation of protocol transfer are of great importance to the tissue engineering community.

Further challenges to bioreactor design are also related to the complexity of regulatory issues, and the design constraints of surgical techniques and the operating theater. For tissue-engineered constructs to be viable and clinically useful, bioreactor design and protocols should be compatible with the transportation of biologically stable tissue engineered implants. Therefore, the application of engineered tissues *in vitro* – as experimental models of development and disease – will remain much easier than the cultivation of engineered tissues for implantation.

Interestingly, the best strategy for engineering functional tissue grafts is, in many cases, a simple one – not everything needs to be recapitulated, and one key factor provided within the right context can make the difference. The application of mechanical or electrical stimulation to high-density cultures of cells on scaffolds is an excellent example of this situation. The field has made remarkable strides with the application of limited sets of molecular and biophysical cues, and identified the next set of challenges that call for true interdisciplinary work of biomedical engineers, basic scientists, and clinicians.

WORKED EXAMPLES

Perfusion bioreactors have been used extensively in tissue engineering in order to provide adequate nutrient supply,
FIGURE II.6.6.8 Schematic of a simple bioreactor with direct perfusion of culture medium through cultured tissues.

as well as mechanical stimuli to the cells inside a scaffold. A round perfusion bioreactor (Figure II.6.6.8) consists of an inlet, an outlet, and a culture chamber, and allows the cultivation of six scaffolds simultaneously. The culture medium coming into the inlet splits into six channels, and flows through the scaffolds into the media chamber. One major function of a bioreactor is to mimic physiologic conditions *in vitro*. In previous studies, bone cells were exposed to physiologic shear stress ranging from 0.25 dynes/cm^2 to 25 dynes/cm^2. In an experiment designed to assess the effect of shear stress on bone tissue engineering, the medium flow rates corresponded to shear stresses of 1 dynes/cm^2 and 10 dynes/cm^2. Cylindrical scaffolds (5 mm in diameter and 5 mm long) can be modeled as 70% porous material consisting of an array of channels 400 μm in diameter (Figure II.6.6.9), with the cells lining the channel lumens. Estimate the flow rate required to provide the low and high shear stress, assuming fully developed laminar flow in the longitudinal direction, steady-state, incompressibility of culture medium, $\mu = 7.7 \times 10^{-4}$ Pa·s, and $\rho = 1$ g/ml.

Solution. The analysis can be done in the single channel within the scaffold.

Flow Rate in the Single Channel. The velocity profile of a fully developed laminar circular pipe flow can be derived from the Navier–Stokes equations:

$$v_z = \frac{1}{4\mu} \frac{\partial p}{\partial z}(r^2 - R^2)$$

The volumetric flow rate of single channel can be determined by:

$$Q_{Channel} = \int_0^{2\pi} \int_0^R V_z r dr d\theta$$

$$Q_{Channel} = \int_0^{2\pi} \int_0^R \frac{1}{4\mu} \frac{\partial p}{\partial z}(r^2 - R^2) r dr d\theta$$

$$Q_{channel} = -\frac{\pi R^4}{8\mu}\left(\frac{\partial P}{\partial z}\right)$$
FIGURE II.6.6.9 Schematic of a single channel within a tissue construct perfused with culture medium.

The relationship can be expressed in terms of the pressure drop:

$$\frac{\Delta P}{L} = -\frac{\partial p}{\partial z}$$

Or:

$$Q_{channel} = \frac{\pi R^4 \Delta P}{8\mu L}$$

The average velocity is:

$$V = \frac{Q}{\pi R^2} = \frac{R^2 \Delta P}{8\mu L}$$

The maximum velocity occurs at the center of the tube:

$$v_{max} = -\frac{R^2}{4\mu}\left(\frac{\partial p}{\partial z}\right) = \frac{R^2 \Delta P}{4\mu L}$$

Hence:

$$v_{max} = 2V$$

The velocity profile can now be written as:

$$\frac{v_z}{v_{max}} = 1 - \left(\frac{r}{R}\right)^2$$

and the shear stress equation becomes:

$$\tau_{maxY} = -\mu \frac{dv_z}{dr}\Big|_{r=R}$$

$$\tau_{maxY} = -\mu\left(-v_{max}\frac{2r}{R^2}\right)\Big|_{r=R}$$

$$\tau_{maxY} = \frac{2\mu v_{max}}{R} = \frac{4\mu V}{R}$$

Now we can solve for the flow rate:

