An additional drawback to the usage of poly(α-hydroxy esters) is that they undergo bulk degradation, which results in sudden failure of the scaffold. Similar to the poly(α-hydroxy esters), poly(propylene fumarate) is a polyester that can be used to fabricate similar scaffolds to the poly(α-hydroxy esters), and also shares the same problems with bulk degradation and acidic degradation products (Lee et al., 2006; Rezwan et al., 2006). Poly[(amino acid ester)phosphazenes] address the negative degradation products found with poly(α-hydroxy esters), and have recently been investigated for bone tissue engineering applications. Poly[(amino acid ester)phosphazenes] degrade into amino acids, which are much easier for the

body to metabolize, and a buffer solution consisting of ammonia and phosphate, which prevents any change in the pH potentially brought about by the increase in the concentration of amino acids. Poly[(amino acid ester) phosphazenes] have also exhibited a more favorable surface erosion degradation mechanism (Allcock et al., 1994; Ibim et al., 1997). Additionally, poly[(amino acid ester)phosphazenes] are suitable for many of the fabrication procedures discussed previously, such as sintered microsphere scaffolds, porogen leaching scaffolds, and electrospun nanofibers (Laurencin et al., 1996; Kumbar et al., 2006a; Brown, et al., 2008b).

The scaffolds fabricated from poly[(amino acid ester) phosphazenes] have illustrated osteoconduction, but studies investigating the osteoinductivity and mechanical properties have yet to be reported (Conconi et al., 2006; Kumbar et al., 2006a). Figure II.6.7.5 provides a representative image of sintered microsphere scaffolds, porogen leaching scaffolds, and electrospun nanofiber scaffolds created with degradable polyphosphazenes. Polyanhydrides are surface eroding polymers similar to polyphosphazenes; however, little research has been performed investigating porous polyanhydride scaffolds for bone tissue engineering (Muggli et al., 1999; Rezwan et al., 2006).

Ceramic-Based Substitutes

Ceramic-based biomaterials are prevalent and widespread as bone graft substitutes. These ceramic biomaterial bone graft substitutes are made primarily from calcium phosphates, calcium sulfate, and Bioglass®, which is a glass formulation containing lower amounts of silicon dioxide, and higher amounts of sodium oxide and calcium oxide compared to conventional glass. This specific glass formulation is bioactive, and undergoes dissolution in the body. Calcium phosphate bone graft substitutes are usually either tricalcium phosphate or hydroxyapatite, which is the primary mineral in bone. One example of a commercially available hydroxyapatite-based bone graft substitute is Pro-Osteon™ from Biomet® Osteobiologics. The Pro-Osteon™ bone graft substitute begins as natural coral, which is primarily calcium carbonate. The coral is then treated with a hydrothermal process in the presence of ammonium phosphate, to convert the calcium carbonate structure to hydroxyapatite (Ben-Nissan, 2003). The resulting structure exhibits a pore structure similar to trabecular bone. Figure II.6.7.6 is a depiction of the coralline hydroxyapatite resulting from the above hydrothermal process. Osteohealth® produces a product through the removal of the organic portion of bovine bone called Bio-Oss®. Bio-Oss® retains the structure of the hydroxyapatite formed in the bovine trabecular bone from which it is obtained.

A similar product to Bio-Oss® is Orthograf® which is manufactured by Dentsply, and which is also derived from bovine bone that has been treated to remove all

organic components. All of the hydroxyapatite-based ceramic bone graft substitutes are slowly resorbed by the body as the bone surrounding the implant remodels. Hydroxyapatite-based ceramic bone graft substitutes are also osteoconductive; however, the porous hydroxyapatite bone graft substitutes typically have compressive strength and moduli that fall below the range of trabecular bone (Rezwan et al., 2006). Whether hydroxyapatite-based biomaterials are osteoinductive is a controversial topic. Osteoinduction appears to occur with hydroxyapatite and other calcium phosphate-based biomaterials.

Initially, the osteoinductivity of hydroxyapatite and other calcium phosphates was believed to be a property

of the ceramic itself (Damien and Parsons, 1991). However, recent evidence suggests that it is a property of the microstructure of the material, which would be similar to results observed with polymer scaffolds (Yuan et al., 2002; Giannoudis et al., 2005; Li et al., 2008). Two calcium phosphate structures, one composed of hydroxyapatite and the other of a blend with 85% hydroxyapatite and 15% tricalcium phosphate, were fabricated into similar macrostructures; however, the hydroxyapatite/tricalcium phosphate structure also had a subcellular microstructure, and was found to be more osteoinductive than the hydroxyapatite with no subcellular microstructure (Yuan et al., 2002). Additionally, an examination of several distinct calcium phosphates with different

chemical and crystal structures fabricated into similar macrostructures illustrated no significant difference in the expression of phenotype markers (Wang et al., 2004). Furthermore, examination of chemically identical types of hydroxyapatite formed into different geometries produced pronounced differences in the expression of phenotype markers, with the hydroxyapatite structure exhibiting a subcellular microstructure being more osteoinductive than the hydroxyapatite with no subcellular microstructure (Li et al., 2008).

An additional type of calcium salt is calcium sulfate. Wright Medical Technology produces a dense bone graft substitute from calcium sulfate called Osteoset®. Osteoset® has been shown to be resorbed nine months post-implantation, and has also been illustrated to be osteoconductive; however, conflicting evidence is found over whether Osteoset® and other calcium sulfate bone graft substitutes improve healing in bone (Clokie et al., 2002; Petruskevicius et al., 2002). Additionally, calcium sulfate bone graft substitutes have been found to be potentially immunogenic (Robinson et al., 1999; Lee et al., 2002).

Of the ceramic-based bone graft substitutes, those fabricated from Bioglass® are the most intriguing. Bioglass® was developed in the late 1960s and has been shown to fit the bone tissue engineering paradigm better than the other ceramics covered (Hench et al., 1971). Porous scaffolds have been fabricated from Bioglass® in a number of ways. One way, that produces a 90–95% porous structure, involves a foam replacement technique where a polyurethane foam is coated with a Bioglass® slurry. The coated foam is then heated, which burns the polyurethane out and processed through a heat-treatment schedule to fuse the Bioglass® particles and obtain the desired density and crystallinity (Vargas et al., 2009). Another technique sinters Bioglass® fibers to form porous mats of Bioglass® fibers. These Bioglass® fiber mats have been shown to be osteoconductive, and promote phenotype progression of preosteoblast cells, which suggests they may be osteoinductive. The compressive strength and modulus of these Bioglass® fiber rafts are in the range of trabecular bone, and they exhibit adequate porosity of around 44% (Brown et al., 2008a). Despite the advantages of Bioglass® over the other ceramics covered, there are only a few commercial applications. Perioglas® is a Bioglass® particulate produced by Novabone™ to serve as bone filler or graft extender. The other commercial Bioglass® product is Biogran®, which is also a particulate and is currently produced by Biomet® 3i.

Cell-Based Substitutes

Cell-based strategies for bone tissue engineering, similar to biomaterial-based strategies for bone tissue engineering, fall into several categories. These are transplantation of autogenous progenitor cells, transplantation of autogenous progenitor cells that have been expanded and/or differentiated in culture prior to implantation, transplantation of genetically modified cells, and transplantation of *ex vivo* generated tissue (Muschler et al., 2004). The simplest of these strategies is the transplantation of autogenous progenitor cells. Typically this is performed by aspirating bone marrow and placing the aspirate at the defect or surgical site, unmodified or centrifuged to remove red blood cells and hematopoietic cells, including monocytes, from the bone marrow. The transplantation of autogenous stem cells provides osteogenic potential to the defect, but does not provide osteoconductivity, osteoinductivity or mechanical strength (Connolly et al., 1989).

The second method involves culturing the progenitor cells extracted in the bone marrow in culture. This can increase the number of progenitor cells available to implant, but it also comes with risks. The added time in culture *in vitro* increases the likelihood of bacteria contaminating the progenitor cell population. Successful expansion of the progenitor cells *in vitro* can ultimately improve the healing at the defect or surgical site. Similar to the non-expanded cells, progenitor cells expanded *in vitro* prior to implantation are osteogenic, but not osteoconductive, osteoinductive or mechanically viable (Patterson et al., 2008).

The third strategy for cell-based bone tissue engineering is the use of genetically modified cells. This is similar to the use of *in vitro* expanded autogenous progenitor cells, except the progenitor cells have been treated with an adenovirus to express a protein of interest. For bone tissue, often the progenitor cells will be transfected to express bone morphogenetic protein 2, (BMP-2). BMP-2-expressing progenitor cells provide the cell-based construct to be osteoinductive as well as osteogenic; however, the construct would still not improve in regard to osteoinductivity or mechanical viability (Lieberman et al., 1999; Cui et al., 2006).

The final strategy for cell-based bone tissue engineering is the most ambitious and the least clinically relevant at present. This is the *in vitro* culture of autogenous or embryonic stem cells with the aid of a bioreactor to ultimately produce a viable piece of bone tissue *ex vivo*. The major limitation in this strategy is material transport in developing tissue, since the issue of developing a vascularized construct has not been solved (Muschler et al., 2004). Despite this limitation there is evidence that mesenchymal stem cells can be induced to form small spheroids and differentiate into osteoblasts (Kale et al., 2000). If successful, the *ex vivo* formation of bone tissue would meet all five criteria outlined in the bone tissue engineering paradigm.

Growth Factor-Based Substitutes

The next strategy for bone tissue engineering is based on the use of factors. Two factors that have been shown to be effective in a clinical setting and are approved by

TABLE II.6.7.1	Summary of the Properties Illustrated by the Different Types of Non-Composite Bone Graft Substitutes and How They Relate to the Desirable Characteristics of an Ideal Bone Graft Substitute			
	Osteoconductive	**Osteoinductive**	**Osteogenic**	**Mechanical Match**
Allograft-based	Yes	Yes	No	No
Microscale biomaterials	Yes	No	No	Yes, within the range of trabecular bone
Nanoscale biomaterials	Yes	Potentially, supported by evidence with nanofibers made by self-assembly or phase separation	No	No
Ceramics	Yes	Potentially, supported by evidence for Bioglass®	No	Yes, range from less than trabecular bone to more than cortical bone depending on porosity
Cells	No	No	Yes	No
Growth factors	No	Yes	No	No

the FDA are recombinant human bone morphogenetic proteins 2 and 7, rhBMP-2 and rhBMP-7, respectively. Bone morphogenetic proteins are part of the transforming growth factor-β super family, and have been shown to exhibit osteoinductive potential (Fouletier-Dilling et al., 2007). Between the two rhBMPs, rhBMP-2 has been shown to be more osteoinductive than rhBMP-7 (Govender et al., 2002b; Ripamonti et al., 2007). Due to the soluble nature of both rhBMPs, they are typically packaged with some sort of carrier, often as simple as a collagen sponge (Gautschi et al., 2007). RhBMP-2 combined with a collagen sponge has been shown to perform better in spinal fusions than the "gold standard" autograft (Geiger et al., 2003).

In addition to spinal fusions, rhBMP-2 combined with a collagen sponge has illustrated effectiveness in fracture healing, where the rhBMP-2/collagen construct illustrated a significant improvement in fracture healing after 10 weeks (Govender et al., 2002a). RhBMP-2/collagen constructs have illustrated improved healing of critical size defects in animal models (Geiger et al., 2003). The use of rhBMP-7 in spinal fusions has been proven more effective than the autograft in high risk patients (Govender et al., 2002b; Gautschi et al., 2007). Medtronic®, Inc. developed a collagen sponge that is combined with rhBMP-2 to improve spinal fusion. This collagen sponge combined with rhBMP-2 and a spinal cage is marketed under the trade name of INFUSE®. The primary limitation to the usage of rhBMPs in bone tissue engineering applications is that they often cost a significant amount more than comparable procedures, and consequently the use of rhBMPs is primarily only in high risk cases where all other options have been exhausted (Gautschi et al., 2007).

Composite Substitutes

The final strategy for bone tissue engineering is based on composites which combine two or more of the elements detailed above. The goal of creating composites is to combine the benefits of each component. Table II.6.7.1 summarizes how the different bone tissue engineering strategies correlate to the bone tissue engineering paradigm. A common composite encountered consists of a biomaterial structure seeded with osteoblasts or osteoblastic cells. This is typically accomplished by either seeding of the biomaterial structure with osteoblast progenitor cells *ex vivo* just prior to implantation *in vivo*, or seeding of the biomaterial structure with osteoblasts or osteoblast progenitor cells followed by culture *in vitro* for several days to weeks prior to implantation.

An example of this technique that is presently used clinically is seeding Grafton® DBM with bone marrow aspirate from the patient *ex vivo*, followed by implantation of the Grafton® DBM/bone marrow aspirate composite at the desired surgical site. This composite combines the osteogenic potential of the progenitor cells in the bone marrow aspirate with the osteoinductive and osteoconductive properties of the Grafton® DBM, and has been shown to be comparable to an autograft in formation of bone at the surgical site (Russell, 2000; Lindsey et al., 2006).

Another example of a cell/biomaterial composite involves seeding a porous polymer scaffold created by selective laser sintering of poly(caprolactone) with fibroblasts transfected to express bone morphogenetic protein-7, BMP-7 (Williams et al., 2005). The selective laser sintered poly(caprolactone) scaffold provides a structure with millimeter scale features that is mechanically adequate and osteoconductive, and the incorporation of the BMP-7-expressing fibroblasts makes the composite construct osteoinductive. However, the fibroblasts are not expected to differentiate to osteoblasts, and consequently this composite is not osteogenic. A second example of composite scaffolds for bone tissue engineering involves the incorporation of a ceramic calcium phosphate with a polymer scaffold. This can be accomplished through several different methods, such as suspension of calcium phosphate particles with the polymer phase

prior to processing to form a scaffold, spontaneous formation of calcium phosphates within the polymer phase during processing, and coating of calcium phosphates on the surface of a biomaterial scaffold through soaking in simulated body fluid. A composite created by incorporation of calcium phosphates with the polymer phase during processing is illustrated by electrospinning a slurry of β-tricalcium phosphate particles in dissolved poly(caprolactone) to create a scaffold consisting of nanofibers exhibiting β-tricalcium phosphate particles on the surface of the fibers (Erisken et al., 2008). The incorporation of the β-tricalcium phosphate particles improves the mechanical properties of the nanofiber scaffold, and may also improve the osteoinductivity of the scaffold; however, an improvement in the osteoinductivity of the nanofiber/β-tricalcium phosphate composite has not been illustrated (Erisken et al., 2008).

A composite created by spontaneous formation of calcium phosphates during processing is illustrated by a technique where microspheres are created by an emulsion technique where the organic phase contains the polymer, and the aqueous phase contains calcium and phosphate salts, which through careful control of temperature and pH precipitate onto the microsphere surface as amorphous hydroxyapatite (Khan et al., 2004). The microspheres are heat sintered to form a porous scaffold, and could yield promising results as a bone graft substitute; however, no published evaluation of these composite scaffolds' performance *in vitro* or *in vivo* is currently available. An example of a ceramic/polymer composite formed by precipitation of calcium phosphates on the surface of a scaffold is demonstrated by a technique where PLAGA (poly(lactic-co-glycolic acid)) microspheres are formed and placed in simulated body fluid, which cause nucleation of calcium phosphates on the surface of the microspheres. The microspheres are then compression molded into porous scaffolds (Davis et al., 2008). These scaffolds illustrate improved osteoconductivity *in vitro*, but do not show any improvement in osteoinductivity over the uncoated microsphere control (Davis et al., 2008).

A third example of a composite scaffold for bone tissue engineering involves the incorporation of growth factors with a polymer or ceramic scaffold. An advanced example of this concept involved the development of cross-linked poly(vinyl pyridine) microspheres containing either rhBMP-2 or rhBMP-7, which were then suspended in a PLAGA foam (Buket Basmanav et al., 2008). The concentration of the poly(vinyl pyridine) and the degree of cross-linking allowed for a staged release of rhBMP-2 and rhBMP-7. The rhBMP-2 was entrapped in the lower concentration and less cross-linked microspheres, and was released more rapidly than the rhBMP-7. The result of this rhBMP-microsphere-loaded PLAGA foam was an increase in the differentiation of bone marrow-derived mesenchymal stem cells *in vitro* as compared to the PLAGA foam loaded with control microspheres not containing any rhBMPs (Buket Basmanav

et al., 2008). The results of this investigation are typical of what is expected by including BMPs into scaffolds, and provides a strategy for making an osteoconductive scaffold osteoinductive as well (Jeon et al., 2007; Buket Basmanav et al., 2008; Kempen et al., 2008). A critical issue with constructs containing growth factors, which is shared by growth factor strategies in general, is that they are prohibitively expensive for developing medical strategies to treat typically non-life-threatening injuries. The above examples of strategies for composite structures for bone tissue engineering represent only a small portion of the composite structures that have been investigated; however, the above examples do provide an accurate representation of the desired outcomes in preparing composite structures for bone tissue engineering.

POROSITY IN BONE GRAFT SUBSTITUTES

An important characteristic of a successful biomaterial-based bone graft substitute that promotes all the features of the bone tissue engineering paradigm involves the pore structure of the scaffold or construct. Without an adequate pore structure, migration into the scaffold is restricted, which subsequently limits the potential of the scaffold to be osteoconductive, osteoinductive, and osteogenic. The pore structure of the scaffold, both pore diameter and porosity, is a critical component in allowing cellular migration.

The concept of pore structure and cellular migration is similar across cell lines, and as such, this discussion focuses primarily on the characteristic dimension of the scaffold and the subsequent requirements to promote cell migration into the scaffold. For microscale scaffolds fabricated through techniques such as microsphere sintering, gas foaming, and particulate leaching the critical design aspects involve maintaining interconnected pores and pore diameters above 40 μm (Akay et al., 2004; Karageorgiou and Kaplan, 2005). An interconnected porosity is necessary to facilitate migration of cells throughout the scaffold, as well as to maintain a supply of nutrients and removal of waste from the cells on the scaffold interior. It was found that scaffolds with large, 100–300 μm, pore diameters facilitated faster migration throughout the scaffold (Borden et al., 2002b; Karageorgiou and Kaplan, 2005); however, despite the decreased rate of migration, the lower, 40 μm, pore diameter scaffolds achieved the same level of cellular penetration as those with larger pore diameters (Karageorgiou and Kaplan, 2005).

When the characteristic dimension of the scaffold shrinks to the nanoscale, these same concepts do not apply (Stevens and George, 2005). No longer does pore diameter appear to be as influential, since nanofiber scaffolds fabricated from self assembly and thermally-induced phase separation have illustrated cell invasion into and throughout the interior of the scaffold, despite pore diameters ranging from 300 nm–10 μm (Zhang, 2003; Semino et al., 2004; Silva et al., 2004; Chen et al., 2006; Horii et al., 2007). Two characteristics shared by
FIGURE II.6.7.7 Flourescent microscopy depicting preosteoblasts on either a flat poly(methyl methacrylate) surface (A); or poly(methyl meth-acrylate) nanofibers (B). The actin cytoskeleton of each cell is red, the protein vinculin, that is localized to points where the cell is adhered to the substrate, is green and the cell nucleus is stained blue. The image was taken 24 hours after the cells were seeded on the substrates. Of interest is how the preosteoblast on the flat surface spreads out radially, whereas the preosteoblasts on the nanofibers extend out along the fibers. What is not clear by the two-dimensional images provided is that the preosteoblast in (A) is much flatter in the z-direction than the preosteoblast in (B). Previously unpublished images.

both of these scaffold architectures are that they illustrate porosities greater than 95%, and that the fibers are randomly oriented in three dimensions (Ma and Zhang, 1999; Zhang, 2003; Horii et al., 2007). Likewise, electrospun nanofibers, which typically exhibit total porosities ranging from 40–75%, with isolated reports up to 90%, and pore diameters ranging from a few microns to 30 μm, have also exhibited cellular infiltration throughout the interior of the scaffold (Kim et al., 2003; Boland et al., 2004; Zhang et al., 2005; Venugopal et al., 2007).

These results illustrating cellular migration into the small pores contradict those previously found for microscale scaffolds, and consequently have raised questions regarding how cells are able to infiltrate nanoscale scaffolds. The ability of cell infiltration with a nanoscale scaffold starts with a fundamental difference in how cells respond to nanodimensional surfaces (Stevens and George, 2005). On nanostructures, cell morphology changes to exhibit pronounced pseudopodia-like processes which extend along individual fibers (Tan and Saltzman, 2004; Patel et al., 2007). Figure II.6.7.7 illustrates preosteoblasts seeded on a flat surface, which mimics a microstructure, and preosteoblasts seeded on nanofibers illustrating the aforementioned pseudopia-like processes. These extensions on randomly orientated fibers produce an image appearing to be a well-spread cell; however, it is important to consider that most imaging techniques depict a two-dimensional field when there is a third dimension not necessarily seen. This implies that cells are extending down into the field of view as much as they are extending out within the field of view, and this theory has been corroborated through the use of confocal fluorescence imaging illustrating cells extending in three dimensions (Silva et al., 2004; Horii et al., 2007). These well-spread cells exhibiting pseudopodia-like processes

have led researchers to conclude that cells utilize ameboidal migration to reach the interior of the scaffold (Friedl and Brocker, 2000a,b; Zhang et al., 2005). Presumably, this ameboidal migration is driven by soluble factors and proteins adsorbed to the surface of fibers below the cells, providing a gradient and driving infiltration to establish a uniform density of cells throughout the construct (Stevens and George, 2005; Patel et al., 2007). In conclusion, microscale scaffolds rely on pore diameter to allow cell migration; whereas nanoscale scaffolds rely on chemical gradients created by adsorbed factors and ameboidal motion to allow cell migration, which suggests that porosity is the critical property of nanoscale scaffolds.

DIMENSION IN BONE GRAFT SUBSTITUTES

In addition to porosity, the characteristic dimension of a polymer scaffold can have tremendous implications to the success of the scaffold as a bone graft substitute. Following are detailed descriptions of two scaffold types with dramatically different characteristic dimensions. The first, sintered microspheres, has a characteristic dimension an order of magnitude larger than that of a cell; while the second, nanofibers, demonstrate a characteristic dimension two orders of magnitude smaller than that of a cell.

Sintered Microspheres

Sintered biodegradable microsphere scaffolds were first developed by Cato Laurencin's laboratory in 1996, and were composed of PLAGA. These initial scaffolds were fabricated both with and without hydroxyapatite, and exhibited mechanical properties and porosity suitable for bone tissue engineering (Devin et al., 1996). Since

that time the microsphere scaffold has undergone several compositional iterations. Microsphere scaffolds have been fabricated from other types of biodegradable polyesters, such as polylactide and poly(3-hydroxybutyrate-*co*-3-hydroxyvalerate) (Nof and Shea, 2002; Zhu et al., 2007). Sintered microsphere scaffolds have been fabricated from a polymer/ceramic composite microsphere composed of poly(lactide-*co*-glycolide) microspheres fabricated in such a way as to spontaneously induce calcium phosphate precipitation on the surface of the microspheres (Khan et al., 2004). Additionally, microsphere scaffolds have been combined with growth factors to provide differentiation cues to the seeded cells (Jaklenec et al., 2007).

A final recent iteration of the microsphere scaffold has dealt with the blend of poly(lactide-*co*-glycolide) with the biopolymer chitosan, as well as blends with other polyesters, such as poly(propylene fumarate) (Jiang et al., 2006; Kempen et al., 2006). The tremendous interest in the sintered microsphere scaffold is due to it being advantageous over other microscale scaffolds produced by such techniques as gas foaming and porogen leaching (Sachlos and Czernuzska, 2003; Rezwan et al., 2006). These advantages are reproducibility, scalability, and controllability over pore size, porosity, and mechanical properties. Microsphere scaffolds rely on the chemical properties of a polymer to sinter uniform spheres into scaffolds by elevating the polymer above the glass transition point, which causes the adjacent polymer chains to migrate and intertwine, forming a cohesive bond when the polymer is cooled (Borden et al., 2002a). Maintaining the temperature, size of microsphere, and time to sinter has proven to produce uniform scaffolds (Borden et al., 2002a). Gas foaming and porogen leaching do not have the same level of reproducibility, due to variation introduced by having multiple phases, either a heterogeneous mixture of a solid and liquid or a liquid and gas. These heterogeneous mixtures can undergo demixing, which introduces inconsistencies in the mixing of the phases and decreases reproducibility (Sachlos and Czernuzska, 2003; Rezwan et al., 2006).

Microsphere scaffolds maintain a very high level of interconnectivity among the pores, and allow control over the total interconnected porosity, as well as the average pore diameter (Borden et al., 2002a). Gas foaming and particle leaching provide control over the total porosity and pore size as well; however, they often have very poor interconnectivity (only 10–30% interconnectivity with gas foaming) of the pores, rendering a percentage of the pores inaccessible (Mooney et al., 1996). The inaccessible pores are formed when the initial heterogeneous mixture lacks contact between the solid or gaseous phases, which causes the resulting scaffold to contain pores surrounded by solid polymer. Another advantage of microsphere scaffolds, when compared to gas foaming and porogen leaching, is that they can be fabricated to exhibit mechanical properties that mimic that of trabecular bone (Borden et al., 2002a, 2004).

High mechanical properties are achievable with gas foaming and porogen leaching; however, to achieve this, the scaffold density must be increased, which causes the internal pore structure to be further compromised (Sachlos and Czernuzska, 2003; Rezwan et al., 2006). Microsphere scaffolds composed of polylactide and poly(lactide-*co*-glycolide) have been produced previously, and have yielded reasonable results in *in vitro* studies, as well as in *in vivo* studies examining critical size defect healing (Borden et al., 2002b, 2004; Botchwey et al., 2003; Yu et al., 2004; Jiang et al., 2006). *In vitro* studies have illustrated that rat calvarial cells demonstrated a phenotype with earlier expression of matrix proteins in a greater magnitude when cultured on microsphere scaffolds, compared with the same cells on tissue culture plastic (Borden et al., 2002b).

Nanofibers

Recent developments in tissue engineering have indicated that nanoscale structures are more advantageous for cellular phenotype expression and morphology when compared to microscale structures (Tuzlakoglu et al., 2005; Wan et al., 2005). A frequently employed type of nanoscale scaffold is based on polymeric nanofibers. Nanofibers can be fabricated through several different techniques. The initial and most common technique is through electrospinning, which has been used for over 70 years (Formhals and Schreiber-Gastell, 1934). Electrospun nanofibers are created by applying a voltage gradient between a target and a drop of polymer, either dissolved or melted (Formhals and Schreiber-Gastell, 1934; Nair et al., 2004; Smith and Ma, 2004). Once the voltage gradient overcomes the surface tension of the droplet, a polymer stream extends toward the target. As this stream travels, it is thinned out and eventually strikes the target as a nanofiber, with the accumulation of these fibers leading to the production of a nonwoven nanofiber mat (Nair et al., 2004; Smith and Ma, 2004).

Initially, electrospun nanofibers were made from non-degradable polymers for applications in filtration; however, recent developments have led to the use of electrospun nanofibers made of biodegradable polymers for tissue engineering applications (Nair et al., 2004). Nanofibers created by electrospinning typically have diameters ranging from 300–1200 nm, depending on the spinning conditions used (Kim et al., 2003; Yoshimoto et al., 2003; Nair et al., 2004; Smith and Ma, 2004; Tuzlakoglu et al., 2005; Kumbar et al., 2006b). Electrospun nanofibers are oriented lengthwise in only two dimensions, with the third dimension created from the stacking of the fibers on top of each other. This is why electrospun nanofiber scaffolds are typically referred to as mats. Nanofibers have also recently been developed using synthetic peptides designed to self-assemble into a three-dimensional

nanofiber network. Self-assembly nanofibers often have a characteristic diameter that is within the range of 5–10 nm (Zhang, 2003; Semino et al., 2004; Silva et al., 2004; Smith and Ma, 2004; Horii et al., 2007). The very thin diameter of the fibers in the network, and the high porosity created with self-assembly, produces a scaffold poor in mechanical properties making them suitable primarily for hydrogel applications.

A final method of nanofiber fabrication is thermally-induced phase separation, which relies on the spinodal liquid–liquid phase separation of a polymer solution into a polymer poor phase and a polymer rich phase when the solution is rapidly cooled. Spinodal phase differs from binodal phase separation in that the two phases separate and exist continuously throughout the original mixture; whereas bimodal phase separation occurs via nucleation sites that build spherical particles. The selection of an appropriate polymer, one with a high degree of crystallinity, will allow the polymer rich phase to crystallize into nanofibers; whereas polymers with low degrees of crystallinity form microstructured foams (van de Witte et al., 1996; Chen et al., 2006). Nanofibers created with the thermally-induced phase separation technique exhibit a fiber diameter of 50–500 nm, which is similar to collagen, and a three-dimensional fiber structure making them very different to that of electrospun nanofibers (Smith and Ma, 2004). Evidence suggests that nanofibers exhibiting a three-dimensional spatial arrangement promote phenotype progression of osteoblasts, and may be osteoinductive (Hu et al., 2008). Producing a three-dimensional nanofibrous mechanically viable implant could be a tremendous leap forward in the field of bone tissue engineering.

Osteoinduction

Osteoinduction is the ability of a substance to cause stem cell differentiation down an osteoblastic lineage. Osteoinduction is known to occur when certain growth factors, such as bone morphogenetic proteins 2 and 7, and to a lesser extent vascular endothelial growth factor, are present (Urist, 1983; Geiger et al., 2003; Habibovic and de Groot, 2007; Dawson et al., 2009). What is less clear is whether a biomaterial can be osteoinductive in the absence of growth factor supplements. Current research has provided contradictory evidence as to whether or not a biomaterial is osteoinductive (Ye et al., 2007; Catros et al., 2009). No particular biomaterial has been conclusively shown to be osteoinductive, independent of structure and growth factors (Habibovic and de Groot, 2007; Habibovic et al., 2008).

This suggests that what may be more important than a particular biomaterial is the structure that the biomaterial is fabricated into. Research suggests that macroscale concavities (Graziano et al., 2008) in a surface, a microporosity (Habibovic et al., 2005), as well as subcellular structures (e.g., nanofibers) (Hu et al., 2008) may all promote osteoinduction. However, each of these elements has yet to be thoroughly challenged to definitively ascertain if they are indeed osteoinductive. For instance, the study investigating macroscale concavities included flat and convex surfaces as controls; however, all three surfaces were made from different materials, and the stem cells used were differentiated to osteoblast progenitors prior to seeding on the substrates. Another intriguing osteoinductive quality of substrates is that mesenchymal stem cell differentiation has demonstrated a dependence on the rigidity of a substrate (Engler et al., 2006; Khatiwala et al., 2007). These elements suggest that developing an osteoinductive bone graft substitute may depend on design and material considerations. Moving forward, research should first investigate how osteinduction occurs, and then deconstruct the independent elements of biomaterial chemistry, surface topography, and porosity to determine which, if any, element provides non-growth factor initiated osteoinduction.

IN VITRO CULTURE TECHNIQUES FOR BONE GRAFT SUBSTITUTES

A critical limitation of static culture conditions is that waste efflux and nutrient influx are governed by diffusion, which becomes exponentially more problematic with large three-dimensional constructs. As time passes, the accumulation of waste within a construct can lead to an acidic microenvironment that impedes calcification of the developing tissue, and compromises the viability of osteoblasts within a construct (Bushinsky et al., 1983; Han et al., 2009). To alleviate these issues the use of bioreactors becomes necessary when trying to achieve significant tissue growth *in vitro*. The bioreactor provides fluid flux that replenishes nutrients and removes waste; additionally, for tissues such as bone, bioreactors can provide mechanical stimulation to encourage the development of a mechanically viable tissue.

The earliest bioreactor that has been applied to bone tissue engineering involves dialysis membranes that are either gas or small molecule permeable (Figure II.6.7.8A). The bioreactor is divided into two compartments that are separated by small molecule permeable membrane, and each compartment also contains a gas permeable membrane (Vogler, 1989). The gas permeable membrane provides a liquid–air boundary to provide oxygen and CO_2, and the membrane between compartments serves as liquid–liquid boundary between the culture media surrounding the cells and a reservoir of fresh media. This boundary provides fresh nutrients while removing waste, but also allows the soluble factor gradients to remain intact during media changes. Recently, this bioreactor design has supported the development of simple osteoid tissue after culturing osteoprogenitor cells for 10 months (Mastro and Vogler, 2009). Despite the development of osteoid tissue, this bioreactor design still relies on passive diffusion to supply nutrients, and therefore limits the ultimate thickness of the construct to only a few cell layers (Mastro and Vogler, 2009).

The next iteration of the bioreactor involved rotation, either of the reactor itself or of the construct within the bioreactor (Figure II.6.7.8C). NASA developed rotating wall bioreactors to simulate microgravity. These bioreactors consist of a cylinder and a gas exchange membrane, either on one face of the cylinder

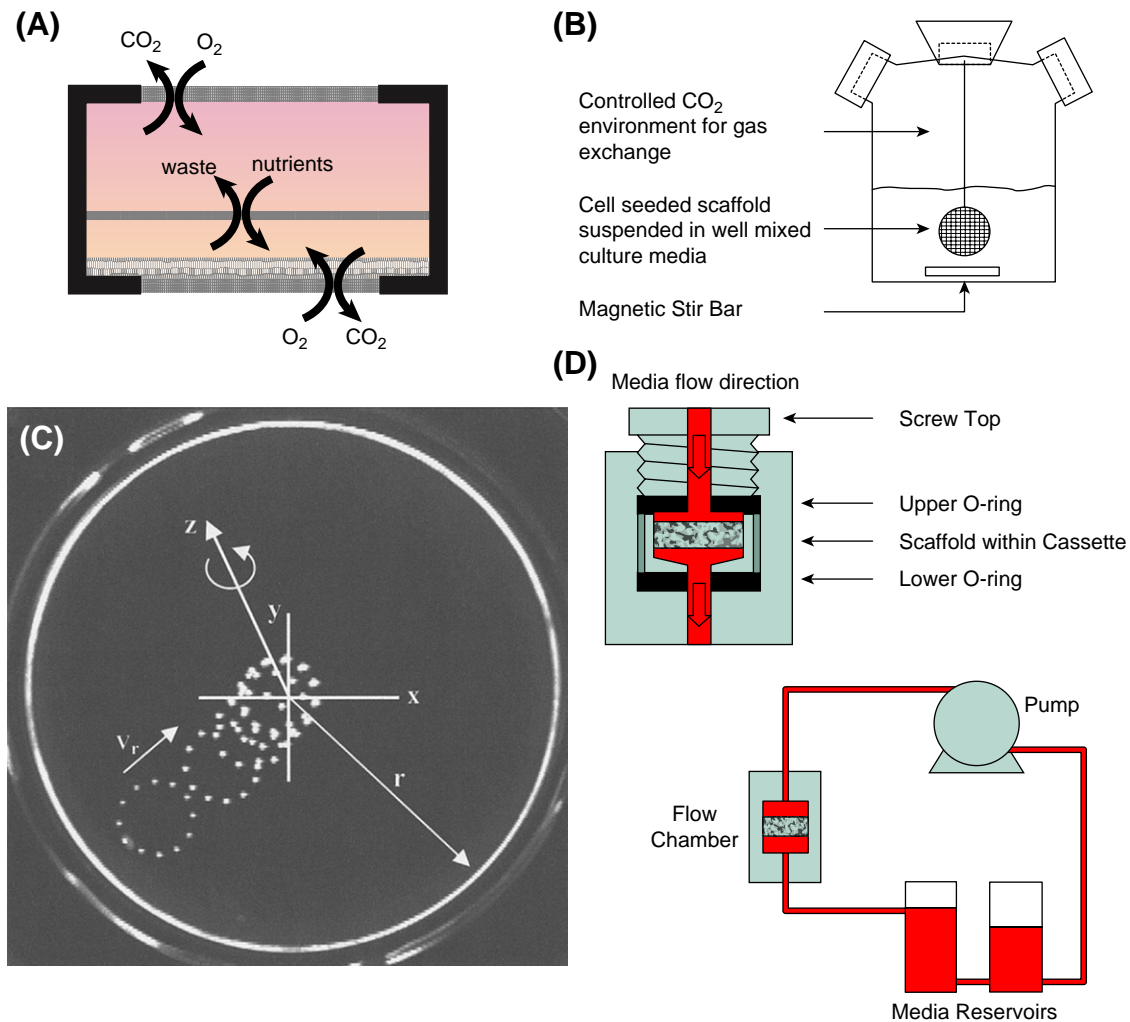

FIGURE II.6.7.8 Graphical depiction of four bioreactors. The simplest bioreactor that supports multi-layered growth of cells on the bottom surface and consists of two gas permeable membranes on the top and bottom and a dialysis membrane in the middle (A). A spinner flask bioreactor that utilizes a stir bar to force nutrient flux through the constructs, which remain in a fixed position (B) (Martin and Vermette, 2005). A high aspect ratio rotating vessel bioreactor demonstrating the trajectory of a lighter than water construct within the rotating wall bioreactor, the fluid shear on the scaffold is low; however, the back panel of the bioreactor is gas permeable membrane and the rotation maintains a large volume of well-mixed media to support nutrient supply (C) (Botchwey et al., 2004). Finally, a schematic illustrating a perfusion bioreactor that utilizes a pump to force media through a construct, which research suggests also promotes bone tissue formation through mechanical stimulation provided by fluid shear forces on the construct (D) (Bancroft et al., 2002). Copyright (2002) National Academies of Sciences, U.S.A.

or as a separate inner cylinder. In this design the shear force exerted by fluid rotation negates the effect of gravity on the constructs, and also provides a well-mixed volume of culture media. This strategy was employed by tissue engineers to culture constructs seeded with osteoblasts, in the hope that the rotating well-mixed volume of culture media would overcome diffusion limitations and allow tissue development throughout the thickness of the construct (Botchwey et al., 2004). Research suggests this is certainly the case, with osteoblasts found throughout the thickness of the construct (Yu et al., 2004); however, the simulation of microgravity seems to (not surprisingly due to a lack of mechanical stimulation) discourage bone tissue development; this is demonstrated both by lower levels of phenotype markers, and by lower mineralization as compared to static cultured constructs (Sikavitsas et al., 2002; Yu et al., 2004).

The next type of bioreactor that involves rotating fluid is the spinner flask (Figure II.6.7.8B). Spinner flask bioreactors suspend the constructs on thin needles that are extended into a stirred flask of media. This configuration not only provides a well mixed environment to avoid accumulation of waste in local environment of the construct, but also provides mechanical stimulation through shear forces on the constructs. Since the spinner flask also provides a well-mixed environment, it is not surprising to see that cells migrate throughout the construct suspended in the spinner flask, similar to those cultured in rotating wall bioreactors (Sikavitsas et al., 2002; Stiehler et al., 2008). Additionally, because the spinner flask provides much higher shear forces than the rotating wall bioreactor, there is a marked increase in the calcification of the construct and the differentiation of osteoblasts in the

spinner flask (Sikavitsas et al., 2002; Stiehler et al., 2008; Wang et al., 2008).

The final bioreactor for bone tissue engineering is a perfusion bioreactor (Figure II.6.7.8D). The perfusion bioreactor works by forcing culture media through a construct with a pump. This system provides intricate control over the shear experienced by the cells in culture. Similar to the spinner flask, osteoblasts generated more calcium and exhibited increased expression of phenotype markers in the perfusion bioreactor (Gomes et al., 2003; Pham et al., 2008).

CONCLUSION

The concepts of tissue engineering have made profound advances in developing clinically relevant solutions for tissue such as skin, bladder, and to some extent bone; however, where the clinical strategies for skin and bladder exist as a straightforward solution based on the requirements of those tissues, bone presents a more complicated situation. Skin and bladder tissue are essentially a uniform two-dimensional sheet; whereas, bone often takes many unusual three-dimensional and non-uniform geometries (Bannasch et al., 2003; Vats et al., 2003; Atala et al., 2006; Bolland and Southgate, 2008).

The evolution of bone tissue engineering began with osteoblasts cultured on rudimentary polymer foams, and has progressed to include an array of bone graft substitutes cultured in bioreactors to drive the development of *de novo* bone tissue. Significant clinical achievements have occurred in using biodegradable scaffolds, with or without growth factors or cells, as synthetic bone grafts to heal large defects in bone tissue (Damron, 2007; Rosa et al., 2008; Wlodarski et al., 2008; Dawson et al., 2009; Gosain et al., 2009). However, despite the ground that has been covered thus far, there persist unmet goals and challenges still ahead. No research has yet demonstrated the capability to grow *de novo* bone in an *in vitro* setting; so far only rudimentary calcified cell masses approaching bone tissue have been developed. Moving forward, future researchers should consider the flexibility in design of the macroscale structure to accommodate the unusual architectures and mechanics necessary for bone graft substitutes, biodegradability of the structure such that natural healthy bone is ultimately all that persists, the osteoconductivity of the bone graft substitute to promote proliferation of progenitor cells and osteoblasts throughout the bone graft substitute, and the osteoinductivity of the bone graft substitute to promote the maturation of the progenitor cells and osteoblasts into organized bone tissue.

To date, the one aspect the earliest bioreactor got right has been lacking in all future designs; the ability to maintain gradients in soluble growth factors secreted by cells. The development of the bioreactor for bone tissue engineering has moved from a series of static chambers separated by dialysis membranes to reactors that provide mechanical stimulation; the future success of the bioreactor will depend on the ability to incorporate aspects of the existing bioreactors: nutrient influx; waste efflux; mechanical stimulation; and the establishment of soluble factor gradients. Providing all four of these bioreactor elements with a bone graft substitute may lead to the development of hierarchical bone tissue, and ultimately the *de novo* formation of bone *in vitro*.