- Low shear stress

$$\tau_{maxY} = 1\,\text{dyne/cm}^2 = \frac{4(0.0077\,\text{dyne} \bullet \text{s/cm}^2)}{0.0200\,\text{cm}}V$$

$$V = 0.649\,\text{cm/s}$$

$$Q_{channel} = \pi R^2 V = 8.16 \times 10^{-4}\,\text{ml/s}$$

Checking the Reynolds number:

$$Re = \frac{\rho V(2R)}{\mu}$$

$$Re = \frac{(1\,\text{g/cm}^3)(0.649\,\text{cm/s})(2(0.02\,\text{cm}))}{(0.0077\,\text{dyne} \bullet \text{s/cm}^2)}$$

$$Re = 3.37 < 2100$$

we confirm that the laminar flow assumption was valid.
- High shear stress

$$\tau_{maxY} = 10\,\text{dyne/cm}^2 = \frac{4(0.0077\,\text{dyne} \bullet \text{s/cm}^2)}{0.0200\,\text{cm}}V$$

$$V = 6.49\,\text{cm/s}$$

$$Q_{channel} = \pi R^2 V = 8.16 \times 10^{-4}\,\text{ml/s}$$

Checking the Reynolds number:

$$Re = \frac{\rho V(2R)}{\mu}$$

$$Re = \frac{(1\,\text{g/cm}^3)(6.49\,\text{cm/s})(2(0.02\,\text{cm}))}{(0.0077\,\text{dyne} \bullet \text{s/cm}^2)}$$

$$Re = 33.7 < 2100$$

we confirm that the laminar flow assumption was valid. where v_z indicates the velocity in the z–direction (see Figure II.6.6.9), μ indicates the viscosity of the fluid, ρ indicates the pressure within the pipe, r indicates the radial position, and R indicates the radius of the pipe. $Q_{channel}$ indicates the flow within a channel, L indicates the length of the channel, V is average velocity, v_{max} is the maximum velocity, τ_{maxY} is the maximum shear in the Y-direction.

Scaffold Geometry.   Cross-sectional area of the scaffold is:

$$A_{scaffold} = \pi(2.5\,\text{mm})^2 = 19.63\,\text{mm}^2$$

Void area of the scaffold is:

$$A_{void} = 0.7A_{scaffold} = 13.74\,\text{mm}^2$$

Cross-sectional area of single channel is:

$$A_{channel} = \pi(0.2\,\text{mm})^2 = 0.126\,\text{mm}^2$$

Therefore, each scaffold contains the following number of channels:

$$\frac{A_{void}}{A_{channel}} = \frac{13.74\,\text{mm}^2}{0.126\,\text{mm}^2} = 109$$

As there are six scaffolds per bioreactor, there are 654 channels in the scaffold.

Total Flow Rate

- Low shear stress:

$$Q_{total} = 654\,Q_{channel}$$

$$Q_{total} = 0.533\,\text{ml/s} = 32\,\text{ml/min}$$

- High shear stress:

$$Q_{total} = 654\,Q_{channel}$$

$$Q_{total} = 5.33\,\text{ml/s} = 320\,\text{ml/min}$$

INTRODUCTION

The use of biocompatible polymeric materials for orthopedic applications, such as bone graft substitutes, has been under investigation since the 1940s (Blaine, 1946; Leveen and Barberio, 1949). By the 1970s the importance of attaining appropriate mechanical properties, an interconnected porosity, and a microstructure that promotes tissue ingrowth was realized (Hench et al., 1971; Weber et al., 1971). Recent research has highlighted the necessity for a subcellular dimension, or nanostructure,

in synthetic bone grafts to promote the appropriate organization of bone cells in an effort to generate or regenerate bone tissue (Christenson et al., 2007; Horii et al., 2007; Hu et al., 2008).

This chapter begins with an overview of the biology of bone to provide a framework for what the application of biomaterials strives to recreate. The chapter then proceeds through a discussion of bone tissue engineering, beginning with the natural bone grafts, moving through bone graft substitutes, and finishing with a discussion of bioreactors used in bone tissue engineering.

BONE BIOLOGY

Bones are vascularized and innervated organs that are composed of bone tissue, bone marrow, and a surrounding connective tissue called periosteum. Bones serve a number of functions such as: support for muscles; protection of internal organs; production of blood; calcium homeostasis; acid/base buffering; and transmission of sound (Bilezikian et al., 2002; Rauschecker and Shannon, 2002). Bone tissue is the rigid calcified portion of the bone organ, and is critical for many of the functions.

Types of Bone Tissue

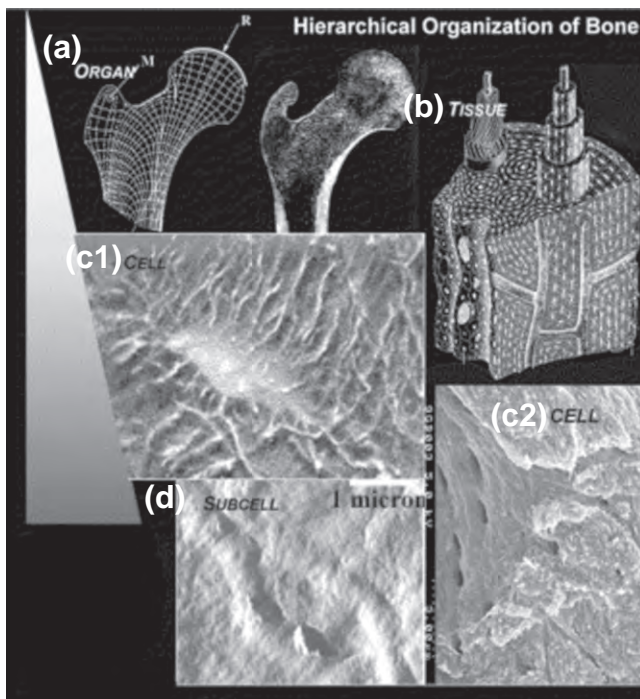
Bone tissue is classified as either cortical bone or trabecular bone. Cortical bone is dense and highly mineralized bone tissue that is found on the peripheral regions of bone. Cortical bone is 80–90% mineralized, and constitutes 80% by mass of the bone tissue in the body (Bilezikian et al., 2002). The high density of cortical bone makes it well-suited for the mechanical and structural properties of bone. The thickness and density of cortical bone is loosely correlated to mechanical loading; however, many other variables are also involved (Pearson and Lieberman, 2004). Trabecular bone is found on the interior of bones adjacent to the marrow cavity. It is approximately 80% porous, and exhibits less than 10% of the compressive strength and less than 5% of the compressive modulus of cortical bone (Bilezikian et al., 2002; Miyakoshi, 2004; Rezwan et al., 2006). However, trabecular bone exhibits higher surface area than cortical bone, and is considered more important for bone functions such as calcium homeostasis and acid/base regulation. Figure II.6.7.1