INTRODUCTION TO CARTILAGE AND LIGAMENT TISSUE ENGINEERING

The musculoskeletal system is responsible for complex movements that are performed many thousands of times over a lifetime. Two connective tissues of the musculoskeletal system, cartilage and ligament, protect the body from injuries during these movements, primarily by absorbing loads and maintaining joint stability, respectively. Relative to other musculoskeletal tissues, cartilage and ligament have low oxygen and nutrient requirements, low cell density, and poor regenerative capacity, yet they experience some of the highest mechanical loads in the body. When these loads exceed a critical threshold that causes permanent tissue damage, or if diseases cause severe tissue degeneration, these problems often result in a significant locomotive impairment. For the repair of both tissues, given their very low self-regenerative capacity, typically the only recourse is surgical intervention. Current surgical reparative techniques rely upon total joint replacement or grafting, and are often accompanied with further musculoskeletal problems; a more ideal solution would be to use a biological approach to repair the defects and fully restore the cartilage or ligament tissue to its pre-injured state. This is the promise of tissue engineering, a new field

which generally aims to incorporate specific cell types into a biodegradable scaffold which, when implanted, will gradually regenerate into a tissue that closely resembles the original tissue and restores functionality. In this chapter, we outline the state of the art of cartilage and ligament tissue engineering, divided into two sections, with emphasis ranging from biomaterial selection and functionalization, cellular activities critical for tissue function, scaffold design to mimic native tissue composition, to recent outcomes of long-term implantation studies in animal models.

CARTILAGE TISSUE ENGINEERING

Introduction to Cartilage Tissue Engineering

Cartilage is a connective tissue that functions to absorb mechanical impact, assist joint motion, provide structural support, and connect soft and hard tissues. There are three types of human cartilage: hyaline, elastic, and fibrocartilage, located at different parts of the body, and each type of cartilage features a unique composition and structure specifically suitable for carrying out the aforementioned tissue functions. Like other musculoskeletal tissues primarily responsible for mechanical and structural functions, cartilage plays an important role in protecting the body from mechanical impacts during physical activities. Therefore, any damage significantly impeding cartilage function may also affect functional capabilities of the musculoskeletal system.

Clinical Relevance and Limitations of Current Repair Strategies. Cartilage damage is a common problem often seen in clinical orthopedics. The causes and mechanisms leading to cartilage damage can be physical, biological or both. Physical causes, such as trauma, often damage the tissue structure and injure cells, creating permanent lesions in cartilage. On the other hand, biological causes, such as those related to autoimmunity and inflammation, trigger catabolic cellular and biochemical activities that degrade cartilage. Among these, osteoarthritis (OA), an aging-related disease, is the leading cause of cartilage degeneration. While OA is a joint problem commonly found in the aged population, the current trend has shown a decrease in the average age of the OA population. Obesity is one of the major factors triggering the early development of OA, and is likely to involve biological and physical mechanisms. As one of the leading causes of disability among the US adult population, OA significantly not only affects the quality of an individual's life, but also brings enormous societal and financial burdens to the healthcare system. Annually, OA treatment incurs more than 185.5 billion US dollars of healthcare cost, and this number is expected to increase rapidly in the next few decades when the baby boomer generation ages (Kotlarz et al., 2009). By the year 2030, it is estimated that 25% or more of the population in the US would likely suffer from arthritis. These demographic and health-cost estimates clearly illustrate the disease burden of OA, and indicate the urgent need to develop an effective therapy to treat OA, as well as other cartilage-related health problems.

Cartilage is a hypo-cellular tissue that does not contain blood and lymphatic vessels to support circulation of repair cells and molecules, such as growth factors and cytokines, to initiate wound healing of lesions once injured. Therefore, cartilage lesions often progress with time in an almost irreversible manner. Current treatments to cartilage lesions include non-surgical therapies and surgical interventions (Hunziker, 2002). Non-surgical treatments, such as drug or physical therapy, are generally used for the early stage of OA or cartilage with a minor lesion, whereas surgical interventions are necessary for mid- and late-stage OA or cartilage with a severe lesion. The clinical gold standard to treat severe cartilage lesions is total joint replacement, an effective but final resort surgical procedure to restore joint functions. For patients with less severe cartilage lesions, other surgical procedures, such as arthroscopic abrasion and debridement, microfracture, osteochondral plug transplantation or mosaicplasty, and autologous chondrocyte implantation, are used to repair lesions. Clinical results have shown that although these surgical procedures are able to provide some improvements to the disease state, there are inherent complications, such as fibrocartilage formation and donor site tissue morbidity.

The Modern Cartilage Engineering Strategy. Cartilage tissue engineering is an emerging method for therapeutic repair and regeneration of cartilage. The first cartilage tissue engineering attempt may be traced back to the 1970s, when a pediatric surgeon, Dr. W. T. Green, cultured rabbit chondrocytes on decalcified bone and transplanted the cellular structure into cartilage defects (Green, 1977). Although the outcome of the study was not satisfactory, this pioneer study introduced the innovative concept of cartilage tissue engineering. In 1991, Vacanti et al. implanted chondrocyte-laden poly(lactide-co-glycolide) (PLGA) scaffolds subcutaneously in nude mice to regenerate cartilage (Vacanti et al., 1991). The research team successfully demonstrated the feasibility of using a tissue engineering approach to regenerate new cartilage. Two years later, Freed and co-workers used a bioreactor system to grow chondrocyte-laden biodegradable scaffolds *ex vivo*, and showed significantly enhanced production of cartilage matrix in the bioreactor-grown cartilage, compared to static culture-grown cartilage (Freed et al., 1993). In the past two decades, the introduction of stem cells, smart biomaterials, and bioreactors have continued to enhance cartilage tissue engineering.

The principal concept of cartilage tissue engineering is to seed chondrocytes or chondroprogenitor cells within a three-dimensional biomaterial scaffold which is then cultured in a bioreactor to produce functional cartilage *in vitro*, which is then implanted *in vivo*. Alternatively,

a three-dimensional biomaterial scaffold is used as a carrier to deliver therapeutic cells to facilitate cartilage regeneration at a defect site, without being pre-cultured *in vitro*. Critical to the success of these cartilage tissue engineering strategies are the physical and chemical properties of biomaterial scaffolds, which must be able to provide mechanical strength, as well as to regulate biological activities of the seeded cells and their chondrocytic phenotype. In the past two decades, a great number of biomaterials and three-dimensional structures, including many novel materials and scaffolds, have been introduced into cartilage tissue engineering. By including cutting-edge nanotechnologies, peptide synthesis and controlled release, novel scaffolds with intelligent materials and structures are capable of changing their physical or chemical properties in response to physiological needs to enhance cell growth and tissue regeneration.

Macromolecular Composition and Structure of Native Cartilage

Cartilage Composition. Chondrocytes are the sole cell type in cartilage, and make up 5–10% of total tissue volume. Besides chondrocytes, other major components of cartilage are specific extracellular matrix (ECM) macromolecules, and water (Buckwalter and Mankin, 1998). The ECM constitutes 20–40% of the tissue volume, and the water content amounts to 70% of the total tissue weight. Despite a minor fraction of the total tissue volume occupied by chondrocytes, activities of chondrocytes are critical to the anabolism and catabolism of cartilage, i.e., chondrocytes continue to synthesize and break down ECM components to maintain healthy matrix turnover under the influence of autocrine or paracrine signals (Stockwell, 1979).

The ECM of cartilage consists of collagens, non-collagenous proteins, and proteoglycans (Buckwalter and Mankin, 1998). Collagenous ECM components include collagen types I, II, VI, IX, X, and XI (Eyre et al., 1992). In hyaline cartilage, a small quantity of collagen type I accumulates in the superficial zone, while collagen type II is ubiquitously present in cartilage and accounts for 90–95% of total collagen (Kuettner, 1992). Both collagen types I and II play a mechanical role in maintaining tissue structure integrity by providing strength to resist tensile loading. Collagen type VI is localized around chondrocytes, and has been postulated to play a role in mechanobiological regulation. Collagen type IX functions as a linker molecule that binds to collagen type II to stabilize collagen type II fibril assembly (Mendler et al., 1989). Collagen type X is produced by hypertrophic chondrocytes, and is mostly found in the calcified zone of the cartilage growth plate. Collagen type XI constitutes 5–10% of the total collagen content. Its function is not clear but likely associated with stabilization of the collagen network (Swoboda et al. 1989).

Non-collagenous proteins of the cartilage ECM are also involved in structuring the ECM and regulating chondrocyte activities (Heinegard and Pimentel, 1992). For example, the proteoglycan link protein serves to link aggrecan with hyaluronic acid (Ruoslahti, 1988), and fibronectin regulates chondrocyte adhesion to the ECM (Hayashi et al., 1996). Proteoglycans make up the bulk of the non-collagenous ECM components of cartilage, including large aggregating proteoglycans, such as aggrecan and versican, and small leucine-rich proteoglycans, such as decorin and biglycan (Prydz and Dalen, 2000). In hyaline articular cartilage, aggrecan is composed of a core protein, covalently modified with sulfated glycosaminoglycan (sGAG) molecules that make up about 90% of the total proteoglycan mass (Roughley and Lee, 1994). Sulfated GAGs, such as chondroitin sulfate, dermatan sulfate, heparan sulfate, and keratan sulfate, have a long polysaccharide chain that consists of repeating disaccharide units with sulfate groups. These sulfated polysaccharides carry a large amount of negative charge to attract and retain water between the matrix molecules, thus creating hydrostatic resistance to compressive loading (Mow and Wang, 1999).

Cartilage Structure. Although the articular cartilage of a human joint is only a few millimeters in thickness, it is capable of mediating smooth joint motion, and protecting subchondral bone from mechanical damage. This property of the articular cartilage is attributed to the existence of four regional zones in the tissue, with specific cell activities, and ECM structure and composition associated with each zone (Buckwalter and Mankin, 1998). The four zones from the top down are the superficial, middle, deep, and calcified zones (Farnworth, 2000). The superficial zone consists of a large amount of fibrillar collagen and water, but a small amount of proteoglycans (Venn, 1978). Collagen fibrils run parallel to each other and the joint surface, conferring high tensile and shear strength (Kempson et al., 1973). Chondrocytes in this zone are flattened, ellipsoid-shaped, and synthesize low molecular weight proteoglycans (Hasler et al., 1999). The middle zone lies beneath the superficial zone, and has several times the volume of the superficial zone. This zone features a lower cell number, the presence of spherical chondrocytes, and a large amount of proteoglycans (Venn, 1978). Chondrocytes produce fewer but larger randomly-oriented collagen fibrils in the middle zone, compared to those fibrils in the superficial zone. Located beneath the middle zone is the deep zone; this zone contains the largest collagen fibrils, the greatest amount of proteoglycans, and the lowest cell number, compared to the other three zones. Chondrocytes in this zone maintain a spherical shape, and the collagen fibrils are perpendicular to the joint surface (Hunziker et al., 1997). The deep zone is capable of providing substantial resistance to compressive loading because of the large amount of proteoglycans and the perpendicular collagen fibrils. The calcified cartilage zone is a transition zone located between the deep zone and subchondral bone. Chondrocytes in this zone are hypertrophic and exhibit low metabolic activities (Bullough and Jagannath, 1983).

Important Considerations in Designing and Fabricating a Cartilage Tissue Engineered Scaffold

Functionally, a tissue engineered scaffold represents an artificial ECM to accommodate, protect, and interact with cells residing in the structure during tissue regeneration. An ideal tissue engineered scaffold should be able to substitute for native ECM, and faithfully carry out ECM functions. In order to design an ideal scaffold for cartilage tissue engineering, it is essential to identify the critical cellular activities and material properties required for robust cartilage regeneration, and to select the biomaterial(s) that is best able to represent these characteristics.

Cellular Activity Requirements

Maintenance of the Phenotypic Spherical Shape of Chondrocytes. Cell morphology is an important aspect of the phenotype of a cell, and is critical in the regulation of cell activities. In native cartilage, chondrocytes are embedded in dense ECM, and exhibit a characteristic spherical morphology which is critical for maintaining the chondrocytic phenotype. Numerous *in vitro* studies have shown that after chondrocytes are isolated from cartilage and cultured as a monolayer surface, the cells change from a spherical to a spindle, elongated shape, and dedifferentiate into fibroblast-like cells. Unlike phenotypic chondrocytes that produce collagen type II and aggrecan, dedifferentiated cells produce collagen type I, decorin, and biglycan. Indeed, spindle shaped dedifferentiated chondrocytes show distinct cell activities, compared to spherical chondrocytes. However, the dedifferentiated cells can be redifferentiated back to phenotypic chondrocytes if they are encapsulated in a hydrogel or cultured on a low-adhesivity surface to re-establish a spherical morphology. Assumption and maintenance of a spherical cell shape is also a requirement for effective chondrogenesis of embryonic limb mesenchymal cells and adult mesenchymal stem cells (MSCs), as exemplified by a high cell-seeding density of these cells used in three-dimensional micromass or pellet culture for chondrogenic differentiation (see below).

Establishment of Biologically Favorable Three-dimensional Cell–Cell and Cell–Matrix Interactions. During embryonic chondrogenesis, mesenchymal cells undergo cell condensation, which is a critical and necessary step for chondrogenic differentiation (Fell, 1925). The cell condensation process is responsible for the initiation of specific, three-dimensional cell–cell interactions, such as N-cadherin mediated cell adhesion and gap junctional communication (Oberlender and Tuan, 1994), to activate chondrogenic signaling events for cartilage formation. For *ex vivo* chondrogenesis, the commonly used high-density cell pellet culture imitates the cell condensation process by densely packing cells via centrifugation to enhance three-dimensional cell–cell interactions. In addition to cell–cell interactions, cell–matrix interactions represent another critical mechanism that is involved in the regulation of chondrocyte activities in mature cartilage. After initial chondrogenesis, the resultant chondrocytes synthesize abundant ECM which is deposited around the cells, thus gradually separating cells from each other. In this manner, in mature cartilage, chondrocytes interact intimately with the pericellular ECM to maintain cartilage functions.

Material Property Requirements

Presentation of Biocompatible Surface Chemistry and Topography on Scaffolds. Surface chemical and physical properties of scaffolding materials must be biocompatible, and not elicit immunogenic or inflammatory responses from seeded cells or adjacent host tissues surrounding the scaffold. In addition, byproducts released from the scaffold as a result of biodegradation or bioresorption must be non-toxic, and not cause undesirable host reactions. Alternatively, any unwanted byproducts must be effectively removed from the local microenvironment. This characteristic is particularly important for cartilage tissue engineering because of the non-vascular nature of cartilage, which precludes vasculature as an efficient means of byproduct removal, with diffusion as the only mechanism available.

Construction of Scaffolding Structures with ECM-Mimetic Geometry. There is mounting evidence that physical properties of a biomaterial scaffold can instruct cell behavior, thus ultimately determining the fate of an engineered tissue. For example, scaffolds with nanosized or microsized structure create different patterns of cell–matrix interaction with seeded chondrocytes to modulate cell morphology and cytoskeletal organization, in turn resulting in different gene and protein expressions (Li et al., 2006a).

Mechanical Properties. In addition to functioning as structural templates to direct tissue growth and to determining the size and shape of regenerated cartilage, scaffolds must also provide protection for the neocartilage from mechanical damage. In the process of cartilage tissue engineering, mechanical challenges could occur during *in vitro* regeneration with mechanical loading stimulating tissue growth or post-implantation when the joints are subjected to natural weightbearing functions. Ideal scaffolds for cartilage tissue engineering must be able to protect cells from damage, and maintain structural integrity of tissue-engineered constructs to provide a mechanically stable environment to seeded cells during the tissue regeneration process.

Biomaterials in Cartilage Tissue Engineering

Synthetic Biomaterials for Cartilage Tissue Engineering. *Poly(α-hydroxy esters)* – Members of poly(α-hydroxy esters) are the most commonly used synthetic biodegradable polymer for cartilage tissue engineering. An advantage of using poly(α-hydroxy esters) as cartilage
FIGURE II.6.8.1 Scanning electron microscopy (SEM) micrograph of electrospun poly(α-hydroxy ester) fibrous scaffolds composed of randomly oriented ultra-fine fibers. (A) PGA; (B) PLGA5050; (C) PDLLA; (D) PLGA8515; (E) PLLA; and (F) PCL. Bar: 10 μm. (Reproduced with permission from Elsevier B.V.)

tissue engineering scaffolds is their prior approval by the US Food and Drug Agency for clinical use as bioresorbable biomaterials. Among the poly(α-hydroxy ester) members, poly(glycolic acid) (PGA), poly(lactic acid) (PLA), PLGA, and poly (ε-caprolactone) (PCL) have been extensively investigated for the use in fabrication of cartilage tissue-engineered scaffolds. PGA is a semi-crystalline, hydrophilic polymer, and may rapidly degrade in an aqueous solution. PLA, with the addition of a methyl group, is a more hydrophobic, semi-crystalline polymer, and degrades more slowly than PGA (Middleton and Tipton, 2000). The three stereoisomers, D, L, and D and L mixture, referring to the different conformation of the methyl group, exhibit distinct properties. For example, poly(l-lactic acid) (PLLA) has a higher melting temperature and degrades more slowly than poly(d, l-lactic acid) (PDLLA). Furthermore, PGA and PLA can be copolymerized in different ratios to form a new polymer, PLGA, with properties different from either of the two constituent polymers. Poly (ε-caprolactone) (PCL) is another semi-crystalline biodegradable polymer. Compared to other poly(α-hydroxy ester) members, PCL is less commonly used in the fabrication of scaffolds, mainly because its slow degradation may interfere with deposition of newly synthesized ECM. Recently, PCL has been blended or copolymerized with other poly(α-hydroxy esters) to fabricate new polymers with controlled properties for meeting the needs of fabricating working scaffolds (Middleton and Tipton, 2000).

The use of PLA scaffolds to culture chondrocytes, followed by implantation of the cell-seeded scaffold in an animal model to regenerate cartilage was first reported in the early 1990s (Vacanti et al., 1991). After this pioneer study, PLA, PGA, and PLGA have been fabricated into various structured scaffolds to culture chondrocytes or MSCs to regenerate cartilage *in vitro* or *in vivo*. Studies have shown that effective *in vivo* cartilage regeneration can be achieved by seeding and culturing chondrocytes

on PGA scaffolds *in vitro*, followed by *in vivo* implantation (Chu et al., 1995; Liu et al., 2002), suggesting that the process of *in vitro* cartilage tissue engineering might allow chondrocytes to produce sufficient ECM to stabilize the newly synthesized tissue structure while PGA undergoes degradation. Unlike natural biopolymers that are often prepared in a hydrogel form, the poly(α-hydroxy esters) are commonly fabricated into various pre-formed structures, such as fiber, foam, and sponge.

Developing nanostructural materials as scaffolds is an emerging trend in tissue engineering. Nanostructured scaffolds, such as nanofibrous scaffolds, can be fabricated using the electrospinning technique. Several poly(α-hydroxy esters) have been successfully fabricated into nanofibrous scaffolds (Figure II.6.8.1) (Li et al., 2006b). These different poly(α-hydroxy ester)-based nanofibrous scaffolds possess a range of mechanical properties and degradation profiles that render them as suitable scaffolds for different engineered tissues. For example, chondrocytes cultured in PLLA or PCL nanofibrous scaffolds maintained their chondrocytic phenotype (Li et al., 2003), and MSCs in the same structure were successfully induced into chondrocytes (Li et al., 2005). Furthermore, an *in vivo* study showed that the chondrocyte- or MSC-laden nanofibrous scaffold was able to repair full-thickness cartilage defects created in pig femoral condyles (Figure II.6.8.2) (Li et al., 2009).

Poly(ethylene glycol) (PEG) or polyethylene oxide (PEO) – PEG or PEO is a non-biodegradable synthetic polymer that has been extensively used for cartilage tissue engineering. The major advantage of using PEG or PEO for scaffold fabrication is that the polymer can be functionalized to conjugate with a peptide or protein of interest to enhance chondrocyte activities or induce chondrogenesis. In addition, the polymer can be chemically modified to carry reactive groups, such as acrylates, that can be activated by high-energy light sources, and cross-linked to improve mechanical and degradation
FIGURE II.6.8.2 *In vivo* cartilage repair using engineered cartilage developed from chondrocyte-laden nanofibrous scaffold. Cultured chondrocytes were seeded into poly(lactic acid) nanofibrous scaffolds and cultured in a rotating wall vessel bioreactor. With the enhanced cell culture medium circulation, the cellular scaffold turned into a mature, functional cartilage implant after 42 days of culture. Artificially created cartilage defects of swine knees were successfully repaired by the engineered cartilage six months after surgery.

properties. Another desirable feature is that a modified PEG or PEO hydrogel mixed with therapeutic cells can be directly injected to fill irregular-shaped cartilage defects using a minimally invasive procedure (Elisseeff et al., 1999a). The minimally invasive implantation significantly reduces the time needed for the healing process.

For cartilage tissue engineering, dimethacrylate-functionalized PEO hydrogels mixed with chondrocytes were injected subcutaneously into mice and photopolymerized *in situ* using UV light (Elisseeff et al., 1999b). The results showed that chondrocytes in the solidified PEO hydrogel survived and actively produced cartilage matrix, and the regenerated neocartilage histologically resembled native cartilage. In addition, for the regeneration of healthy functional cartilage, PEG scaffolds have been designed to degrade at a controlled rate to free part of the scaffold space for natural ECM deposition. Functional groups, such as esters, can be chemically linked to unmodified PEG to improve biodegradation of the PEG hydrogel, since the ester linkage can be hydrolytically cleaved in culture medium (Bryant and Anseth, 2003). Various natural and synthetic polymers have also been grafted with PEG (Metters et al., 1999; Temenoff et al., 2002) to enhance cartilage-specific ECM production (Bryant and Anseth,

2003) and cartilage regeneration (Lee et al., 2003a; Wang et al., 2003).

Natural Biopolymers for Cartilage Tissue Engineering. Natural biopolymers, including protein-based and carbohydrate-based polymers, are derived from animals or plants, and have a long history of being used as biomaterials. The advantage of using natural biopolymers is that they have biofunctional molecular domains that can act to enhance cellular activities, such as cell adhesion and migration. On the other hand natural biopolymers for scaffolds also have drawbacks. They may have varying properties between different batches and may elicit immune response.

Protein-Based Materials. *Collagen* – Collagen represents the major protein type in the body, and has been widely used in various medical applications. Among the 29 identified collagen types, collagen type I is the most commonly used collagen for culturing chondrocytes (Fuss et al., 2000) or MSCs (Wakitani et al., 1994) in both *in vitro* and *in vivo* cartilage tissue engineering. Clinically, collagen type I, CaRes®, and collagen type I/III bilayer membrane, such as Maix® or Chondro-Gide®, have been approved to treat cartilage defects. Collagen types I and II have been compared in terms of their

capability as a scaffold for cartilage repair (Frenkel et al., 1997; Lee et al., 2003b), and the results suggest that collagen type II is a more suitable scaffold material to maintain chondrocytic phenotype (Nehrer et al., 1997). However, in comparison to collagen type I, isolation and preparation of collagen type II in a sufficient quantity for scaffold fabrication is more challenging, because collagen type II is present exclusively in hyaline cartilage, whereas abundant collagen type I is found in many other tissues. As a biomaterial, collagen can be prepared in the form of a hydrogel, dehydrated porous sponge or electrospun fibrous structure for scaffold applications. Regardless of the structure type, the principal hurdle of using collagen matrices for cartilage tissue engineering is the short-term durability of the matrix, which reduces the structural stability of cell-seeded constructs during cartilage regeneration.

Fibrin – Fibrin, a component of the extrinsic coagulation cascade, is found commonly in blood clots. This biopolymer is an insoluble fibrillar protein converted from a soluble fibrinogen through the enzymatic activity of thrombin, and has been widely used as a clinical fixative or biological glue for many years, including recently as a biomaterial for cartilage tissue engineering. Specifically, it has been used as a glue to secure other scaffolds at the repair site, as a three-dimensional scaffold to culture chondrocytes (Silverman et al., 1999) and MSCs (Worster et al., 2001) for tissue regeneration, or as a carrier to deliver growth factors (Fortier et al., 2002) to facilitate cartilage repair. Like collagen, a fibrin-based glue, Tissucol®, is also approved to repair cartilage defects clinically. A previous study with 12-month post-surgery results showed more effective cartilage repair in patients implanted with fibrin embedded with autologous chondrocytes, compared to patients treated with a cartilage abrasion technique. Although the outcome appears promising, the inherent poor mechanical property and the immunogenicity of fibrin may limit its use in cartilage tissue engineering.

Silk fibroin – Fibroin, the principal component of insect silk, is another natural biopolymer that has recently been used in cartilage tissue engineering. Natural silks from different species, for example the spider or the silkworm, have different material properties, because the constituent silk fibroin can be arranged differently to construct different molecular structures. Owing to its considerable mechanical properties, silk holds great promise as a tissue engineering scaffold, particularly in a highly mechanically demanding tissue environment, because as that in cartilage. Silk fibroin has been made into a sponge scaffold to culture chondrocytes for rabbit cartilage repair, or fabricated into foam, microfibrous, or electrospun nanofibrous scaffolds to culture MSCs for both *in vitro* and *in vivo* cartilage tissue engineering.

Polysaccharide-Based Materials. *Alginate* – Alginate is a brown algae-derived carbohydrate polymer consisting of repeating L-guluronic acid and D-mannuronic acid. Alginate can be gelled in the presence of calcium or other divalent cations, and reversibly re-solubilized upon removal of the cations. In addition, alginate is capable of encapsulating cells in the matrix to maintain their spherical shape, which makes alginate a desirable scaffold for studying redifferentiation of chondrocytes (Liu et al., 1998), or promoting chondrogenic differentiation of MSCs (Caterson et al., 2001). Alginate scaffolds with varying stiffness can be fabricated by using different concentrations of alginate solutions or by varying cation concentrations during cross-linking (Kuo et al., 2001; 2008). By varying alginate concentration, mechanical properties of the resultant hydrogel can be significantly improved. However, the major concern with the use of alginate in cartilage tissue engineering is that the slow degradation of alginate often causes inappropriate immune response *in vivo* (Pier et al., 1994).

Agarose – Another carbohydrate polymer, agarose, is purified from brown seaweed, and contains a repeated disaccharide sequence of L- and D-galactose. Similar to alginate, the stiffness of the agarose hydrogel can be manipulated by varying its concentration. Dependent on the type and molecular weight, agarose gels have different solidification temperatures. By altering the temperature, agarose can change between a liquid gel form and a solidified structure form, which is a preferred property for convenient cell seeding. For cartilage tissue engineering applications, agarose has been extensively used as a three-dimensional scaffold to redifferentiate chondrocytes (Benya and Shaffer, 1982) or differentiate MSCs into chondrocytes (Fukumoto et al., 2003; Huang et al., 2004) *ex vivo*. However, the use of agarose for *in vivo* applications is limited by its extremely slow degradation rate (Cook et al., 2003) that could elicit foreign body giant cell reaction (Rahfoth et al., 1998).

Hyaluronic acid – The most widely used carbohydrate-based biopolymer in cartilage tissue engineering is hyaluronic acid. The biopolymer is a polysaccharide composed of repeating glucuronic acid and N-acetylglucosamine. Because hyaluronic acid is one of the major ECM components of cartilage, its use as a scaffolding material is biologically compatible for the activities of chondrocytes. Nevertheless, the applicability of native, unmodified hyaluronic acid is limited because the highly hydrophilic molecule is easily degraded in culture medium, and the hyaluronic acid gel does not possess sufficient mechanical strength. Therefore, a number of chemical modifications, including esterification (Campoccia et al., 1998) and other chemical cross-linking (Vercruysse et al., 1997), have been developed to improve its properties. For example, Hyaff 11® is a commercially available, three-dimensional structure based on an esterified derivative of hyaluronic acid, which exhibits improved degradation and mechanical properties, and has been used as a tissue engineering scaffold to seed chondrocytes and MSCs for cartilage tissue engineering (Facchini et al., 2006). A three-year clinical study using

the esterified hyaluronic acid scaffold with autologous chondrocytes has shown satisfactory results on cartilage repair.

Chitosan – Chitosan is composed of repeating glucosamine and N-acetylglucosamine disaccharides, and is derived from chitin, a type of polysaccharide commonly found in shellfish exoskeletons. Insoluble chitin becomes soluble chitosan after sufficient acetyl groups in a chitin polymer are removed. Because chitosan carries high cationic charges, it can interact with a variety of anionic polymers, such as chondroitin sulfate, to form a hydrogel (Denuziere et al., 1998). In addition, owing to its excellent biocompatibility and the ease of scaffold fabrication, chitosan is considered a promising biomaterial for cartilage tissue engineering. Chondrocytes cultured in a chondroitin sulfate-augmented chitosan hydrogel maintained their chondrocytic morphology and produced collagen type II (Lahiji et al., 2000; Sechriest et al., 2000). An *in vivo* study showed that chitosan injection effectively repaired defects of rat knee cartilage (Lu et al., 1999).

Chondroitin sulfate – Chondroitin sulfate is the major sulfated glycosaminoglycan of cartilage proteoglycan. Due to its excellent biocompatibility, and biological and functional roles in the cartilage ECM macrostructure (Bryant et al., 2004; Li et al., 2004), chondroitin sulfate has been shown to help wound healing and restore arthritic joint functions. Chondroitin sulfate monomers are commonly modified with methacrylate or aldehyde groups to produce reactive side-groups. With UV-activating these functionalized side-groups, a chondroitin sulfate gel can be solidified via photopolymerization. A number of *in vitro* studies have demonstrated the viability of encapsulated chondrocytes in the cross-linked chondroitin sulfate gel, suggesting potential applications for cell delivery to repair cartilage defects. To improve the stability of the chondroitin sulfate hydrogel in culture medium, non-biodegradable PEG (Li et al., 2004) or polyvinyl alcohol (PVA) (Bryant et al., 2004) has been incorporated into chondroitin sulfate to produce a co-gel. Within the co-gel, the negatively charged chondroitin sulfate attracts water into the gel to create a swelling pressure that contributes to mechanical stiffness of the material, similar to that in native cartilage.

Advanced Scaffolds and Signaling Factors in Cartilage Tissue Engineering

Recent advances in the fields of material science, protein chemistry, control release, and nanotechnology have increasingly been applied to the development of cartilage tissue engineered scaffolds. These next generation biomaterial matrices, so-called "smart" scaffolds, are made of materials with a bio-inspired, functionalized surface, constructed of an ECM-mimetic structure, or capable of releasing biomolecules in a controlled release manner.

The "smart" scaffold is designed to actively instruct cell behavior to facilitate cartilage regeneration.

"Smart" Scaffolds with Controlled Release Capability. One of the emerging research trends to enhance cartilage regeneration is the development of "smart" tissue engineered scaffolds with the capability of controlled release of growth factors, such as transforming growth factor-beta (TGF-β) and insulin-like growth factor-1 (IGF-1), that act to enhance matrix production of chondrocytes or induce chondrogenic differentiation of MSCs (Park et al., 2009). Delivery of growth factors can be achieved via biodegradation of scaffolding polymers, with the release kinetics of target molecules controlled as a function of the degradation properties of the polymer (Basmanav et al., 2008). Indeed, by using biodegradable polymers with differential degradation properties, it is possible to develop "smart" tissue engineered scaffolds capable of sequentially delivering different growth factors to enhance tissue regeneration (Yilgor et al., 2009). In addition to the capability of controlled release, the "smart" scaffolds should also function to protect delivered molecules from denaturation. Conventionally, growth factors are embedded in polymeric scaffolds by direct incorporation into a polymer solution during a fabrication process; however, scaffold fabrication usually involves organic solvents or chemical reactions that are likely to harm biological activities of to-be-delivered growth factors. Recently, several research groups have developed dual-structure scaffolds to protect bioactivities of delivered molecules by encapsulating the molecules with microparticles embedded in scaffolds (Holland et al., 2004).

Nanostructured Scaffolds with Biomimetic Architecture. In addition to biological signals, effective tissue engineering-based cartilage regeneration in *ex vivo* culture requires that scaffolds provide appropriate physical and chemical cues to guide cellular activities, such as cell differentiation and matrix production. Therefore, a biologically favorable culture environment must be used for effective cartilage regeneration. It is thus noteworthy that the size of the structural elements of a biomaterial scaffold have been proven to be crucial to cell activities. Recent studies (Webster et al., 2000; Dalby et al., 2002) have shown that cells cultured on substrates with varying topography exhibit different behaviors; a substrate composed of nanometer-scale components is biologically preferred. Among nanostructures, a nanofibrous structure composed of ultra-fine, continuous fibers feature the properties of high porosity, high surface area-to-volume ratio, and most importantly, morphological similarity to natural ECM, making it well-suited for tissue engineering applications (Li et al., 2002). To fabricate nanofibers, several fabrication approaches are available, and among these approaches, the electrospinning technique is considered a convenient and highly versatile approach. Electrospinning has been used for fiber production in the textile industry since 1934 (Formhals, 1934), and has recently been used

for tissue engineering applications. Research evidence has shown that the unique physical features of electro-spun nanofibers induce biologically favorable activities (Li et al., 2003), and nanofibrous scaffolds are ideal for tissue engineering and regenerative medicine applications (Li et al., 2009).

LIGAMENT TISSUE ENGINEERING

Introduction to Ligament Tissue Engineering

Ligaments are a dense connective tissue between bony segments with specific macromolecular composition and arrangement, enabling a defined response to the unique loading state at each ligament. Their strength and elasticity permit our rigid skeletal frame to rotate around specialized joints and produce complex movements, while retaining mechanical stability. The normal response to load is nonlinear, anisotropic, and viscoelastic, with significant stress relaxation (Kwan et al., 1993) to slowly dissipate elastic energy (Hukins et al., 1990). A tear or dislocation in the tissue (Kennedy et al., 1974) or prolonged ligament immobilization (Woo et al., 1987) will compromise ligament function and joint stability, and result in a reparative response with subsequent scar formation. Several studies with animal models have demonstrated that injured ligaments do not recover normal mechanical properties, even after one year of healing (reviewed by Woo et al., 2006).

Clinical Relevance and Limitations of Current Repair Strategies. The poor healing ability of ligaments is compounded by the fact that ligament injuries are not rare, as an estimated 100,000 anterior cruciate ligament (ACL) reconstructions are performed each year in the US (CDC, 1996), with injury rates among females between ages 14–17 increasing at the fastest rate (Csintalan et al., 2008). Thus there has been a tremendous effort among clinicians, scientists, and engineers to improve the rate and outcome of recovery after a ligament injury. There are three standard reconstructive treatments for serious ligament injury. For more than a decade, the most common surgical reconstruction technique for ligament injury has involved the transplantation of healthy autografted (self-donated) connective tissue, particularly patellar or semitendinosus-gracilis (hamstring) tendon tissue. This is not an ideal solution, since removal of local non-regenerative tendon tissue at the knee joint disrupts the normal biomechanical state, which has been found to require up to six months to recover to preoperative strength and endurance (Soon et al., 2004). Further, one study found that after seven years, knee flexibility, sensitivity, and laxity still remained significantly reduced (Lidén et al., 2007). Alternatives to autografting, such as allograft transplantation, for ligament reconstruction have been found to be more prone to rupture, and afford reduced functionality compared to autografts, mainly

due to chemical treatments (Krych et al., 2008). Furthermore, concerns remain regarding potential immune reactions and disease transmission of untreated donated tissue. Finally, non-degradable synthetic polymer grafts made from materials such as polytetrafluoroethylene or polypropylene have been found to suffer from mechanical problems, such as particle wear and failure rates on the order of 40–80%, primarily from fatigue rupture (Vunjak-Novakovic et al., 2004).

The Modern Ligament Engineering Strategy. Given these issues, there is a need for a treatment that could restore normal ligament function immediately, and retain or improve upon that level of function over the long term. We, and others, consider tissue engineering as an exciting alternative, offering the possibility of replacement with normal, living tissue. The modern ligament engineering strategy involves culturing cells of stem or fibroblastic phenotype onto a three-dimensional biodegradable scaffold, usually fibrous, and typically with a biochemical or physical stimulus to maintain or enhance ligament regeneration. Complex bioreactors have been developed that provide simultaneous dynamic fluid flow and cyclic tensile stimulation in heated and humidified environments. Central to the success of this strategy is the biomaterial which the cells are cultured on; the choice of biomaterial is important to the extent of cellular adhesion, initial scaffold strength and mechanical properties, scaffold degradation rate, and long-term implantation success. Tissue engineers generally obtain the best results when they design their regeneration strategy to mimic the tissue of interest, and thus it is critical to define and design for native ligament properties as summarized in the following section.

Native Ligament Macromolecular Composition and Structure

Ligament Composition. Ligaments derive their tensile strength and elasticity from the basic primary building block of their structure: collagen fibers. Collagen types I and III are primary constituents, along with elastin, and more minor proteins including fibronectin, decorin and tenascin. The mass ratios of these protein constituents to overall ligament mass depend upon location in the body, and vary especially with elastin content, which is most dense in ligaments that experience high tensile strains, such as spinal ligaments. The elastin affords greater flexibility (ductility) at the expense of strength, and also minimizes energy losses during elastic recovery, as exploited by some purely elastin ligaments found in cows and horses associated with grazing. Circumferentially oriented around the collagen fiber bundles are specialized elongated fibroblast cells, commonly referred to as tenocytes, which are responsible for maintaining the density and composition of the ligament matrix. The tenocytes adhere to the fiber bundles, and are surrounded by a glycosaminoglycan-rich matrix which enables fibers to slide along each other during bending, and also provides

limited blood vessel and nerve supply. The neural innervations are primarily proprioceptive in nature, and act to provide feedback on the degree of joint flexion/extension. **Ligament Structure.** Since ligaments are responsible for maintaining joint stability, their structure is designed to withstand high tensile loads. Beginning with a single triple-helical collagen molecule, the collagen molecules are organized in parallel nanometer-scale fibrils, and subsequently into micrometer scale fibers. The parallel collagen fiber matrix and surrounding proteoglycan-rich matrix reside in the middle zone, and resist tensile and sometimes simultaneous torsional loads, as seen in the anterior cruciate ligament (~90° twist). Within a few millimeters of bone, the ligament structure gradually becomes more bone-like, which is a critical region of normal function. The ligament insertion into bone, known as the enthesis, is typically described as a gradual, four-layer progression from non-calcified collagen fibers to fully calcified bone matrix. In-between are two layers of cartilaginous tissue containing fibrocartilagenous cells aligned with the collagen fibers, wherein the layer proximal to the bone contains calcium, and the layer proximal to the ligament does not.

Important Considerations of a Ligament Tissue Engineered Scaffold

Cellular Activity Requirements. One of the most important design considerations for ligament tissue engineering is that despite their white appearance, ligaments are not avascular tissues, and an active oxygen supply is critical for cell survival. This can be especially challenging, since ligaments must also be strong, stiff and elastic, often requiring densely packed natural or synthetic fibers. Additionally, tenocytes are natively distributed throughout the ligament both radially and longitudinally. The native long, spindle-like morphology of ligament cells is likely also important for normal genetic expression, and should be permitted by the scaffold geometry. The fabrication of three-dimensional scaffolds with fully distributed cells, and with adequate O_2 supply, remains a formidable challenge in ligament tissue engineering, especially with ligament thicknesses greater than the oft-cited oxygen diffusion limit of 200–300 μm. Several authors have been actively addressing these cellular activity requirements, which will be discussed in upcoming sections.

Material Property Requirements. In addition to cellular activity requirements, there are four principal material property requirements for engineering ligaments. First, the material must enable cellular adhesion and proliferation, and must not be cytotoxic or immunogenic to attached cells, local surrounding tissues or the overall body. Second, the scaffold material should have an architecture that enables full cellular distribution, additional tissue ingrowth (e.g. endothelial or connective), and is biomechanically capable of resisting major planes

of stresses expected to be seen *in vivo*. Third, the material must possess adequate elastic modulus, strength, and ductility, especially under tension, and should also have similar viscoelastic properties to native ligament. Mechanical mismatches are particularly important since ligament is a loadbearing tissue; they can result in scaffold rupture (too weak), stress-shielding effects where local connective tissues begin to atrophy (too strong) or joint laxity and energy imbalances (potentially from incorrect viscoelasticity). Finally, the material should biodegrade without toxic byproducts at a rate that is equal to the rate of tissue formation, and ideally be completely eliminated from the body at a time coincident with full ligament regeneration.

While at present no material or system has met all of these requirements, they have been actively investigated through a number of different single and composite material approaches using synthetic and natural biopolymers, as reviewed in the following paragraphs.

Biomaterials in Ligament Tissue Engineering

Synthetic Biomaterials in Ligament Tissue Engineering. An ideal engineered ligament would contain enough starting material for immediate loadbearing post-implantation, and would degrade at a rate comparable with that of developing cellular and tissue ingrowth. After a period of several weeks or months the starting material, or scaffold, would be completely replaced by regenerating ligament cells and matrix. The requirement for biodegradability and fabrication into specific ligament-like geometries has generated interest in the use of synthetic polymer materials for ligament tissue engineering, dating back to at least 1999 (Lin et al., 1999).

Polyhydroxyesters degrade by hydrolysis, and thus have been very popular for ligament tissue engineering because the degradative molecule, H_2O, is naturally present in abundance *in vivo*. An early cell attachment study by Ouyang et al. (2002) found that on two-dimensional matrices anterior cruciate ligament (ACL)-derived fibroblasts adhered and proliferated on PCL, PCL/PLA (50:50), and PLGA (50:50) substrates at a rate that was not significantly less than tissue-culture plastic (O_2-plasma treated polystyrene). However, high hydrophilicity of certain polyhydroxyesters is thought to be detrimental to general cell adhesion (van Wachem et al., 1985), and hence it is regarded that a balance of hydrophobic and hydrophilic components should be considered for ligament tissue engineering. Several studies have utilized these findings, and extended ligament cell culture into three dimensions by fabricating ligament-like polyhydroxyester scaffolds, several of which are reviewed here.