FIGURE II.6.7.1 Hierarchical organization of bone. This figure provides a view of the organization of bone beginning with organ level: (a) and moving to a depiction of the tissue level (b), which illustrates the network of osteocytes organized radially around Haversian canals. An individual osteocyte with the mineralized matrix removed is depicted in (c1) and clearly illustrates multiple processes extending away from the cell body; on the contrary, (c2) depicts the mineralized matrix without the cell, and illustrates on the left-hand side the interior of the lacuna where the osteocyte cell body would reside, and shows canals called canaliculi where the processes extending away from the osteocyte cell body ultimately connect with other osteocyte process. Finally, (d) depicts the interior of canaliculi and shows the presence of striations created by collagen fibers that formed the initial framework for the mineralized matrix (Knothe Tate, 2003).

illustrates the hierarchical organization of bone, moving from the tissue level down to the subcellular level.

CELLS INVOLVED

Osteoblasts

There are several distinct cell types involved in the formation and remodeling of bone tissue. These cells are osteoblasts, bone lining cells, osteocytes, and osteoclasts. Osteoblasts are the workhorses of bone formation. Osteoblasts are fully-differentiated cells derived from preosteoblasts or osteoprogenitor cells, which are progenitor cells derived from mesenchymal stem cells found in the bone marrow or the periosteum (Franz-Odendaal et al., 2006; Marie, 2008). The transition from a preosteoblast to an osteoblast occurs when the preosteoblast is stimulated to differentiate via soluble factors, such as bone morphogenetic proteins and wingless-int proteins (Franz-Odendaal et al., 2006; Zaidi, 2007). Once stimulated to differentiate, the preosteoblasts cease proliferation and begin to secrete proteins indicative of an osteoblast phenotype. The new osteoblasts are found at the surface of developing bone tissue, and exhibit a cuboidal morphology. They actively secrete a nonmineralized osteoid matrix at the location of newly forming bone. This osteoid matrix is the organic portion of bone extracellular matrix, and is composed primarily of collagen type I, which makes up approximately 90% of the matrix (Toole and Linsenmayer, 1977; Bilezikian et al., 2002). The remaining portion of the osteoid matrix is composed of proteoglycans and noncollagenous proteins, such as osteopontin, osteocalcin, and osteonectin.

The active production of the osteoid matrix, as well as the presence of the membrane protein alkaline phosphatase, distinguishes the osteoblast phenotype. The osteoid matrix around the osteoblast begins to calcify, and approximately 20% of the buried osteoblasts transition to osteocytes (Franz-Odendaal et al., 2006). The osteoblasts that do not transition to osteocytes undergo apoptosis.

Bone Lining Cells

Bone lining cells, much as their name suggests, are found lining the surface of bone. Unlike osteoblasts on the bone surface, bone lining cells have a long, slender, and flat morphology. Bone lining cells were initially considered to be preosteoblasts (Bilezikian et al., 2002); however, this is no longer thought to be the case. Instead, the current opinion is that osteoblasts that do not undergo apoptosis or differentiate to osteocytes become bone lining cells (Karsdal et al., 2002; Khosla et al., 2008; Matsuo and Irie, 2008). Two of the key phenotypic differences between the bone lining cells and osteoblasts are that bone lining cells express intercellular adhesion molecule 1, and they do not express osteocalcin (Everts et al., 2002). Recent research has shown that bone lining cells

anchor hematopoietic stem cells, and provide these stem cells with appropriate signals to keep them in an undifferentiated state (Kollet et al., 2006). The bone lining cells then play a crucial role in the transitions involved with bone remodeling by communicating through gap junctions with osteocytes deep in the bone matrix, promoting differentiation of hematopoietic stem cells into osteoclasts (Kollet et al., 2006; Matsuo and Irie, 2008).

Additionally, the bone lining cells are responsible for preparing the surface of the bone by removing nonmineralized collagen fibrils through the use of matrix metalloproteinases. After remodeling, the bone lining cells deposit a smooth layer of collagen over the bone surface (Everts et al., 2002; Karsdal et al., 2002; Khosla et al., 2008; Matsuo and Irie, 2008).

Osteocytes

Osteocytes are terminally differentiated cells derived from mature osteoblasts that have become encased within a calcified matrix. In the transformation from an osteoblast to an osteocyte, the expression of many of the proteins that constitute an osteoblast phenotype, such as type I collagen, alkaline phosphatase, osteocalcin, and bone sialoprotein, are no longer produced (Franz-Odendaal et al., 2006; Zaidi, 2007). Additionally, osteocytes create a network among themselves by extending many long processes to adjacent osteocytes. This network, the lacunar–canalicular network, is used for nutrient and waste transfer, as well as for communication between the osteocytes via gap junctions (Franz-Odendaal et al., 2006).

The osteocyte cell body resides in the lacuna, and the osteocyte's processes extend out through the canaliculi to adjacent osteocytes and Haversian canals. The Haversian canals provide vasculature to suuply and remove nutrients. The concentric arrangement of the lacunar–canalicular network of osteocytes around a Haversian canal is referred to as an osteon (Bilezikian et al., 2002). The organization of the osteocytes within bone is illustrated in Figure II.6.7.1. Additionally, osteocytes have been implicated as the primary mechanosensors in bone. The mechanotransduction that occurs in osteocytes is believed to be initiated by fluid flux within the canaliculi, created by pressure gradients between lacunae when the bone is loaded. The fluid motion triggers depolarization of the osteocyte process, and is propagated to other osteocytes via gap junctions. The mechanotransduction in osteocytes contributes to the recruitment of osteoblasts or osteoclasts, depending on the loading condition (Wang et al., 2000; Goulet et al., 2008).

Osteoclasts

Osteoclasts, unlike the cells discussed thus far, are multinucleated cells derived from hematopoietic stem cells, as opposed to mesenchymal stem cells. It has been established that hematopoietic stem cells anchored to bone lining cells are induced to differentiate into osteoclasts in response to osteocyte–bone lining cell signaling (Kollet et al., 2006; Matsuo and Irie, 2008). The role of osteoclasts in bone metabolism is the resorption of bone. Osteoclasts exhibit a polarized plasma membrane. Osteoclasts involved in resorbing bone exhibit two distinct plasma membrane regions on the basal surface of the osteoclast; a ruffled portion of the plasma membrane which is where the resorption of the bone occurs, and a sealing region that binds the ruffled border to the bone extracellular matrix (Bilezikian et al., 2002; Vaananen and Laitala-Leinonen, 2008). The combination of the ruffled and sealing regions of the plasma membrane forms the resorption lacuna.

Initially, the osteoclast dissolves the mineralized portion of the bone matrix by secreting hydrochloric acid. After the mineral content is removed, the protein portion of the matrix is degraded by proteolytic enzymes (Kollet et al., 2006; Coxon and Taylor, 2008; Vaananen and Laitala-Leinonen, 2008). The resulting matrix fragments, and potentially the ions created from matrix dissolution, are transported through the osteoclast in vesicles that are emptied into the extracellular space on the basolateral side of the osteoclast. Much like the basal plasma membrane, the basolateral plasma membrane of the osteoclast is polarized and exhibits a functional secretory domain in the middle of the basolateral membrane. The functional secretory domain of the basolateral membrane is rich in microtubules, and is the site where the vesicles are emptied after the transcytotic transportation of the bone matrix degradation products (Kollet et al., 2006; Coxon and Taylor, 2008; Vaananen and Laitala-Leinonen, 2008).

BONE TISSUE DEVELOPMENT

Calcified bone tissue is formed by two distinct modes of ossification or calcification. These methods of ossification are classified as either intramembranous ossification or endochondral ossification (Bilezikian et al., 2002; Franz-Odendaal et al., 2006). The method of ossification depends on the type of bone being formed. Intramembranous ossification is involved in the formation of flat and irregularly shaped bones, such as the cranial bones. Endochondral ossification is involved in the formation of long bones (bones that are longer than they are wide), such as the femur, humerus, and metacarpal (Bilezikian et al., 2002).

Intramembranous Ossification

Intramembranous ossification begins without a preexisting cartilage model. Instead, mesenchymal stem cells form clusters. The mesenchymal stem cells then differentiate into osteoblasts, and the newly formed osteoblasts start to secrete an osteoid matrix. The osteoid matrix

is calcified to form bone spicules. Osteoblasts trapped within the bone spicules either differentiate to osteocytes or undergo apoptosis. The bone spicules radiate outward from where the mesenchymal cluster originally formed. Eventually, spicules initiated by separate mesenchymal stem cell clusters join together to create a layer of calcified bone. Mesenchymal stem cells apical to the calcifying tissue differentiate to form the periosteum, whereas those basal to the calcifying tissue differentiate to osteoblasts which form subsequent layers of calcified tissue. The resulting bone tissue is classified as woven bone. Woven bone is formed quickly, and is characterized by randomly oriented collagen fibrils; however, it is not as mechanically viable as lamellar bone. Woven bone will be remodeled over time through resorption and deposition by osteoclasts and osteoblasts to form lamellar bone (Bilezikian et al., 2002; Franz-Odendaal et al., 2006; Shapiro, 2008).