Lu et al. (2005) fabricated three-dimensional braided scaffolds of PGA, PLGA, and PLLA filaments at two levels of bundling using a circular braiding loom designed to mimic the hierarchical structure of native ligament. To improve cellular adhesion, these investigators modified
FIGURE II.6.8.3 ACL fibroblast growth and matrix formation on different synthetic braided scaffolds visualized with SEM (Lu et al., 2005). Images were taken after 14 days of *in vitro* culture in 10% fetal bovine serum. (Left) Culture with PGA resulted in substantial matrix degradation from acidic byproducts. (Middle)-co-glycolic acid (PLAGA) in an 82:18 mass ratio showed more sustainable matrix formation, particularly with the addition of fibronectin (Fn). (Right) PLLA scaffolds also displayed considerable matrix formation, which again was amplified by the addition of Fn. (Reproduced with permission from Elsevier B.V.)

the surfaces by immersing the scaffolds in a solution of human recombinant fibronectin (Fn). Ligament cells were isolated from rabbit ACL tissue by digestion in collagenase, and grown to confluence before being added to the scaffolds. After 14 days of culture, using scanning electron microscopic analysis it was found that cells seeded on PLLA-Fn and PLAGA-Fn scaffolds produced the most matrix, and that PGA was detrimental to matrix formation, owing to rapidly produced acidic byproducts (Figure II.6.8.3).

Furthermore, PGA-Fn had significantly reduced cell numbers compared to PLAGA-Fn and PLLA-Fn scaffolds, which were not significantly different from each other. The authors concluded that both the PLLA-Fn and PLAGA-Fn scaffolds would be effective for ligament tissue engineering, but acknowledged that the PLLA-Fn scaffolds may be the more appropriate choice because of their slower degradation rate. A study of the tensile properties of braided PLGA 10:90 scaffolds found ultimate tensile strengths in the range of 100–400 MPa, and with a circular braiding scheme a maximum load of over 900 N, both of which were considered practical and safe for initial implantation in a human ACL replacement surgery (Cooper et al., 2005). Recent work has also elucidated ideal braiding angles of these scaffolds to most accurately mimic the non-linear stress–strain relationship of native ligament (Cooper et al., 2007). Taken together, these studies show great promise for future use of braided synthetic scaffolds for ligament replacement, particularly if the degradation profiles are optimally balanced against tissue ingrowth using an animal model.

PLGA 10:90 scaffolds have also been fabricated with collagen type I to form porous, rolled microsponges for ligament tissue engineering (Chen et al., 2004). These hybrid scaffolds were considered advantageous because of the combined cellular binding affinity and mechanical

strength afforded by collagen and PLGA, respectively. To fabricate the microsponges, the PLGA was immersed in a solution of bovine collagen type I, freeze-dried, and cross-linked with glutaraldehyde (unreacted aldehyde groups were blocked with glycine). In this study, ligament cells were isolated from beagle ACL samples with collagenase and cultured for 16 days *in vitro* before rolling and subcutaneous implantation into nude mice. Using paraffin sectioning with hematoxylin and eosin staining, coupled with SEM, the authors concluded that cells were viable in the scaffold even after 12 weeks of implantation, and that the hybrid scaffolds may be appropriate for ligament tissue engineering.

One of the advantages of synthetic polymers is that they can be processed relatively easily into fibers with nanometer-scale diameters – on the order of native collagen fibrils. As presented earlier, nanofibers are typically fabricated using the 70+ year old electrospinning process, which utilizes an electric field (typically kV potentials over ~5–20 cm) to overcome surface tension of a viscous polymer solution and form a chaotic nanodiameter polymer jet that is deposited onto a surface of interest (Pham et al., 2006). Lee et al. (2005) produced aligned polyurethane nanofiber scaffolds with average fiber diameter of 650 nm and 82% porosity using an electrospinning apparatus and a rotating collector target. Seeded human ligament cells were cultured for 48 hours then subjected to 5% uniaxial strain at 0.083 Hz using vacuum flexion on a silicone membrane for an additional 24 hours. It was demonstrated that cells seeded onto aligned scaffolds produced significantly more collagen mass per cell of DNA, compared to randomly oriented fiber controls, and that the aligned nanofibers enabled cell morphologies most comparable with *in vivo* morphology. This study was one of several demonstrating the potential applicability of aligned nanofibers for ligament tissue engineering. Composite nanofiber and microfiber

scaffolds have also been fabricated for ligament tissue engineering (Sahoo et al., 2006). In this study, electrospun PLGA (65:35) nanofibers with 300–900 nm diameter range were deposited onto a mesh of 25 μm diameter PLGA (10:90) microfibers producing scaffolds with 0.8–1.3 mm thickness and 2–50 μm pores (evaluated with SEM). The rationale for this system was that the microfibers would provide mechanical strength and degradation resistance, and the nanofibers would provide hydrophilicity and a very high surface area for optimal cell attachment. The authors seeded porcine bone-marrow derived mesenchymal stem cells (BMSCs), and observed an average collagen production of 1.55 ng/cell after seven days, which was considered high relative to previous studies with other scaffold geometries. Furthermore, mRNA expression levels of critical ligament genes, including collagen type I, decorin, and biglycan relative to the GAPDH housekeeping gene, were all slightly upregulated (5–20%), suggesting partial differentiation into ligament lineages. The authors acknowledged, however, that the ultimate tensile strengths and failure loads were still far below those of native ligament, and that it was difficult to have confidence that the cells were directed into ligament lineages. Nevertheless, the high level of matrix production demonstrates the potential of the method, and a follow-up study (Sahoo et al., 2007) reports further optimization of these scaffolds using surface modifications including PCL and collagen type I deposition to enhance cell attachment and proliferation, and also a right-angle fiber weaving method to increase failure load by ~50% over knitted fabrication.

These studies demonstrate some of the advantages imparted by synthetic nanofiber technologies for ligament tissue engineering, which will continue to expand and evolve as more specific ligament cell–nanofiber interactions are elucidated. At present, it appears that most studies show results favoring aligned nanofibers over randomly oriented fibers, likely due to their resemblance to native ligament fibril orientation, but the ideal fiber materials, diameters, spacing, and angles remain unresolved for ligament tissue engineering. Currently, a single material is typically used, but the opportunity exists to incorporate fibers of different diameters and mechanical properties into a single aligned scaffold in an effort to mimic the multi-protein matrix of ligament, e.g., collagen type I, collagen type III, and elastin. Finally, the rapid degradation rate of synthetic nanofibers must be controlled, and perhaps decelerated, before *in vivo* implantation will be feasible. Overall, however, synthetic nanofiber scaffolds are cytocompatible and have tailorable diameters and degrees of alignment, and are one of the most exciting prospects for the design of engineered ligaments.

Natural Polymeric Biomaterials in Ligament Tissue Engineering. We have seen that synthetic polymeric biomaterials have reproducible mechanical and chemical properties, are easily fabricated into different shapes and sizes, degrade by hydrolysis, and are efficacious for

ligament engineering research. However, they may lack functional chemical groups for cellular binding, and furthermore they may release acid byproducts or unnatural polyesters into the bloodstream during degradation. For these reasons there has been considerable interest in the application of natural, protein-based fiber materials as scaffolds for ligament tissue engineering. The most direct and obvious choice for this material is collagen type I, because of its prevalence in ligament tissues. Unfortunately, no method yet exists to organize and cross-link collagen fibers in a cytocompatible manner, and as such collagen gels remain exceptionally weak with typical elastic moduli between 10–30 kPa and ultimate tensile strengths between 5–10 kPa (Roeder et al., 2002). Thus, collagen-based scaffolds, while useful to investigate mechanisms of tendon differentiation and regeneration (Kuo and Tuan, 2008), are challenging to be used for ligament replacement.

Silk fibroin, rather than collagen, has been the most popular natural polymeric biomaterial for ligament tissue engineering. Silk fibroin is one of two proteins excreted by *Bombyx mori* silkworms during cocoon production, and is typically isolated from its sister protein sericin using sodium carbonate, urea, and/or soap detergents and near-boiling temperatures (Yamada et al., 2001). *B. Mori* silk fibroin is 70–80% by mass of the silk bicomplex (Kato et al., 1998), contains a heavy (350 kDa) and light chain unit (25 kDa), and is held together by the sticky sericin protein, which unfortunately is cytotoxic. The principal advantage of silk is its remarkable tensile strength and toughness (area under stress–strain curve) which is unmatched for natural proteins. Reported tensile mechanical properties of *B. Mori* silk fibroin range between 5–9 GPa for elastic modulus, 250–400 MPa for tensile strength, and 23–26% for failure strain (Jiang et al., 2006). The protein also displays surface amino acids for cell adhesion, remains structurally whole in aqueous solutions but slowly degrades (weeks–months) proteolytically *in vivo* (Minoura et al., 1990; Greenwald et al., 1994), and can be fabricated into gels, films, braided fibers or nanofibers. These characteristics make silk fibroin one of the best natural polymers for support of cellular and tissue ingrowth for tissue engineering.

Silk fibroin has been used for several decades as a suture material because of its strength and slow biodegradability, and since at least 2002 has been considered for ligament tissue engineering. Altman et al. (2002a) were one of the first to design a braided silk fibroin scaffold and test for adherence, proliferation, and genetic expression of seeded bone-marrow derived MSCs. A braided geometry with four levels of bundles twisted with 0.5 cm pitch was chosen to effectively reduce the linear stiffness of a single fiber, to better model native ACL stiffness and minimize stress-shielding effects. To model physiological performance a 400 N cyclic load was applied to a 3.67 mm diameter scaffold (designed to fit a human knee bone tunnel),

and a subsequent fatigue analysis with linear extrapolation indicated a matrix life of 3.3 million cycles, which was expected to far outlast *in vivo* degradation. After 14 days of *in vitro* culture with human MSCs, the authors found that DNA content (and thus cell number) increased five-fold compared to 24 hours of culture; this was complemented by scanning electron microscopic analysis showing considerable matrix deposition over the culture period. Furthermore, mRNA expression levels of ligament-associated genes were comparable to those in native human ACLs, especially an average collagen type I to type III ratio of ~9, an absence of collagen type II and bone sialoprotein (which would indicate cartilage or bone differentiation, respectively), and baseline expression of the tendon/ligament marker tenascin-C. The success of this initial work was considerable and highlighted the potential applicability of silk fibroin that has been properly processed and organized for *in vivo* ligament replacement. It also led to several modifications, optimization studies, and *in vivo* evaluation studies for utilizing silk fibroin in ligament tissue engineering, several of which are reviewed below.

Scaffold geometries other than braided structures have also been fabricated with silk fibroin. Liu et al. (2008) surmised from previous studies of synthetic braided ligaments that such braided structures may have limited nutrient diffusion and tissue infiltration, particularly towards the center on the radial axis. To circumvent this potential issue, the authors fabricated a silk fibroin hybrid scaffold with geometries at two levels – a knitted scaffold and an interspersed microporous silk sponge. The knitted scaffold was fabricated using a 40-needle knitting machine, and the sponge was added by immersing the knitted scaffold in a low concentration silk solution, freeze-drying to form pores, and then immersing in a methanol solution to prevent resolubilization. Human MSCs were seeded by pipetting onto knitted-sponge or knitted-alone scaffolds, with unseeded scaffolds as a secondary control and a total culture time of 14 days. Compared with knitted scaffolds alone, the knitted-sponge scaffolds showed significantly higher biological responses with nearly every evaluation method, including cellular proliferation, GAG production, viable cell density, mRNA expression of collagen types I and III, and tenascin-C, and collagen-based matrix production, confirming the positive benefit of the microporous silk sponge. However, no significant differences in maximum tensile load or stiffness were recorded compared to unseeded scaffolds after 14 days, suggesting that the secreted matrix did not contribute towards scaffold strength. Also, the tensile strength and stiffness were far below (<20%) those of the adult human ACL (Woo et al., 1991). Nevertheless, the cytocompatability and rapid ligament-like matrix development is impressive, and further demonstrates the effectiveness of a cyto-friendly composite structure. With the design of a stronger starting matrix, the knitted-sponge scaffold may be an attractive candidate for *in vivo* ligament

replacement, conferring rapid tissue regeneration and (importantly) initial tensile strength.

In addition to synthetic scaffolds, multi-material or composite natural scaffolds have also been successfully fabricated for ligament tissue engineering applications (Chen et al., 2008). In this work a knitted silk-fibroin base matrix was infiltrated with a freeze-dried collagen type I microsponge creating a similar composite structure to that used by Liu et al. (2008), but with a collagen type I sponge instead of a silk sponge. MSCs were seeded into the scaffolds which were then implanted into a rabbit medial cruciate ligament (MCL) transection model to evaluate *in vivo* repair potential over a total of 12 weeks. *In vitro*, the authors found that gene expression levels of ligament-associated genes by cells seeded in silk–collagen scaffolds compared to silk alone were considerably higher, with collagen type I elevated by 250%, and decorin elevated by over 500%. Histological analysis with H&E and Masson's trichrome staining of the repairing MCL found more tissue ingrowth compared to silk alone and untreated MCLs after 2, 4, and 12 weeks; Figure II.6.8.4 shows the repair results after 14 days of implantation.

In addition, the mean collagen diameter of the repaired region observed with transmission electron microscopy was closer to that of native ligament (~65 nm). Although the mechanical properties of the repair tissue were considerably less than those of native MCL, the results suggest that a silk and collagen sponge matrix may be an effective treatment for MCL transections, particularly because of its support of rapid tissue ingrowth. Future anlaysis comparing *in vitro* and *in vivo* repair between knitted silk scaffolds, with either a collagen type I sponge or silk-fibroin sponge, would provide additional information for the optimization of sponge pore size.

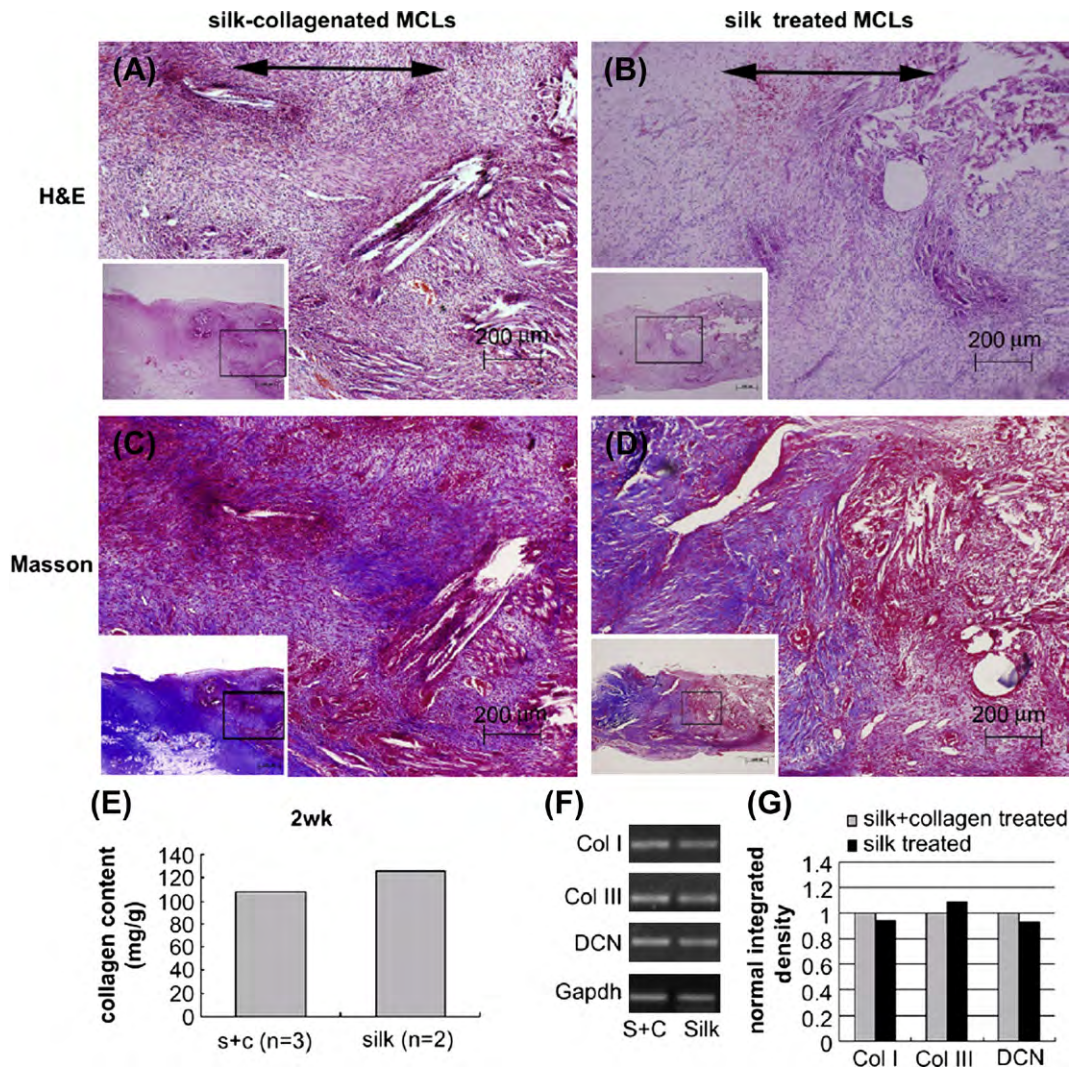
One of the most important evaluation tests in ligament engineering is the success of an engineered graft to be regenerated by the body into a functional ligament. Recent studies by Fan et al. have investigated silk scaffold ligament regeneration in rabbit (Fan et al., 2008) and pig models (Fan et al., 2009), providing new insights into the kinetics of ligament tissue ingrowth and scaffold degradation. First, a rabbit ACL reconstruction model was tested by transecting healthy rabbit ACLs and surgically implanting an MSC-seeded knitted silk scaffold with microporous silk sponge. *In vitro*, cells were seeded onto the silk grafts for an eight-hour adhesion time before implantation by anchoringinto bone tunnels of rabbit knees. A morphological and histological evaluation of implanted silk grafts replacing the rabbit ACL after eight weeks suggested substantial production of collagen type I, collagen type III, and tenascin-C, and that the ligament–bone attachment was stable (evaluated with micro-CT). Similar to other studies with knitted silk scaffolds, the tensile strength and stiffness were unfortunately below those of native human ACL.


FIGURE II.6.8.4 Histological and gene expression analysis of the extent of *in vivo* repair after 14 days using silk and silk/collagen scaffolds in a rabbit model of MCL transection by Chen et al. (2008). (A,B) H&E staining showed relatively unorganized matrix formation but a higher cell density in silk/collagen scaffolds than silk alone. (C,D) Masson's trichrome staining revealed the beginnings of collagen fiber formation (indicated by blue areas), and more collagen deposition in the silk/collagen scaffold group. (E) Total collagen content was reduced in the silk/collagen group (S + C), but, as detected by RT-PCR (reverse transcription-polymerase chain reaction) shown in (F,G), this could have been due to a reduction in the expression of collagen type III, a less appropriate collagen type for the ligamentous phenotype than collagen type I and decorin, both of which are showing higher levels of expression in the silk/collagen scaffold group. (Reproduced with permission from Elsevier B.V.)

A subsequent study using the larger porcine model showed similar encouraging results. To compensate for the additional loadbearing, the knitted-sponge silk scaffold was rolled around a braided silk cord and again was seeded with MSCs for eight hours before implantation. After 24 weeks, the gross morphological and histological characteristics were evaluated and as before, collagen type I, collagen type III, and tenascin-C were all distinctly present, as seen by immunohistochemistry. However, with an average failure load of 398 N, the authors noted that regenerated scaffolds at 24 weeks could be effective for mild daily loadbearing, but would likely not survive trauma or vigorous exercise. Unfortunately, the scaffold strength at earlier time points was not measured; it is clear, however, that 24 weeks would likely be too long for most patients to wait before mild loadbearing

would be feasible. Nevertheless, the clinical implications of this study are profound, and demonstrate the *in vivo* effectiveness of a multi-structural silk scaffold for ligament tissue engineering.

Because of their inherent biocompatibility, natural polymeric macromolecules will likely remain at the forefront of biomaterials for ligament tissue engineering. Although collagen type I gels may eventually be the scaffold material of choice, their ultimate tensile strength and elastic modulus are currently too low to act as a loadbearing material. In the interim, silk fibroin has emerged as an excellent natural biomaterial alternative to collagen, and has already been shown to regenerate ligament in large-scale animal models. Assuming the success of longer-term animal trials, it is anticipated that impending clinical trials with silk fibroin-based

engineered ligaments will confirm the efficacy of silk to restore ligament function after injury, and offer exciting new options for ACL or general ligament repair.

Advanced Scaffolds and Signaling Factors in Ligament Tissue Engineering

Functionalized Ligament Scaffolds. One of the key factors in effective application of material scaffolds in tissue engineering is the optimization of cell–biomaterial interactions, particularly in terms of the ability of cells to adhere, proliferate, and secrete matrix onto the scaffold. Synthetic and natural polymers are effectively long chains of repeating chemical units, and it is thus possible to link small molecules covalently to their surfaces to enhance cell adhesion, proliferation, and matrix production. Such an approach has high potential, since biomaterials that natively lack chemical cell attachment groups can also be functionalized, thus expanding the range of implantable biomaterials. Cell–matrix interactions are typically mediated via cell surface integrin receptors, which are specialized transmembrane proteins that are connected cytoplasmically to the actin cytoskeleton. The most common example of an integrin-interacting matrix epitope is the peptide sequence, RGD (arginine–glycine–aspartic acid) (Orlando and Cheresh, 1991), which has been used to functionalize a number of biomaterials.

The practice of functionalizing grafts to improve engineered tissues is sometimes done passively by merging one scaffold with another for the purpose of combining mechanical properties with integrin-binding capability. An example of passive functionalization is a recent work by Garcia-Fuentes et al. (2009) who blended hyaluronan, a common native glycosaminoglycan, with silk fibroin and seeded MSCs for general regenerative applications. Matsumura et al. (2004) conducted a more direct functionalization study, and modified polyethylene-co-vinyl alcohol (PEVA) films with carboxyl groups (COOH) and subsequently covalently attached collagen type I, designed to enhance periodontal ligament adhesion to PEVA-coated titanium dental implants. Other general tissue engineering applications have used a variety of functionalizing groups, including phosphate (PO_4^{3-}), amide ($R_1(CO)NR_2R_3$) and sulfonate groups (RSO_2O^-).

There has been some interest in adding functional groups to non-degradable synthetic graft surfaces in the hope of enabling tissue growth and avoiding poor tissue integration, foreign body immune responses, and high failure rates. Zhou et al. (2007) functionalized polyethylene terephthalate (PET) grafts with poly(sodium styrene sulfonate) (PNaSS) functional groups and observed fibroblastic cell response. PET is used for an array of commercial applications including containers, water bottles, polar fleeces, and wind sails, and does not degrade *in vivo*. These investigators functionalized PET by first exposing PET fabrics to ozone gas (O_3), which is unstable and breaks into O_2 and $O\cdot$, the latter of which transfers its free radical to the PET surface making it much more reactive. Under an inert argon atmosphere, the samples were then immersed in a bath of monomer 15% w/v sodium p-(styrene sulfonate) (NaSS) at 65–70°C, forming polyNaSS on the PET surface by radical polymerization. The human fibroblast McCoy cell line was seeded onto the functionalized PET surface and observed after four days of culture with calcein AM, a fluorescent label that is only retained inside living cell membranes. Captured images revealed considerably more cell adherence onto functionalized fibers than non-functionalized fibers. Additionally, dynamic fluid testing indicated that cells adhered to polyNaSS-PET scaffolds compared to PET alone required 12-fold more shear stress for 50% of the adhered cells to be removed (12 dyn/cm^2 compared to 1 dyn/cm^2). The authors attributed these profound results to two factors: the enhanced surface hydrophilicity enabling cell spreading; and the opportunity for fibronectin to bind to the PNaSS, increasing the number of focal adhesion contacts and the potential for organized cytoskeletal formation. It will be particularly interesting when these functionalized grafts are implanted *in vivo* to test if the foreign body capsulation response is still present, and if not, how they perform over long-term implantation.

Decellularized Ligament Scaffolds. It has been argued that the best replacement biomaterial for ligaments is those derived from the ligaments themselves (when they are available), because the tissues already have ideal mechanical properties and because the endogenous integrin-binding sites are abundant and present in the native ECM. However, some studies have suggested that allograft tissues can contain residual donor cells, even with strict sterilization and cleaning (Zheng et al., 2005), and may cause significant inflammatory response when implanted *in vivo* (Malcarney et al., 2005). Furthermore, there are concerns about the extent and efficiency of cellular infiltration, particularly to the dense center areas of the graft. Thus, the application of chemical treatments to yield a fully decellularized and more porous scaffold, as opposed to the use of minimally treated allografts (Musahl et al., 2004), is preferred for ligament tissue engineering. Whitlock et al. (2007) recently addressed this issue with a novel oxidative chemical treatment and a battery of *in vitro* cytocompatibility and tissue tests. The authors isolated adult chicken flexor digitorum profundus tendons and added 1.5% peracetic acid to act as an oxidizing agent (using OH radicals) to create pores in the tissue and remove loose DNA. Simultaneously, the detergent Triton™ X-100 (polyethylene glycol octylphenyl ether) was also added at 2% concentration to lyse cell membranes. When compared to non-treated controls, the oxidized scaffolds had no nuclei visibly present (H&E, DAPI staining), and at minimum 70% less total DNA,

which was considered a very promising result. The scaffolds also appeared much more porous, as observed by SEM, and on average had 25% less elastic modulus and stiffness, which was not statistically significant. Results from a subcutaneous rat *in vivo* cell infiltration study showed that after three weeks, cell nuclei were present in the outside layers and some inner layers of the scaffold, and no inflammatory reaction or capsule formation was present. Future studies with human ligament allografts utilizing a combination of a lysing agent and oxidative agent are warranted, and these treatments may prove to be effective in minimizing the foreign body and capsulation responses found with standard allografts.

The Effects of Growth Factors on Natural and Engineered Ligaments. One of the most promising strategies to augment natural regeneration is the introduction of growth factors with specific activities on target tissues. Of the many growth factors in the body, the following five growth factors have received the most attention for ligament engineering, due to their notable upregulation during ligament healing (Molloy et al., 2003): insulin-like growth factor-I (IGF-I); transforming growth factor-β (TGF-β); vascular endothelial growth factor (VEGF); platelet-derived growth factor (PDGF); and basic fibroblastic growth factor (bFGF). Once considered impractical due to extreme costs, growth factors have recently been re-evaluated for their possible application for ligament tissue engineering, made possible by biotechnological advancements in the production and purification of recombinant proteins. Of these five growth factors, bFGF has shown particular efficacy and has been known as an effective promoter of ligament regeneration since early wound-healing studies of canine dental defects (Murakami et al., 1999), and is now beginning to be incorporated into full ligament tissue engineering strategies. Sahoo et al. (2009) blended bFGF with PLGA, and produced electrospun nanofibrous scaffolds capable of releasing 60% of the growth factor over the course of one week. When these scaffolds were seeded with bone marrow-derived rabbit MSCs and compared against scaffolds without bFGF, the authors found significant increases in cell proliferation, immunostaining of tenascin-C and collagen types I and III, and gene expression levels of collagen types I and III, fibronectin, and biglycan over 14 days, which are all promising indicators of enhanced ligament differentiation. Recently, bFGF was also employed *in vivo* in a rabbit ACL repair model via loading into gelatin hydrogels to form a three-part engineered ligament consisting of a braided fibronectin-coated PLLA core, a collagen membrane wrapping sheet, and the bFGF-loaded gelatin hydrogels (Kimura et al., 2008). Observation at eight weeks after implantation revealed that the addition of bFGF increased both the maximal strength and stiffness of the regenerated ACL by approximately 50%, increased collagen mass in the regenerated tissue by 2.5–4-fold, and produced histological cross-sections that more closely resembled native ligament. This study

demonstrates that local and controlled release of growth factors such as bFGF can be potent accelerators of ligament regeneration *in vivo*.

In addition to bFGF, TGF-β has also been implicated as an important growth factor in tendon and ligament development, and is actively being investigated for applications in ligament tissue engineering. We characterized the spatiotemporal distribution of TGF-β in the developing chick tendon during embryonic days 13–16 (Figure II.6.8.5) (Kuo et al., 2008). Histologic results demonstrated rapid tissue organization and development during this time period. Immunohistochemical staining showed TGF-β2 and -β3, but not TGF-β1, were present within the tendon mid-substance on all days studied. TGF-β2 and -β3 exhibited similar distribution patterns, but differed in timing and intensity. Taken together, these findings strongly support the postulate that TGF-β2 and -β3 are involved in tendon development, and that these isoforms may have independent roles. In the near future, as production of purified growth factor continues to become more economical, more research on regenerative growth factors will be done, leading to information that will guide the use of growth factors as integral components of functional ligament replacement tissues.

The Effects of Cyclic Strain on Engineered Ligaments. It is well-known that locomotion induces tensile strain on ligament tissues, and for more than 100 years it has been theorized, and later demonstrated, that the density and remodeling of bone is related to its loading state. Thus, it should be no surprise that since nearly the inception of the field, tissue scientists have studied the effect of forces on fibroblasts (Chiquet-Ehrismann et al., 1994) and later on ACL cells (Toyoda et al., 1998). Subsequent to these preliminary experiments, more elaborate bioreactors with uniaxial or multiaxial applied forces were developed for musculoskeletal tissue engineering. Altman et al. (2002b) developed a novel cyclic strain bioreactor that simultaneously applied 10% tensile strain and 25% torsional strain to MSC-seeded collagen type I gels, designed to mimic the natural 90° twist on ACL collagen fibers during knee flexion/extension. The stimulation was applied at a rate of 0.0167 Hz for up to 21 days. Compared to static construct controls, the mechanically stimulated gels had significantly higher cross-sectional cell density and a 2.5-fold increase in cell alignment. The most striking finding was that the mRNA expression of collagen type I, collagen type III, and tenascin-C in mechanically stimulated gels were all significantly upregulated compared to static controls, and approached native ligament expression, although bone and cartilage markers were not upregulated. This was the first study to demonstrate that MSCs could begin to be differentiated into ligament-like lineages using mechanical stimulation alone. The application of cyclic strain in stem cell-based bioreactor systems to
FIGURE II.6.8.5 Histology of intermediate tendon of chick embryos at developmental days 13, 14, 15, and 16. (Top) Hematoxylin-eosin staining. (Bottom) Mallory's trichrome staining. Low magnification, Bar = 200 μm; high magnification, Bar = 50 μm.
FIGURE II.6.8.6 Histology of MSC-collagen constructs harvested after 1 and 7 days of static and cyclic loading. Longitudinal 5 μm thick sections histologically stained with Mallory's trichrome. A higher level of matrix staining is seen consistently in constructs subjected to cyclic loading.

promote cell proliferation, cell alignment, and ligament-marker expression is now an accepted and widely utilized method in ligament tissue engineering. This and other studies have demonstrated enhanced matrix production by MSCs when cyclically loaded under uniaxial tension in long-term cultures, but have not elucidated the mechanisms for these results (Bhatt et al., 2007; Riboh et al., 2008; Zhang et al., 2008). To investigate potential mechanisms, we conducted short-term studies with human MSCs in a similar model system utilizing collagen type I scaffolds and uniaxial tensile loading, and investigated putative tendon marker expression (Kuo and Tuan, 2008). Results showed that while static uniaxial tensile loads upregulated scleraxis expression, cyclic loading significantly enhanced collagen matrix production (Figure II.6.8.6). Cyclic loading was necessary to sustain mRNA levels of scleraxis, a tendon-specific marker gene, and differentially regulated additional developmental and mature tendon marker molecules including collagens, Wnts, and MMPs. The results of this study supported the premise that dynamic mechanical loading enhances tenogenesis of hMSCs, and provided insights into the mechanisms of this process.

Synthetic biomaterials have also been implemented in cyclic strain bioreactors for ligament tissue engineering. Moe et al. (2005) seeded human dermal fibroblasts on PLGA 10:90 knitted scaffolds and applied 1.8% tensile strain for four hours daily over two weeks at either static, 0.1 Hz or 1 Hz strain rates. Using H&E staining, the authors found the most substantial cellular alignment with a 0.1 Hz applied strain rate; however, the scaffold stiffness of mechanically stimulated constructs was significantly less than that of static controls. Unfortunately, the stiffness was not normalized to cross-sectional area (i.e., elastic modulus), thus it is difficult to know if cell contraction and/or matrix formation was partially responsible for this result. Raif and Seedhom (2005) also seeded cells on a knitted scaffold, but used non-degradable PET fibers and bovine synovial cells, which appear to have the capacity to be dedifferentiated into multipotent cells (De Bari et al.,

2001). The applied strain parameters varied considerably between 0.65–4.5% strain magnitude at 1 Hz and were applied for 1–4 hours per day for either 1 or 35 days. The authors found that cell proliferation during short-term application was reduced 1 hour post-stimulation, but was upregulated 22 hours later. Furthermore, cell proliferation increased as cyclic strain amplitude was increased, suggesting a higher affinity for differentiation or matrix production at lower strain amplitude, or simply less cell proliferation. The long-term (35 day) study did not find significant differences, except that higher strains tended to result in a higher scaffold cellular density.

In addition to mechanical stimulation, recent studies have investigated the combinatorial effect of mechanical stimulation and cellular alignment. The developing underlying theory of the influence of patterned scaffold structures is known as "contact guidance," which states that cellular response, especially alignment and proliferation, is dependent on the size and type of the channeling structure. Mechanically stimulating ACL cells seeded on polydimethylsiloxane (PDMS) micropatterned surfaces with an applied 8% uniaxial strain at 0.5 Hz for four hours a day over two days revealed the expression of several novel genes influenced by mechanical stimulation (Park et al., 2006). Specifically, microarray-based real-time PCR analysis showed that expression of the following genes decreased during normal culture, but increased after mechanical stimulation: MGP (matrix Gla-protein, 3.8-fold); GADD45A (growth arrest and DNA damage-inducible gene, 2.3-fold); UNC5B (unc-5 homolog B, 1.6-fold); TGFB1 (transforming growth factor-β1, 1.4-fold); COL4A1 (collagen type IV α1, 1.2-fold), and COL4A2 (collagen type IV α2, 1.2-fold); The authors noted that MGP is a small matrix protein that may be involved in cellular differentiation, and that GADD45A may influence cell cycle proteins and play a role in genomic stability. The exact functions of some of these genes in ligament biology are not well-understood, and certainly warrant further investigation, especially with other cell types. In a similar study, Jones et al. (2005) seeded rat MCL cells on a

Groove and Stretch Direction

10 microns

Nonaligned   **Aligned**
FIGURE II.6.8.7 Fluorescence images of actin filaments (red) and nuclei (blue) of MCL fibroblasts cultured on collagen-coated PDMS surfaces (Jones et al., 2005). (Left column) Cells cultured on smooth PDMS substrates showed randomly aligned cytoskeletal and nuclear morphology, even after 3.5% cyclic strain at 1 Hz for 2 hours (c). (Right column) Cells cultured in PDMS microgrooves with 10 μm width and 6 μm depth were substantially more aligned, based on cytoskeletal and nuclear morphology, compared with smooth PDMS, especially after being cyclically strained (d). (e,f) Control cells grown in the custom cyclic strain incubator without strain applied showed similar results to cells cultured in a standard incubator (a,b). (Reproduced with permission from Elsevier B.V.)

microgrooved PDMS substrate and applied 3.5% strain at 1 Hz for two hours. The authors found considerably more alignment in the groove and stretch direction, compared to cells grown on a smooth PDMS surface (Figure II.6.8.7), and that intercellular propagation of mechanically induced Ca^{2+} flux was significantly enhanced with the application of cyclic strain, but not when grooves alone were introduced. Taken together, these findings suggest that uniaxial mechanical stimulation, and not only forced cellular alignment, is necessary to produce positive benefits for ligament tissue engineering.

While mechanical stimulation is a relatively new practice in tissue engineering, it is actively being employed to develop a variety of musculoskeletal engineered tissues, including ligament, tendon, muscle, and bone constructs. In most, if not all, cases the addition of cyclic strain has conferred a positive benefit especially with cell proliferation, density, and differentiation of stem cells towards musculoskeletal lineages. However, one important admonition is that the ideal mechanical stimulation regime is far from being described, and specific biological models of mechanical stimulation to tissues are lacking. Thus, there is a need for further optimization of applied tissue strains with ligament tissue systems, and perhaps in the future applying an optimized mechanical stimulation regime to engineered ligaments will be commonplace.

Summary of the State of the Art of Ligament Tissue Engineering

The field of ligament tissue engineering is progressing at an incredibly rapid pace; in just 10 years engineered

ligaments have advanced from concept to large animal studies. The potential healthcare implications of engineered ligaments are extensive, and with an aging population will become more important with time. Although ligament engineering has thus far focused on ACL and MCL regeneration, research may eventually expand to target all ligaments of the body.

We have seen that design factors for ligament engineering include native ligament anatomy, biomaterial mechanical properties, biomaterial degradation rate, cellular adherence/spreading on biomaterials, and matrix formation. From a biomaterials perspective, it is clear that matching biomaterial properties to the native ligament structure and function is a critical consideration. Yet what has also been important for the progression of the field has been the utilization of combinatorial approaches – researchers often merge two concepts into one to produce an improved outcome. Examples of this include merging braided scaffolds with sponges, or merging two materials into a single scaffold, or functionalizing a biodegradable surface, or adding mechanical stimulation to aligned cells. In all cases there is not one superior engineered ligament design, and thus far the ideal engineered ligament has yet to be created. Some of the important future milestones of ligament tissue engineering include improving the strength and biological integrity of the ligament–bone junction of implanted engineered ligaments, developing scaffolds and models that match the rate of scaffold degradation with the rate of tissue formation, matching native ligament elastic and viscoelastic mechanical properties, and developing ligament disease models through tissue engineering. Meeting the demands of these requirements will require concentrated interdisciplinary efforts from biologists, chemists, biomaterials scientists, tissue engineers, and clinicians which will eventually provide a new and improved option for repair of injured ligaments to thousands of patients in need of help.

CHAPTER II.6.9 BLOOD VESSEL TISSUE ENGINEERING

Stacey C. Schutte[1] and Robert M. Nerem[2]
[1]Emory University School of Medicine, Woodruff Memorial Building, Atlanta, GA, USA

[2]Georgia Institute of Technology, Atlanta, GA, USA

INTRODUCTION

Cardiovascular disease (CVD) is a major clinical and economic issue, as well as a leading cause of death in developed nations. It affects 80 million Americans and was attributed to 35.3% of all deaths in the United States in 2005. Atherosclerosis is the most common form of CVD and leads to narrowing of the arteries, most commonly the coronary, carotid, and peripheral arteries, which can lead to reduced function or myocardial infarction, stroke or amputation of limbs. Coronary artery disease is the most prevalent CVD accounting for 52% of all CVD (American Heart Association, 2008; Rosamond et al., 2008). Coronary stenosis can be treated by coronary artery bypass grafting (CABG) or by percutaneous coronary intervention (PCI), commonly known as angioplasty, which is used today with endovascular stents (see Chapter II.5.3). While PCI has become a common alternative, CABG is still considered the "gold-standard" of treatment, is the preferred treatment option for patients with left main or triple-vessel coronary artery disease with reduced left ventricular function (Bravata et al., 2007; Taggart, 2007; Malvindi et al., 2008), and requires significantly fewer repeated procedures than PCI (Bravata et al., 2007; Dixon et al., 2008).

There are several choices of material for bypass graft conduits. Autologous venous grafts, most commonly from the saphenous vein, were the material of choice at the advent of CABG surgery. More recently autologous arterial grafts, especially from the internal mammary artery, have gained popularity in CABG procedures, due to the lower incidence of intimal thickening (Canver, 1995; Bahn et al., 1999; Hayward et al., 2008). Although preferred, not all patients have sufficient amounts of healthy tissue necessary for bypass grafting. There are several non-autologous tissue options, such as the use of allogeneic umbilical or saphenous vein or xenogeneic bovine internal thoracic artery, which are often made nonviable through use of glutaraldehyde fixation. The patency rates for these grafts are low, ranging from 65% for cryopreserved saphenous vein grafts to less than 16% for xenografts (Canver, 1995). Synthetic materials, such as expanded polytetrafluoroethylene (ePTFE) and Dacron® have been used successfully to replace larger diameter vessels (>6 mm); however, these materials have not been successful for small diameter (diameter ~3 mm) bypass procedures (such as coronary artery bypass grafts) due to occlusion (Edelman, 1999).

While there is a significant need for bypass graft material due to the prevalence of disease, there are two other areas where there is a need for tissue-engineered blood vessels: pediatrics and shunts for hemodialysis. Conduits of ePTFE are widely used for pediatric vascular repair (Petrossian et al., 2006), with Dacron® and homografts used to a lesser extent. One major limitation of these grafts is the lack of growth potential. Without a graft that can be remodeled and grow with the patient, repeated procedures are required to replace grafts that the patient has outgrown. A graft capable of repair is also ideal for hemodialysis shunts. Creation of a fistula is the preferred method for dialysis access; however, not all patients have vasculature such that a fistula can be created. Healing of the area can take several weeks, and the area where the artery and vein are joined is small. There is a risk of failure, as repeated punctures can result in aneurysm. An arteriovenous (AV) shunt can be used in place of the fistula, where a graft is placed between the artery and vein in the arm, allowing for greater access. Healing is more rapid allowing for earlier access; however, grafts are usually made from ePTFE which can become stenotic due to thrombosis, and the damage due to numerous punctures can cause graft failure.

Tissue engineering may provide a solution to these problems. An ideal graft would be non-immunogenic, non-thrombogenic, have mechanical properties similar to native vessel, be capable of being remodeled, and be vasoactive. "Off-the-shelf" availability is also desired, as many patients cannot wait for these life-saving treatments. This chapter will discuss the enabling technologies and current research into the creation of a tissue engineered vascular graft that could address these needs.

ENABLING TECHNOLOGIES

In the tissue engineering of a blood vessel substitute there are a number of critical issues that are being addressed by a wide variety of investigators. One of these relates to the scaffold that will be used in creating the assembly of cells into the architecture required for a blood vessel. Figure II.6.9.1 shows a cross-section of an artery that engineers are trying to reproduce. Here the enabling technology is that of biomaterials, and since this book is devoted to that topic, any further discussion will be left to the following section in this chapter where the use of biomaterials in different tissue engineering approaches will be outlined. Other critical issues include the sourcing of cells to be used, the achievement of appropriate mechanical properties, and the vascularization of the wall of an engineered blood vessel. It is these three issues that will be discussed in this section.