Endochondral Ossification

Endochondral ossification occurs in several steps. Initially, endochondral ossification begins with a pre-existing cartilage template. The cartilage template begins to be calcified. As the cartilage template calcifies, the chondrocytes in the cartilage become hypertrophic and undergo apoptosis (Bilezikian et al., 2002; Tuan, 2004; Franz-Odendaal et al., 2006). Then, mesenchymal stem cells in the membrane surrounding the calcifying cartilage, periosteum, differentiate to osteoblasts. These osteoblasts lay down an osteoid matrix around the exterior of the cartilage template. At the same time, a bud of cells originating from the periosteum invades the interior of the partially calcified cartilage template. This periosteal bud leads to vascularization and innervation of the developing bone. The periosteal bud also supplies mesenchymal and hematopoietic stem cells to the center of the cartilage template. The mesenchymal stem cells differentiate to osteoblasts, and the hematopoietic stem cells differentiate to osteoclasts. These osteoblasts and osteoclasts remodel the partially calcified cartilage into woven bone, which is ultimately remodeled to become lamellar bone. Lamellar bone contains collagen fibrils that are arranged in parallel areas, and exhibits greater strength compared to woven bone (Shapiro, 2008). As the bone tissue created from cells originating from the periosteal bud increases, it radiates outward and eventually joins the bone tissue created by the osteoblasts on the surface of the cartilage template (Bilezikian et al., 2002; Franz-Odendaal et al., 2006; Shapiro, 2008).

Bone Tissue Engineering

Tissue engineering is the application of biological, chemical, and engineering principles toward the repair, restoration or regeneration of living tissue using biomaterials, cells, and factors alone or in combination

(Laurencin et al., 1999). Strategies for tissue engineering often focus on one of the three elements; using biomaterials, cells or factors. For example, a common tissue engineering strategy involves fabricating biomaterials into porous scaffolds to facilitate cell growth and the eventual repair, restoration or regeneration of the tissue (Langer and Vacanti, 1993). These biomaterial scaffolds can be used without any further modification *in vivo*. The next iteration in the application of biomaterial-focused tissue engineering strategies involves culturing the biomaterial scaffold seeded with cells *in vitro*. The ultimate strategy for the *in vitro* use of a biomaterial scaffold involves seeding the scaffold and culturing *in vitro* to develop a replacement tissue that, on implantation, functions exactly as did the original host tissue (Langer, 2000).

Applying this tissue engineering strategy, a paradigm for a successful bone graft emerges. This paradigm is that the graft or construct should be osteoconductive, osteoinductive, osteogenic, resorbable or degradable, and possess mechanical properties near to that of the implant site. Osteoconduction refers to the ability of a scaffold or implant to promote attachment of osteoblastic cells on the surface and throughout the interior of the scaffold or implant. In an *in vitro* setting, osteoconduction is seen as an ability to promote the attachment, migration, and proliferation of osteoblasts (Kneser et al., 2002). Osteoinduction refers to the ability of a scaffold or implant to promote the differentiation of mesenchymal stem cells down an osteoblastic lineage, ultimately leading to the formation of mineralized tissue. Osteoinduction can also be viewed as an ability to promote phenotype progression of an osteoblast from an early osteoblast to a mature osteoblast, followed by differentiation to an osteocyte (Kneser et al., 2002).

Osteogenicity refers to the ability of a scaffold or implant to promote *de novo* bone formation, which would occur in the absence of host cell invasion. For a scaffold to be osteogenic, cells would need to be seeded on the scaffold prior to implantation (Kneser et al., 2002). The necessity of a bone tissue engineering construct to be degradable arises from the fact that bone is constantly remodeling. A non-resorbable or non-degradable implant would impede the natural remodeling process of bone, and extend the time it takes for the organ to return to natural function (Hutmacher, 2000). Finally, the graft, scaffold or implant should have mechanical properties that match that of the native bone tissue. The range for the mechanical properties depends on whether the bone tissue is cortical or trabecular. For trabecular bone the compressive strength varies from 4–12 Mpa, and the compressive modulus varies from 100–500 Mpa (Rezwan et al., 2006). Cortical bone exhibits a compressive strength from 130–180 Mpa, and a compressive modulus from 12–18 Gpa (Rezwan et al., 2006).

A problem with mechanical properties that exceed these ranges is stress shielding. Stress shielding results

when the load on the bone is redistributed, with the scaffold or implant being the loadbearing region, and the surrounding bone being unloaded. The result of stress shielding is osteopenia of the bone surrounding the implant (Pitto et al., 2007). To solve the bone tissue engineering paradigm, there are presently a range of bone grafts and bone graft substitutes that fulfill all or some of the bone tissue engineering paradigm.

BONE GRAFTS

Autograft

Bone grafts are pieces of bone that are harvested from the patient, a donor or a cadaver, and placed at the desired site of bone repair, regeneration or restoration as needed. The long standing, and considered "gold standard," bone graft solution to the bone tissue engineering paradigm is an autograft (Greenwald et al., 2001; Kneser et al., 2002; Laurencin et al., 2006). Autografts are sections or fragments of bone removed from one site on the patient, typically the iliac crest, and implanted to another site based on need. Figure II.6.7.2 depicts an example of where two autografts were harvested from a patient, and shows the harvest site beginning to heal and reform bone after five months, with the help of a metal plate to serve as a template for the new bone growth.

Autografts harvested from the iliac crest are mostly trabecular bone with a thin shell of cortical bone. Since autografts originate within the patient, they are readily incorporated at the implant site and rarely elicit any immune responses, which allow autografts to have excellent wound healing properties. Autografts fulfill all four elements of the bone tissue engineering paradigm, primarily because they consist of native bone tissue moved from one region of a patient's body to another region. However, autografts have a few drawbacks;

FIGURE II.6.7.2 X-ray of an individual that required an autograft harvest from both iliac crests. The right hip (left side of image) was harvested five months prior to the left hip. Both were reconstructed with a metal plate fixed with screws (most visible on the left hip). Notice how even five months post-harvest there persists a significant amount of bone that has not regrown (Huemer et al., 2004).

there is often donor site morbidity indicated by necrosis and infection at the location of autograft harvest that may cause the patient more pain from the harvest site than the implant site (Greenwald et al., 2001; Laurencin et al., 2006). Additionally, autografts are limited in availability to the amount of tissue that can be harvested from the donor site (Greenwald et al., 2001; Laurencin et al., 2006). The problem of autograft bone tissue availability increases in cases where the need is the highest; those that involve osteoporotic, pediatric or patients afflicted with bone cancer (Meister et al., 1990). It is these shortcomings plaguing the autograft that has increased the effort to find other bone graft substitutes.

Allograft

The next bone graft solution to the bone tissue engineering paradigm is the allograft. Allografts are bone fragments obtained from donors or cadavers that are typically first frozen, irradiated and/or lyophilized. These steps are implemented to reduce the likelihood of disease transmission. Allografts are readily available in an array of shapes and sizes. Since allografts originate from a donor or cadaver there is no additional surgical site on the patient, which removes complications such as donor site morbidity (Greenwald et al., 2001; Kneser et al., 2002; Laurencin et al., 2006). However, the sterilization procedures performed on allograft bone tissue are not without consequence. In comparison to autografts, allografts are less osteoconductive, less osteoinductive, and are not osteogenic (Greenwald et al., 2001; Laurencin et al., 2006). Additionally, allografts that have been lyophilized exhibit much less mechanical integrity compared to autografts (Laurencin et al., 2006). Due to allografts being non-native tissue, they have been shown to occasionally produce an immune response, which requires allograft recipients to be placed on immunosuppressant drugs to prevent rejection of the allograft tissue (Paskert et al., 1987). The complications that arise from autografts and allografts have fueled the search for bone graft substitutes.

BONE GRAFT SUBSTITUTES

Bone graft substitutes can offer solutions to the bone tissue engineering paradigm, and are based on the tissue engineering concepts that arise from the definition of tissue engineering. These tissue engineering principles lead to bone graft substitutes that can be classified as those based on biomaterials, cells, factors or any combination of the three.

Allograft-Based Substitutes

Biomaterial-based bone graft substitutes can be further subdivided into allografts, natural polymers, synthetic polymers, and ceramics. Allograft-based bone graft

substitutes use allograft bone tissue that has been thoroughly sterilized, decellularized, and demineralized. The methods by which manufacturers sterilize, decelluarize, and demineralize the bone graft substitutes are carefully controlled to create a product that retains the collagen, non-collagenous proteins, and some of the growth factors present in the original bone tissue (Gazdag et al., 1995). The result is demineralized bone matrix (DBM), which has been used in a variety of commercially available bone graft substitutes either as is or mixed with glycerol, hyaluronic acid or calcium phosphates to improve the handling and performance characteristics of the product (Martin et al., 1999; Schwartz et al., 2007). Osteotech, Inc.® has a line of DBM products under the trade name Grafton®. The Grafton® line of products contain materials that are simple DBM fragments, such as Grafton® DBM Crunch, as well as intact pieces of DBM that has been precut to a desired shape, such as Grafton® DBM Matrix PLF, DBM Matrix Plugs, and DBM Matrix Strips. Osteotech, Inc.® also has a number of commercially available DBM products that have been mixed with glycerol and other proprietary agents to create an injectable gel, Grafton® DBM Gel, moldable putty, Grafton® DBM Putty, and flexible strips, Grafton® DBM Flex and A-Flex™. Figure II.6.7.3 depicts a representative image of DBM formed into a simple rectangular solid, and also shows the presence of cells growing on the DBM. DBM-based bone graft substitutes exhibit a variable degree of osteoinduction based on the processing parameters (Kneser et al., 2006; Laurencin et al., 2006).