Cell sourcing is a critical issue for blood vessel tissue engineering, with each cell type having its own unique challenges. While there is some debate over the need for autologous cells for the smooth muscle cells of the medial layer and fibroblasts of the adventitia layer, the need for autologous endothelial cells is agreed upon. Both Advanced Tissue Sciences, Inc. and Organogenesis, Inc. conducted animal experiments using allogeneic smooth muscle cells that, over a period of up to a month, exhibited no immune-mediated rejection. Unfortunately, the results of these studies were never
FIGURE II.6.9.1 Cross-section of a rat muscular artery. The sections are stained with Masson's trichrome which stains collagen blue, nuclei purple, and cytoplasm and muscle fiber red. The entire cross-section is shown (A). The different layers of the artery can be seen more clearly at higher magnification (B). The innermost layer is the intima, a confluent monolayer of endothelial cells sitting on a thin basement membrane. This layer provides a non-thrombogenic lining. The innermost layer is the medial layer; it consists primarily of collagen, elastin, and smooth muscle cells. The thickness and amount of elastin depends on the type of blood vessel. The medial layer provides the mechanical integrity and the vasoactive response of the blood vessel. The outermost layer is the adventitia; it is primarily collagen and fibroblasts, and provides anchoring and allows for ingrowth of nerves and the vasa vasorum.

published. These studies do suggest that at least the possibility of using allogeneic smooth muscle cells exists; however, it must be emphasized that there is a general consensus that autologous endothelial cells could only be employed if there was a strategy to create immune acceptance.

In an acellular graft, endothelial cells migrate no more than 1–2 cm into the graft (along the luminal surface), leaving the remainder of the graft exposed and prone to thrombosis; thrombosis is especially problematic in small diameter grafts where it often leads to significant stenosis or occlusion. There are several endothelial cell sources that have been explored that are summarized in Table II.6.9.1. Along with endothelialization, there are strategies for creating non-thrombogenic linings to minimize thrombosis, often with a short-term goal of prevention until endothelialization can occur. These strategies include use of heparin, thrombomodulin, and surfaces modified to release nitric oxide (Jordan and Chaikof, 2007).

Moreover, large numbers of smooth muscle cells are needed for blood vessel tissue engineering. Expanding smooth muscle cells *in vitro* is common practice, but can result in a modulation to a more synthetic smooth muscle cell phenotype where cells lose much of their contractile apparatus. Cell culture techniques designed to avoid this phenotypic shift result in very long culture times, and are only successful for a small number of passages. After prolonged culture, modulation back to a contractile phenotype is uncertain, but may be possible under some culture conditions such as serum starvation. The long culture times are also a problem in instances where "off-the-shelf" availability is desired. Recruitment of smooth muscle cells *in vivo*, use of allogeneic cells, and use of stem cells each could provide a solution.

Fibroblasts are not always used in every approach, but can be used in the creation of an adventitial layer or in place of the smooth muscle cells to create the medial layer. Fibroblasts secrete extracellular matrix (ECM) and

TABLE II.6.9.1	Possible Endothelial Cell Sources
Endothelial Cell Source	**Comment**
Autologous endothelial cells (biopsy)	Requires *in vitro* expansion Not available "off-the-shelf" Used in early clinical trials
Allogeneic endothelial cells	Possible "off-the-shelf" availability Required immune acceptance strategy
Genetically engineered cells	Possible "off-the-shelf" availability Engineered to provide endothelial cell function
Adult progenitor cells or adult stem cells	Autologous cells or immunoprotected cells Could be recruited from bone marrow or blood Provide endothelial-like function
Embryonic stem cells	Unlimited supply, rapidly expanding Scientific and ethical hurdles Long-term fate of cells uncertain

Adapted from Nerem and Ensley, 2004.

have contractile apparatus, potentially allowing for the use of fibroblasts in place of smooth muscle cells. While the adventitia is often ignored, recent studies have shown that tissue-engineered blood vessels with an adventitia layer containing both fibroblasts and endothelial cells had improved vascularization when implanted subcutaneously (Guillemette et al., 2008).

Adult Stem Cells and Blood Vessel Tissue Engineering

While embryonic stem cells have been studied as a cell source in tissue-engineered blood vessels, these have been investigated primarily as an endothelial cell source. Adult stem cells have become a popular choice, due to the lack of ethical concerns and relative ease

in harvesting. Mesenchymal stem cells (MSC) are a popular choice for tissue engineering. They have been shown to express smooth muscle cell phenotypic markers to different degrees under different culture conditions (Gong and Niklason, 2008); when MSCs are combined with endothelial progenitor cells (EPCs), pulmonary artery patches can remain patent *in vivo* (Mettler et al., 2008). MSCs have also been investigated as a potential endothelial cell source; genetic modification resulted in MSCs that produce nitric oxide (Zhang et al., 2006a). Other adult stem cells have also been studied and may be potential cell sources. Muscle-derived stem cells have been shown as a possible cell source when used with a biodegradable scaffold (Nieponice et al., 2008), and hair follicle cells have been shown to express smooth muscle cell markers, as well as generate a contractile force in engineered tissue (Liu et al., 2008a). Research will continue in these areas as many adult stem cells are immunoprotected and can provide necessary function, possibly eliminating the need for allogeneic cell sources.

Another critical issue in the tissue engineering of a blood vessel is achieving the appropriate mechanical properties. This includes having a strength that is comparable to a native artery, but also having similar compliance and visco-elastic properties. The mechanical stress environment within a blood vessel is quite complex. Blood vessels are subjected to shear stress, transmural pressure, and axial extension, each of which has an effect on the blood vessel wall, as depicted in Figure II.6.9.2. Flow through the lumen produces a shear stress on the endothelial cells lining the blood vessel wall. The wall shear stress influences not only endothelial cell alignment, but also behavioral characteristics of this inner lining of cells (Fisher et al., 2001). The direction and magnitude of the shear stress thus influences the health of the vessel wall. Areas of disturbed or stagnant flow are prone to forming atherosclerotic plaques, and
FIGURE II.6.9.2 Effects of hemodynamics on blood vessel. Increased blood flow results in an increase in the inner diameter of the blood vessel. Blood flow also influences endothelial cell alignment and is correlated with atherosclerosis. Areas of oscillatory or stagnant flow are prone to atherosclerotic plaques. Increased pressure results in an increase in wall thickness; this occurs during development and growth, as well as during prolonged hypertension. Axial stretch results in an increase in vessel length.

such atherosclerosis is a highly localized disease. Transmural pressure produces hoop stress in the vessel wall. This hoop stress influences the organization of collagen and elastin in the wall. Elevated stress, such as with long-term hypertension, will result in remodeling and thickening of the vessel wall. The blood vessels also see axial stresses that affect cell and matrix organization, and vessel length.

In order to mimic the physiological environment of the artery, including its mechanical nature, bioreactors are often employed. The most common form of mechanical stimulation is the application of cyclic strain; cyclic strain of the engineered tissue has been shown to increase tissue strength (Seliktar et al., 2000; Isenberg and Tranquillo, 2003), and to promote a more contractile cell phenotype (Stegemann and Nerem, 2003). Cyclic strain increases matrix metalloproteinase 2 (MMP-2) activity, which can have beneficial or detrimental effects depending on the duration and magnitude of the MMP activity (Seliktar et al., 2003). The ideal strain profiles are still being determined; strain amplitude and rate influences the mechanical properties of the engineered tissue, and recent studies show that a more complex profile incrementally increasing strain rate may yield better results (Syedain et al., 2008).

Early work looked only at the application of cyclic strain, and often required the use of an internal silicon sleeve for transference of strain due to insufficient mechanical properties of the engineered tissue. Since then, several groups have developed bioreactors combining cyclic strain with other stimuli. Cyclic strain has been combined with flow through the lumen (Hoerstrup et al., 2001; Hahn et al., 2007; Iwasaki et al., 2008), perfusion and shear (Sodian et al., 2002; Williams and Wick, 2004), electrical stimulation (Abilez et al., 2006; Mantero et al., 2007) or longitudinal extension (Mironov et al., 2003; McCulloch et al., 2004). Figure II.6.9.3 shows a tissue-engineered blood vessel in a bioreactor capable of imparting cyclic strain, shear, and longitudinal extension (Zaucha et al., 2009). While the use of bioreactors can provide a more physiological environment for culturing and studying tissue-engineered blood vessels, it may not be necessary. There are several approaches that will be discussed in the next section that avoid the use of bioreactors in order to minimize the culture time and try to achieve off-the-shelf availability.

Finally, a critical issue for any thick tissue engineered structure is that of vascularization. Without a vascular network, cell death will occur in tissues greater than 1–2 cm thick, and some experiments and the structure of natural aorta suggest that a tissue thicker than approximately 0.2 cm requires an intrinsic vasculature (called the *vasa vasorum*). Microfabrication techniques such as plasma etching and lithography can be used to create capillary-like networks while maintaining tolerances to ±0.1 μm (Borenstein et al., 2002). These techniques have been used to fabricate devices and networks in both natural and synthetic polymers, including silk fibroin

FIGURE II.6.9.4 Creation of a hydrogel-based engineered blood vessel. Smooth muscle cells are mixed with the solubolized ECM solution. The solution is placed into a tubular mold and incubated. After the solution gels, approximately 1 hour, the tissue is removed from the outer mold and placed into culture.

FIGURE II.6.9.3 Culture of an engineered blood vessel in a bioreactor capable of luminal flow, cyclic strain, and axial stretch. The bottom picture shows a collagen-based tissue-engineered blood vessel within the culture chamber. (As described in Zaucha et al., 2009.)

(Bettinger et al., 2007), poly(lactic acid) (PLA) (Richards Grayson et al., 2003), and poly(glycerol sebacate) (PGS) (Bettinger et al., 2006).

TISSUE ENGINEERING APPROACHES

The different approaches used in creating a tissue-engineered vascular substitute can be divided into three scaffolding approaches: two of which employ scaffolds that are either biologic or synthetic polymer in nature, and a third in which cells secrete ECM to form their own scaffold.

Since the time of Weinberg and Bell (Weinberg and Bell, 1986), type I collagen hydrogels have been explored for use in vascular tissue engineering. These are a popular choice as the hydrogels are easy to mold, provide a more natural environment, and are free of cytotoxic degradation by-products. Smooth muscle cells or fibroblasts can be easily encapsulated with the hydrogel, and will compact and remodel the gel; endothelial cells can be seeded and will form confluent monolayers on the

lumen (L'Heureux et al., 1993). Figure II.6.9.4 shows the process used for creating a tubular cell seeded hydrogel. Due to the ease of fabrication, hydrogels have been created using fibrin (Grassl et al., 2003) and collagen–fibrin mixtures (Cummings et al., 2004; Rowe and Stegemann, 2006), resulting in improved strength and collagen production. While fibrin-based tissue has demonstrated substantial strength, ε-amino caproic acid (ACA) is needed to prevent proteolytic degradation; ACA concentration is an important factor as it also affects the fibrin gel compaction and strength (Rowe et al., 2007). The hydrogel scaffolds are quite weak, so several strategies have been used for improving mechanical properties. Support sleeves of poly(ethyleneterphthalate) (Dacron®) (Weinberg and Bell, 1986), and cross-linked collagen (Berglund et al., 2003) have all been used. Several non-cytotoxic cross-linking agents have been investigated to improve strength. Methylacrylamide photo-cross-linking (Brinkman et al., 2003), enzymatic cross-linking by transglutaminase (Orban et al., 2004), overexpressed lysyl oxidase (Elbjeirami et al., 2003), and non-enzymatic glycation (Girton et al., 1999) have also been employed to improve collagen gel strength. Biochemical stimulation such as with transforming growth factor-β (TGF-β), insulin, and aprotinin have all been shown to improve the mechanical properties of the tissues (Neidert et al., 2002; Yao et al., 2005; Williams et al., 2006).

ECM proteins can also be formed into tubular structures using other techniques. Collagen has been nanopatterned, improving the strength of the tissue to levels close to that of native arteries (Zorlutuna et al., 2009). Silk fibroin has been electrospun into tubular forms and cell seeded (Zhang et al., 2009). Fibronectin–fibrinogen scaffolds have been fabricated using a dip coating/extrusion method (Harding et al., 2002). Woven chitosan has been coated with a chitosan/collagen layer (Zhang et al., 2006b). Esterified hyaluronic acid (HYAFF) has also been used as a scaffold for blood vessel tissue engineering. Tubular shapes have been made by suturing sheets into a tubular form (Remuzzi et al., 2004) or by coagulating a HYAFF coating in an ethanol bath and then air drying (Zavan et al., 2008). Grafts made by the latter method have been tested *in vivo* in a pig model. The HYAFF grafts promoted elastin synthesis and deposition, although several grafts were found to have partial or complete occlusion after harvesting.

TABLE II.6.9.2	Examples of Synthetic Materials Used in Vascular Tissue Engineering	
Polymer	**Comments**	**Reference**
Poly(glycolic acid) (PGA)	Easily modified, can be synthesized in bulk; after dynamic culture provides strong, vasoactive tissue	Niklason et al., 1999
Poly(D, L-lactide)-7 co-(1,3-trimethylene carbonate)	Low cost microsponge; after dynamic culture mechanical properties were similar to human artery	Buttafoco et al., 2006b
Polydiaxonone (PDO) – Elastin	PDO has slower resorption rate with low inflammatory response and thrombogenicity. Elastin allows for cell adhesion and growth and improved elasticity	Sell et al., 2006
Poly(ethylene glycerol) (PEG)	Elastic with tunable mechanical properties; resists thrombosis; dissolves in aqueous solution, and can be photopolymerized in presence of cells	Hahn et al., 2007
Poly(1,8-octanediol citrate) (POC)	Elastomer with tunable compliance; can withstand physiological burst pressures	Webb et al., 2007
PGA/Polycaprolactone (PCL)	Two wrapped sheets; similar strength and compliance to native artery	Iwasaki et al., 2008
Poly(glycerol sebacate) (PGS)	Elastomer that promotes cell adhesion and proliferation; promotes elastin deposition in dynamic culture	Gao et al., 2008
Fibrin-Poly(lactide) (PLA)	Strong polymer for initial strength; fibrin for cell adhesion and promotion of ECM synthesis. Led to supraphysiological strength	Tschoeke et al., 2009
Poly(lactide-co-β-malic acid) with extended carboxyl arms (PLMA-ECA)	Improved hemocompatability and cell affinity compared to PLA	Wang et al., 2009

One limitation of many approaches is the lack of mature elastin. Most approaches appear to assume that mature elastin will be synthesized *in vivo*, although few approaches have demonstrated an ability for adult smooth muscle cells to produce, deposit, and appropriately assemble mature elastin in an engineered tissue. Several methods have been used to incorporate elastin into the engineered tissue prior to implantation. Intact elastin scaffolds can be isolated from arteries and incorporated into the tissue-engineered blood vessel (Berglund et al., 2004). Tubular scaffolds of collagen and elastin have been created by electrospinning (Buttafoco et al., 2006a).

To provide a more natural ECM environment, decellularized tissues have been used; decellularization methods are important and can affect the mechanical integrity of the tissue and the cell viability of seeded cells (Dahl et al., 2003; Jo et al., 2007). This approach also allows for the use of xenogeneic tissue that can be cellularized *in vitro* or could be populated with autologous cells *in vivo*. Use of a decellularized artery is a natural choice; it has similar mechanical properties as fresh artery (Liu et al., 2008b). Decellularized veins with venous valves have been explored, and have clinical application for grafting of peripheral veins such as the femoral vein (Teebken et al., 2009). Decellularized ureters have been explored as vascular grafts (Derham et al., 2008). Endothelialized decellularized ureter grafts have similar compliance as compared to the coronary artery, and remain patent in canine models (Narita et al., 2008). Small intestinal submucosa (SIS) has been tested for use as a vascular graft and has similar mechanical properties to native vessels (Roeder et al., 1999). The SIS grafts have been tested successfully *in vivo* in a growth model showing that they are

not only able to arterialize, but also to adapt and grow in a pediatric model (Robotin-Johnson et al., 1998). The intestinal collagen layer of the small intestine was also used as a vascular graft. When treated with heparin, the small diameter grafts remained patent in a rabbit carotid (Huynh et al., 1999).

While use of ECM scaffolds is popular, synthetic polymer scaffolds do have some benefits and have been widely explored. The mechanical properties of synthetic scaffolds are tunable, and the resulting grafts can have "off-the-shelf" availability. Many of the materials can be made in bulk at low cost and are easily modified. Dacron® and ePTFE are popular choices for bypass grafting of larger vessels; however, they are not appropriate for small diameter blood vessel grafting or pediatric applications, since they do not remain patent and cannot be remodeled as needed for growth. For these applications biodegradable polymer scaffolds have been studied. The most widely used polymer is polyglycolic acid (PGA). Because it is rapidly resorbed, *in vitro* culture is required prior to implantation. There are many different single and combination polymers that have been tested for vascular tissue engineering applications. Table II.6.9.2 shows a variety of synthetic materials that are being used for vascular tissue engineering. Many are still in the development stages, while others listed in Table II.6.9.3 have progressed to the point of preclinical or clinical testing. There has been limited clinical success with grafts made with P(LA/CL) and either PGA or PLA which have been used in low pressure pediatric applications. There are concerns with synthetic materials though; cell adhesion and ingrowth are a challenge. To overcome this the polymers can be modified with adhesion motifs or combined

TABLE II.6.9.3	Tissue Engineering Approaches Tested *In Vivo*	
Polymer	**Comments**	**Reference**
Tested *In Vivo*, Preclinical		
SIS	Used as carotic graft in canine model. After 2 months, all were patent. Remodeling led to changes in mechanical properties becoming close to that of the surrounding tissue	Roeder et al., 2001
PGA	Remained patent during 24-day study in porcine model	Niklason et al., 1999
PGA-Polyglactin	Remained patent for 24 weeks when implanted as a segment of ovine pulmonary artery	Shinoka et al., 1998
PGA-Polyhydroxyalkanoate (PHA)	Remained patent with no anyeurism for 5 months as ovine abdominal aorta segment	Shum-Tim et al., 1999
Autologous, cell self-assembled in peritoneal or pleural cavity	Used as femoral artery interposition graft in canine; 8 of 11 patent after 6.5 months	Chue et al., 2004
Decellularized umbilical artery coated with Poly(steryne sulfonate)/Poly(allylamine hydrochloride) (PSS/PAH)	Remained patent during 12-week study as carotid artery bypass in rabbit model	Kerdjoudj et al., 2008
PGA-Poly(4-hydroxybutyrate) (P4HB)	No stenosis or aneuryism for ovine pulmonary patch. Seeded with EPCs and mesenchymal stem cells	Mettler et al., 2008
PCL	Longer degradation time; 12 weeks in rat abdominal aorta showed cell in-growth with confluent endothelial cell monolayer by 12 weeks	Pektok et al., 2008
PGA/collagen-Poly(L-PLLA)	Patent for 12 months in porcine aorta	Torikai et al., 2008
Poly(ester-urea) urethane-Poly(2-meth-acryloyloxyethyl phosphorylcholine-co-methacryloxyethyl butylurethane) (PEUU-PMBU)	Addition of PMBU improved patency in rat aorta	Hong et al., 2009
PLLA coated with Poly(L-lactide-co-ε-caprolactone)(P(LA/CL))	Remained patent without anyeurism for 1 year as infrarenal aortic interposition graft in mice	Mirensky et al., 2009
PCL/collagen	Maintained structural integrity as rabbit aortoiliac bypass (1 month)	Tillman et al., 2009
Tested *In Vivo*, Clinical		
PGA or PLA with P(LA/CL)	Results reported for 23 patients as extracardiac total cavopulmonary connection. No graft related failures	Shinoka and Breuer, 2008
Autologous fibroblast cell secreted scaffold	60% patency in 8 patients after 6 months	McAllister et al., 2009

with other synthetic polymers or ECM proteins. Immunogenicity and thrombogenicity have been a problem for many of these materials, especially in the smaller diameter applications. Degradation by-products are a concern as well, as they may alter the local environment and lead to alterations in cell function or cell death (Athanasiou et al., 1996; Agrawal and Athanasiou, 1997). *In vitro* culture prior to implantation would allow for the material to degrade, but would require long culture times for complete degradation of the materials.

The third method has employed a cell secreted scaffolding material. The two notable approaches are the cell sheet approach, and the use of the body as a bioreactor. In the cell sheet approach, the smooth muscle cells or fibroblasts are cultured until they are post-confluent and have formed a tissue. The sheets are wrapped around an inner mandrel to create a tube, and cultured to promote adhesion of the layers. All three layers of the blood vessel can be created by wrapping the fibroblast layer around the smooth muscle layer and then seeding endothelial cells into the lumen (L'Heureux et al., 1998). In private communication this laboratory has discussed their modified approach using a single step to create the media and adventia layers. Using a

compartmentalized tissue culture plate with a custom spacer, the smooth muscle cells and fibroblasts can form tissue. The spacer can then be removed to form a single layer of tissue with two distinct regions. This approach leads to a small reduction in culture time, and also results in better adhesion between the two layers. Use of a single rolling step also improves manufacturability. A similar cell sheet approach is being used by Cytograft Tissue Engineering Inc. to create autologous tissue. These tissue-engineered blood vessels use fibroblasts to create the medial layer; endothelial cells are seeded prior to implantation. Mechanical testing of an engineered blood vessel using fibroblast sheets only has been shown to have burst pressures comparable to artery, and compliance between that of an artery and vein (Konig et al., 2009). Figure II.6.9.5 shows the completely autologous tissue engineered AV shunt for dialysis prior to implantation.

In order to form a tissue-engineered blood vessel with autologous cells in a shorter amount of time, the use of the body as a bioreactor to create a blood-vessel-like structure was developed (Campbell et al., 1999). The body's foreign-body response forms granulation tissue around a silastic mold, resulting in a blood-vessel-like structure
FIGURE II.6.9.5 Tissue engineered blood vessel created using cell sheet technology. Shown is the Cytograft tissue being tested as an AV shunt. (Reprinted with permission of Cytograft.)

with myofibroblasts and a monolayer of mesothelium. The tissue is removed from the tubing and everted so that the mesothelium is facing the lumen. In canines the tissue-engineered blood vessels cultured in the peritoneal cavity for three weeks resulted in a tissue with a burst strength over 2500 mmHg; when implanted as a graft in the same animals, 73% of the grafts remained patent (Chue et al., 2004). This approach is promising due to its short culture time and its use of autologous cells; however, off-the-shelf availability will likely be needed for some patients. Thus, even though this approach has relatively short culture times, it would not meet the needs of all patients.

CONCLUDING DISCUSSION

In spite of the progress reported in this chapter, there still is much that needs to be done, and there are many questions that investigators are trying to answer. As an example, what is the best source of cells? Should the approach be based on an allogeneic source so as to have off-the-shelf availability or an autologous source so as to bypass the immunogenicity issue? Or does one implant an acellular substitute and employ methods for recruiting the patient's own cells?

What is the best scaffold material to be used in fabricating the implant, whether it be an acellular one or one seeded with cells? Recognizing that the behavior of cells is orchestrated by a symphony of signals, a symphony that includes signaling from the extracellular matrix, does this make the biological scaffolds better or can this be incorporated into a synthetic scaffold by attaching appropriate ECM molecules to the surface of the synthetic material?

How can the appropriate physiological properties be achieved? This includes having mechanical properties that mimic those of native vessels, but what about vasoactivity? In the large vessels that have been the focus of efforts to tissue engineer a blood vessel and that are not resistance vessels, how important is it for this engineered vessel to be able to regulate its diameter?

Finally, what about vascularization? Will the wall of an engineered blood vessel be thick enough to require this? If so, what are the approaches that could lead to vascularization? And then the related question, what about neural control?

Thus there are many questions that remain, and that provide for the ongoing research that is taking place. Even so, there are some initial clinical studies, and these are starting to see some success in the arena of tissue-engineered blood vessels. The clinical studies to date have been very small in number. As the numbers grow and the applications increase, additional information and challenges will occur. Remodeling or host cell recruitment is key for most of the vascular tissue engineering approaches. Interpatient variability will have a significant impact on the rate of remodeling and the mechanical integrity of the tissue. Age, sex, health, and lifestyle of the patients will have significant effects. Degradation and synthesis of new ECM must be controlled so that the graft material does not weaken to the point of aneurysm or rupture.

Tissue-Engineered Blood Vessels in the Clinic

Advances in tissue engineering of blood vessels have resulted in recent clinical successes. For the pediatric population, synthetic vascular grafts of P(CL/LA) with PGA or PLA have been used successfully as grafts for extracardiac total cavopulmonary connection. This graft has "off-the-shelf" availability and a high success rate; only one of the 23 patients had any graft-related complications (Shinoka and Breuer, 2008). Despite its success, this material is not suited for all applications. The mechanical strength reported for these grafts is too low to be expected to survive in a high pressure environment, and significant stenosis has been found in conduits that are smaller than 18 mm.

Grafts using the cell sheet technique are in clinical studies as AV shunts (Cytograft Tissue Engineering, Inc., CA). There were promising results after six months in a population with a high risk of failure (McAllister et al., 2009). These living grafts use autologous fibroblasts that secrete their own matrix, resulting in tissue with burst strengths greater than 2000 mmHg. There were also several failures due to aneurysm in this high risk population. Additionally, the process to create the grafts is very long; the grafts in the published study took 6–9 months to create. The lack of "off-the-shelf" availability may limit the patient population that could benefit from the engineered tissue.

In closing, it is clear that considerable progress has been made in the last 10–15 years. There is even some initial clinical success. Even so, there is much still to do, and the tissue engineering of a blood vessel will remain a fertile area for research for years to come.

CHAPTER II.6.10 HEART VALVE TISSUE ENGINEERING

Frederick J. Schoen[1] and Simon P. Hoerstrup[2]

[1]Professor of Pathology and Health Sciences and Technology (HST), Harvard Medical School, Executive Vice Chairman, Department of Pathology, Brigham and Women's Hospital, Boston, MA, USA

[2]Cardiovascular Surgery Research University and University Hospital Zurich, Zurich, Switzerland

As summarized in Chapter II.5.3B of this book, diseased heart valves are usually replaced by mechanical prostheses or tissue-derived valves. Heart valve replacement is today a common procedure that is lifesaving and enhances quality of life in many patients (Rahimtoola, 2010). However, there remain key limitations to the uniform success of currently available substitute heart valve technology. In particular, mechanical prosthetic valves necessitate long-term anticoagulation to reduce thromboembolic complications; as a consequence, patients so treated assume a significant risk of hemorrhagic complications (Schoen, 2001). Moreover, tissue failure by cuspal mineralization and non-calcific structural damage frequently leads to failure of bioprostheses fabricated from glutaraldehyde fixed (and hence non-viable) porcine aortic valve or bovine pericardium (see Chapter II.4.5 of this book and Schoen and Levy, 2005). There is also evidence that the recently introduced bioprosthetic heart valves implanted through a catheter may suffer dysfunctional degeneration due to procedure-related mechanical damage as a consequence of prosthesis "crimping" (Noble et al., 2009; Zegdi et al., 2011 as well as the typical bioprosthesis-related complications). Aortic heart valve allografts derived from deceased humans used as transplants are severely limited in availability, and suffer durability limitations (Mitchell et al., 1998). Thus, currently available substitute valves have characteristic complications, and neither mechanical nor bioprosthetic devices, nor allograft valves permit growth of the prosthesis to accommodate the somatic growth of the recipient. In patients with congenital heart disease, this often necessitates multiple valve replacement operations during childhood and adolescence, to permit implantation of successively larger valves to match patient growth. Indeed, much of the motivation for the tissue engineering approach to heart valve replacement has derived from the particular need for heart valve replacement in children. Nearly 20,000 children are born with congenital heart defects each year in the United States; many congenital cardiac defects are either valve-related or require surgical intervention that replaces or repairs a valve. Examples are congenital aortic or pulmonary valve (AV or PV) stenosis, or complex congenital cardiac anomalies (such as tetralogy of Fallot), which include reconstruction of the right ventricular outflow tract with a valved conduit. These conduits often fail. Moreover, in this young patient population with congenital heart disease, the anticoagulation required with mechanical valves is particularly dangerous, and tissue valve substitutes undergo accelerated calcification (see Chapter II.5.3.B of this book).

Recent scientific and technological progress has stimulated the goal of generating a living valve replacement device that would not only obviate the limitations of conventional valve replacement, but would also have viable cells that would permit not only adaptation to changing environmental conditions in the recipient but also growth of the valve with a rapidly growing patient. Moreover, owing to the understanding that the mechanisms of bioprosthetic and other tissue valve calcification are potentiated by non-viable components (see Chapter II.4.5 of this book), a healthy, living valve would likely not suffer calcification. Innovative work toward a living valve fabricated from engineered tissue is active in many laboratories, and may eventually lead to clinical application.

> … much of the motivation for the tissue engineering approach to heart valve replacement has derived from the particular need for heart valve replacement in children. Recent scientific and technological progress has stimulated the goal of generating a living valve replacement device that would … have viable cells and thereby permit adaptation to changing environmental conditions in the recipient, and growth with a growing patient.

This chapter provides a contemporary review of key concepts of heart valve tissue engineering (HVTE). We describe the evolving understanding of heart valve function and biology (which provides key design criteria), the promise and difficulties demonstrated by *in vivo* studies done to date, and the critical challenges that will be encountered and hopefully surmounted in translating the promise of this potentially exciting therapeutic modality from the laboratory to the clinical realm. The reader is referred to comprehensive recent reviews of HVTE for additional information (Breuer et al., 2004; Vesely, 2005; Mendelson and Schoen, 2006; Schoen, 2008, 2011; Hjortnaes et al., 2009; Sacks et al., 2009a; Weber et al., 2011a).

DESIGN CRITERIA AND CHALLENGES IN TISSUE-ENGINEERED HEART VALVE (TEHV)

The design criteria and characteristics for engineered tissue valve substitutes were originally articulated for conventional replacement heart valves in 1962 by pioneering heart surgeon Dr. Dwight Harken (Harken et al., 1962), a modified formulation is shown in Table II.6.10.1. The realization of the HVTE principle requires a living, functional tissue whose cellular components can assume a homeostatic functional state, repair ongoing structural injury to cells and extracellular matrix (ECM), and accommodate somatic growth of the recipient.

Key Structure–Function Correlations in the Cardiac Valves

Heart valves are structural specializations of the cardiac tissues that ensure unidirectional blood flow through the heart; they open and close approximately 40 million times a year and three billion times over an average lifetime. Normal valves are free of obstruction in the open position, and without regurgitation in the closed position. The motions of the heart valves during opening and closing are driven by mechanical forces exerted by the surrounding blood and heart. Heart valve opening and closing induces repetitive and substantial changes in the shape, dimensions, and stress of the leaflets and supporting valvular structures (Figure II.6.10.1) (Sacks and Yoganathan, 2007; Schoen, 2008; Sacks et al., 2009b). Their ability to permit unobstructed forward flow depends on the mobility, pliability, and structural integrity of the moving parts of the valves; these are delicate flaps, that are generally called *leaflets* (in the tricuspid valve (TV) and mitral valve (MV)) and *cusps* (in the pulmonary valve (PV) and aortic valve (AV)). An engineered tissue valve and its components must not only accommodate those deformations, but must also have ongoing strength, flexibility, and durability, beginning at

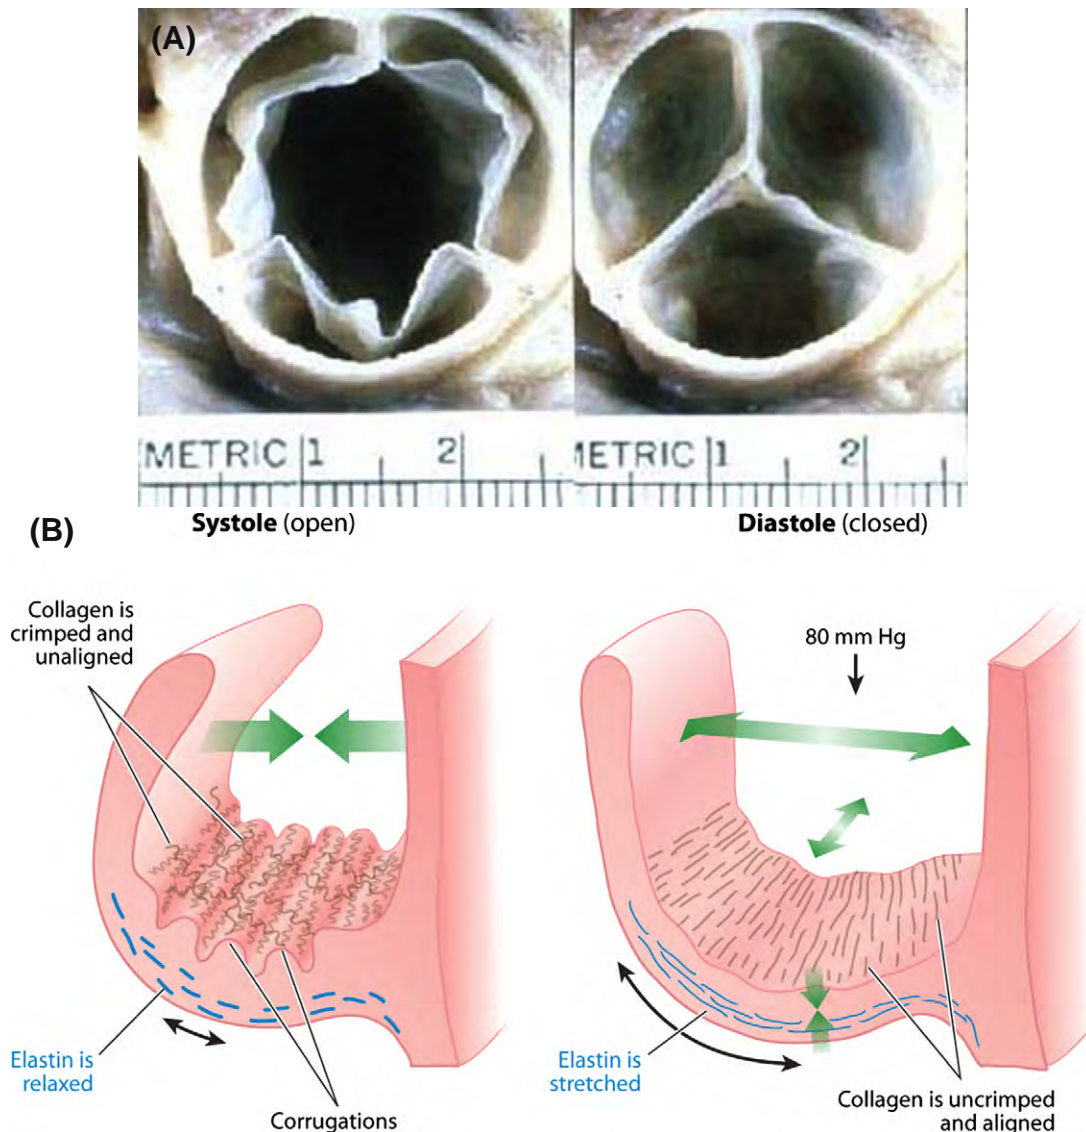
TABLE II.6.10.1	Design Objectives For and Characteristics of Replacement Heart Valves	
Feature to Optimize	**Conventional (Mechanical, Bioprosthetic)**	**Tissue-Engineered**
Closure of leaflets	Rapid and complete	Rapid and complete
Size of orifice area	Less than that of natural valves	Better
Mechanical properties	Initially suitable and stable	Initially suitable and stable
Surgical insertion	Easy and permanent	Easy and permanent
Risk of thrombosis	Yes, especially mechanical valves, which require anticoagulation, causing vulnerability to hemorrhage	No, endothelial surface to inhibit thrombogenesis
Risk of structural dysfunction	Degradation of synthetic materials rare with mechanical valves Tissue degradation and calcification of leaflets with bioprosthetic valves	Resistant to degradation, calcification
Risk of infection	Ever present	Resistant to infection
Cellular viability	No	Yes, able to repair injury, remodel, and potentially grow with patient


FIGURE II.6.10.1 Aortic valve functional structure at both macro- and microscopic levels. the instant of implantation and continuing indefinitely thereafter, despite potentially evolving tissue architecture owing to remodeling. This key requirement, coupled with the realization that the consequences of failure are likely to be serious, renders the heart valves a particularly challenging application for an engineered tissue.

Most frequently diseased, most frequently substituted (often from AV derived from animals or deceased humans), and most widely studied, the AV provides a paradigm for functional valvular architectural specialization, tissue dynamics, and biological interactions. Individual AV cusps (of which there are normally three) attach to the aortic wall in a crescentic (or semilunar) fashion, ascending to the commissures (where adjacent cusps come together at the aorta), and descending to the

basal attachment of each cusp to the aortic wall. Behind the cusps are dilated pockets in the aortic root, called *sinuses of Valsalva.*

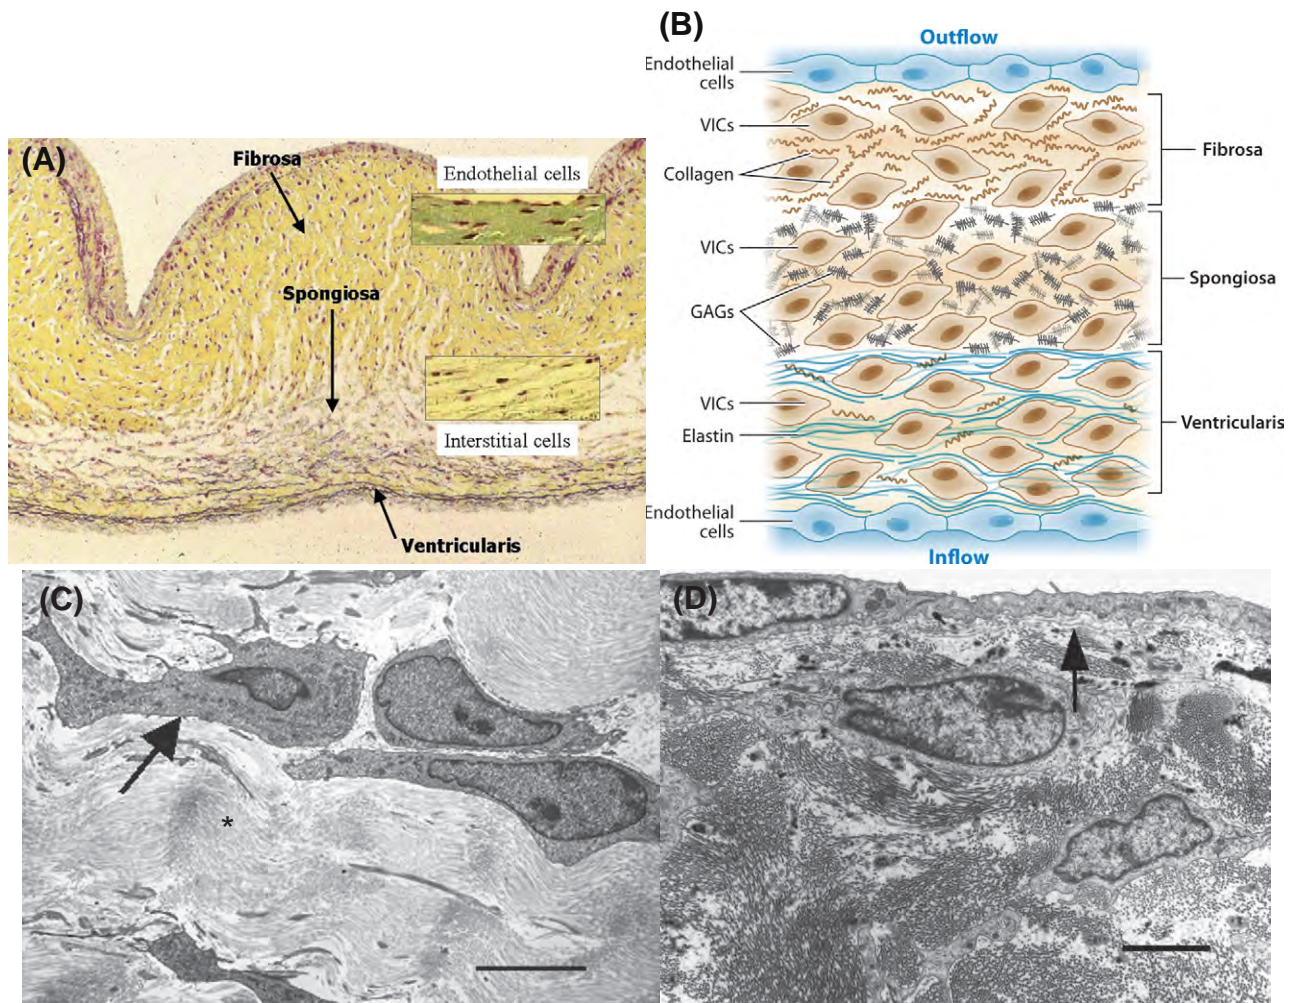
Moreover, the cusps and leaflets of the heart valves are vital and dynamic tissues that respond to changes in local mechanical forces and other environmental conditions (Schoen, 2008). The combination of substantial changes in the size and shape of the valve cusps during the second-to-second movements of the cardiac cycle and sufficient strength and durability to withstand repetitive and substantial mechanical stress and strain over billions of cycles is accomplished by a highly dynamic and complex internal microarchitecture, consisting of specialized cells and extracellular matrix (ECM). The four cardiac valves have a qualitatively similar, layered architectural


FIGURE II.6.10.2 Aortic valve histology and ultrastructure. (A) Aortic valve histology, shown as low-magnification photomicrograph of cross-section cuspal configuration in the nondistended state (corresponding to systole), emphasizing the three major layers: ventricularis, spongiosa, and fibrosa. (B) Schematic tissue architecture at the level of cells and extracellular matrix, highlighting layered structure and layer-specific cellular components and ECM. In (A) and (B) the outflow surface is at the top. (A) Original magnification 100 ×. Movat pentachrome stain (collagen is yellow; elastin is black). (C) Transmission electron photomicrograph of fresh porcine aortic valve at 0 mm Hg transvalvular pressure (characteristic of the systolic configuration), demonstrating the fibroblast morphology of valvular interstitial cells (VICs, arrow), the dense, surrounding closely apposed collagen (asterisk) with wavy crimp, and the potential for VIC–collagen and VIC–VIC interactions. (D) Transmission electron photomicrograph of the surface of the aortic valve demonstrating valvular endothelial cell (VEC; arrow) and proximity of deeper VICs, and potential for VEC–VIC interactions. In (C) and (D), bar = 5 microns. ((A) Reproduced by permission from Schoen, F. J. & Edwards, W. D. (2001). Valvular heart disease: General principles and stenosis. Springer-Verlag, Inc.: New York, NY, pp. 193–233.)

pattern composed of cells, including the valvular endothelial cells (VECs) at the blood-contacting surfaces and the deep valvular interstitial cell (VICs), and valvular extracellular matrix (VECM), including collagen, elastin, and amorphous ECM (predominately glycosaminoglycans (GAGs)) (Figure II.6.10.2 and Table II.6.10.2). Thus, the AV (and analogously the PV) has a dense collagenous layer close to the outflow surface and continuous with valvular supporting structures, which provides strength (the *fibrosa*); a central core of loose connective tissue (the *spongiosa*) rich in glycosoaminoglycans

(GAGs); and a layer rich in elastin below the inflow surface (the *ventricularis*). PV structure is analogous to, but less robust than, that of the AV, consistent with the lower pressure environment (Joyce et al., 2009). Moreover, since heart valves are sufficiently thin (approximately 200–300 microns in thickness) to be nourished by diffusion from the blood bathing the valves, normal leaflets and cusps have only scant and inconsistent blood vessels.