There is evidence that supports improved osteoinduction with demineralization due to exposure of soluble factors that would be occluded in mineralized bone (Gazdag et al., 1995; Peterson et al., 2004); however, DBM-based bone graft substitutes have limited osteoconductivity, no osteogenicity, and mechanical properties that are less than the desirable range (Gazdag et al., 1995; Peterson et al., 2004).

Natural Polymer-Based Substitutes

Natural polymers are gaining interest among the research community for bone tissue engineering applications, and there are also commercial bone graft substitutes derived from natural polymers available. One example of a commercially viable natural polymer product is Healos® from DePuy Orthopaedics, Inc. Healos® is a collagen microfiber matrix that has been coated with hydroxyapatite (Neen et al., 2006). The recommended use of Healos® involves coating it with bone marrow aspirate prior to implantation. By supplying the matrix with bone marrow aspirate there are progenitor cells present on the Healos® matrix, which makes it osteogenic in addition to being osteoconductive (Neen et al., 2006). There is no evidence that Healos® is osteoinductive, and it has poor mechanical properties (Neen et al., 2006). In addition to collagen, fibrin and chitosan are two other natural polymers that are being investigated for bone tissue engineering applications (Khan et al., 2008; Osathanon et al., 2008). The structures created by these polymers are typically fibers or foams (Wahl and Czernuszka, 2006; Osathanon et al., 2008; Song et al., 2008). These structures provide excellent osteoconduction; however, osteoinduction, osteogenicity, and mechanical properties are less than those provided by autograft tissue (Wahl and Czernuszka, 2006; Khan et al., 2008).

Synthetic Polymer-Based Substitutes

Synthetic polymer solutions for bone tissue engineering applications are varied and abundant in current research. The use of synthetic polymers provides control over the surface chemistry, degradation kinetics, and geometry in much finer detail than can be accomplished with natural polymers. Clinically, only a handful of synthetic polymers are US Food and Drug Administration (FDA) approved for use in non-life-threatening applications, such as bone graft substitutes. These are the following poly(α-hydroxy esters): poly(lactide); poly(glycolide); poly(lactide-*co*-glycolide); and poly(caprolactone). Figure II.6.7.4 illustrates a lattice structure made of poly(caprolactone) rods that has been implanted into a pig, and imaged three months post-implantation with μCT (micro-computed tomography) to demonstrate where new bone formation is occurring, which is not adjacent to existing bone tissue (Jones et al., 2004).

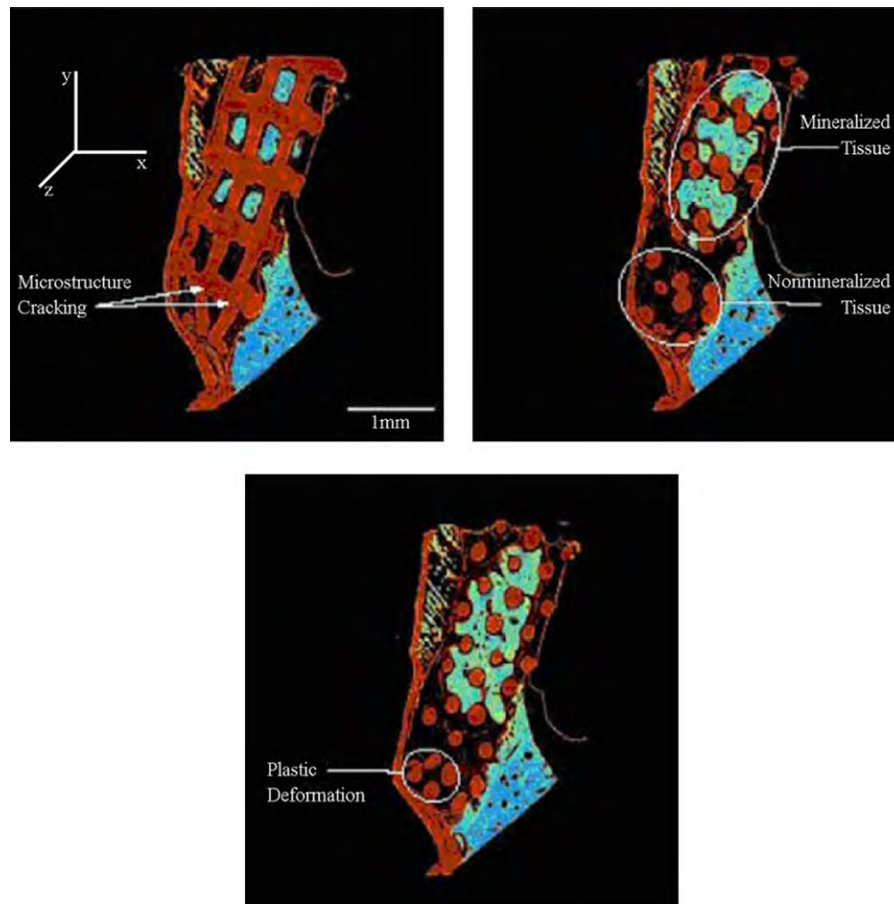
The mechanical properties of the construct are not documented, and the cracking and plastic deformation
FIGURE II.6.7.3 Demineralized bone cut into a rectangular solid (a); and a high magnification fluorescent image showing the presence of viable cells on the demineralized bone matrix (b) (Ma et al., 2007).