The major stress-bearing component within the heart valves is collagen, particularly in the fibrosa, which undergoes realignment and crimping to accommodate

TABLE II.6.10.2	Key Cellular and Extracellular Matrix Components of the Aortic Valve		
Component	**Location**	**Putative Function**	**Comments – Key Questions**
Endothelial cells	Lining inflow and outflow valve surfaces	Provide thromboresistance, mediate inflammation	Role in transducing shear and modulating VIC function; functional differences from vascular wall EC; differences in inflow side to outflow side functions/responses largely unknown
Interstitial cells	Deep to surface, throughout all layers	Synthesize and remodel matrix elements	Presently considered the major modulator of long-term valve durability and a key mediator of disease; regional heterogeneity; regulation of activation and functional role of contractile potential poorly understood
Elastin	Concentrated in *ventricularis* layer	Extend in diastole, recoil in systole	Potential mechanistic role in disease not defined
Glycosoamino-glycans	Concentrated in *spongiosa* layer	Absorb shear of relative movements and cushion shock between ventricularis and fibrosa during cyclical valve motion	Potential mechanistic role in disease not defined
Collagen	Concentrated in *fibrosa* layer	Provide strength and stiffness to maintain coaptation during diastole	Likely the most important structural element; crimp and orientation/alignment provide directional anisotropy of properties, and accommodate cyclical cuspal shape changes

Modified from Schoen, F. J. (1997). Aortic valve structure–function correlations: Role of elastic fibers no longer a stretch of the imagination (Editorial). *J. Heart Valve Dis*. **6**, 1–6.

the repetitive changes in the size and shape of the cusps during the cardiac cycle. In the closed phase of the AV (*diastole*), the back pressure (normally approximately 80 mm Hg) stretches the valve cusps as they come together to seal the orifice, to prevent backward leakage of blood. Moreover, the direction of collagen fibers in the cusps determines the directions in which the tissue has the greatest compliance (i.e., orthogonal to the collagen fiber orientation) or can withstand the greatest tensile stresses (i.e., parallel to the collagen fiber orientation). The strains during valve closure and the mechanical properties of the AV cusps are anisotropic (i.e., different in different directions). Since the need for compliance and stretching in the radial direction is greater than that in the circumferential direction, and the need for stiffness correspondingly greater circumferentially (i.e, toward the attachments) the collagen fiber orientation is predominantly circumferential. The second-to-second cyclical internal rearrangements in collagen (i.e., alignment of fibers and extension of microscopic crimp) are extremely sensitive to the instantaneous mechanical stresses, and are completed very early following closing. In contrast, during valve opening (*systole*), the tissue of the cusps that was stretched during diastole becomes relaxed, owing to recoil of the elongated, taut elastin (in the ventricularis). This elastic recoil restores the retracted configuration of the cusp, with a decreased cuspal surface area, a more random directional distribution, and crimp (i.e., folding/pleating) of collagen fibrils. The GAG-rich spongiosa is thought to facilitate the relative rearrangements of the collagenous and elastic layers during the cardiac cycle. Since the dynamics described above are crucial for normal valve function, the quantity, quality, and architecture of the valvular ECM, particularly collagen, elastin, and GAGs, are the major determinants of both the short-term function and long-term (lifetime) durability of a valve.

VICs, the most abundant cell type in the heart valves and distributed throughout all the valve layers, synthesize the valvular ECM and express matrix degrading enzymes (including matrix metalloproteinases (MMPs) and their inhibitors (TIMPs)) that mediate and regulate remodeling and repair of collagen and other matrix components. When stimulated by the mechanical environment, certain chemicals, and as a part of the response to injury, VICs are highly plastic and may transition from one phenotypic state to another during valvular homeostasis, adaptation and pathology (Liu et al., 2007; Schoen, 2008). Thus, VIC health is critical for normal valve function; likewise, VIC's are likely to be the key cell in tissue-engineered heart valves.

> The quantity, quality, and architecture of the valvular ECM, particularly collagen, elastin, and GAGs, are the major determinants of both the short-term function and long-term (lifetime) durability of a valve. Since VICs maintain and remodel the ECM, VIC health is critical for normal valve function. Likewise, VICs are likely to be the key cell in tissue-engineered heart valves.

The VECs that line blood contacting surfaces of the valves share some characteristics of circulatory endothelial cells generally. However, they are phenotypically different in some key features from vascular endothelial cells in the adjacent aorta and elsewhere in the circulation. For example, in response to fluid shear stress, porcine aortic VECs align perpendicular to flow (Butcher et al., 2004), whereas endothelial cells from the nearby aorta align parallel to flow, and the transcriptional gene expression profile of aortic wall and aortic VECs are different when the different cells are exposed to the same mechanical environment (Butcher et al., 2006).

TABLE II.6.10.3	Key Concepts of Heart Valve Function and Pathology That Inform Tissue Engineering
Valve function/durability depends on collagen and other ECM	
ECM quality depends on VIC viability and function	
VIC have a complex phenotype	
VIC elaborate and remodel valvular ECM	
Non-viable VIC are deleterious	
Valve degeneration is caused by calcification (in cells) and mechanical/chemical damage to collagen	
VICs are damaged during processing of tissue valves	
Thus, a key goal of an engineered tissue valve is an environment whereby viable VIC can repair structural injury, remodel ECM in the appropriate quantity spatial pattern and quality, and permit valve growth	

Adult heart valve VIC's *in situ* have characteristics of fibroblasts; they are quiescent, without synthetic or destructive activity for ECM. However, VICs are activated during intrauterine valvular maturation by abrupt changes in the valvular mechanical stress state, and in disease states. Additionally, valvular cells continuously repair the low level of injury to the valvular ECM that occurs during physiological function (Liu et al., 2007; Schoen, 2008). Since the macroscopic mechanical state of the valve is likely transmitted to the VICs through their interactions with the surrounding VECM, there is considerable interest in the effects of mechanical forces on VIC function, the mechanisms of response of VICs to their physical environment, and the mechanical properties of isolated VICs. Thus, in disease states and with bioprosthetic, allograft, and autograft valves, healthy, functional valve cells are beneficial; they mediate ongoing valve function and remodeling over a lifetime (Aikawa et al., 2006). In contrast, stressed or injured valve cells can potentiate significant pathology (as summarized in Table II.6.10.3) (Schoen, 2008, 2012).

Role of Heart Valve Developmental Biology

Some of the processes and regulatory pathways active in valvular development and maturation may be recapitulated in tissue-engineered valves; an understanding of developmental biology, physiology, and pathophysiology of heart valves will likely inform tissue engineering (Armstrong and Bischoff, 2004; Combs and Yutzey, 2009). During embryological development, the three germ layers – *ectoderm*, *endoderm*, and *mesoderm* – give rise to cells that differentiate to form the body's tissues and complex organs. The heart develops primarily from the embryonic layer called mesoderm, in which the initial commitment of precursor cells to a cardiac lineage depends on complex signaling pathways. Cardiac myocytes become organized into a linear heart tube that subsequently undergoes looping; further growth of the looped heart tube and development of septa leads to the multichambered heart.

Subsequently, the valve cusps and leaflets originate as outgrowths (known as *endocardial cushions*) from the mesodermal-derived connective tissue called *mesenchyme*. Endothelial cells lining the inside surface of the cushion forming area undergo an *epithelial-to-mesenchymal transition* (EMT) and migrate from the blood-contacting internal heart surface deep into the connective tissue of the subendocardium (called *cardiac jelly*) to become precursors of mature VIC (Figure II.6.10.3). EMT comprises a series of cell–cell and cell–matrix interactions that release epithelial cells from a surface, and confer the ability to move through three-dimensional ECM and synthesize ECM components (Armstrong and Bischoff, 2004). The newly formed mesenchymal cells remodel the cushions into leaflets and cusps. Evidence for EMT is provided by mesenchymal cellular expression of α-SMA, a marker that is not typically expressed by endothelial cells. Numerous signaling pathways, growth and transcriptional factors (including vascular endothelial growth factor (VEGF), nuclear factor in activated T cells (NFATc1), and Notch) regulate the process of heart valve formation.

TISSUE ENGINEERING APPROACHES TO HEART VALVES

Engineering of heart valve tissue is an active goal of many laboratories, and this technology may eventually achieve clinical application. As emphasized above, the long-term success of an engineered tissue heart valve will depend on the ability of its living cellular components (VECs and VICs) to function normally, to maintain homeostasis, and to repair structural injury to the ECM.

There is a spectrum of approaches to engineered tissue heart valves, utilizing processes with overlapping features: (1) formation of a tissue *in vitro* by seeding cells on a biodegradable scaffold and maturing a living tissue model *construct* (to be implanted *in vivo*) in a bioreactor; (2) cell-seeded natural biodegradable scaffolds; (3) guided tissue regeneration via implanted degradable tissue which is remodeled by endogenous cells; (4) implantation of decellularized valvular material; and (5) other approaches that use endogenous pathophysiologic processes to generate and/or functionally differentiate tissue *in vivo* (variations on these themes are summarized in Figure II.6.10.4).

The most widely-studied paradigm of tissue engineering to facilitate valve regeneration uses cells that are pre-seeded on a synthetic, biodegradable polymer scaffold fabricated in the shape of a trileaflet valve, and matured *in vitro* in a controlled metabolic and mechanical environment (in a *bioreactor*). The intent is for the cells to differentiate, proliferate, and produce ECM to form the construct. Subsequently, the construct is implanted orthotopically (i.e., in the appropriate valve site) as a valve prosthesis, and further remodeling *in vivo* is intended to recapitulate the normal functional architecture of a valve. The cells produce matrix materials (structural proteins and polysaccharides) and other bioactive
FIGURE II.6.10.3 Overview of heart valve development. (A): Looped heart tube showing locally expanded swellings of cardiac jelly and mesenchymal cells at cardiac cushions. (B): The developing heart tube contains an outer layer of myocardium and an inner lining of endothelial cells separated by an ECM referred to as the cardiac jelly. During heart valve formation, a subset of endothelial cells overlying the future valve site are specified to delaminate, differentiate, and migrate into the cardiac jelly, a process referred to as endothelial–mesenchymal transition, transformation or transdifferentiation (EMT). Locally expanded swellings of cardiac jelly and mesenchymal cells are referred to as cardiac cushions. In a poorly understood process, cardiac cushions undergo extensive remodeling from bulbous swellings to eventual thinly tapered heart valves. (Reproduced by permission from Armstrong, E. J. & Bischoff, J. (2004). Heart valve development: Endothelial cell signaling and differentiation. *Circ. Res.,* **95,** 459–470. Copyright American Heart Association.)

components (e.g., chemical signals, matrix metalloproteinases MMPs and inhibitors, etc.). The ECM provides the basic framework for the tissue and is primarily responsible for the tissue structural and mechanical properties. The polymer scaffold temporarily provides matrix on which cells can organize, grow, proliferate, and produce ECM, and the temporary biomechanical characteristics for the replacement "tissue" until the cells produce the ECM which will ultimately provide the structural integrity and biomechanical profile. The general principles involved in tissue engineering, including considerations for cells, scaffolds, and bioreactors, are summarized in chapters II.6.2, II.6.3, and II.6.6, respectively, of this book. Thus, key pathophysiologic

processes occur during the *in vitro* and *in vivo* phases of tissue formation and maturation in TEHV, including: (1) cell proliferation, sorting and differentiation; (2) ECM production and organization; (3) degradation of the polymer scaffold; and (4) remodeling and, potentially, growth of the tissue commensurate with the growth of the individual.

Tissue-engineered heart valves grown as valved conduits from autologous cells (derived from vascular wall or bone marrow) seeded on biodegradable synthetic polymers and matured *in vitro* have been explored by several groups working in the US and abroad.
FIGURE II.6.10.4 Spectrum of approaches to heart valve tissue engineering, with overlapping features. The generation of natural decellularized matrix-based constructs involving cell seeded (A), unseeded (B), and *in vitro* conditioned constructs (C). The formation of a tissue *in vitro* by seeding autologous cells onto a biodegradable starter matrix and maturing a living tissue model, called the *construct*, in a bioreactor (D). The use of cell-seeded natural biodegradable scaffolds without *in vitro* biomimetic conditioning, also referred to as the *single step* or *in situ* approach (E); The concept of guided tissue regeneration via implanted degradable tissue, which is remodeled by endogenous cells (F); and other approaches that use endogenous pathophysiologic processes to generate "functionalized" starter matrices stimulating tissue maturation *in vivo* (G). After *in vitro* generation, the valvular replacement (H; TEHV) can be implanted via conventional open-heart surgery (I) or using novel cathether-based approaches involving valve crimping (J).

Tissue-engineered heart valves grown as valved conduits from autologous cells (derived from vascular wall or bone marrow) seeded on biodegradable synthetic polymers and matured *in vitro* have been explored by several groups working in the US and abroad. Cells used have varied across a wide spectrum, from mature vascular wall cells, to VICs, to bone marrow-derived mesenchymal stem cells (Schmidt et al., 2007). In this location, implanted constructs generated *in vitro* have evolved *in vivo* to a complex structure that, at the level of light microscopic histology, resembles that of the native aortic valve described earlier in this chapter. Moreover, the progression of the cell and ECM changes are analogous to those occurring during development and physiologic valve remodeling described earlier (Rabkin-Aikawa et al., 2004), suggesting that the dynamic, chemical, and mechanical environment *in vivo* provides signals that induce functional organization of the tissue construct to

a heart valve. This approach has been used to produce pulmonary arterial wall (without a valve) replacements to repair complex congenital heart disease in children (Shin'oka et al., 2005). Pulmonary arterial wall replacements fabricated from vascular wall cells (predominantly vascular smooth muscle cells) seeded onto a biodegradable polymer and implanted into very young lambs enlarged proportionally to overall animal growth over a two year period (Hoerstrup et al., 2006). Although wall thickness remained constant over the observed growth period, it is not yet fully understood whether this "functional growth," as we have called it, is comparable to physiological growth with new tissue accretion, or is rather passive dilation with valve cuspal and conduit enlargement.

The scaffold must also have appropriate geometrical design, density, and mechanical characteristics (e.g., strength and compliance) that allow valve-like function during *in vivo* "maturation" of the TE construct, and have non-toxic original materials and degradation products, biocompatibility, and a controlled rate of resorption. Hoerstrup et al. (2000) implanted PGA/P4HB valve constructs seeded with vascular wall cells and incubated *in vitro* for three weeks in lambs. Valves so fabricated have functioned in the pulmonary circulation of growing lambs for up to five months (Figure II.6.10.5). Postoperative echocardiography demonstrated mobile functioning leaflets without stenosis, thrombus or aneurysm up to 20 weeks. Histology (16 and 20 weeks) showed uniform layered cuspal tissue with endothelium. Complete degradation of the polymers occurred by eight weeks, and extracellular matrix content (collagen, glycosaminoglycans, and elastin) and DNA content increased to levels of native tissue and higher at 20 weeks. Stock has also demonstrated formation of pulmonary artery tissue with histology very similar to native tissue (Stock, 2000). Sutherland et al. (2005) utilized mesenchymal stem cells isolated from ovine bone marrow seeded on a polyglycolic-lactic acid/polyglycolic acid (PGLA/PGA) biodegradable scaffold to create autologous semilunar heart valves, and implanted into the pulmonary position of sheep. The valves were evaluated by echocardiography at implantation and at four months. These valves demonstrated trivial or mild regurgitation at implantation, and minimal gradients. Histology showed disposition of ECM and distribution of cell phenotypes in the engineered valves somewhat reminiscent of that in native pulmonary valves.

Interestingly, these studies have shown the gradual development of a tri-layered structure, including variations in collagen, GAG, and elastin after 4–5 months. However, it remains unknown whether these layers are functionally equivalent to those of the native valve, and what mechanisms guide their formation *in vivo*. Measurements of the mechanical properties of TEHV leaflet tissue suggest that these compare favorably with those of the native PV (Sacks et al., 2009a).
FIGURE II.6.10.5 Tissue-engineered heart valves *in vitro* and *in vivo*. (A): Gross photo of TE heart valve after 14 days of conditioning the cell seeded polymeric scaffold in a bioreactor (*in vitro*). (B), (C), (D) and (E): Photomicrographs of engineered heart valve cusps *in vitro* and *in vivo*, demonstrating evolution to near-normal structure after 16–20 weeks. (B): After 14 days of pulsatile flow, leaflet portion is composed of dense fibrous tissue near surface and loose central core (hematoxylin and eosin stain, magnification x 20). (C) At six weeks, there is early organization of tissue predominantly in outer (outflow) layer (top) (magnification 50 ×). (D): Cross-section of leaflet at 16 weeks shows layered cellular fibrous tissue, which is more dense near outflow surface (top) (original magnification 100 ×). (E) Cross-section of leaflet at 20 weeks demonstrates collagen (yellow), GAGs (blue), and elastin (arrow, inflow surface; original magnification 100 ×). (B), (C) and (D): Hematolylin and eosin. (E) Movat stain. (From Hoerstrup, S. P., Sodian, R., Daebritz, S., Wang, J., Bacha, E. A. et al. (2000). Functional living trileaflet heart valves grown *in vitro*. *Circulation,* **102,** III-44–49. Copyright American Heart Association)

In the second heart valve tissue engineering approach, fibroblast- or VIC-seeded natural degradable scaffolds under investigation include degradable scaffolds such as hyaluronan or fibrin gel (Masters et al., 2005; Robinson et al., 2008). Cell-free collagen constructs fabricated by directed collagen gel contraction are also being investigated (Shi et al., 2006).

The third, alternative tissue engineering strategy, called "guided tissue regeneration" (Brody and Pandit, 2007),

uses an implanted scaffold of a naturally-derived biomaterial or decellularized valve designed to attract circulating endothelial and other precursor cells, and provide a fertile environment for their adherence, growth, and differentiation. In this approach, and in contrast to the preparation of conventional bioprosthetic heart valves, the materials are not aldehyde-fixed or otherwise chemically preserved, as are conventional bioprosthetic heart valves. Cell-free porcine small intestinal submucosa (SIS)

has been investigated experimentally in a single valve cusp model (Matheny et al., 2000). In general, natural tissue-derived valve scaffolds possess desirable three-dimensional architecture, mechanical properties, and potential adhesion/migration sites capable of promoting cell attachment and ingrowth.

This concept is further employed in the fourth strategy, in which decellularized natural valve tissue is intended to become recellularized, and not to undergo early remodeling. Rather, the goal is to provide a durable and functional substrate. In some cases, *in vitro* "re-endothelialization" is performed prior to implantation, with the goal of catalyzing recellularization *in vivo*. Decellularized tissue scaffolds derived from valve (in some cases with *in vitro* "re-endothelialization" performed prior to implantation of the valve) have been used in clinical studies in the pulmonary position (Cebotari et al., 2006; Dohmen et al., 2007). However, decellularized porcine valves implanted in humans as aortic valve replacements elicited a strong inflammatory response and suffered structural failure, which has inhibited further use (Simon et al., 2003). The specific patient and implant variables accounting for the spectrum of outcomes are not yet understood, and the long-term fate of these implants, the role of endothelial cell seeding, and the extent of cellular ingrowth into decellularized tissue *in vivo* are not yet known.

Finally, other strategies have included the creation of a cellularized graft by maturation of tissue formed in association with either a microporus polyurethane valve assembly implanted into the subcutaneous space in rabbits (Hayashida et al., 2007, 2008) or a photooxidized bovine pericardial valve implanted intraperitoneally in sheep (de Vissscher et al., 2007). Additionally, in principle, a functional valve might be grown *de novo* in the valve location, as a synthetic valve replacement that undergoes transformation to valvular tissue over time via endogenous processes. Accumulating evidence suggests that circulating cells can be recruited *in vivo* to adhere to intravascular sites of injury or prosthetic material, via a pathway that likely mimics the adherence of inflammatory cells during physiological inflammation (Kumar et al., 2010). Thus, a potential strategy may be to coat a degradable polymer scaffold in the configuration of a valve with appropriate cell-signaling molecules (or use a biological matrix already containing such information as discussed above), in an effort to encourage and direct endothelial progenitor cell (EPC) and other cell adhesion and differentiation. An experiment utilizing decellularized porcine aortic valves containing fibronectin and hepatocyte growth factor suggested that the growth factor enhances early endothelial cell recruitment to, and coverage of, the grafts (Ota et al., 2005). Attempts to attract EPCs from peripheral blood onto grafts via antibodies directed at proposed EPC markers, such as anti-CD34 antibodies and kinase insert domain receptor (KDR), are under investigation (Aoki et al., 2005; Rotmans et al., 2005; Markway et al., 2008).

CHALLENGES FOR FUTURE TRANSLATION OF ENGINEERED TISSUE VALVES TO THE CLINIC

Translation of heart valve tissue engineering from the laboratory to the clinical realm has exciting potential, but also has formidable challenges and uncertainties. Although modest progress has been made toward the goal of a clinically useful tissue-engineered heart valve, ultimate human benefit will be dependent upon advances in biodegradable polymers and other scaffolds, cellular manipulation, strategies for rebuilding the extracellular matrix, and techniques to characterize and potentially non-invasively assess the speed and quality of tissue healing, remodeling, and potential complications. Specific hurdles include optimization and scale up of processing components and conditions *in vitro* to generate a highly functional and durable valve *in vivo*, selection and validation of suitable animal models, development of guidelines for characterization, and assurance of the quality of an *in vitro* fabricated tissue-engineered heart valve destined for human implantation, validation of the hypothesis that tissue evolution *in vivo* can be predicted and measured, and the development of strategies to understand, monitor, and potentially control patient variability in tissue remodeling *in vivo*. Additional technical (e.g., sterilization, storage, shelf-life, etc.), regulatory, and other challenges remain before this form of therapy can be validated as sufficiently safe and effective to warrant translation to clinical use. The major identifiable challenges and the research directions that will be necessary to overcome them are summarized in Table II.6.10.4.

> The possibility of therapeutic regeneration of the heart valves is indeed exciting; however, immense technical, regulatory, and other challenges remain before this form of therapy is validated as sufficiently safe and effective to warrant translation to clinical use.

A number of groups have attempted to develop engineered heart valve tissues *in vitro* using a variety of approaches described above, and although the goals of these studies were often to form functional tissue though a variety of cell types, the elucidation of predictive determinants (including cells, scaffold, bioreactor conditions) influencing reproducible tissue formation *in vitro* has proved difficult. Additionally, although many groups have focused much effort on controlling and quantifying EMC deposition, and emphasized that construct tissue properties are enhanced by dynamic conditioning using bioreactors with a flow regime that mimics that of the intended application (Cox et al., 2010; Ramaswamy et al., 2010), a rigorous evaluation of the *quality* of ECM produced is only beginning (Eckert et al., 2011). Though encouraging, current engineered tissue heart valve work is largely empirically-based, limited in scope, and has not yet clarified the time course of changes in structure

TABLE II.6.10.4	Major Challenges in Clinical Translation of Heart Valve Tissue Engineering
Challenges	**Research Directions**
TEHV components and their interactions are complex, heterogeneous, and dynamic	Define cell/scaffold/bioreactor combinations that optimize construct composition and properties (*in vitro*)
Correlation of *in vitro* generated construct structure and properties with *in vivo* outcomes has not been demonstrated	Determine and validate correlations between *in vitro* conditions, elements, structure, properties, and *in vivo* function
Quality control of construct structure and function is likely to be difficult	Develop guidelines, tools, and metrics for the pre-implantation characterization of TEHV structure, function, and quality
Animal models may not reliably predict human outcomes	Develop and validate animal models that will test key biological processes and correlate with human outcomes
TEHV structure is likely to be evolving *in vivo* and ongoing function may be less predictable than with conventional valve replacement technology	Develop guidelines, tools, and metrics for the *in vivo* characterization of dynamic TEHV structure, function, and quality
TEHV function will depend upon patient response to implantation, and integration with the recipient's tissues more than with conventional valve replacement, and individual patient responses may be highly variable	Identify/validate biomarkers that predict and assess patient variability in implant success/failure and are capable of non-invasive *in vivo* monitoring and potential control
Remodeling processes after implantation may release or change seeded cells and recruit host cells	Develop tools to monitor the fate of transplanted and endogenous cells (location, function, viability, phenotype)
Regulatory processes and approaches are not yet well-established	Create suitable regulatory approaches to engineered tissue valves that will ensure safety and efficacy

and mechanical behavior concurrent with tissue formation and remodeling, and, or demonstrated, the ability to measure tissue evolution.

A particularly difficult challenge is to develop appropriate methodologies to evaluate the evolving structural remodeling and functionality of valves implanted *in vivo*, especially in a non-invasive manner, so that a particular valve can be followed over time, without necessitating animal sacrifice (Hjortnaes et al., 2009). A schema for the interrelationships among and challenges in tissue characterization for clinical heart valve tissue engineering is summarized in Figure II.6.10.6. To establish such criteria, preclinical animal studies with long-term follow-up are required, based on derivation of predictive

models that can be used for evaluating the outcome of implanting tissue-engineered heart valves in humans. Evaluation of valve durability, biocompatibility, biomechanical properties, and the capability to repair and remodel *in vivo* are the principal elements. These properties need to be evaluated against a gold standard before and after implantation. With respect to autologous tissue-engineered heart valves, the aim must be for a design that mimics functionally, if not structurally, the performance of a healthy native heart valve *in vivo*, or at least be of similar and preferably better, functional quality as the heart valve replacements currently in use. It is also imperative, with respect to the role of tissue-engineered heart valves in treating congenital heart disease in pediatric patients or young adults, to show that the tissue-engineered heart valve has the ability to grow and remodel (Figure II.6.10.7).

As a component of an agenda for translating the notion of TEHVs from an extraordinarily interesting research curiosity to a clinically useful surgical tool, it is necessary to understand mechanisms, define animal models, develop biomarkers, develop assays/tools, define surrogate and true endpoints – and the major clinical goals – "i.e., to characterize and assure quality tissue constructs, accommodate patient-to-patient heterogeneity in tissue remodeling, and predict outcomes as early as possible. While studies using animal models such as sheep suggest some level of efficacy and safety, further detailed studies will be needed in these models, other animal models, and in humans. There is considerable controversy over to what extent results from available animal models translate directly to humans, and the most suitable animal model for testing tissue-engineered valves has not yet been determined. Juvenile sheep, for example, have been used for preclinical testing of conventional cardiovascular implants by the FDA and other regulatory agencies, since they replicate some of the features of clinically observed calcific degeneration due to the increased calcium metabolism associated with rapid growth (Barnhart et al., 1982). However, sheep produce an exuberant fibrotic response to cardiovascular implants; valves implanted in sheep generally overgrow more rapidly with fibrotic tissue than they do in humans, and, in tissue engineering studies, may overestimate tissue remodeling relative to humans. Non-human primates and perhaps senescent models may be more appropriate to investigate remodeling phenomena of tissue-engineered heart valves (Weber et al., 2011b). In addition, owing to immunologic considerations, the choice of an animal model for preclinical testing for allogenic or xenogeneic cell-based therapies presents unique challenges.

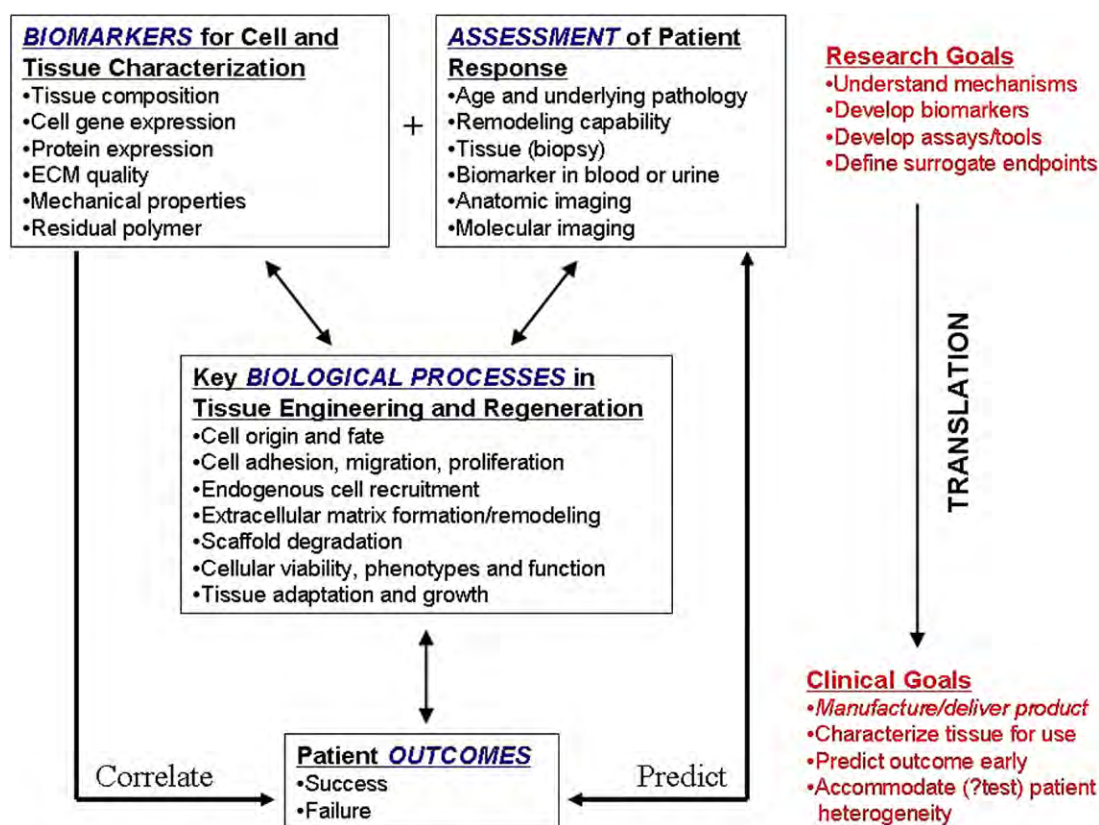
Moreover, currently available heart valve replacements have predictable behavior in many recipients, whereas *in vivo* remodeling of tissue-engineered heart valves will likely display considerable variability among patients, owing to heterogeneity among individuals in physiological tissue remodeling potential. Principles


FIGURE II.6.10.6 Paradigm for translating research in heart valve tissue engineering from the laboratory to the clinic. Biomarkers for cell and tissue characterization in conjunction with structural, chemical, and molecular information obtained via *in vitro* and *in vivo* models are necessary for understanding key biological processes in tissue engineering and regenerative medicine. These concepts and data can be used to predict and measure patient success and failure. Data from clinical experience further informs the development of appropriate biomarkers, which may result in reassessment of the appropriate characterization parameters. (Reproduced by permission from Mendelson, K. & Schoen, F. J. (2006). Heart valve tissue engineering: Concepts, approaches, progress, and challenges. *Ann. Biomed. Engin., 34,* 1799–1819. Copyright Springer)

analogous to those of pharmacogenetics, a field which seeks to understand the role of genetics in inter-individual variation in drug metabolism, may be useful (Pereira and Weinshilboum, 2009). Some patients might remodel their tissue-engineered valves too slowly, and this could lead to failure (Figure II.6.10.8). Person-to-person variation could be a result of mutations or polymorphisms in key proteins central to ECM remodeling. Indeed, as implants have become more interactive and integrative with the host tissues, there has arisen a corresponding need to understand and potentially control human variation in different facets of biomaterial–tissue interaction and the healing process.

To understand, monitor, and potentially control patient-to-patient differences in wound healing and tissue remodeling capability *in vivo*, measurable biomarkers that predict implant outcomes must be identified. Specific molecular biomarkers may be identified and validated by assessing tissue healing and remodeling during *in vitro* and *in vivo* experiments; suitable biomarkers will need to be followed *in vivo*, possibly via chemical assays in the serum or urine or via molecular imaging. Key targets for characterizing tissue-engineered constructs include tissue composition, cellular gene expression and

phenotype, ECM, key effectors of tissue remodeling, and tissue quality. These biomarkers could correlate directly with success and failure in order to generate surrogate endpoints, namely outcome measurements (such as laboratory assays or imaging results) that substitute for but reflect the mechanism of a significant clinical event or characteristic (such as valvular regurgitation, on stenosis, thromboembolism, calcification, infection, or death). Validated surrogate end points could be assessed longitudinally in an individual patient, in order to predict outcome as early as possible in the patient's course, and influence necessary changes in management.

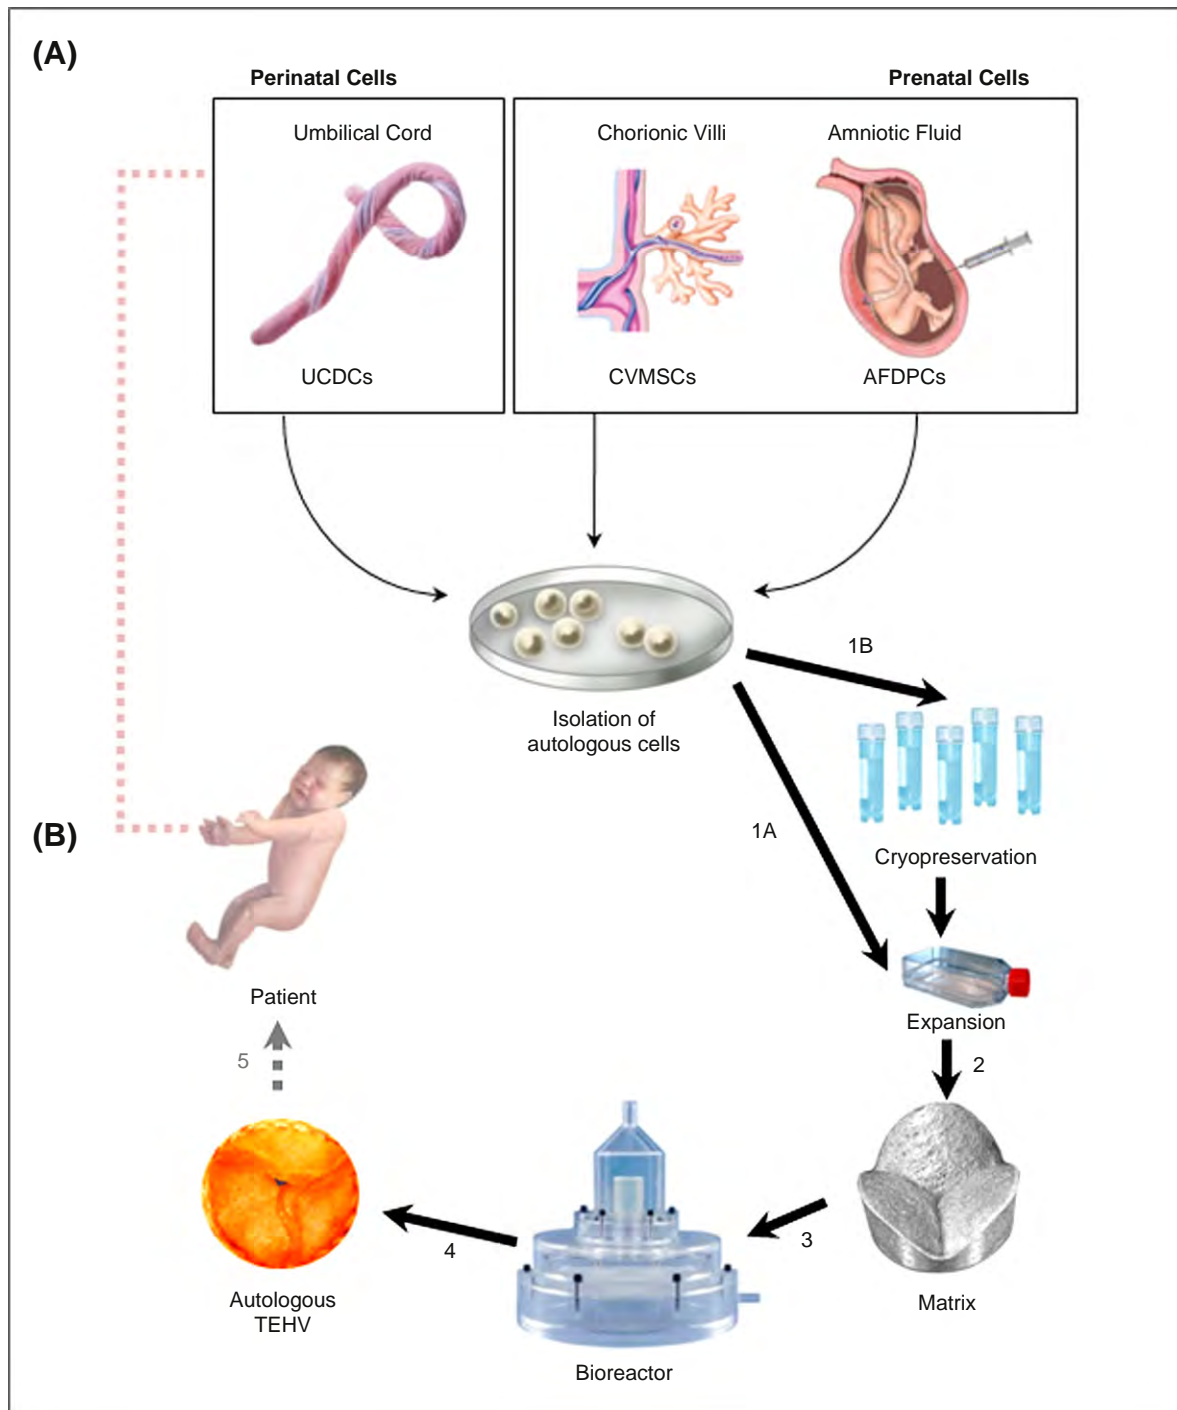
Conventional and innovative invasive and/or non-invasive anatomic and functional imaging modalities will certainly be important tools to assess success and failure. Molecular imaging is particularly exciting in this regard; it requires the identification of a molecular target, selection of a ligand that binds the target, selection of an appropriate imaging system, and synthesis of a molecular imaging agent to detect the desired target. *In vivo* molecular imaging has been used to demonstrate key enzymatic and cellular events in atherosclerosis and thrombosis (Jaffer et al., 2009). Molecular imaging can probe polymorphisms of ECM gene expression *in vivo*


FIGURE II.6.10.7 Pediatric heart valve tissue engineering. The concept of pediatric heart valve tissue engineering uses peri- and pre-natally accessible cell sources (A), for the fabrication of autologous tissue-engineered constructs prior to or shortly after birth (B). For this purpose fetal cells are harvested prenatally or perinatally, expanded *in vitro,* and either directly further processed (1A) or cryopreserved for later use (1B) depending on the ideal time window for surgical correction. Relevant cell sources include umbilical cord- or cord-blood-derived cells (UCDCs), chorionic villi-derived multipotent stem cells (CVMSCs), and amniotic fluid-derived progenitor cells (AFDPCs). After expansion, cells are seeded onto a biodegradable scaffold (2). After a short static phase, the constructs are positioned in a bioreactor system (3), and conditioned *in vitro*. When optimal tissue formation is achieved, tissue-engineered constructs (4) are ready for implantation (5).

in models of wound healing and cardiovascular disease, and can potentially be translated to perform real-time *in vivo* characterization of scaffold matrices (either seeded or with the potential of attracting endogenous cells) implanted in animal models.

Another important laboratory consideration for seeded scaffolds relates to the origin and fate of the cells seeded *in vitro*, and whether the seeded cells remain viable and attached to the scaffold following *in vivo* implantation. Molecular imaging could be utilized to track the
FIGURE II.6.10.8 An hypothesis for inter-individual variability in tissue remodeling. While most individuals will remodel tissue with a usual speed and quality of remodeling, some people will display slow and poor quality of remodeling while others will show fast and better quality of remodeling. Inadequate remodeling could lead to implant failure and its consequences for the patient. The threshold of properties needed for tissue-engineered heart valves and the means of conducting post-implantation surveillance of the patient and graft need to consider this variability. Success or failure may be followed and predicted non-invasively. (Reproduced by permission from Mendelson, K. & Schoen, F. J. (2006). Heart valve tissue engineering: Concepts, approaches, progress, and challenges. *Ann. Biomed. Engin.,* **34,** 1799–1819. Copyright Springer)

presence, migration, proliferation, and function of bone marrow-derived progenitor cells used to seed scaffolds both *in vitro* and *in vivo*. In future experiments, endothelial progenitor and mesenchymal stem cells might be labeled during the *in vitro* stage, and then analyzed *in vivo* using molecular imaging to ensure that they differentiate into appropriate cell lineages and that they remain functional and attached to the scaffold over time.

Since risk–benefit relationships of engineered tissue may be less predictable than those of accepted technology, and since contemporary heart valve replacements have considerable success in most situations (notwithstanding the limitations, and except in pediatrics), acceptance of tissue engineering by the surgical community may be slow. Finally, there may be practical hurdles and barriers that relate to commercialization that go beyond the "academic" considerations discussed above, including the ethics of use in children, especially where the long-term durability has not been proven (or been possible to prove), and the costs of this therapy are likely to be high. A hypothetical case study was developed for bioengineering students and is concerned with choosing between two devices used for development of a pediatric tissue-engineered heart valve (TEHV) (Merryman, 2008). The specific issues faced by start-up, development-phase, and established companies in the general field of tissue engineering/regenerative medicine in the product development, intellectual property, and regulatory arenas have recently been discussed (Johnson et al., 2010).

Several investigators have attempted to develop engineered tissue heart valves that could be deployed through a catheter (Metzner et al., 2010; Schmidt et al., 2010; Weber et al. 2011b), a mode of delivery that now uses

valves and is a procedure presently clinically restricted to elderly and otherwise high-risk patients (Walther et al., 2007). The valve substitutes presently used for minimally invasive replacement procedures are non-viable bioprosthetics (e.g., glutaraldehyde-fixed, etc.), and therefore are potentially vulnerable to calcification and progressive dysfunctional degeneration similar to that which occurs in conventional (surgical) non-viable tissue valves. In addition, as stated at the beginning of this chapter, there is growing evidence that catheter-based bioprosthetic valves show mechanical damage, and even accelerated degeneration, as a result of the substantial deformations that occur during the crimping/deployment procedures (Noble et al., 2009; Zegdi et al., 2011). Thus, a living engineered valve with the capacity for self-repair might be a more durable treatment option and enable the application of minimally invasive treatment modalities, especially in younger patients (Fernandes et al., 2007). Conceptually, the combination of minimally invasive valve replacement procedures with tissue engineering is appealing. Moreover, when combined with minimally invasive cell harvest (e.g., autologous adult stem cells), a clinically relevant complete minimally invasive tissue-engineered valve is particularly exciting, and may emerge as a useful clinical approach (Weber et al., 2011b) that synergizes the benefits of two novel technologies.

CONCLUSIONS

The goal of heart valve tissue engineering is to regenerate a functional structure containing endothelial and interstitial cells capable of continuously remodeling the ECM that functions structurally and biomechanically

as a valve leaflet. Despite an exciting potential for tissue-engineered heart valves, significant technical barriers must be overcome before widespread clinical application can be envisioned. Further success toward a clinically useful tissue-engineered heart valve will be dependent upon additional advances in biodegradable polymers, stem cell and other cell manipulation, strategies for recreating the ECM, understanding how to harvest the potential of endogenous recruitment of cells, and techniques to non-invasively assess the speed and quality of tissue healing and remodeling, both *in vitro* and *in vivo*. This need is likely to engender a host of novel testing strategies and methods, which will include *in vitro* safety studies, *ex vivo* performance characterization in functional testing devices akin to bioreactors, and *in vivo* preclinical studies. The key concepts that unify the dynamic pathobiology of heart valves and the mechanisms of heart valve disease may be used to improve biologic valve substitutes, and potentially enable heart valve regeneration.

CHAPTER II.6.11 CARDIAC MUSCLE TISSUE ENGINEERING

Amandine Godier-Furnemont and
Gordana Vunjak-Novakovic
Department of Biomedical Engineering, Columbia University,
New York, USA

INTRODUCTION

The human heart is a hugely complex tissue composed of multiple cell types that interact in a highly ordered manner as a compact and densely vascularized synctium. In this chapter we will focus on tissue engineering of cardiac muscle (myocardium). The metabolic demands of cardiac tissue, as well as the unique electromechanical properties governing its function, make the heart an especially challenging tissue to grow *in vitro* and regenerate *in vivo*. Development of human sources of cardiac cells, and the biomaterial scaffolds and bioreactors to appropriately recapitulate the right environment for these cells, have been crucial to progress within the field of cardiac tissue engineering. In this chapter we discuss the key requirements for tissue engineering of functional heart muscle, and how these requirements can be met in a laboratory setting. We describe selection of biomaterials, signaling paradigms, and the evaluating criteria for engineered heart tissue. Next, we describe advances in cardiac tissue engineering, envisioned applications of the tissue for *in vivo* therapeutic use (regenerative medicine) and as *in vitro* models of disease. Lastly, we address the challenges in engineering heart tissue *in vitro* and subsequent translation to the clinical setting.

CARDIOVASCULAR DISEASE AND THE NEED FOR ENGINEERED MYOCARDIUM

Cardiovascular Disease

A healthy heart will beat about three billion times during an average lifespan, pumping blood through our vasculature. However, once damaged, the heart does not heal by itself. Cardiovascular disease (CVD) is responsible for almost 30% of deaths worldwide. In the US, CVD is responsible for almost 40% of all deaths, with about 70 million Americans living with heart disease (American Heart Association, 2008). For those living with cardiovascular disease, it can lead to significant disabilities and contribute significantly to escalating healthcare costs. In the US, the economic burden of cardiovascular disease is approximately $300 billion per year, and this figure is expected to rise. The standard therapy for end stage heart failure remains heart transplantation, and the shortage of donated organs contributes to serious loss of life while waiting for an organ, with no other viable means to treat the heart. With practically no ability of cardiac cells to regenerate, scientists are working to develop functional muscle replacements in the laboratory setting that may be used to prevent deterioration of heart function or even contribute to regenerate the muscle.

Characteristics of Native Myocardium

The myocardium is a densely packed, highly ordered, and anisotropic structure, whose function is governed by the propagation of electrical signals, which induce mechanical contraction of cardiac myocytes. A specialized group of cardiac cells, pacemaker cells, initiate an electrical signal that is propagated throughout the heart; intercalated discs connect cardiomyocytes, with gap junctions allowing for rapid signal propagation, and synchronized contraction of the heart. Electrical conduction induces calcium release, and causes mechanical contraction of the cell's myofibrils.

The myocardium consists of cardiomyocytes, cardiac fibroblasts, and endothelial cells that populate the dense, embedded vascular network. Cardiomyocytes comprise about 20–40% of the total cells by number, and about 80–90% of the total tissue by volume. Cardiomyocytes are multinucleated and elongated cells that orient themselves parallel to the heart wall. The aligned cells are interspaced by dense vascular bed, with typical inter-capillary distances being only 20 μm (Rakusan and Korecky, 1982), which is the cross-sectional width of a single cell. This extensive vascular network supports the high metabolic activity of the heart tissue through transport of nutrients and, most critically, oxygen. The exchange of oxygen and its metabolic product carbon dioxide between the cells and blood occurs via hemoglobin in the blood. As an oxygen carrier, hemoglobin allows for a 100-fold increase in the amount of oxygen that can be transported through the capillaries to tissue, significantly increasing the total tissue mass that can be sustained.

Mechanical contractions of cardiomyocytes are mediated by the heart's dynamic extracellular matrix (ECM). Collagen is the primary loadbearing protein that makes up the connective tissue, although it alone constitutes a minute amount of the heart's mass. Collagen transduces the force expended by the myocytes in systole, as well as providing a passive stiffness during diastole, preventing dilation and edema of the muscle over time. Collagen type I makes up 85% of the fibrillar collagen in the heart, and collagen types IV and VI constitute the basement membrane. The heart's extracellular matrix includes fibronectin, laminin, vitronectin, and elastin, all of which contribute to cell adhesion and the loadbearing capacity of the heart.

At the cellular level, various proteins are involved in the mechanotransduction underlying the macroscopic beating of the heart. While collagen is responsible for diastolic stiffness, preventing further extension of already elongated cardiomyocytes, intracellular titin is responsible for passive stiffness at short sarcomere lengths. Active muscle contraction is regulated at the cellular level, starting with cell membrane depolarization that activates intracellular calcium release from the Sarcoplasmic Reticulum (SR), and raising cytoplasmic calcium concentrations. The free

cytoplasmic calcium binds to the troponin–tropomyosin complex, activating movement of the tropomyosin to unblock the attachment site for the myosin cross-bridge and allowing it to attach to the actin, resulting in contraction. The uptake of calcium into the SR reverses the process. The function of the heart is maintained by intercellular communication and junctions, which are in turn maintained by a functional extracellular matrix providing the necessary alignment, elasticity, and stiffness necessary to sustain the mechanical demands of the muscle.

Myocardial Infarction

Upon myocardial infarction, a patient can lose 50 grams of muscle mass. This substantial loss of functional muscle is due to hypoxia – lack of oxygen supply to the cells due to the interrupted blood flow – leading to the release of apoptotic factors that ultimately cause cell death. The inflammatory response elicited by myocardial infarction leads to rapid macrophage invasion, formation of granulation tissue, and ultimately remodeling of the myocardium into fibrous tissue.

The heart undergoes a three-step healing process that is characterized by the inflammatory, proliferative, and maturation phases. Within seconds of myocardial ischemia, hypoxia sets in in the myocardium, and within minutes, adenosine triphosphate (ATP) depletion of cardiomyocytes leads to an inability to contract, and eventually necrosis of the myocytes. During the inflammatory phase, dying cardiovascular cells release pro-inflammatory signals, leading to rapid infiltration of neutrophils that begin to clear the cell debris within the infarct. Within 24 hours, the myocardium is invaded by monocytes, which phagocytose apoptosed neutrophils, leading to the release of cytokines such as TGF-β that initiate fibrotic tissue remodeling during the proliferative phase (Frangogiannis, 2008). The first phase recruits Ly-6C^{hi} monocytes via CCR2 chemokines, while the second phase recruits Ly-6C^{lo} monocytes via CX$_3$CR1 chemokines. Ly-6C^{lo} monocytes exhibit phagocytic, proteolytic, and inflammatory properties, while Ly-6C^{lo} monocytes promote healing via myofibroblast accumulation, angiogenesis, and matrix deposition (Nahrendorf et al., 2007).

During phase I, monocytes are recruited to the site of injury, and begin to differentiate into macrophages. Initially, classical (M1) activation of monocytes and macrophages takes place, leading to the production of nitric oxide (NO) and pro-inflammatory cytokines such as IL-1β, IL-6, and TNF-α. M1 activation is typically associated with inflammation, tumor resistance, and graft rejection, and is followed by phase II with the recruitment of anti-inflammatory monocytes, and their activation into anti-inflammatory macrophages (alternative macrophage activation, M2).

M2 monocytes/macrophages exhibit a non-inflammatory profile with the expression of arginase 1 and 2, and TGF-β.

M2 activation is associated with immunoregulation, matrix deposition, remodeling, and graft acceptance (Martinez et al., 2006; Nahrendorf et al., 2007; Brunelli and Rovere-Querini, 2008; Lambert et al., 2008). M2 macrophages become the dominant macrophage at the later stages of myocardial remodeling, and continue to turn over the ECM during scar formation, as well as activating resident and infiltrating endothelial and fibroblast cells promoting angiogenesis. The scar tissue alters the ECM content in the myocardium, reduces contractile function of the heart, and leads to wall thinning and dilatation, extracellular matrix remodeling, and ultimately heart failure.

CONSIDERATIONS FOR ENGINEERING CARDIAC MUSCLE

The limited ability of the heart to regenerate following infarction has spurred the current therapies for terminal heart failure that involve the injection of stem cells (experimental therapy, with variable results), and heart transplantation (clinical therapy, limited by the scarcity of donor hearts). Tissue engineering could radically change the way we treat heart disease, if some of the recent advances in the derivation of human cardiomyocytes and the development of technologies for cell delivery and tissue engineering are translated into clinical practice.

Engineered heart muscle must be able to support physiologic levels of diastolic loads, while producing sufficient systolic force to result in whole muscle contraction that is sufficient to create the pressure needed to pump blood through the body. The structure supporting the cardiac myocytes must not fatigue over time, or lead to dilation and thinning, but must rather be able to withstand the change in force and contraction of the muscle with sufficient compliance to sustain the heart cells. The graft must not illicit an immune response, present phenotypic stability of cells throughout its lifetime, and must be prepared to function and survive in the ischemic environment of failing heart tissue. Most importantly, engineered heart muscle intended for clinical use must have the ability to integrate both electrically and mechanically with the host muscle, and a graft will need to establish a vasculature *in vivo* that is sufficient to supply the graft with the oxygen and nutrients necessary to support long-term survival and function, and prevent necrosis of the tissue.

The myocardium is a very complex tissue, and the macroscopic function of the heart is made possible from specialized cell organization and control at every hierarchical level, from the subcellular to the macroscopic. We discussed how molecular interactions enable nanoscale movements of actin, resulting in microscopic contraction of individual cells – an action propagated throughout the heart and resulting in the whole organ contraction. At the macroscopic scale, tissue engineers need to develop constructs that will effect change in the ailing heart. To engineer a centimeter thick muscle (human myocardium

is ~1.5 cm thick), we will need to overcome the current limitations of diffusional supply of nutrients and, most critically, oxygen necessary to sustain dense cell populations *in vitro*. At the mm scale, cell alignment and intercellular connections necessary for assembling the anisotropic structure of the heart can be facilitated by scaffolds with grooves or aligned fibers, and further facilitated by electrical and mechanical stimulation. To induce cell alignment and coupling, cells must be cultured at a high density (~10^8 cells/cm^3), and to sustain them, vascularization must be addressed, as will be discussed in detail in the section on Challenges and Future Applications.

At the μm and nm scale, the cell's cytoskeleton must be fully developed to enable the physical contraction of cells. Engineers must address cell adhesion kinetics and scaffold stiffness that enables cells to display the appropriate morphology to orient their scaffold in a way that permits physiological cell contraction. Several groups have demonstrated the importance of cell shape in determining cytoskeletal arrangement and resulting contractile capabilities. At the subcellular and nanometer scale, functional gap junctions and channels must develop in the cardiomyocytes to enable intracellular junctions capable of electrical impulse propagation – a conduction velocity of about 0.5 m/s through the ventricular mass. Additionally, cell–matrix adhesions dictate morphology and cell orientation, and proper ion channel kinetics to allow for ion transfer to induce physiologic cell contractions.

Tissue engineering offers the possibility of controlling the assembly of myocardium at each of these levels – from the subcellular to macroscopic tissue organization. The general approach of tissue engineers is shown in Figure II.6.11.1, and involves three principle components: (1) cells; (2) scaffold; and (3) bioreactor.

Cells act as the building blocks of tissue. Responding to the signaling imparted by the scaffold and bioreactor, cells adapt to their environment and themselves engineer new tissues, changing their individual phenotypes, forming intracellular junctions, and creating and interacting with the extracellular matrix. Engineered scaffolds provide the three-dimensional environment for cells to adhere to, and to interact with each other. Scaffolds tailored to a specific application can be engineered to be bioactive (interact with the cells), with specific porosities, mechanical properties, and degradation rates to complement tissue development. In tissue engineering applications for the heart, scaffolds are generally intended to provide instructional and temporary support to cells – inducing alignment, providing appropriate stiffness to induce cells to generate physiological force, but also to degrade over time, as the cells digest the scaffold and replace it with generated extracellular matrix proteins.

Lastly, bioreactors provide cells seeded on scaffolds, with environmental control that is biomimetic. Bioreactors are engineered to provide basic control at the level of carbon dioxide and oxygen control, up to the inclusion of perfusion loops for medium flow, and electrical and mechanical apparatus for stimulation of the constructs. The inclusion of such tools for the culture conditions, and the manner in which bioreactors are constructed,
FIGURE II.6.11.1 Cardiac muscle tissue engineering paradigm. Cardiovascular cells are cultured on a biomaterial scaffold, in a bioreactor providing environmental control and biophysical stimulation. The resulting engineered constructs are studied *in vitro* (as models of disease, for drug testing), and *in vivo* (in the implantation model of cardiac ischemia).

enable scientists to provide dynamic spatiotemporal control over the culture of scaffolds. Overall, the use of cells seeded on scaffolds and cultured in advanced bioreactors can provide the overall culture conditions conducive to cardiac tissue formation *in vitro*. Each of these components will be discussed in further detail below.

The Heart Does Regenerate Itself … Sort of

It has been widely thought that the heart does not regenerate itself, with cardiomyocytes arrested in a post-mitotic state. In 2009, Bergmann et al. in their landmark paper in *Science* (Bergmann et al., 2009), reported that cardiomyocytes do in fact renew themselves at a rate of 1% per year during the first 25 years of life, and this is decreased to a rate of 0.45% per year by the age of 75. This means that less than half of the heart cells we are born with are changed during the average lifespan. How did they figure this out? Researchers took advantage of Cold War nuclear bomb tests that released Carbon-14 (prior to these tests mainly Carbon-11 was found in nature) into the atmosphere, which was subsequently incorporated into our DNA, to effectively carbon-date our cells.

Cardiovascular Cell Populations

The traditional cell model for cardiac tissue engineering has been neonatal rat cardiac myocytes. Neonatal rat cardiomyocytes are commonly used because they are relatively easy to obtain and culture, and exhibit phenotypic stability for up to 10 days in monolayer culture. Additionally, the neonatal cells provide a baseline from which maturation of the cells with biophysical signaling can be studied, and an excellent opportunity for comparing data between numerous studies from different research groups. With the use of neonatal rat myocytes, there is a mixed population of cardiovascular cells, although this can be enriched to select for cardiomyocytes, cardiac fibroblasts or endothelial cells.

It is becoming increasingly clear that a functional cardiac graft cannot uniquely contain cardiomyocytes, but rather should include various subpopulations, including vascular cells and cardiac fibroblasts. It has been shown that preculture of scaffolds with cardiac fibroblasts and/or endothelial cells may contribute to the stabilization of cardiomyocytes, and overall enhancement of the graft's function. This is likely due to the secretion of soluble factors and extracellular matrix components that increase adhesion and promote a functional phenotype in the co-cultured cardiac myocytes. Furthermore, endothelial cells have the unique capability to form stable vessel-like structures within the tissue, which may become functional vascular networks over time.

To make cardiac tissue engineering a clinical reality, human sources of cardiomyocytes and supporting vascular cells need to be established. Adult cardiomyocytes are terminally differentiated, and have an extremely low rate of self-renewal (Bergmann et al., 2009), necessitating the use of stem and progenitor cells. The presence

of resident cardiac progenitor cells in the heart has been demonstrated (Laugwitz et al., 2005); however, the low frequency of these cells and very difficult harvesting do not make them a practical cell source. Adult stem cells (e.g., from bone marrow, blood or fat) have demonstrated little proliferative and myogenic potential that could be readily scaled to the necessary numbers needed for clinically relevant pieces of muscle. At this time, exogenous human stem cell sources – embryonic and induced pluripotent stem (iPS) cells – represent the two sources of cells with myogenic potential that are being actively explored. As with their application to other tissue types, the use of embryonic and iPS stem cells will need to be closely monitored for tumorigenic potential and genetic stability before they can be safely introduced into the clinical setting. Overall, the selection of specific cell populations will play an important role in the outcome of experiments, and each cell type will likely require optimization of the derivation and differentiation methods to achieve the formation of functional tissue grafts.

Choice of the Biomaterial Scaffold

Biomaterials for cardiac tissue engineering must have the appropriate porosity, structural arrangement, and stiffness and compliance characteristic of native myocardium. Several types of biomaterials have been explored for cardiac applications, and some of these categories are shown in Figure II.6.11.2. Broadly, these can be categorized as porous, fibrous or hydrogel based, and can be fabricated in a variety of ways to seed or encapsulate the cells within. For each of these categories, it is important to mimic the native architecture of the heart matrix at certain developmental stages. Numerous studies have been performed to achieve this goal using: (1) a porous matrix that allows for rapid inoculation of cells that will self-align; (2) a fibrous scaffold that provides the appropriate organization for alignment at the micrometer scale; or (3) a biologically derived hydrogel. Mechanical properties are dependent on the material and fabrication techniques, and are an important parameter, as substrate stiffness has been shown to affect stem cell lineage specification (Engler et al., 2006) and cardiomyocyte contraction.

Gel substrates used for cardiac tissue engineering include collagen, Matrigel, fibrin, and hyaluronic acid. Native tissue-derived porous scaffolds include decellularized myocardium (Ott et al., 2008; Wainwright et al., 2009) (discussed in the section Biophysical Stimuli: Biological, Electrical, and Mechanical Signals), which boast fully maintained ECM components, as well as intact mechanical properties and ultrastructure. Other ECM-derived products are commercially available as powders (that can be used to make hydrogel) or porous sheets. The biocompatibility, constituency and preserved bioactivity can make ECM a biomaterial of choice for *in vivo* cardiac applications.

Synthetic biomaterials including various polyesters (e.g., polyglycolic acid, PGA; polylactic acid, PLA) have

Examples of Biomaterials for Cardiac Muscle Tissue Engineering

2. Hydrogel
3. Biologically active material
4. Engineered heart matrix
5. Native tissue-derived matrix
FIGURE II.6.11.2 Examples of biomaterials for cardiac muscle tissue engineering.

been explored (Akhyari et al., 2008), yet their lack of biological function makes these materials less amenable to tissue growth, and typically elicit an immune response *in vivo*. Various polymer structures have integrins and binding proteins tethered to them to increase cell adhesion and survival. Others incorporate microspheres loaded with various growth factors, with tailored kinetics such that local delivery of the growth factors to the cells within the polymer is time-dependent and can be used to induce differentiation or stabilize phenotype of the cell population. This custom tailoring of scaffolds for specific applications has enabled control of the physical environment of the cells, and – in a very precise manner – control of the temporal dynamics of the cellular microenvironment. A scaffold with bound targeted gene sequences has even been introduced as a means for ischemia-activated gene therapy for the heart with spatiotemporal control (Tang et al., 2005).

Structural scaffold design for the heart is particularly appealing given the anisotropy, high cell density, and high metabolic demand of the cells. Tailored to these three criteria, several groups have developed channeled and grooved scaffolds to foster cell alignment and elongation, and at the same time ensure sufficient cell infiltration in the scaffold and access to the oxygen and nutrients. Some examples include aligned woven or fibrous scaffolds (Boublik et al., 2005; Lunkenheimer et al., 2006), organ-printing methods with hydrogels (Mironov et al., 2003; Fedorovich et al., 2007), engineered honeycomb-like structures (Engelmayr et al., 2008), and use of passive or dynamic tension of hydrogels to induce cell alignment (Zimmermann et al., 2006a,b).

The combination of various biomaterials has led to results that may strike a balance between mechanical properties, biological function, and structural integrity. Using hydrogels to encapsulate cells and inoculate fibrous scaffolds is an approach that provides a way to infuse and retain cells within a stiff matrix, and have a biologically relevant microenvironment for the cell, while retaining the mechanical properties characteristic of the tissue (Radisic et al., 2004, 2007).

Biophysical Stimuli: Biological, Electrical, and Mechanical Signals

In recent years, there has been a general consensus that physiological stimuli need to be applied to the cultures of cells on scaffolds, to guide the functional assembly of tissues. The heart's complex function revolves around organized sequences of electrical and biological signals that induce mechanical contraction, and various groups have sought to apply one or more sequences of this paradigm in the *in vitro* cultivation of cardiac tissue. The biochemical, hydrodynamic, mechanical, and electrical signals have been explored both independently and in combinations, with a growing notion that a "biomimetic" approach, in which the cells are subjected to sequences of signals they encounter *in vivo*, is necessary to unlock the full biological potential of the cells.

Biochemical Cues. The inclusion of soluble factors in culture media is critical for inducing and maintaining the differentiation of stem cells into cardiac phenotypes. In grafts that include vascular cell populations, growth factors such as VEGF and PDGF are also needed to promote vascular network formation within the tissue, *in vitro* or *in vivo*. Finally, the supporting cells (e.g., pericytes) or the factors they release may be needed to stabilize and mature the newly formed vascular conduits.

A 2007 paper by Laflamme and Murry (Laflamme et al., 2007) described the use of a "prosurvival cocktail" (PSC) to protect against apoptosis of embryonic stem cells that are injected directly into the ischemic heart environment and exposed to harsh apoptotic and pro-inflammatory factors. The inclusion of such factors utilized in this cocktail with grafted engineered tissues may prove instrumental in the survival of the muscle in the *in vivo* setting.

One of the major constituents of the PSC includes Matrigel to act against anoikis (apoptosis due to an inability of a cell to form cell–matrix adhesions). Additional factors include IGF-1 (insulin-like growth factor 1) to activate the Akt pathway (involved in cell survival via anti-apoptotic processes); pinacidil (KATP channel

opener which mimics ischemic preconditioning); cyclosporine A, to block cyclophilin D-dependent mitochondrial death pathways; the pan-caspase inhibitor z-VADfmk (anti-inflammatory and anti-apoptotic agent); and a cell-permeant TAT peptide from BclXL, to block mitochondrial apoptotic pathways. Interestingly, Matrigel, a mouse basement membrane preparation, was the only factor shown to induce significant protection when used alone, suggesting that anoikis due to cell detachment is an important path to death after cell transplantation. In addition to promoting cell adhesion through integrin receptors, Matrigel can facilitate cell retention.

> Matrigel is a heterogenous solution made of collagen and laminin, rich in extracellular matrix components and growth factors, that promotes the survival and differentiation of various cell types. Matrigel is unique in its ability to induce endothelial cells to form tube-like structures, and has been used extensively in cardiac tissue engineering applications. Radisic et al. (2004) used it to seed Ultrafoam collagen sponges, and with electrical signaling induced functional tissue assembly of neonatal rat cardiomyocytes. Using the same cells, Zimmermann et al. (2002a, 2006a) used a collagen and Matrigel mixture to achieve similar results using mechanical stimulation, and further demonstrated successful engraftment in injured hearts of rats. Lastly, Laflamme et al. (2007) used Matrigel as a delivery vehicle for embryonic stem cells to the heart, and cited its value in guarding against cell anoikis in the infarct. The repeated use – and advantages – of Matrigel in cardiac tissue engineering is not yet fully understood, but it appears critical to the success of tissue assembly and successful engraftment *in vitro*.

Electrical Cues. The first report that electrical stimulation could be used to enhance functional tissue assembly by cardiac myocytes cultured on biomaterial scaffolds came in 2004 (Radisic et al., 2004) (the study is discussed in the section on Biomimetic Culture Systems for Cardiac Tissue Engineering). This system utilized carbon electrodes to deliver the current to the culture media, wherein an electric field was established. Since this landmark study, others have explored different methods and parameters for stimulating the cells, and several platforms for electrical stimulation of cultured cells and tissue constructs have been proposed (Tandon et al., 2009).

The same group later analyzed various candidate electrodes (nanoporous carbon, stainless steel, titanium, and titanium nitride) to determine the best electrode for cardiac tissue engineering applications (Tandon et al., 2006). By studying electrode characteristics and charge-transfer profiles, including Faradaic and non-Faradaic charge transfer, current injection, carbon was identified as the best electrode for such an application. This was further confirmed by the quality of engineered cardiac tissues that resulted from exposure to electrical fields, including assessment of the amplitude, and threshold of contraction and maximum capture rate.

In 2011, the Radisic group compared monophasic and biphasic stimulation of cardiac constructs with differing ratios of cardiovascular cell populations (Chiu et al., 2011). The biphasic stimulation group significantly differed from monophasic stimulation, and achieved higher cell density, upregulation of Cx-43, electrical excitability, three-dimensional organization and elongation of cells, and – most importantly – lower excitation thresholds than constructs subjected to monophasic stimulation. Additional studies have determined that direct currrent (DC) stimulation of cardiomyocytes, a regime relevant to early cardiac development, may also enhance cell elongation and migration. The electric field-mediated effects of galvanotaxis and galvanotropism may play a future role in three-dimensional cultures, as the directionality of cells plays an especially important role for the heart tissue.

The use of microarray bioreactors and bioreactors with interdigitated arrays of electrodes has allowed systematic studies of electrical stimulation of single cells, embryoid bodies formed from human embryonic stem cells, and cardiac tissue constructs (Marsano et al., 2008; Cimetta et al., 2009a; Serena et al., 2009; Tandon et al., 2009). These technologies have provided critical information regarding how an external electric field is processed by cardiomyocytes, and continues to contribute to our understanding of electrical stimulation on centimeter-scale tissues.

Mechanical Conditioning. As an electrical signal propagates through the gap junctions of cardiomyocytes in the form of ions each individual cardiac myocyte contracts, resulting in the synchronized contraction of the heart muscle. Fink et al. (2000) proposed that directly applying the mechanical stretch to embryonic chick or neonatal rat heart cells cultured in hydrogel would increase cell alignment and function. In that and later studies (Zimmermann et al., 2006a,b), unidirectional and cyclic stretch of the hydrogel constructs resulted in mature, adult like engineered heart tissue, and *in vivo*, led to stable muscle grafts that prevented deterioration of heart function and exhibited electromechanical integration with the host tissue. While the mechanism by which heart cells sense and generate force in response to exogenous factors is not totally understood, these research groups have demonstrated that their role is instrumental in forming functional cardiac tissues. Various mechanical stimulation studies are discussed in detail in the section on Culture in Hydrogel with Mechanical Stimulation.

Mass Transport

In the human body, oxygen transport through the blood and to the tissues relies on the combination of convective (bulk movement of oxygen in blood) and diffusive (passive movement to tissue driven by concentration gradients) components. Hemoglobin inside red blood cells enables high concentrations of oxygen to be transported

to tissues. Oxygen has low solubility in blood (only ~7 mg/liter), but when bound to hemoglobin, the oxy-hemoglobin complex can be carried through blood, enabling a high rate of oxygen transport to provide sufficient oxygen supply to all of the cells in the body (Boron, 2002). The delivery of oxygen from red blood cells to tissues is facilitated by oxygen gradients. Oxygen must unbind from the hemoglobin and be transported across the blood vessel walls before reaching tissue. The oxygen gradients allow for primarily transcellular transport through capillary endothelium, as well as some convective-driven transport through the intercellular clefts in the capillary endothelium. Oxygen concentration gradients facilitate its movement through the depth of tissues, allowing a rapid and continuous supply of oxygen to reach tissues at the rate at which it is consumed.

To achieve sufficient mass transport throughout engineered tissue, researchers have used perfusion-based tissue culture, channeled scaffolds, and oxygen carriers, to enhance availability of oxygen and nutrient supply throughout the depth of the tissue (Radisic et al., 2005, 2006a,b, 2008). Early studies characterized the diffusion limits of cardiac tissue, demonstrating oxygen gradients prevent sustained cell viability in engineered tissue at >100 μm construct depth, whereas cardiac muscle is typically 1 cm in thickness. It was demonstrated that perfusion of culture medium supplemented with perfluoro-carbons (PFCs) significantly enhanced cell viability, and penetration of oxygen and nutrients into greater depth of cultured constructs.

To enable the application of convective regimes of oxygen transport, specific scaffold architectures needed to be developed. While medium flow through porous scaffolds enables higher cell survival, perfusion of medium through the scaffolds resulted in non-physiologic shear stress on the cells. In native tissue, blood flows through the vasculature lined with endothelial cells that are exposed to the shear forces, while the muscle is shielded from these forces. Exposure of muscle cells to shear may affect their phenotypic stability and ability to form the cell–matrix interactions necessary for function.

To provide a native-like oxygen supply, without exposing cells to hydrodynamic shear, channeled scaffolds have been introduced as a means of mimicking vasculature (Radisic et al., 2008). While tailoring scaffolds to increase porosity was an early approach to minimizing diffusion limits to provide oxygen and nutrients to the cells, later advances in scaffold development used porous elastomers that were laser pierced to enable medium perfusion through the channels, rather than through the cell-seeded bulk phase of the scaffold. This is shown in the bottom left panel of Figure II.6.11.3. While the channels made thus far have been in the order of 200 μm in diameter, and spaced several hundred μm apart, *in vivo* capillaries are in the order of 10 μm, with intercapillary distances of about 20 μm, approximately one capillary between every two cardiomyocytes (Rakusan and

Recent Studies in Cardiac Muscle Tissue Engineering
FIGURE II.6.11.3 Recent studies in cardiac muscle tissue engineering.

Korecky, 1982). Patterning of high resolution features to create vascular structures at physiological density and size, within engineered heart muscle, may be the next step forward in scaffold development to combat the issue of sustaining engineered heart muscle.

Bioreactor systems with medium perfusion are also very convenient for achieving spatially uniform, high-density seeding of cells on scaffolds with the maintenance of cell viability. Perfusion of media through non-channeled scaffolds exposed cardiac cells to non-physiologic hydrodynamic shear, as intramyocardial capillaries typically shield cardiomyocytes from shear stress while allowing for mass transport throughout the depth of the tissue. Channeled scaffolds were introduced into perfusion culture systems to mimic the capillary bed and reduce the amount of shear seen by muscle cells. Channels were strategically placed to ensure sufficient oxygen and nutrients would diffuse to the cells in thick constructs. Methods developed for direct perfusion (interstitial flow) cell seeding were later extended to seeding of channeled scaffolds to breach closer to the *in vivo* setting. The main technical problem that needed to be solved is to perfuse cell suspension through the scaffold pores, while keeping the channels open.

A perfusion culture system was developed for use with channeled, porous or fibrous scaffolds, and the PFC-supplemented media to provide *in vivo*-like oxygen supply (Radisic et al., 2005). Mathematical modeling was also used to predict interstitial flow through each scaffold type that would support low levels of hydrodynamic shear to ensure cell viability, and the ability for cells to elaborate their matrix was not compromised.

More recently, methods for perfusion seeding of both non-channeled and channeled scaffolds with cardiomyocytes have been developed (Radisic et al., 2008). Notably, these methods enable spatial specificity of the seeded cells, with cardiomyocytes seeded into the porous bulk phase, and endothelial cells seeded onto the channel walls.

The use of perfusion-based culture systems combined with other biophysical signaling paradigms in advanced bioreactors may further enable researchers to culture thick, functional cardiac tissues for large animal-scale studies in the future. One of the conditions for the effective use of these systems is the development of biomaterial scaffolds with porosity in the bulk phase (to allow cell attachment, and protect the cells from flow-induced hydrodynamic shear), and an array of parallel channels (to allow organized flow of culture medium, with short diffusional distances, and lumens for the attachment of endothelial cells).

Biomimetic Culture Systems for Cardiac Tissue Engineering

Several groups have undertaken development of bioreactors to recapitulate the *in vivo* milieu in a controllable, *in vitro* system (Bursac et al., 1999; Zimmermann et al., 2002b, 2006b; Radisic et al., 2004; Gerecht et al., 2007; Marsano et al., 2008; Tandon et al., 2008, 2009; Cimetta et al., 2009b,c; Serena et al., 2009). A combination of scaffolds and bioreactors allows for integration of environmental control (temperature, pH, osmolality, oxygen levels, nutrients, and metabolites) and biophysical stimuli (electrical, mechanical, perfusion, hydrodynamic shear) to guide cell differentiation and assembly into a syncytium. Environmental control, as well as modular systems for introducing mechanical and electrical signals, allows for these culture systems to be used as high-throughput screening platforms for drugs. In cardiac tissue engineering, the principal requirements include sufficient oxygen supply, mechanical and electrical signals, and the application of molecular factors.

Evaluation of Engineered Cardiac Tissue

Engineered cardiac constructs are evaluated with respect to their molecular composition (marker expression, composition), structure (cell morphology, ultrastructure, tissue organization, and anisotropy), and function (electromechanical coupling, signal propagation, force generation, responses to pharmaceutical agents) (Zimmermann et al., 2002a, 2006a; Radisic et al., 2004).

Both *in vitro* and *in vivo* assessments can be used to characterize the function and therapeutic potential of engineered cardiac muscle. Gross assessments include the seeding distribution, morphology, and survival of cells in a scaffold. Additional staining can be done for cardiac proteins (connexin-43, cardiac troponin I, α- and β-Myosin Heavy Chain), as well as cytoskeletal proteins (actin), and high-magnification imaging (TEM) to evaluate ultrastructure (A, I, M, Z bands, mitochondria, and cardiac-specific subcellular structures).

Functional assessments include quantifying the frequency and fractional area or volume change of an engineered construct and can be done optically, by taking videos and using an algorithm to quantify the contractions. Additionally, inclusion of a force transducer allows for estimation of the force of contraction generated by the cells. To assess electrophysiological parameters, constructs are paced with an electric field, to determine excitation threshold and maximum capture rate. Alternatively, electrodes and imaging with voltage sensitive dyes are used to measure signal propagation and conduction velocity.

Translational studies involve *in vivo* models of human disease, in which engineered heart tissues are tested for their ability to prevent deterioration of, or reverse, heart damage. Animals undergo a surgical ligation of their left anterior descending (LAD) artery to prevent blood flow to the left ventricle (induce a myocardial infarction). This is the most common model of myocardial infarction, and engineered muscle constructs are implanted over the injured site; in some studies, the damaged ventricle is excised and replaced with the engineered tissue. Following several days to weeks *in vivo*, animals are sacrificed, at which point hearts are excised for histological analysis. Typically, researchers look for signs of an immune response, integration of the implant with host tissue, cell migration, differentiation or change in phenotype, vascularization of the infarct or construct, and signs of apoptosis or necrosis in the graft.

Functional assessments *in vivo* include standard echocardiography measurements of the heart that can be taken at various stages, including before and after infarction of the heart, and at various time points following implantation of a graft. Echocardiography can provide critical information regarding the function of the heart. Key parameters include ejection fraction, cardiac output, end systolic diameter, end diastolic diameter, and fractional shortening. An imaging technique, SPECT (Single Photon Emitting Computed Tomography) can be used to determine perfusion in the heart and graft, and various cell-labeling techniques can be employed to track the movement and fate of cells *in vivo*.

SOME REPRESENTATIVE STUDIES IN CARDIAC TISSUE ENGINEERING

There are several approaches for engineering cardiac tissues designed to overcome diffusional limitations of mass

transport, and to maximize the conductive and contractile functions in a different way, that use a remarkably diverse range of biomaterials. The most extensively used approaches include cell cultivation: (1) in stackable cell sheets; (2) anisotropic cardiac-like scaffolds; (3) on porous scaffolds derived from native heart tissue; (4) in hydrogels with mechanical stimulation; (5) in porous scaffolds with electrical stimulation; and (6) injectable hydrogels.

Scaffold-Free Methods: Cell Sheets and Discs

The simplest form of cardiac tissue engineering is scaffold-free cultivation of cell sheets. In their 2002 paper Tatsuya Shimizu and colleagues (Shimizu et al., 2002), reported the creation of scaffold-free cardiac grafts using a novel cell-sheet stacking technique. The group cultured neonatal rat cardiomyocytes on temperature-sensitive polymer surfaces that, with temperature change, allowed for detachment of intact monolayer cell sheets from the adhesive surface, leaving gap junctions, integrins, and extracellular matrix produced by the cells intact. The group stacked four monolayer sheets and demonstrated the formation of intracellular junctions between the layers, resulting in three-dimensional cardiac constructs approximately 80 μm thick. The study demonstrated the viability and contractile function of cardiac grafts for up to three months when implanted subcutaneously, stressing the utility of this approach. In this study, only four sheets were layered to form a graft, although it is conceivable that thicker cardiac tissue grafts could be generated in this manner. To address the diffusion constraints associated with multiple-layer stacking, the authors propose that endothelial monolayer sheets could be placed between layers to promote vascularization.

The approach of engineering heart tissue without the use of a scaffold has been more recently explored by the Murry group (Stevens et al., 2008), whose development of a scaffold-free cardiac patch with human embryonic stem cells demonstrated that hES matrix formation and cell aggregation alone were sufficient to generate synchronously contracting cardiac tissue. The group cultured embryonic stem cell-derived cardiomyocytes in a rotating orbital shaker over 11 days, where cell aggregates into macroscopic cell discs ranging from 1.9 to 10.7 mm in diameter, depending on cell number. Embryonic stem cells differentiate into a heterogeneous cell population, and can give rise to any of the three germ layers.

To characterize the cardiac patches, researchers used antibodies against epithelial, endodermal, and neuro-ectodermal markers, and observed minimal presence of non-cardiac cell populations by day 11 in culture. To complement this trend, an enriched cardiomyocyte population was observed over time, as non-cardiomyocyte populations appeared to diffuse out of the disc into the media, while cardiomyocyte populations within the graft matured. At day 2 of culture, cardiomyocytes exhibited

high levels of Nkx 2.5 (an early stage embryonic cardiac marker), but low levels of ß-MHC (a marker of maturation), demonstrating the maturation of Nkx 2.5 expressing cells as they increasingly expressed ß-MHC. Calcium transients were imaged to show that the cardiomyocytes were electromechanically coupled, and that synchronous beating was associated with increases in intracellular calcium levels that are necessary to initiate cell contractions.

Reporting that greater than 75% of the cells within the graft were cardiomyocytes, with the remaining 25% most likely a mixture of cardiac fibroblasts and endothelial cells, the Murry group demonstrated a feasible way to generate synchronous cell aggregates *in vitro* (Stevens et al., 2008). Further studies would need to characterize the mechanical integrity of the grafts, three-dimensional architecture and organization of cells, and quantify their ability to generate sufficient force to adapt to the *in vivo* environment.

Both studies that we discuss here demonstrate the possibility to develop cardiac tissues without the use of biomaterial scaffolds. However, it remains to be seen whether the scaffold-less cardiac tissues withstand mechanical forces required to function as cardiac muscle, and imposed by engineered biomaterials specific for cardiac tissue engineering.

Cardiac-Specific Biomaterials

With the aim of modeling the anisotropy of native cardiac tissue, Lisa Freed's group at MIT developed an "accordion-like honeycomb" using microfabrication technologies and Poly (glycerol sebacate) (PGS) polymer (Engelmayr et al., 2008) (Figure II.6.11.2, panel 4). The goal was to mimic the anisotropy of the heart through varying alignments of pores, rather than use typical scaffolds that provide unidirectional alignment representative of only small regions of isotropy in the heart. PGS has been extensively used in cardiac tissue applications, because of its high and controllable elasticity and stiffness, as well as slow degradation via hydrolysis. Scaffolds were fabricated to have physiological mechanical properties, and extensive testing of the honeycomb-like scaffolds demonstrated remarkable stability over time (determined via fatigue testing over 24 hours to 3 weeks), and had anisotropic mechanical properties.