FIGURE II.6.7.4 Representation obtained of a synthetic bone graft after three months *in vivo* using µCT. The synthetic bone graft is a simple poly(caprolactone) (PCL) scaffold (red), with nonmineralized tissue (black), and mineralized tissue (blue green). The native bone is visible in the lower right corner of each image. The three images are different sections separated by 280 µm. The poly(caprolactone) scaffold was made by a rapid prototyping process, and consists of a simple three-dimensional lattice of connected rods. Also visible in the series of images are two defects caused by either degradation of the PCL, which the authors note that after three months has caused the diameters of the rods to shrink from 500 µm to 300 µm, or due to excessive loading on the scaffold compromising the material prior to degradation (Jones et al., 2004).

visible after three months indicates the material may not be mechanically viable. The first porous bone tissue engineering constructs fabricated from poly(α-hydroxy esters) were foams created by various porogen leaching techniques (Thomson et al., 1995). The porogen in these foams is typically a substance that readily dissolves in water, such as gelatin, salt or sugar (Thomson et al., 1995; Mooney et al., 1996). These scaffolds are created by dissolution of the poly(α-hydroxy esters) in an organic solvent. The dissolved polymer is then mixed with the porogen and cast. After the solvent has evaporated, the construct is immersed in water to remove the porogen (Thomson et al., 1995; Mooney et al., 1996; Rezwan et al., 2006). This technique can produce scaffolds that are highly porous.

The primary issue with porogen leaching is that the increase in porosity is directly correlated with a decrease in mechanical integrity. Additionally, at low porosities, which are more robust mechanically, the polymer surrounds each individual porogen, resulting in poor interconnectivity among the pores (Mooney et al., 1996; Rezwan et al., 2006). The sintered microsphere scaffold

fabricated from poly(α-hydroxy esters) succeeded the scaffolds created with porogen leaching, and also resolved several of the problems with scaffolds created by porogen leaching. The maximum porosity achievable by the sintered microsphere scaffold is only around 45%, based on random packing of spheres; however, the interconnectivity of the porosity is 100%, which was a dramatic improvement over the scaffolds fabricated with porogen leaching (Devin et al., 1996; Mooney et al., 1996; Borden et al., 2002a,b; Rezwan et al., 2006). More recently, microscale scaffolds have been fabricated with a very specific architecture from poly(α-hydroxy esters) by using solid free-form fabrication techniques (Sachlos and Czernuszka, 2003; Ge et al., 2008). Solid free-form fabrication uses computer aided design to build structures layer by layer through techniques such as stereolithography, selective laser sintering, and three-dimensional printing (Hutmacher et al., 2004).

All of the scaffolds created with the above microscale technologies provide similar performance. The mechanical integrity of the scaffolds can be fabricated into a range that suits bone tissue applications, the scaffolds degrade

in a controllable manner based on the selection of the poly(α-hydroxy esters), and they are all osteoconductive. However, for the preparation of microscale structures, each of the techniques is limited to a resolution an order of magnitude larger than a cell, and the resulting materials are not osteoinductive nor are they osteogenic without supplementing the structure with growth factors or osteoblastic cells (Rezwan et al., 2006). The research community has moved to examine scaffolds composed of poly(α-hydroxy esters) that exhibit a subcellular dimension. These scaffolds are almost invariably fiber based, and are made either with electrospinning, phase separation for crystalline poly(L-lactide), and precipitation in a non-solvent of a continuous fiber stream from a polymer solution (Yoshimoto et al., 2003; Smith and Ma, 2004; Tuzlakoglu et al., 2005). The diameter of these fiber scaffolds can vary from 50 nanometers to several micrometers (Yoshimoto et al., 2003; Smith and Ma, 2004). The subcellular dimension provided by nano- and microfibers has illustrated improved osteoconductivity as compared to the supercellular dimension of the microstructures covered previously. Additionally, there is some evidence that nanofibers may promote osteoinduction; however, the gains that nano- and microfibers make with osteoconduction and osteoinduction are compromised by the mechanical properties under compression of the nano- and microfiber structures (Patel et al., 2007; Hu et al., 2008).

Nano- and microfiber scaffolds exhibit near negligible compressive strength when compared to the microscale structures created by sintered microspheres, solid free-form fabrication, and porogen leaching (Kjelstrup-Hansen et al., 2006; Rezwan et al., 2006). The next degree of control being explored for bone tissue engineering constructs involves moving away from the FDA approved poly(α-hydroxy esters) and on to other biodegradable polymers that provide better degradation by-products or improve the osteoconductivity of polymers through the incorporation of integrin binding peptides, such as RGD (Arginine-Glycine-Aspartic Acid peptide) or, within the synthetic polymer structure. A noted drawback of poly(α-hydroxy esters) is that they degrade into carboxylic acids, which can be immunogenic (Bostman and Pihlajamaki, 1998; Mosier-Laclair et al., 2001).