These scaffolds were cultured with neonatal rat heart cells, but without any external stimuli. The honeycombs successfully guided cells to orient in the preferred direction, and engineered grafts achieved DNA content to be in line with previously reported engineered tissues. Electrophysiological recordings demonstrated synchronous contractions of cells within scaffolds, and when comparing engineered accordion-like versus rectangular and square honeycomb tissues, a hierarchical dependence of mechanical properties on degree of anisotropy was found. Specifically, accordion-like honeycomb has a higher degree of anisotropy as compared to rectangular

honeycomb, whereas square honeycomb is isotropic. Using accordion-like honeycomb structures, engineered tissues were found to have mechanical properties most closely resembling right ventricular myocardium of the rat. The study demonstrated the importance of microstructure and scaffold architecture on the ability for cells to electrically couple and achieve physiological mechanical properties, although the 250 μm thickness of the grafts necessitates further development for *in vivo* relevance, where vascularization of thick grafts remains crucial.

Native Myocardium as a Biomaterial

A 2008 study reported by Doris Taylor's group (Ott et al., 2008) revealed that decellularized rat hearts could be seeded with cardiomyocytes and endothelial cells, resulting in regions of contractile activity observed following four days in culture. Decellularization of tissues, pioneered by the Badylak laboratory (Robinson et al., 2005), removes all cellular elements from a tissue, leaving an intact, functional extracellular matrix (process demonstrated in Figure II.6.11.2, panel 5). The architecture and mechanical properties of the native tissue matrix provide a natural environment for cells to orient, integrate, and remodel their environment. Decellularized hearts were first perfusion seeded with endothelial cells to line the native vasculature, followed by seeding of cardiomyocytes to repopulate the acellular myocardial regions. Continuous perfusion of culture media through the heart's vasculature took advantage of the natural network that allows for sufficient nutrient and oxygen exchange throughout the depth of the tissue. Adaptations of this approach may be promising for creation of cardiac patches, using pieces of intact decellularized myocardium as a scaffold. Additionally, further work similar to that of the Badylak lab, where decellularized tissues are emulsified and reconstituted as an "extracellular-matrix" gel may prove beneficial, as it incorporates cardiac-specific extracellular matrix components in the appropriate ratios, and enables tailoring of mechanical and degradation scaffold properties.

Culture in Hydrogel with Mechanical Stimulation

The model system of Eschenhagen and Zimmermann used mechanical conditioning of neonatal rat cardiomyocytes encapsulated in ring-shaped hydrogel made of a mixture of collagen and Matrigel. Early studies using this system (Fink et al., 2000) used a mixture of collagen type I and Matrigel with encapsulated neonatal rat myocytes to form gels that were subjected to unidirectional and cyclic stretch over six days. The functional improvements in cell morphology, their increased mitochondrial density and force of contraction, were again demonstrated in their subsequent studies. Using an improved

set-up for mechanical stretch, the same group compared the engineered heart tissue (EHT) to newborn and adult rats, concluding that mechanical stimulation drove the constructs to a more mature cardiac muscle structure (Zimmermann et al., 2002b). This was further evidenced by the presence of mature sarcomeric structure, membrane junctions (adherens, gap junctions, desmosomes), T-tubule system (transverse tubules are central to electromechanical coupling), and the presence of a basement membrane surrounding myocytes (suggesting they secrete ECM to enhance and stabilize their alignment). Force generation of the EHTs approached that of native heart muscle (0.4–0.8 mN twitch force, 0.1–0.3 mN restin tension), stable, typical resting membrane potentials (–66 to –78 mV) and characteristic waveform kinetics.

In their 2006 study Zimmermann and colleagues (Zimmermann et al., 2006a), implanted 1–4 mm thick, 15 mm diameter EHTs into immunosuppressed rats, and at 28 days postoperatively found significant (400 μm thick) engrafted muscle layers in the host heart tissue. A schematic of the culture and implantation is shown in Figure II.6.11.3, top left. The grafts demonstrated complete integration and functional coupling with the host tissue, as evidenced by undelayed signal propagation through the muscle, no evidence of arrythmias, and additionally the grafts delayed wall dilation, contributed to ventricular wall thickening, and demonstrated improved fractional area shortening (FAS) as compared to all control groups. Overall, the tissue engineering systems developed by this group have rigorously demonstrated the importance of mechanical forces in regulated tissue development from the subcellular to macroscopic level, with functional EHTs *in vitro*, and their success at delaying heart deterioration *in vivo*. Further understanding of the role of mechanical stimulation, and how conditioning regimes can be tailored to complement the mechanical properties of scaffolds, should provide great insight into regulating development of force by cells, preventing hypertrophy, and even affecting differentiation pathways of stem cells as they mature to cardiomyocytes.

Culture in Porous Scaffold with Electrical Stimulation

In the 2004 study by the Vunjak-Novakovic group (Radisic et al., 2004), electrical stimulation has been established as a method for aiding in the function assembly of myocardium in a three-dimensional culture system. Neonatal rat myocytes cultured in Matrigel on porous collagen sponges were precultured before being subject to electrical stimulation for 5 days. A schematic of this set-up is shown in the top right panel of Figure II.6.11.3. The electrical stimulation regimen was designed to induce synchronous contractions during cell culture, by selecting physiologically appropriate parameters: 1 Hz, 2 ms pulse duration, at 5 V/cm, monophasic, square wave.

In comparison to non-stimulated controls, this study demonstrated that electrical stimulation resulted in cell alignment, increased the frequency of gap junctions, and increased amplitude of synchronous construct contractions. The functional organization of the cardiac muscle was further evidenced by ultrastructural organization, with upregulation of cardiac troponin I, sarcomeric alpha-actin, Cx-43, alpha-MHC, and beta-MHC. The number of mitochondria present between myofibrils was also increased, which is another significant finding, as mitochondria function as calcium stores in mature cardiomyocytes, allowing for rapid contraction of cells when calcium is released and binds to TnC to initiate contraction.

The study also showed that the outcomes of electrical stimulation strongly depended on the time when electrical activity was initiated. Introducing the signals too early in culture deteriorated the cardiac phenotype rather than enhanced their contractile apparatus, as was seen when electrical stimulation began on day 5 of culture. This study introduced electrical stimulation as a key regulator of functional tissue assembly, and the differentiation and maturation of differentiated stem cells.

Additional studies have explored the importance of electrical signal type (AC versus DC, biphasic versus monophasic, square waveform versus others) as it relates to functional cardiac tissue assembly (Chiu et al., 2011). It may be that different stimulation paradigms play a definitive role at different time points in tissue development, as is true in the developing embryo, and further studies will need to elucidate which signals are appropriate for which culture regimen. Further understanding of electrical–ion interfaces, and signal transport through media and scaffolds to the cells, will help us fully understand what signals are being seen by the cells themselves. Development of conductive biomaterials to facilitate signal transduction to cells, and foster intercellular communication, may provide a means for cells to couple to each other at the culture phase (*in vitro*) and at the integration phase (*in vivo*).

Injectable Hydrogels

Currently, cell therapy in humans for cardiovascular diseases injects adult stem cells into the heart in a saline or physiologic solution. Localization and method of cell delivery, introducing cells into the ischemic environment of an injured heart, without the ability to form cell–matrix junctions, limits the survival and engraftment rate of delivered cells. This method is shown in the bottom right panel of Figure II.6.11.3.

To address this issue, Martens et al. (2009) introduced the idea of using hydrogels as a delivery vehicle to introduce and retain cells *in situ*. The advantages of such an approach include providing a cell-friendly microenvironment to engrafted cells to prevent anoikis and shield cells from the infarcted muscle, and the ability to deliver cells directly into the muscle rather than laying over a cardiac patch that must integrate with the muscle and vasculature from the surface. Hydrogels can be tailored to polymerize as a result of chemical- or temperature-dependent conditions, and can be delivered with cells by minimally invasive catheter-based procedures, with high accuracy of cell localization to the area of interest.

CHALLENGES AND FUTURE APPLICATIONS

Cardiac muscle engineering remains a relatively young and emerging field, and many of the key signals that regulate the tissue's assembly have already been identified. As researchers strive towards creation of full-thickness, functional heart muscle, they face many of the same challenges as other tissue engineering applications.

Some of the key challenges facing cardiac tissue revolve around the complexity of both biochemical and physical signaling that is involved in the tissue function. The high density and metabolic activity of the tissue demands that researchers find a way to vascularize the tissue even *in vitro*. Achieving the density of highly packed myocardium is an additional challenge, where both availability of cells for such studies, and the ability to successfully maintain such high densities in culture, make this difficult to achieve. Although millimeter-thick cardiac tissues may be sufficient for *in vitro* studies, clinically relevant pieces of tissue on the order of centimeters need to be developed to conduct appropriate translational studies.

The ability for engineered constructs to generate physiologic force remains a challenge, although initial results show that mechanical conditioning of constructs enhances the threshold of force generation. Evaluation of force generation, as well as contraction and electrical activity of the cardiac tissue, is further compounded by the heterogeneity of current constructs. Past studies using neonatal rat heart cells will contain cardiac myocytes, but also fibroblasts and endothelial cells which do not contain the appropriate contractile apparatus to participate in electromechanical activity. Without control of the cell type distribution, as well as non-uniform cell seeding, it is difficult to distinguish between signal propagation and force generation that is due to the contribution of pure cardiomyocytes. Thus, it may be useful to study pure cardiomyocytes to probe signal propagation and force generation of the cells, as well as develop better controlled distribution of cell types within the engineered constructs.

Generating Cardiac Grafts. Generation of replacement tissues for the human body is the ultimate goal of tissue engineering. For cardiac tissue engineering to become a clinical reality, scientists will have to select the appropriate cells, biomaterials, and regulatory factors. One possibility is to guide endogenous cells to repopulate an engineered biomaterial implanted in the body. Another possibility is to grow a fully functional piece of tissue in the laboratory. Stem cells remain the most promising

source of cells, and various groups are exploring human adult, embryonic, and induced pluripotent stem cells.

Challenges in the translation of engineered cardiac grafts will require phenotypic stability of the cells and mediating the immune host response to the graft. Specifically, engineered cardiac grafts will have to: (1) be conditioned to tolerate the stiff, ischemic environment of injured myocardium; (2) generate enough force to enable heart function and prevent further remodeling of the heart; (3) electrically couple with host cells to prevent arrhythmias; (4) connect to host vasculature to ensure graft survival; and (5) be resilient to immune cells, inflammatory and apoptotic signals present in the heart following myocardial infarction.

Our inability to effectively vascularize tissue grafts, and most critically cardiac tissue grafts, remains the main factor limiting the size of grafts. This problem has been approached in various ways, including vascular cells in the construct to facilitate functional vessel formation, using channeled scaffolds seeded with endothelial cells to mimic native vasculature, and including pro-angiogenic factors to attract native vasculature to infiltrate into the scaffold once implanted *in vivo*. Yet, for many applications in tissue engineering, these approaches have not been sufficient to enable cell survival *in vitro*, and especially not *in vivo*. The critical challenge *in vivo* is that once an engineered tissue is removed from its *in vitro* culture system, where medium perfusion enables nutrient transport, it does not have the ability to immediately reconnect with the host vasculature. Until the graft is vascularized, insufficient supply of oxygen and nutrients renders it ischemic, and ultimate apoptosis and cell necrosis lead to a failed graft. Future approaches will need to address this critical period, from when a construct is removed from its *in vitro* culture and is implanted, until sufficient revascularization occurs. Solutions to enable immediate vascularization or sustained cell survival until that point is reached will greatly advance graft survival and function.

Models of Human Disease. Developing functional heart tissue *in vitro* has the added benefit of being used as a model of human disease. Scientists may use engineered heart tissues for drug screening assessments, and apply different physical strains on the heart to study the onset on various pathologies. Furthermore, the emergence of induced pluripotent stem cells will allow scientists to investigate the onset and progression of various diseases in an *in vitro* setting. Cells obtained from patients with a history of cardiovascular disease can be made into iPS cells and differentiated to cardiovascular cells. These populations may then be used to engineer tissues and study various pathologies in the *in vitro* models of human disease. Such studies may prove valuable in screening for new technologies and treatments, and provide an additional assessment between animal studies and clinical translation by predicting how various therapies may fare in the human body.

Scaffolds of the Future. This chapter focused on cardiac tissue engineering for various applications – regeneration of the ailing heart, models of studying human disease, and drug screening. The complexity of heart muscle demands the use of multiple physical and biochemical signaling, similar to those that govern cell differentiation during normal development. The scaffold remains a key component in the tissue engineering paradigm, as it determines interactions between the cells and their environment. To date, researchers have developed scaffolds that guide cell alignment and improve accessibility to oxygen and nutrients through networks of channels in conjunction with medium perfusion. The mechanical properties – stiffness, elasticity, degradation rates – have been tailored to aid the development of functional cardiomyocytes with physiologic force generation. In addition, the adhesion molecules facilitate cell–matrix interactions, and tethered growth factors promote cardiac development. When placed into bioreactors, the cells in scaffolds can be subjected to stretch, hydrodynamic shear, and electrical stimulation.

The next great advances in tissue engineering may require novel scaffold development, with the creation of scaffolds that are adaptable to their environment, facilitating the communication between cells and exogenous signals. Cardiac tissue engineering scaffolds will ultimately need to facilitate functional tissue assembly by inducing the cells to align, interconnect, and communicate in the anisotropic fashion of native heart muscle. The scaffold should ideally act as that basement membrane surrounding individual myocytes, yet allow for 100 million cells to be packed in 1 cm^3.

> Microtechnologies have been extensively used to study developmental processes of cardiac cells and tissue assembly, and to build *in vitro* cardiac models for study of disease processes. In their 2009 paper, Cimetta et al. (2009b) describe microbioreactors for cultivation of embryonic stem cells, demonstrating that controlling transport phenomena can direct regulatory signals in a spatiotemporal manner and enable us to recreate physiological states *in vitro*. Similarly, Khademhosseini et al. (2007) and Cimetta et al. (2009c) used micropatterning to create cardiac organoids that can be used as *in vitro* models for physiological studies of cardiac processes at the level of a single cardiac fiber.

WORKED EXAMPLE

The heart is a densely packed, metabolically demanding muscle, which is highly vascularized to ensure sufficient supply of oxygen and nutrients through the depth of the tissue. Metabolically demanding cardiomyocytes demonstrate poorer organization and weaker cardiac phenotype at oxygen concentrations of less than 80 μM. Channeled scaffolds have been proposed as a way to enhance nutrient supply throughout the thickness of engineered cardiac tissue by mimicking vasculature in cardiac muscle (Figure II.6.11.4).
FIGURE II.6.11.4 Schematic presentation of engineered cardiac muscle tissue with channels for flow of culture medium within a scaffold populated with cardiac cells. Convective-diffusive transport of oxygen is analyzed in cylindrical coordinates.

Culture medium has an oxygen concentration of 220 μM, and the scaffold has 100 μm diameter channels, spaced 400 μm apart. Values for consumption (k) of resting, non-contractile cardiac tissue and the diffusion constant can be found below.

Assume: (1) an isotropic, constant diffusion term; (2) a steady-state system; (3) constant tissue consumption rate; and (4) axisymmetric, well-mixed media flowing through the channel.

Boundary Conditions: Media is well mixed, with constant oxygen concentration $C(r = a) = C_0$; no supply from neighboring vessels (no flux at $r = R$, so $\partial C/\partial r$ $(r = R) = 0$, where r and R are the radii of the channel and tissue cylinder as described in Figure II.6.11.4 and (a) is an arbitrary radial position with the tissue.

(a) Given the following equation and above assumptions, develop an expression to describe the oxygen concentration within tissue surrounding a channel, based on the radius of the channel, and dependent on the radius from the channel. Is the oxygen concentration at the midpoint between channels elevated enough to sustain the cardiomyocytes?
(b) How may channeled scaffolds contribute to increased tissue viability in standard culture systems?
(c) Name two additional components that can be added to a culture system to increase cell viability in cardiac constructs.

ϱ_{tissue} = 1.06 g/mL
$r_{channel}$ = 50 μm
$d_{interchannel}$ = 400 μm
κ = 2.0 mL O_2 /min*100 g tissue
D = 2.0 * 10^{-5} cm²/s
ϱ_{O2} = 1.308 g/L
t(s) = time
C(r, t) = oxygen concentration

SOLUTION

(a)
$$\frac{\partial C}{\partial t} = div(D \nabla C) - \kappa$$

$\partial C/\partial t$ disappears based on Assumption 2.
∇D disappears based on Assumption 1.
$\partial^2 C/\partial\theta^2$ and $\partial^2 C/\partial z^2$ disappears from Assumption 4.

K = constant based on Assumption 3.
where:
    z = axial distance (Fig. II.6.11.4)
    theta = angle around the central axis

Apply assumptions to starting equation to arrive at an expression.

$$\frac{\partial C}{\partial t} = div(D \nabla C) - \kappa$$
$$\frac{\partial C}{\partial t} = \nabla D \nabla C + D \nabla^2 C - \kappa$$
$$D\nabla^2 C - \kappa = 0$$
$$D\left\{\frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial C}{\partial r}\right) + \frac{1}{r^2}\frac{\partial^2 C}{\partial \theta^2} + \frac{\partial^2 C}{\partial z^2}\right\} - \kappa$$
$$\frac{D}{r}\frac{\partial}{\partial r}\left(r\frac{\partial C}{\partial r}\right) = \kappa$$
$$\int\frac{\partial}{\partial r}\left(r\frac{\partial C}{\partial r}\right)dr = \int\frac{\kappa}{D}rdr$$
$$r\frac{\partial C}{\partial r} = \frac{\kappa}{D}\frac{r^2}{2} + A$$
$$\frac{\partial C}{\partial r} = \frac{\kappa}{D}\frac{r}{2} + \frac{A}{r}$$
$$\int\frac{\partial C}{\partial r}dr = \int\left(\frac{\kappa}{D}\frac{r}{2} + \frac{A}{r}\right)dr$$
$$C(r) = \frac{\kappa}{4D}r^2 + A \ln r + B$$

where:
    A, B = integration constants

Apply first boundary condition: $C(r = a) = C_0$

$$\frac{\partial C}{\partial r} = 0$$
$$\frac{\partial C}{\partial r} = \frac{\kappa}{D}\frac{r}{2} + \frac{A}{r}$$
$$\frac{\partial C}{\partial r}(R) = \frac{\kappa}{D}\frac{R}{2} + \frac{A}{R} = 0$$
$$A = -\frac{R^2\kappa}{2D}$$

Apply second boundary condition: $\partial C/\partial r(r = R) = 0$

$$C(r = a) = C_0$$
$$C(r = a) = \frac{\kappa}{4D}a^2 + A \ln a + B$$
$$C(r = a) = \frac{\kappa}{4D}a^2 - \frac{R^2\kappa}{2D}\ln a + B = C_0$$
$$B = C_0 - \frac{\kappa}{4D}a^2 + \frac{R^2\kappa}{2D}\ln a$$

Substitute in Integration Constants, *A* and *B*, to achieve final expression:

$$C(r) = \frac{\kappa}{4D}r^2 - \frac{R^2\kappa}{2D}\ln r + C_0 - \frac{\kappa}{4D}a^2 + \frac{R^2\kappa}{2D}\ln a$$
$$C(r) = \frac{\kappa}{4D}(r^2 - a^2) + \frac{R^2\kappa}{2D}\ln\frac{a}{r} + C_0$$
$$C(r) = \frac{\kappa}{4D}\left(r^2 - a^2 - 2R^2\ln\frac{r}{a}\right) + C_0$$

Now, given the distance between these channels and physiological parameters, what is the minimum concentration of oxygen that will be sustained throughout the engineered tissue (occurs at the midpoint between two channels)?

$C_{O2,culture\ medium}$ = 220 μM or 0.00538 O_2/g after conversion

Channel radius: $r_{channel} = 50$ μm

Inter-channel distance: $d = 2R = 400$ μm

Oxygen consumption (κ) in resting, non-contractile heart: 2.0 mL O_2 per minute per 100 g tissue

= 3.53 ml $O_2/cm^3 s$ after conversion

Diffusion constant: D = 2.0 * 10^{-5} cm^2/s in tissue

Plug into master equation:

$$C(r) = \frac{\kappa}{4D}\left(r^2 - a^2 - 2R^2 \ln\frac{r}{a}\right) + C_0$$

Solve for $C(r = R)$.

$C(r = R) = 0.0021$ ml/g or ~85 μM O_2 at the midpoint between two channels. This is sufficient to sustain the cardiomyocytes.

(b) Channeled scaffolds decrease the diffusion distance required for oxygen and nutrients to penetrate the tissue at sufficient levels to sustain the cells.

(c) An oxygen carrier such as perfluorocarbons can substantially increase the amount of oxygen carried in culture media, as hemoglobin does in blood. The inclusion of flow through channeled constructs would eliminate diffusion as the sole source of mass transport in the tissue, and increase the amount of oxygen and nutrients that may be transported to the cells inside the scaffold.

CHAPTER II.6.12 TISSUE-ENGINEERED SKIN SUBSTITUTES

J. N. Mansbridge
Histogen, Inc. San Diego, CA, USA

INTRODUCTION

Skin substitutes were among the earliest tissue-engineered devices, and much experience has been obtained at all levels, from bench models to therapeutics. The earliest systems were devised by Bell (Bell et al., 1979), in the late 1970s. He grew three-dimensional fibroblast cultures by casting fibroblasts in a collagen gel. Since then, this system has become the basis of testing and therapeutic skin substitutes. Several other scaffold systems have been developed, human-derived, animal-derived, and using synthetic polymer materials, to give a variety of products with a wide range of properties. This chapter will survey skin substitutes, their properties and applications, and will provide some insight into the factors affecting the design and implementation of a commercial system to produce a therapeutic skin substitute. I will provide an example in the form of the TransCyte® manufacturing process that illustrates many of the principles involved.

The basis of many tissue-engineered skin substitutes is the collagen gel system that was introduced by Bell (Bell et al., 1981). Collagen is soluble at low pH, but forms a gel if the pH is raised. This system has been much studied and has given rise to commercial laboratory test systems and also to therapeutics. When cast in a collagen gel, fibroblasts respond to the collagen environment by changing their gene expression pattern and modifying the arrangement of the collagen strands (Guidry et al., 1992). Strikingly, the gel contracts more than 90% and increases in strength, forming a structure with some resemblance to the dermis (Auger et al., 1995). While such a structure, if seeded with keratinocytes, has many features of skin, many other systems have been developed recently involving other three-dimensional culture techniques, that show

a lesser or greater degree of complexity. The collagen gel technique has been applied very widely in university research and in research institutes. While academic studies may aim for systems that resemble human skin most closely, commercial production entails other considerations, such as issues of manufacture, production cost, and selling price.

TYPES OF SKIN SUBSTITUTES

Skin substitutes may be broadly divided into those intended for therapeutic application and those designed for testing products applied to the skin or for investigative experimental purposes. The issues related to the two types of product differ considerably. The differences in the types of skin function that they attempt to reproduce and the manufacturing processes are very different. However, at least one commercial product, Apligraf®, has been used for both therapeutic and experimental applications (Nouri et al., 2005).

The goal of a skin substitute is ultimately to generate material that mimics the properties of normal skin or that can be used to replace skin. Skin has many properties. Apart from providing a tough and self-maintaining surface to the body, it also provides initial contact between the outside world and the defensive systems of the body, and serves a variety of other physiological functions such as temperature control, neurological sensing, and so forth. It is also host to structures such as sweat glands and hair follicles. None of the skin substitutes achieve all these functions, and usually concentrate on a limited range.

Test materials are usually cell based, and use culture systems that are based on classical tissue culture techniques. While all are based on fibroblasts and keratinocytes, they may use other cells derived from different areas of the skin, such as the gingiva or the vagina, and may include other cells of the skin, such as Langerhans cells or melanocytes. Inclusion of these cells provides systems that may be used to investigate the responses of the skin immune system or its response to light.

Therapeutic products are designed to aid in the healing of wounds, either large, acute wounds, such as those following burns or chronic wounds such as diabetic foot ulcers and venous stasis ulcers. The production of therapeutic entities is highly regulated and will be considered in detail below.

Therapeutic skin substitutes have taken many forms from constructs made from non-biological polymers through to complex cellular structures involving the differentiation of cells *in vitro*. Representative samples are given in Table II.6.12.1.

Clearly, the amount of effort and expense involved in making therapeutic skin substitutes increases with the complexity of the product. In particular, cell culture is inherently expensive (cost of media, aseptic operation, etc.) and generates issues related to immunological response. Sterility and storage are also factors of increasing difficulty when using living cells. Thus, attempts have been made to produce acellular products. Indeed, some of the earliest products in this area were of this type (Yannas et al., 1980).

The simplest therapeutic skin substitute device consists of a degradable polymer, which may be textured to permit ingrowth of cells that can be manufactured by well-established methods then terminally sterilized. Storage of the finished product is not an issue. Such devices cause a foreign-body capsule to form which, if the structure is of suitable porosity, forms a dermis-like provisional matrix, which persists after loss of the scaffold (Yannas et al., 1989; Compton et al., 1998; Yannas, 1998). The cells used are autologous and the system uses well-optimized, physiological mechanisms of wound healing. Their products do not provide enhanced wound healing components, such as growth factors, that may be required in cases where healing has stalled, such as in chronic wounds.

The second type of dermal template uses biological molecules to form the scaffold. These are usually collagen with or without chondroitin sulphate (Boyce and Hansbrough, 1988). An optimal physical structure, such as porosity, is obtained by varying the composition and lyophilizing under conditions that cause ice crystals of the required size to form. Sterilization of the finished product is straightforward, and the material may be stored in alcohol or lyophilized. Materials of this kind have had a long and successful history in the treatment of acute wounds. Host fibroblasts will bind to collagen, but it is likely that other molecules, such as fibronectin and vitronectin, which also bind to the collagen, provide additional adhesion sites for the cells. A provisional matrix is formed, related to a foreign-body response, and remodeling of this and the scaffold forms a dermis-like material. These materials have also been seeded with fibroblasts and keratinocytes as the basis for cell-based therapy (Boyce et al., 1993; Still et al., 2003).

While the precise composition of the collagen preparations in terms of the proportions of types I, III, V, etc., and the modifications of the chondroitin sulphate may be uncertain, the systems discussed above are reasonably well-defined. The next stage of complexity involves other matrix proteins, which substantially increases the uncertainty of composition. These products include matrices derived from decellularized dermis, human (AlloDerm®, Graftjacket®) or animal (PrimiMatrix™), from pig intestinal submucosa (Oasis® and its derivatives), bladder or using human cells grown in culture (TransCyte®, currently discontinued). While the exact composition cannot be comprehensively ensured with these products, it is assumed that since they are generated by living cells, they will be cell-compatible and not toxic to cells. Since these materials are obtained directly or indirectly from living animals or humans, freedom from disease (HIV, hepatitis, transmissable animal pathogens, etc.) has to be ensured. The above products have not been found to cause any clinically important, immunological reaction. Sterilization has to be balanced between destruction of microorganisms and destruction of the material, but is comparatively straightforward using

ethylene oxide, UV, γ or electron beam irradiation. Preservation is straightforward using alcohol, lyophilization or cryopreservation. It is thought that these materials provide binding proteins and structures that promote healing, in addition to those present in a collagen-based construct. Claims are made for the presence of growth factors. Since most of these materials are derived from adult tissues that are usually quiescent and contain only very small quantities of growth factors and other molecules associated with healing (such as fibronectin, vitronectin, tenascin), their contribution may be very limited. An exception is TransCyte®, in which the matrix is laid down by rapidly growing cells that secrete substantial amounts of growth factors, some of which bind to the matrix. By contrast, materials derived from mature dermis or other tissues do provide structures, such as blood vessel tracks, that can be used to improve inosculation and colonization of the implant.

Inclusion of living cells in a product brings many complications related to the cost of materials, cell source, immunological considerations, complexity of manufacture, sterility, preservation to provide shelf-life, transport, regulatory issues, and so forth. These issues will be discussed in the remainder of this chapter. As a result, these products are inevitably expensive, and it is important that they show real benefit from the inclusion of cells. A few reasons for cell inclusion are the provision of growth factors and cytokines, provisional matrix proteins, active and non-senescent cells for tissue regeneration, and responsiveness to environmental conditions. These capabilities have been shown, in the case of skin substitutes, to improve the healing of chronic wounds and their cost is less than the cost of the sequelae of a non-healing wound such as amputation.

Among cellular three-dimensional skin substitutes, several strategies have been followed. At the simplest level, three-dimensional skin substitutes consist of just fibroblasts and their culture products. When seeded in a three-dimensional scaffold, fibroblasts grow rapidly and secrete extracellular matrix that consists of collagens types I, III, V, and VI, with some collagen IV as well as other collagens. Many non-collagenous proteins are also present, e.g., the tissue forms of fibronectin, tenascin, decorin, SPARC, etc. The material is a provisional matrix that resembles foreign-body capsule in many respects. As

[1]Several products at different levels of keratinocyte differentiation adapted to testing for corrosivity, phototoxicity, and differentiation markers.

discussed elsewhere in this volume, if material of non-host origin, such as a polymer fragment or certain bacteria, is placed in connective tissue, a foreign-body response ensues that consists of the formation of multinucleated giant cells and a fibrous capsule. It appears that capsule formation is an independent fibroblast function that may account for the deposition of extracellular matrix in the three-dimensional fibroblast culture. At the next level, a structure is formed with a fibroblast-populated dermal-like layer overlain with keratinocytes that may form a stratified epithelium as a bilayered structure. In general, the fibroblast layer is based on isolated collagen (usually bovine or rat-tail), either as a gel (Apligraf®) or as a sponge (Orcel®). In a collagen gel, fibroblasts respond to their environment by activating protein kinase Cζ (Xu and Clark, 1997), and switching off collagen synthesis (Mauch et al., 1988). In some test systems, the bilayered construct may be further augmented with other cells of the epidermis, such as Langerhans cells or melanocytes.

For therapeutic purposes, the keratinocyte layer is seeded as a submerged culture, and then raised to the air–liquid interface after a few days. It is then grown until it stratifies and forms multiple layers including a basal layer, a spinous layer, a granular layer, and a stratum corneum (Prunieras et al., 1983). For testing purposes it may be harvested at an earlier stage to make a model of corneal or a simple epithelium. The single keratinocyte layer corneal model is the basis of models to test corrosivity and irritancy to replace the controversial Draize test, in which responses are assessed by placing new products on a rabbit eye. Other epithelia, such as gingival or vaginal, may also be used with a similar fibroblast/collagen gel substratum. In some cases, the fibroblasts and epithelial cells may be obtained from the same biopsy.

A totally different approach to the generation of cellular skin substitutes is used by XGene in the production of AccuSkin™. Here, a slurry of cells, both fibroblasts and keratinocytes, is seeded. The fibroblasts and keratinocytes retain the capacity to sort themselves into a dermis and an epidermis without the use of any scaffold. Materials of this type are used for testing, as well as for therapeutic purposes.

Table II.6.12.2 lists a series of skin substitutes that are used as toxicological model systems for testing products that may come in contact with the skin. This includes a very wide range of cosmetics, household products, and other items. In general, the skin substitutes are used to evaluate the ability of the test material to kill the cells in the construct (corrosivity) or their ability to activate an immune response (irritancy). In addition, testing for phototoxicity, photoprotection, and other properties is also performed. Assays used to assess corrosivity generally include cell viability, frequently determined using MTT reduction, enzyme release (such as lactate dehydrogenase) or dye uptake (Triglia et al., 1991; Faller and Bracher, 2002). Irritancy is determined by the release of inflammatory cytokines, such as IL1 or prostaglandins (zur Muhlen et al., 2004) from the construct. There is a major movement in Europe and America towards replacing animal testing, which has been used traditionally, with *in vitro* testing (Edwards et al., 1994). Many of the systems kits used are commercial versions of laboratory tissue culture, but several involve multiple cell types and three-dimensional culture. While quality control of these products is critical, they do not entail the regulatory requirements of therapeutics, and are simpler to produce. Nonetheless, these systems all involve live cells, which entail additional considerations such as their limited shelf-life.

Three-dimensional systems have also been used extensively for investigating mechanisms in skin biology (Smola et al., 1993), e.g., growth factor interactions, wound healing, and as models of dermatological diseases. For instance, Asselineau has developed models of xeroderma pigmentosum using cells derived from patients of complementation group C showing specific morphological and DNA repair changes relative to normal, and the feasibility of correcting the defects by genetic modification (Bernerd et al., 2004).

COMMERCIAL PRODUCTION OF SKIN SUBSTITUTES

This discussion is primarily directed towards therapeutic products, as their regulatory requirements are generally more stringent than those used for testing. However, many of these general principles also apply to the manufacture of test systems.

Overall Considerations

Production of therapeutic skin substitutes is highly regulated by the US Food and Drugs Administration (FDA) to ensure safe and reliable products. This entails extensive quality assurance procedures. Of particular importance is detailed documentation of every aspect of the development and manufacturing processes including design, protocols, completion of manufacturing stages, deviation from protocols, correction of the deviations and measures to prevent deviations from protocols, adequacy and execution of quality control systems, traceability of components, environmental monitoring, facility maintenance, etc. Essentially all aspects of the operation of the process of making skin substitutes are covered by quality assurance operations, which represent a substantial cost. Examining records to ensure correct completion of all steps and correction of mistakes is frequently a rate-limiting step in the release of a product.

Cell Source

Sourcing of cells for tissue-engineered skin substitutes is comparatively easy, as this organ is on the surface of the body and biopsies can be taken easily. In addition, discarded skin is often available as the result of surgical procedures, such as circumcision, facelift, breast reduction, and abdomenoplasty. Indeed, keratinocytes may be obtained from plucked hairs (Vermorken et al., 1985). Many of the cells obtained in this way are derived from a region (the hair follicle bulge) that contains the stem cells for hair follicles and, under some circumstances, also for the inter-follicular epidermis (Cotsarelis et al., 1990). The various skin sources provide cells that vary in age and sex, and thus may be optimal for different applications. In general, therapeutic products are made from neonatal tissues, but adult tissues may well be adequate for making products for testing purposes. In the case of testing, there may be further advantages in using a cell bank pooled from many sources. This reduces variation that might be found between individuals and may detect responses that may occur in a minority of the population. The use of stem cells, adult, embryonic or induced, would involve substantial additional expense and is unnecessary for skin substitutes.

The ease of obtaining skin cells has made it possible to compare allogeneic and autologous sources in therapeutic applications. Early applications employed autologous sources to avoid any complications from immunological rejection and this approach is still used. However, it has become evident that the use of autologous cells is unnecessary and imposes substantial practical burdens that make commercial manufacture difficult (see Box 1). Several companies have, therefore, explored allogeneic approaches and the experience has indicated that immunological barriers to such implants are, at worst, minor. No case has been recorded of immunological rejection of a skin substitute in the clinic, despite the implantation of several hundred thousand constructs (Mansbridge, 2007).

BOX 1 | Immunological Rejection of Skin Substitutes

Medawar demonstrated that transplanted organs are almost invariably acutely rejected (Medawar, 1957) within a couple of weeks. This has become a dogma of transplant biology. However, extensive experience with allogeneic skin substitutes has shown no evidence for rejection. Not only has acute rejection not been observed clinically, but investigation of antibody formation and attempts to activate lymphocytes in response to constructs have failed (Briscoe et al., 1999; Laning et al., 2001). It appears that at least some tissues grown in culture fail to elicit an immune response. The probable explanation is that tissue-engineered constructs lack antigen presenting cells (APCs). Indeed, incorporation of APCs into a skin substitute causes it to become susceptible to immunological attack (Rouabhia, 1996). Skin normally contains endothelial cells, Langerhans cells, and other cells which are APCs, and which normally cause the rejection of unmatched skin grafts. These cells are lost during the culture expansion steps that are involved in generating skin substitutes. Similar types of immunity to acute immunological rejection are also seen in certain anatomical locations, such as the cornea, that have long been regarded as "privileged." These tissues may also lack the characteristic cell types required to cause rejection. The scope of cells showing this type of immunity has not been determined. It appears that fibroblasts, smooth muscle cells, and probably keratinocytes and chondrocytes show the same property. In addition, it has been found that fibroblasts are capable of inhibiting T-cell activation (Haniffa et al., 2007) and, on a second restimulation of the T-cells, directing them towards an IL-10, Th2 response. The inhibitory activity of the fibroblasts is stimulated by T-cell-derived γ-interferon. It may be noted that the response of fibroblast in another immunologically-related property, HLA Class II induction, is much reduced in some tissue-engineered constructs (Kern et al., 2002).

A second form of rejection, chronic rejection, also occurs. This takes place months or years after transplantation and, in the case of organs, causes loss of the transplant. This type of rejection has not been observed clinically with skin substitutes. However, transplanted cells are lost rapidly during the completion of wound repair, and then slowly during the ensuing months, and are presumably replaced by the host. Thus, in this case, chronic rejection may be masked by cell loss. However, in a transplant where continued presence of the cells is required, as in correction of a genetic defect, chronic rejection may become a problem. Indeed, where allogeneic skin substitutes have been used clinically to correct various forms of the genetic disease epidermolysis bullosa (Sibbald et al., 2005) the effects, although much more durable than other methods of treatment, ultimately require repeated application.

Supplementary Proteins and Genetic Modification

Two areas exist in which supplementary proteins or genetic modification might be important. These are the correction of genetic diseases and enhancement of wound healing. Considerable effort has been put into the first of these with some success in model systems, although few have been applied to human clinical studies. An example of this approach to the group of skin diseases comprising epidermolysis bullosa is given in Box 2. In general, the number of patients suffering from any individual genetic disease is very small and, even with relaxed regulatory requirements (such as orphan disease status), it is difficult to sustain such a product as a commercially viable operation.

Wound healing is clearly regulated by growth factors and over the last two decades many attempts to enhance wound healing by the addition of growth factors have occurred. Factors added in one way or another include PDGF (Pierce et al., 1991), FGF1 (Pandit et al., 1998), FGF2 (Pierce et al., 1992), FGF7 (Xia et al., 1999), FGF10 (Jimenez and Rampy, 1999), TGF-α (Schultz et al., 1991), EGF (Chen et al., 1993), and TGF-β (Jones et al., 1991). While many factors have been claimed to show some effect in animal experiments, only one gave rise to a commercial product. This is PDGF-B chain (Becaplermin, Regranex) that has shown clinical efficacy in treating chronic wounds (Steed, 1995). In clinical trials, the improvement in wound healing was about the same as that found with unmodified skin substitutes. This growth factor is normally released by platelets at the wound site,

and is specialized for retention in wounds. PDGF-B chain has a matrix binding domain and will remain at the wound site. In general, other growth factors have been found to provide insignificant benefit in humans.

Efforts have been made to extend the persistence of added growth factors by supplying them in the form of DNA, either as plasmids to be taken up by host cells or by using transformed cells (Tyrone et al., 2000). Such measures have been successful in animal tests, but have not reached the market. In general, this approach has not generated results sufficiently striking with respect to issues of safety and cost to make it worthwhile to pursue them as commercial products.

It is difficult to choose agents that are likely to improve wound healing. Each cell in the wound carries a complete genome, including all the growth factors and cytokines, together with the control systems required to regulate the production and secretion of these proteins. These systems have been optimized over millennia, and it is unlikely that we can improve wound healing by adding factors. An exception to this may be the addition of an antimicrobial peptide, β-defensin, as suggested by Supp (Smiley et al., 2007) or cathelicidin (McFarland et al., 2008). The approach is to provide cells in a wound with a capability they would not otherwise have, such as antimicrobial activity. While keratinocytes and cells such as neutrophils and macrophages secrete such peptides, others, such as fibroblasts, do not. Further, it might be possible to use peptides from a non-human source. However, these peptides are extremely variable between species, and may be adapted to the skin flora of the host species. This makes it unlikely that peptides from other species, such as frog or moth peptides (magainins or cecropins), would have optimal activity against the contaminants of a chronic human wound (Zasloff, 2002).

Cell Expansion

In general, cell sources (biopsies, foreskins, surgical discards, differentiated stem cells) supply limited quantities of cells that need to be expanded to provide adequate numbers of cells for tissue engineering purposes. Several devices have been developed for performing this operation: roller bottles, large flasks, the cell cube, automated plate devices (Prenosil and Villeneuve, 1998), and bioreactors using beads or some other support. Expansion in roller bottles is a well-established and reliable technique, widely used, and works very well for cell lines (such as CHO and HeLa) that have undergone evolution *in vitro* and been adapted to culture conditions. However, roller bottles have disadvantages, particularly for recently isolated primary cell strains. Cell seeding, every medium change and harvesting the cells all require multiple aseptic operations for each bottle, raising the likelihood of adventitious contamination and requiring skilled operators. It is also very difficult to control the oxygen tension in roller bottles. Bottles could be gassed

BOX 2	**Epidermolysis Bullosa – an Example of Genetic Disease**

Epidermolysis bullosa is a group of severe blistering diseases of the skin caused by mutations in any of at least 10 genes. Mutations in keratins 5 and 14 cause epidermolysis bullosa simplex, which causes a break in the basal keratinocyte layer which, while severe in children, tends to ameliorate with age. Mutations in collagen VII cause the dystrophic form of the disease, in which a split between dermis and epidermis occurs below the basement membrane, together with syndactyly and susceptibility to squamous cell carcinoma. Mutations in any of the three subunits of laminin 332 cause junctional epidermolysis bullosa. It shows a split in the basement membrane and is frequently rapidly fatal. Other mutations causing related diseases occur in integrins a6 and b4, the bullous pemphigoid antigens, and in plectin. Details are outside the scope of this discussion, but may be found in many reviews such as Uitto and Richard (2005). While many of the attempts to treat these diseases have been based on gene therapy approaches (Robbins et al., 2001; Ortiz-Urda, 2002), skin substitutes using genetically normal cells have been used on several occasions with comparative success. Skin substitutes provide wound covering, relief of pain, and comparatively durable healing (Eisenberg and Llewelyn, 1998; Dellambra et al., 2000; Falabella et al., 2000; Fine, 2000; Jiang et al., 2002; Fivenson et al., 2003; Ozerdem et al., 2003; Dagregorio and Guillet, 2005; Sibbald et al., 2005).

with the correct mixture of nitrogen, carbon dioxide, and reduced oxygen, to avoid problems associated with high (atmospheric) oxygen tension as described in Box 3. However, they must then be incubated under conditions to maintain the gas composition, requiring low oxygen incubators, which are cumbersome and expensive to run. Bioreactors using bead carriers avoid the large number of aseptic operations, and oxygen tension is much more easily controlled. Moreover, it is much easier to control the nutritional composition of the medium in bioreactors by continuous flow techniques.

Fibroblasts are traditionally grown in Dulbecco's Modified Eagle Medium (DMEM) that was developed for this purpose in the early days of tissue culture. It is routinely supplemented with serum, glutamine, nonessential amino acids and, in conventional tissue culture, with antimicrobials (penicillin, streptomycin, gentamycin, amphotericin, etc.). While antimicrobials may be used for the production of skin substitutes for testing purposes, they have to

---

BOX 3 | Effects of Culture Conditions on Cellular Aging

The use of high glucose (0.4%) DMEM (Dulbecco's Modified Eagle Medium) arises from the view that living systems benefit from the provision of abundant supplies of nutrients. The concentration of glucose present in high glucose DMEM is comparable to levels reached by uncontrolled diabetic patients, where it is known to cause long-term deleterious effects, such as the formation of advanced glycation products (AGEs), which are inflammatory through the receptor for AGEs, RAGE (Vlassara, 1990). The use of low glucose DMEM has not been investigated, but may be superior, although it may entail more frequent changes of medium. Fibroblasts, when grown in three-dimensional culture in high glucose DMEM, metabolize glucose mostly by glycolysis over about 5–8 days, producing large amounts of lactate and alanine (using nitrogen from glutamine). Oxidation through mitochondria, which generates nine times as much ATP per glucose, increases subsequently. It is not clear whether the cells use glycolysis early to achieve a high glucose charge during cell proliferation, changing to higher yielding oxidation when collagen is being deposited, or just as a consequence of glucose availability.

Oxygen is another factor that is frequently regarded as beneficial when supplied in non-limiting quantities, but may be deleterious to cells at high concentrations. In traditional tissue culture, cells are grown in atmospheric oxygen tension (21% of atmospheric pressure), but the oxygen tension in tissues is rather less (equivalent to 5–6% of atmospheric pressure), and fibroblasts have been demonstrated to grow better at low partial pressures of oxygen (Falanga and Kirsner, 1993; Falanga et al., 2002). Oxygen is a di-free radical and very reactive, oxidizing proteins and lipids, and generating DNA adducts such as 8-oxoguanosine. Oxidation of proteins may lead to inactivation, oxidation of lipids to signal transduction related to inflammation and damage to DNA that invokes repair processes that block cell proliferation and other processes. The phenomenon of senescence in fibroblast cultures has been largely attributed to these processes, and is termed Stress Induced Premature Senescence (SIPS) (Toussaint et al., 2002). Culture of cells in reduced oxygen tension may be difficult to achieve in traditional tissue culture, but is facilitated by the use of bioreactors.

---

be omitted from medium used for therapeutic products. They may obscure contamination that could become evident when applied to a patient and lead to adverse consequences. All tissue culture for therapeutic skin implants is performed under antibiotic-free conditions.

The use of fetal calf serum in fibroblast tissue culture has become standard. The original media developed for the cells (fibroblasts) available at the time all required supplementation by fetal serum. Despite numerous attempts, a serum-free medium for fibroblasts that will sustain more than 6–8 passages (subcultures) has not been devised. This is insufficient cell expansion for tissue engineering where, for fibroblasts, at least 60 generations (more than 20 passages) are required from isolation to the final product. This includes a margin to be sure that the cells are not senescent when implanted into the patient, which is desirable. While some sort of serum appears essential for fibroblast replication, it has been found that fetal calf serum may be replaced with calf serum at much lower cost, with little or no loss in proliferation rate or growth potential.

Several systems have been developed for the expansion of keratinocytes. A widely used system was developed early by Rheinwald and Green that used non-proliferative (irradiated or mitomycin C-treated) mouse 3T3 cells as a feeder layer. Under these conditions, keratinocytes can be expanded for 30 or more generations. However, for therapeutic purposes, the contact with mouse cells leads to human keratinocytes being considered as xenogeneic from a regulatory point of view. Thus, cells expanded in this way are suitable for test systems, but not for implants. For implants, keratinocytes are expanded in serum-free medium in the presence of bovine pituitary extract. Under these conditions, the cells cannot be subcultured beyond about 6–8 passages, so the cell banks have a limited life.

Construct Manufacture

The manufacturing process needs to be designed to fulfill multiple goals simultaneously. Its first basic function is to provide adequate nutrition and mass transport to allow the development of the tissue-engineered skin substitute (see Chapter II.6.6). In addition, the system needs to be scaleable, able to maintain sterility for long periods, to maximize automation, and to provide a product adapted to the users' needs. Several design concepts to achieve this have emerged.

The scaleability allows expansion without substantial additional resources, and thus economies of scale. Simple addition of production units does not provide this. This consideration is one of the major drawbacks of autologous tissue engineering, as complete tissue culture suites are required for each patient and no economy is achieved with expansion.

Secondly, tissue culture has to be performed under sterile conditions. It follows that the parts of the equipment in contact with the product (product contact parts)

should be sterilizable, either portable so that the can be sterilized in a radiation (gamma or e-beam facility), treatable with ethylene oxide or able to be steam-treated. In general, radiation treatment of disposable systems is most convenient in small- to moderate-sized installations, although some commonly used scaffolds, such as PLGA, are radiation sensitive.

It is also important to minimize aseptic operations. Every aseptic operation is an opportunity for contamination, and has to be performed using skilled operators. This consideration and the impossibility of terminal sterilization of a living product are the reason that the bioreactor (either a Petri dish-like device or a closed bioreactor) has been incorporated in the final product in skin substitutes.

Thirdly, the manufacturing system should be designed to maximize automation. There are two reasons for this. The first is to minimize labor costs and to allow the use of trained but less highly educated personnel. By comparison, tissue culture systems require periodic assessment by highly skilled practitioners. The second and more important reason is that machine failures are less frequent than operator errors. While most of the operator errors are minor (e.g., not signing a document where and when required), they still require expensive quality assurance investigation.

A fourth consideration is that since the bioreactor in many current systems forms part of the final packaging, for reasons given above, the customer has to be able to apply the contained product easily. For this reason, the bioreactor should be designed to allow easy access to the skin substitute. This is less of a problem in the case of test products, but therapeutics may be used in an operating theatre and the requirements of entry into the sterile field should be built into the bioreactor design.

It is also important that the system should be reliable and consistent. Tissue-engineered systems for manufacturing skin substitutes are very consistent by comparison with classical tissue culture systems. For instance, Dermagraft® is held by specifications to less than ±25% in one of its most variable properties (MTT reductase activity).

Shelf-Life

Shelf-life is a valuable property to incorporate into a tissue-engineered product. It is less critical for skin substitutes used for testing, as scheduling delivery with the customer is straightforward and it is rare that a test system is required instantly on an emergency basis. Therapeutic skin substitutes also usually have some latitude, but quantities of a burn product might be required very quickly. The availability of product off-the-shelf may alleviate inventory control. However, the real value is ensuring consistent quality. Testing for sterility or mycoplasma takes from 2–4 weeks. If it is to be ensured that the product is sterile, a shelf-life of this duration must be incorporated. For non-living products, there is little problem. Most of the skin substitute products of this type

are sterile and stable, and can be maintained at refrigeration temperatures for years. TransCyte® was originally stored at –80°C, which required special equipment. It was subsequently found to store at –20°C in a frost-free freezer for 18 months without loss of efficacy. Methods of stasis preservation are discussed in Box 4.

BOX 4 | **Long-Term Preservation of Skin Substitutes**

Many techniques for maintaining viable cells *in vitro* have been studied. The simplest involve maintenance in the cold or at room temperature in the presence of suitable media containing sugars or gelling agents, such as agarose. Many cells will survive for several weeks under these conditions in a quiescent state. For storage periods of months, three methods have been investigated – cryopreservation, vitrification, and desiccation (anhydrobiosis).

Cryopreservation systems have been developed for both Apligraf® (Watson and Toner, 1999) and Dermagraft® (Applegate and Kim, 1998). Both methods are based on slow cooling in the presence of cryoprotectants (glycerol in the case of Apligraf, and dimethylsulphoxide in the case of Dermagraft). The techniques are based on those successfully developed and routinely used for suspended cells, sperm, ova, etc., and are well-understood on a theoretical basis (Karlsson and Toner, 1996). Development of systems that might be applied to three-dimensional tissues on the scale of tissue-engineered constructs has proved more difficult than to isolated cells. Much of the understanding of the process is related to mechanisms involved in slow cooling so as to avoid lethal ice formation. However, experiments with Dermagraft indicated a substantial range of cooling rates over which satisfactory survival could be obtained. The method requires storage below –70°C. This can be achieved using dry ice, and transport, while needing precautions, is possible. This approach has been realized on a commercial scale (Applegate et al., 1999).

Vitrification involves very rapid cooling of tissues in the presence of high concentrations of cryoprotectants that promote glass formation. In this process, water forms a glass rather than ice crystals as it cools, and this has been used successfully for tissues that are small enough to allow the high heat transfer rates that are required. The technique requires storage at temperatures below –120°C, usually using liquid nitrogen, which causes transport problems (Fujita et al., 2000; Elder et al., 2005).

Experience with Dermagraft and Apligraf indicated that thawing was at least as important as the freezing process, and should be optimized with the same care. In general, it should be performed very rapidly to minimize ice crystal growth as thawing occurs. In the case of Apligraf, additional prolonged incubation was required for removal of the cryoprotective agents and the process was only performed in-house. Dermagraft was shipped frozen to the final customer, who was responsible for the thawing and cryoprotectant removal process. This required careful training of customers.

Anhydrobiosis is a technique of achieving survival by dehydration; a method of stasis achieved by many organisms. It has been applied successfully to human platelets, and is promising in the case of human cells (Wolkers et al., 2002). Achievement of anhydrobiosis has tremendous potential in tissue engineering. Storage is at room temperature, so it does not require special freezing systems and product preserved in this way can be easily transported. At the time of writing, anhydrobiosis remains a dream, but its advantages make it a worthwhile goal to pursue.

Quality Control

Before release, the product is tested to ensure safety, in particular that it is free of pathogens, and that it achieves analytical properties that have been found to provide efficacy in a clinical trial. However, analytical testing may cover other aspects of product development, such as demonstration of equivalence to a predicate device (for a 510k submission) or a prototype. There is a marked contrast between release testing and equivalence testing. Equivalence testing is only performed a small number of times, and should include everything that might be important for the expected function of the device. Since testing of this kind is only performed a small number of times, expensive tests are practical if they provide the necessary information. By contrast, release testing is performed on every lot, and should include the minimum of testing sufficient to show that the product has reached the required standard. Since such tests are performed many times, cost becomes a major issue.

Specifications for testing should be established early. For equivalence, the range of values satisfying a criterion can be obtained from the predicate device, the prototype or by consideration of the expected function of the device (e.g., the minimal strength required for efficacy). Release criteria are generally set initially from the performance of the manufacturing system using a factor of three standard deviations either side of the mean. This range may be tightened subsequently, based on improved manufacturing performance or the results of a clinical trial.

THE TRANSCYTE® SYSTEM

Introduction

TransCyte® was designed as a temporary covering for severe burns. Following third degree burns, burn eschar (dead tissue) is removed as soon as the patient can be sufficiently stabilized. This process leaves a large open wound that must be covered. The traditional treatment, and still the gold standard, is to apply cadaveric skin. This provides an excellent covering for about two weeks, but is then rejected and subsequent applications of cadaveric skin are rejected more rapidly. TransCyte was intended to replace the cadaveric skin, the advantages being the reduced possibility of disease transmission, and the finding that it did not appear to be rejected.

The production of TransCyte illustrates several of the approaches, developed at Advanced Tissue Sciences, which are valuable in the commercial production of tissue-engineered constructs. These include considerations of efficient mass transport, scalability, minimal aseptic operations, maximum automation, and "user friendly" packaging, as described above. In addition, as much of the assembly of the bioreactor systems as possible was performed in clean, although not aseptic, conditions prior to sterilization, much of the process could be performed by operators without a college degree. The

reasons that this device was discontinued are discussed at the end of this section.

Product Concept

The TransCyte bioreactor was of clamshell design (Figure II.6.12.1) that was a compromise between efficient manufacture and ease of use by the burn surgeon. After thawing, draining, and removal of a closure device, the bioreactor could be opened and presented to the surgeon like a book, from which the TransCyte could be lifted and applied. Care had to be exercised here as TransCyte had two different sides, so labeling to ensure correct application had to be devised.

The material was based on a known biocompatible wound dressing, Biobrane™, which was used as the scaffold. Biobrane consists of a knitted nylon fabric, backed by silicone and "porcine collagen peptides" (essentially denatured pig collagen). The silicone has laser-punched holes at intervals that allow drainage of excess fluid. This material was used as a scaffold for the three-dimensional culture of fibroblasts, which laid down a provisional matrix, consisting of collagen, fibronectin, tenascin, etc. (Table II.6.12.3). At the end of the manufacturing process, the material was frozen for storage, which killed the cells, leaving extracellular matrix. This material was colonized by fibroblasts from the host, endothelial cells,

etc., and provided a conductive substrate for keratinocyte migration. In clinical trials on third degree burns, TransCyte proved at least as good as cadaveric skin, and remained adherent for much longer (Hansbrough et al., 1997). It subsequently proved efficacious on severe second degree burns, reducing pain and, in some cases, obviating the need for further surgery.

Manufacturing System

During production of the construct in the bioreactor, fibroblasts were fed by a continuous flow system. The bioreactor, including the Biobrane sheets and the closure device, was assembled, sterilized, and attached to a system of tubes that recirculated medium. This system included all parts that came in contact with the medium, except for medium and waste bags, and could be sterilized as a unit by gamma radiation. Gamma radiation was the chosen sterilization method for its convenience and lack of residue. The scaffold material and other components were not affected by γ-radiation.

The flow rate (about 5 mL/min) resulted in complete medium replacement in the bioreactor in about eight minutes. Considerable care was taken to ensure that the fluid motion was laminar and uniform. This flow was maintained by peristaltic pumps, one channel per bioreactor. Other systems were investigated in early experiments in which the flow through manifolded bioreactors was controlled by capillary constrictions. However, this proved to be unreliable, and the product was unacceptably variable. Fibroblast growth under a flow regime was superior to static cultivation and, in retrospect, a higher flow rate might be an improvement. Care was taken to ensure that the flow was laminar, as turbulence might have led to uneven growth.

This system could be sterilized as a unit of 12 bioreactors, and connected to medium and waste with two or three aseptic steps. It then ran automatically for 2 to 4 days until the next medium change, which required another two to three aseptic steps. Thus, automation was maximized and aseptic steps minimized.

Harvest Time, ATP Estimation

In an ideal system, the manufacturing process is sufficiently reliable that times of harvest, feeding, and so forth are reliably repeatable. In practice, using cells, there is always some variability and a method is needed to determine the correct harvest date. In the case of TransCyte, this was performed by determining a quantity based on the amount of energy consumed by the culture. It was reasoned that the proliferation of the cells and deposition of extracellular matrix would consume energy at a reproducible rate. Since most glucose is consumed in generating energy (glucose consumed is about 20 times the weight of cells plus matrix) a number was derived, based on glucose used and lactate secreted, that was related to the amount of ATP used by the cells. Both glucose and lactate had to be determined to allow for the switch from glycolysis to full oxidation (Figure II.6.12.2.) Glucose and lactate were measured at each medium change and at harvest. The notional quantity of ATP consumed, accumulated over the three-dimensional culture period, was correlated with quality control specifications, such as the number of cells (from DNA determination) and collagen deposited (by Sirius Red binding), to provide a predictable window within which the process would result in acceptable product.

Quality Control

The quality control parameters used for the release of this product were estimates of DNA (determined by Hoechst 33258 fluorescence), which demonstrated that cells had
FIGURE II.6.12.2 Production of lactate by TransCyte® as a function of time in culture. A ratio of lactate production to glucose consumption of 1 represents 100% glycolysis. The declining ratio represents increasing oxidation of glucose.

actually grown during the production process, and collagen (determined by Direct Red binding), which demonstrated that extracellular matrix had been deposited.

In an alternative approach, it was reasoned that a satisfactory product had to adhere to the wound, and remain attached for an extended period of time (more than two weeks) and be easily removed. This was tested during the characterization phase of development by determining the force required to remove the implant using the apparatus developed by Richard Skalak and colleagues (Dong et al., 1993). It was, however, too complex to use as a release criterion.

Reason for Failure of TransCyte

TransCyte is, at present, discontinued as a commercial product. The major reason for this was the size of the market rather than the manufacturing process. The number of severe burns in the US is comparatively small, and while TransCyte had distinct advantages over cadaveric skin in terms of availability and duration of adhesion, its high price resulted in lack of acceptance and only a moderate revenue stream. Attempts were made to extend the market. TransCyte proved effective in second degree burns and, particularly, in severe second degree burns by preventing progression to third degree burns. However, this was insufficient to make its manufacture worthwhile. The conclusion of this analysis is that tissue-engineered or regenerative medicine products have to be either made in sufficient quantities or command a sufficiently high price, to provide enough incentive to establish the commercial manufacturing process. The same issues are important in developing treatment for genetic diseases, which are frequently rare and unable to sustain a commercial approach. As a result, when the TransCyte manufacturing process was shut down during a transition from one company to another, its restarting was delayed. Thus, while the manufacturing process was well adapted to commercial production and achieved consistently high yields, the market and effort involved in recommissioning the system prevented its resumption.

CONCLUSION

Skin substitutes are the most straightforward of the tissue-engineered organ constructs, and have been developed over many years for the testing of commercial products, therapeutics, and as models of skin biology and pathology. They are based on the ability of fibroblasts and keratinocytes to form a skin-like structure spontaneously, but have been extended by the inclusion of other cell types to provide models of the very wide range of properties displayed by intact skin. The production of these constructs on a commercial scale, particularly for therapeutic purposes, provides a series of challenges and room for ingenuity in the balancing of large-scale production of reliable product with the business requirements of a viable commercial enterprise.

CHAPTER II.6.13 ESOPHAGEAL AND GASTROINTESTINAL TISSUE ENGINEERING

Buddy D. Ratner

Professor, Bioengineering and Chemical Engineering,
Director of University of Washington Engineered Biomaterials (UWEB), Seattle, WA, USA

INTRODUCTION

The gastrointestinal (GI) tract, extending from the mouth to the anus, is over 5 meters long, and is responsible for taking in food and liquids, extracting useful dietary components from that input, excreting unneeded components of that input and also less well defined regulatory processes. A functional GI system is critical for a good quality of life, though life can be sustained bypassing the GI tract, for example with parenteral feeding through a catheter into a large, central vein. The GI system can be damaged due to cancer, trauma, other diseases, acid reflux (esophagus), use of certain drugs, accidental or intentional ingestion of toxins and excess alcohol consumption. Congenital defects such as esophageal atresia, tracheoesophageal fistulas and short bowel syndrome

also comprise the functionality of the GI tract. In many cases, surgical repair of the GI tract may be called for. Largely, surgical repair associated with the GI tract has high morbidity rates from stricture, leakage, infection, scarring, ulceration, migration and overall problematic healing. To address these issues and return patients to a reasonable quality of life, tissue engineered replacement of parts of the GI tract may be a solution. Numerous publications have appeared in recent years on tissue engineering for repair of esophagus, stomach, colon and small intestine.

ANATOMY AND STRUCTURE

To understand issues in tissue engineering of GI tract components, an appreciation of the gross anatomy and the microscopic anatomy is valuable. Figure II.6.13.1 illustrates the major components of the GI tract. Figure II.6.13.2 is a schematic of the tissue structure throughout the GI tract. Figure II.6.13.3 illustrates the microscopic structures of intestinal tissue. Note that every portion of the GI tract as illustrated in Figure II.6.13.1 has a unique microscopic structure, often different from that seen in Figure II.6.13.3, but following the pattern suggested by Figure II.6.13.2. Within the many layers

seen in figures II.6.13.2 and II.6.13.3 are structures comprised of epithelial cells, smooth muscle cells, striated muscle cells, fibroblasts, endothelium (blood vessels) and nerve.
FIGURE II.6.13.1 The human gastrointestinal (GI) tract.

TISSUE ENGINEERING OF GI TISSUES

Tissue engineering replacement tissues for the GI tract require that each of the considerations below be addressed and emulated in the neo-tissue that is produced.

Biomechanics

Tissues of the GI tract are relatively strong (tough) and typically they are radially elastic and less elastic longitudinally. A tissue engineering construct must demonstrate biomechanics close to that of the natural tissue being replaced.

Muscular

GI tract tissues all contain smooth muscle and skeletal muscle responsible for swallowing and for peristalsis.

Mucosal Lining

The lining protects the digestive tract, secretes substances and, in some parts of the tract, absorbs products of digestion.

Innervation

Parasympathetic and sympathetic nerves are found throughout the GI tract. These nerves sense stimuli to the GI tract, control peristalsis and control digestion.

A Blood Vessel Network

The GI tract tissue is well vascularized to nourish and oxygenate cells and remove wastes.
FIGURE II.6.13.2 General structure of the multilayer epithelial tissue comprising the GI tract.
FIGURE II.6.13.3 An illustration showing the microscopic structure of the intestinal wall.

Cell Types

Multiple cell types comprise the GI tract tissues including epithelial cells, smooth muscle cells, striated muscle cells, fibroblasts, endothelium and nerve. The engineered tissue needs the correct cells that demonstrate appropriate functionality and are located were they are supposed to be located.

Scaffolds

A scaffold structure is generally used to physically support, orient and instruct cells (see II.6.3).

Bioreactor Issues

Where cells are preseeded on scaffolds, the desired tissue formation typically has to be initiated in culture thereby increasing total cell number, producing an extracellular matrix and, in many cases, permitting mechanical conditioning of cells prior to implantation (see II.6.6).

Surgical Issues

When the tissue is formed after bioreactor growth and conditioning, how will the surgeon implant the tissue?

The integration of the tissue engineered construct can often be accelerated by placing it in contact with a highly vascularized tissue such as the omentum to speed blood vessel ingrowth.

Considering the above issues, a number of strategies have been applied to re-engineer damaged parts of the GI tract with living replacements or regeneration. Predominant among these approaches have been seeding cells on scaffolds and the use of decellularized extracellular matrices (decellularized matrices can be used unseeded, or pre-seeded with cells). Specific studies will not be discussed in this short summary, but a number of more detailed works are lists in the bibliography, below.

CHAPTER II.6.14 NEURONAL TISSUE ENGINEERING

Ravi V. Bellamkonda, Isaac P. Clements, and Jennifer M. Munson
Department of Biomedical Engineering, Georgia Institute of Technology, Atlanta, GA, USA

The human nervous system gathers, transmits, processes, and stores information with remarkable speed and fidelity. These capabilities are made possible by networks of highly specialized neural cells, organized within an intricate three-dimensional framework of interconnected neural tissue. Only through a gradual and complex sequence of development does this neural tissue form and mature, in a process beginning soon after conception, and continuing long after the time of birth.

Due to its level of complexity and specialization, the nervous system is vulnerable to damage that exceeds its natural capacity to heal or regenerate. It should not be surprising, therefore, that neural structures originally formed and refined over the timespan of years are not always trivially restored after injury. Recovery is also hindered by a variety of other factors, including the limited capacity of neurons to proliferate, and a scarring response to injury that limits the extent of damage, but also interferes with healing.

Despite intrinsic challenges to the repair of neural tissue, effective therapeutic strategies are not beyond reach. An increasing understanding of the nervous system, coupled with advances in engineering and materials science, has formed the basis of the field of neural tissue engineering. Neural tissue engineering strategies use biomaterials to influence the physical and chemical environment at the site of neural injury or disease. By controlling the spatial and temporal distribution of various types of signaling cues, pro-regenerative environments can be engineered for the purpose of restoring the complex physical and biochemical architecture of neural tissue.

CHALLENGES TO NEURAL TISSUE HEALING AND THE ENABLING THERAPEUTIC ROLE OF BIOMATERIALS

The vertebrate nervous system can be subdivided into the central nervous system (CNS) and peripheral nervous system (PNS). The chief components of the CNS are the brain and spinal cord, while the PNS includes the peripheral nerves that branch out from the CNS. Within both of these divisions, neural tissue is composed primarily of neurons and supporting glial cells. However, basic cell types and tissue organization vary greatly between the brain, spinal cord, and peripheral nerves. Consequently, each of these divisions responds uniquely to injury, and therapeutic interventions must be specialized accordingly.

Peripheral Nervous System

Neurons of the PNS connect the CNS with sensory and motor targets. The cell body of each PNS neuron is located in or near the spinal cord or base of the brain. From this cell body, a long axon extends uninterrupted to the tissue it innervates (up to one meter or more). A single peripheral nerve can contain thousands of motor and sensory axons, enveloped along with other cell types within flexible tubes of collagen and other supporting extracellular matrix (ECM) components.

The glial cells of the PNS are Schwann cells, which wrap around the axons in concentric layers to form insulating sheaths rich in the protein myelin. These myelin sheaths enhance the speed of signal conduction down the length of the axon. Schwann cells also provide trophic support to the axons and play a major role in injury response.

Peripheral Nerve Injury. When a peripheral nerve is damaged such that axons within it are severed, the portions of the affected axons lying distal to the injury site are cut off from the centrally located cell body. These distal axon segments subsequently degrade, and the resulting debris is cleared away by macrophages and Schwann cells as part of a process termed Wallerian degeneration. The Schwann cells proliferate and take on a pro-regenerative phenotype, rearranging themselves into aligned tracts called "bands of Bungner" and secreting factors conducive to the in-growth of regenerating axons.

Meanwhile, the portions of the injured neurons proximal to the damage site prepare for regeneration. The cell body of each injured axon undergoes major metabolic changes and initiates a program of protein synthesis to support axonal regeneration. At the tip of each injured axon, a growth cone develops which leads the regenerating axon through the intact structure of the distal nerve segment and back toward its original target, at the approximate rate of 1–3 mm per day (Gutmann et al., 1942).

Treatment for Nerve Injury. The process of peripheral nerve regeneration occurs spontaneously, as long as the injury does not result in an extended gap in the nerve. In cases where a small gap exists, the two nerve stumps can be surgically re-apposed. However, when the nerve gap is longer, this procedure creates unacceptable tension on the nerve. In these cases, an autografted segment of nerve is the clinical gold standard for treatment. Healthy segments of nerve are harvested from elsewhere in the body, and used to bridge the gap across the injury site. Unfortunately, this technique comes with several drawbacks, including the need for an additional surgery and a loss-of-function at the site from which the donor nerves are taken. Furthermore, patient recovery after autograft treatment is less than ideal.

For these reasons, much research has been devoted to developing a biomaterials-based implant as an alternative to an autograft. The goal of this research has been to engineer a construct that can be implanted across an injury gap in place of a nerve graft to provide support and guidance to regenerating cells and axons. Such a

construct would employ biomaterials to recreate a pro-regenerative environment, similar to that which is found in the distal segment of injured nerve. For example, the bands of Bungner found in the distal nerve segment provide a physically aligned surface topography containing oriented tracks of adhesive molecules. Diffusible biochemical trophic and signaling factors are also released by cells in the distal nerve stump. In the following sections, we will see how appropriately selected biomaterials can be employed to recreate these types of natural physical and chemical cues, for the purpose of guiding migrating cells and regenerating axons across the nerve gap, and into the distal nerve segment (Figure II.6.14.1).

Spinal Cord

In some ways, spinal cord architecture resembles that of the peripheral nerves. Both types of neural tissue contain extended cables of bundled axons that are myelinated and supported by associated glial cells. Spinal cord neurons, however, are not limited to connecting the neurons of the brain with those of peripheral nerves, but can also synapse with each other to form reflex loops and complex processing circuits. As part of the CNS, spinal cord glial cells include oligodendrocytes and astrocytes. The former myelinate and support axons, while the latter serve a variety of roles, including injury response and maintenance of the blood–brain barrier (BBB). This barrier is composed of tight cell junctions surrounding the vasculature, and restricts the passage of molecules from the bloodstream to the CNS. The CNS also contains microglia, scavenger-like cells that carry out similar roles to macrophages, and also play a major role in the response to injury.

Response of the Spinal Cord to Injury. In contrast to the injury response of peripheral nerves, the sequence of physiological events resulting from traumatic injury to the spinal cord serves to inhibit rather than to promote axonal regeneration. The spinal cord injury response can be divided into two major phases. The primary, or acute,

phase of events results from direct damage to spinal cord tissue caused by mechanical forces. A fractured vertebra, for example, might crush a section of the spinal cord, destroying neural cells, severing axonal connections, and disrupting the local vasculature. Within minutes of the initial injury, the spinal cord swells, further disrupting blood flow, and uncontrolled waves of neural activity spread through the area. These events disrupt ionic concentrations that are normally tightly regulated, leading to a loss of local neural function and regulation of the remaining vasculature.

In response to this primary set of events, a cascade of secondary injury events ensues, expanding the zone of cell death and tissue damage beyond the site of initial injury. Edema and ischemic cell death continue, due to disruption of the vasculature. Excitatory neurotransmitters, normally used to transmit signals across synapses, are released in bulk from neurons during the initial injury. The resulting excitotoxicity triggers the production of damaging free radicals, and also mediates cell death by several mechanisms. In one chain of events, excitatory transmitters open gated membrane channels, allowing an influx of calcium that triggers programmed pathways of cell death (apoptosis).

The secondary cascade of events also contributes to establishing barriers to regeneration. Cell death, coupled with infiltration of cells and other factors through the compromised blood spinal cord barrier triggers a destructive inflammatory response. Resident astrocytes and microglia take on a reactive phenotype, and contribute to the formation of a glial scar around the zone of necrotic cell death. This scar tissue contains growth-inhibitory factors such as chondroitin sulfate proteoglycans (CSPGs), which impede axonal regeneration across the injury site. Other major growth-inhibitory components include various molecules exposed from within damaged myelin sheaths.

Treatment for Spinal Injury. Current treatments for spinal cord repair and regeneration are limited. Because acute injury events occur so quickly after the initial

damage, existing therapies are typically designed to limit the extent of secondary injury, often with the administration of high doses of steroids (Bracken et al., 1990). Even for this purpose, few options for clinical intervention exist.

Tissue-engineered therapies offer the potential to more effectively modulate the spinal cord's secondary response to injury. For example, biomaterials can be used to engineer advanced delivery systems for drugs able to influence secondary injury events. These types of systems can be designed to deliver biochemical factors with a level of control and precision not achievable with conventional approaches.

Another biomaterials-based treatment approach is to facilitate axonal regeneration across the injury site. Contrary to former and longstanding beliefs, axons in the CNS have an inherent capacity to regenerate. It is mainly due to the growth-inhibitory nature of the post-injury environment that regeneration is prevented from occurring. Two main strategies for promoting axonal regeneration include: (1) making the environment of the injury gap less inhibitory to axonal growth; and (2) providing an engineered nerve bridge as an alternative pathway for regeneration (similar to a PNS treatment approach).

As we'll see in the following sections, biomaterials offer the ability to pursue each of these strategies. By controlling the physical and chemical environment of the injury gap, axonal regeneration can be promoted (Figure II.6.14.2). Significantly, the task of inducing regenerating axons to re-enter spinal cord tracts distal to the injury site poses a second set of challenges.

Brain

The brain and spinal cord are both part of the CNS, and so they share many basic structural similarities, including glial cell types and the presence of the blood–brain barrier (BBB). For these reasons, the responses of the brain and spinal cord to injury bear much in common. As in the spinal cord, acute injury events involved in traumatic brain injury (TBI) are defined as those resulting from direct tissue damage. Again, the acute phase is followed by a sequence of secondary events that result in an expanded zone of cell death, inflammation, and glial scarring. Similar strategies for limiting secondary injury events are applicable in both tissues.

In other ways, the structure of the brain and its response to injury are unique. Even more so than in the spinal cord, neurons in the brain exhibit a wide variety of distinct morphologies. Some neuronal cell types branch extensively, synapsing with other neurons over large regions. Others span only small distances, transmitting localized information. This complex and distributed architecture of brain tissue complicates strategies for directing the functional repair of neural circuitry.

The brain is also unique, in that it is divided into distinct structures, many of which are composed of neurons specialized to perform specific tasks. Pathological conditions stemming from injury, disorders, and disease can selectively target certain regions of the brain, causing a characteristic result. For example, Parkinson's disease is a neurodegenerative disease that targets regions of the basal ganglia, destroying neurons responsible for producing the neurotransmitter dopamine.

A variety of tissue engineering-based treatment strategies are emerging for the treatment of neurodegenerative disease and TBI (Figure II.6.14.3). These approaches rely on biomaterials, which can be used to alter the local chemical and physical environment around the injury site, in order to encourage tissue repair and correct biochemical deficits. Significantly, biomaterials-based constructs also confer the ability to transplant cells as an additional therapeutic approach for treating neural injury and disease.

Biomaterials-based implant

Biomaterials-based implants can limit secondary injury events and promote regeneration.

* Patterned biomaterials can increase cell migration and guide regenerating axons

* Released drugs can limit secondary injury, modulate growth inhibitory environment, stimulate cell migration, and promote axonal regeneration

* Transplanted cells can replace support cells and neurons to enhance repair and regeneration and limit secondary injury events.

FIGURE II.6.14.2 (A) This simplified diagram summarizes constraints to spinal cord regeneration. (B) An implanted biomaterials-based construct can reduce damaging post-injury events and contribute to neural repair and regeneration.

Traumatic brain injury and degenerative disease can result in neuronal loss and biochemical deficits

* As in the spinal cord, secondary injury cascades cause further damage and cell death

* Growth inhibitory molecules block regenerating axons, and CNS neurons cannot proliferate

* Injury and neurodegenerative diseases can cause imbalances of neurotransmitters resulting in severe loss of function

Biomaterials-based implants can restore balances of biochemical cues

* Patterned materials can increase cell migration and axonal growth

* Released drugs can limit secondary injury and promote regeneration

* Released drugs can restore biochemical imbalances

* Transplanted cells can replace support cells and neurons to limit secondary injury, enhance repair, and restore neural function.

FIGURE II.6.14.3 The use of biomaterials in treatment strategies for neurodegenerative disease and traumatic brain injury.

BIOMATERIALS-BASED CUES FOR THE TREATMENT OF NEURAL INJURY/DISEASE

Neural cells are highly responsive to natural cues present in their surrounding environment, especially during periods of growth and development. The course of a regenerating axon, for example, is guided by such factors as the physical topography and chemistry of the surface along which it grows, as well as by signaling molecules in the local environment. These physical, biochemical, and even electrical cues exert great influence on cellular viability, growth, and activity.

A fundamental strategy in tissue engineering-based treatment approaches is to artificially recreate environmental cues in such a way as to influence neural cell behavior. This task is often delicate, however, as natural cues are presented in complex combinations within the intricate terrain of neural tissue. Accordingly, neural cells are sensitive to the precise nature of a given type of cue, as well as to its precise spatial location and time course.

Significantly, the effective use of biomaterials within tissue-engineered constructs enables spatiotemporal control over the presentation of environmental cues, such that the repair and regeneration of neuronal deficits can be engineered. Tissue engineering techniques also employ biomaterials to transplant cells for the purpose of replacing or supplementing the function of injured or diseased neural cells. Cell transplantation constructs can present cues able to influence not only the host neural tissue of the implantation site, but also the transplanted cells contained within the constructs.

Structural and Topographic Cues Can Physically Support and Guide Neural Repair Mechanisms

Structural Support. At the most basic level, tissue-engineered scaffolds can promote neural repair by providing physical support through the mechanical structure of their component biomaterials. This macro-level physical support might serve, for example, to isolate an area of injured tissue to establish a local environment conducive to healing or regeneration. In some applications, the mechanical properties of a scaffold might also serve to provide physical support in the place of lost surrounding tissue.

The influence on neural tissue of scaffold structure can be illustrated by the case of engineered nerve guidance channels, which can be used in place of nerve grafts to promote nerve regeneration across extended gaps in peripheral nerves. In its most basic embodiment, a nerve guidance channel consists of an empty tube of inert material, such as smooth silicone. The ends of the injured nerve stumps can be affixed into the ends of the tube, which serves to provide an isolated pathway conducive to regeneration. The walls of the tube block the in-growth of scar tissue forming cells, holding open a space through which regenerating cells and axons can grow (Figure II.6.14.4).

In many neural repair applications, implanted biomaterials are required to serve only a temporary function. In these situations, it is often desirable to use biodegradable materials, which usually consist of natural or synthetic polymers. Common synthetic polymers used in such applications include poly(α-hydroxy-acids), such as poly(lactic acid) (PLA), poly(glycolic acid) (PGA), and the copolymer poly(lactic-*co*-glycolic acid) (PLGA) (see Chapter I.2.6). Each of these synthetic biodegradable polymers is broken down by hydrolysis of ester bonds to release nontoxic by-products. The use of the copolymer PLGA is especially useful, because adjusting the copolymer ratio can be used to tune the rate of biodegradability. This breakdown time can be tailored to range from less than a month to several years, depending on the specific application.

Other biodegradable polymers, including collagen, fibrin, chitosan, and alginate are derived and purified from natural sources. These natural polymers are typically degraded by intrinsic enzymes, and are attractive because of their inherent biocompatibility and low toxicity. A disadvantage of natural polymers is that their chemical composition is not as well-defined as that of synthetic materials.

Influence of Topographic Cues on Cellular Behavior. Biomaterials with patterned surfaces can provide fine topographic cues in addition to tissue-level structural support. Topographic cues are physical features of the appropriate geometry and size to influence individual cells. Cellular attachment, alignment, migration, growth,
FIGURE II.6.14.4 Peripheral nerve regeneration through an empty nerve-guidance tube occurs in an ordered sequence. (A) The ends of a severed nerve are attached into a nerve-guidance tube. (B) The tube fills with plasma derived from the nerve stumps. Fibrin precursors from within the plasma coalesce into an oriented fibrin bridge that physically bridges the nerve gap. (C) Cells involved in regeneration, including fibroblasts and Schwann cells, migrate through this aligned fibrin cable and begin to proliferate and differentiate to prepare the way for regenerating axons. (D) Axons regenerate from the proximal stump along with the migrating Schwann cells, bridging the gap and re-entering the distal nerve stump.

FIGURE II.6.14.5 The reorganization of cytoskeletal components can be constrained by the surface topography of the surrounding substrate, resulting in cellular alignment and directed migration. (A) A cell cultured on a flat surface contains cytoskeletal components radiating predominantly from the centralized nucleus. (B) When the same type of cell is cultured on a grooved surface, the orientation of the cytoskeletal components are constrained by the grooved surface topography. (Figure adapted from Wilkinson et al., 2002, with permission.)

and gene expression can all be regulated by controlling the nature and distribution of topographic cues provided by the component biomaterials of a tissue-engineered construct.

The capacity of cells to respond to artificial topographic cues stems from the sensitivity of cells to natural topographic cues in their normal biological surroundings. Cells are particularly sensitive to topography during periods of growth, development, and regeneration. For example, during neural tissue development, aligned extracellular matrix (ECM) plays a major role in guiding neural cell migration and differentiation (Rakic, 1971). By mimicking the natural structures along which neural cells develop and reside, engineered substrates with particular topographies can greatly influence cellular behavior.

The mechanisms by which topographic cues influence cellular behavior are complex, but involve interactions between the substrate topography and cellular structures that are sensitive to physical cues and able to effect cell-wide changes in behavior. For example, neural growth cones, located at the front of extending axons or neurites, are particularly sensitive to topographical features as they guide neuronal extension during periods of growth and development. Filipodial protrusions on the end of the growth cones continually advance or retract in response to physical and chemical cues as they "explore" their surrounding environment. Ultimately, growth cones direct axon/neurite extension by mediating reorganization of the neuronal cytoskeleton.

This cytoskeletal reorganization is required for changes in cellular orientation as well as for growth and migration. The cytoskeleton is rearranged by depolymerization and polymerization of its component microtubules, intermediate filaments, and microfilaments (Wilkinson et al., 2002). It is hypothesized that these rod-like structures are limited in their capacity to bend, similar to a railroad track, and that their polymerization is thus dependent on the surrounding topography. This hypothesis might explain, for example, why cellular alignment and growth can be directionally constrained by certain types of topographic features, such as aligned grooves (Figure II.6.14.5).

Size Scales of Topography

The response of a cell to its surrounding topography strongly depends on the size of the topographic cues. Micron scale features might act at the cellular level, while sub-micron and nanoscale features act at subcellular levels (Seidlits et al., 2008). Significantly, biological structures such as growth cone filopodia lie within the nanometer range, and are highly sensitive to nanoscale topographic cues (Dalby et al., 2004). For example, basement membranes, across which axons typically grow, are composed of a dense meshwork of three-dimensional topography, featuring pores and fibers with dimensions ranging from tens to hundreds of nanometers (Flemming et al., 1999; Abrams et al., 2000).

Due to the sensitivity of neural cells to nanoscale cues, attention must be given to nanoscale topography in the process of tissue engineering design. Significantly, few choices of biomaterials are truly smooth at the nanoscale, so most implanted materials present nanoscale cues, whether intended or not (Curtis and Wilkinson, 1997).

Engineering Topographic Cues to Control Cell Behavior. One of the most basic ways of altering the topography of a biomaterial is to vary its roughness by randomly modulating its surface texture (Norman and

Desai, 2006) (see Chapter I.2.15). Biomaterials roughened to include surface features at the appropriate size scales have been shown to promote cellular adhesion and viability. For example, silicon substrates treated with chemical etchants or reactive ion etching techniques to include surface features down to the nanoscale have been shown to increase the adhesion and survival of both neurons and glia (Turner et al., 1997; Fan et al., 2002). It is proposed that nanoscale surface roughness promotes cellular adhesion by increasing cell membrane contact area as cells conform to fit the roughened surface (Fan et al., 2002).

More precisely defined topography can be used to influence cellular behavior in a more controlled manner. The ability to pattern arbitrary physical features allows for the fabrication of patterned surfaces that more closely mimic the surfaces of physiological structures and supporting cells. Cell culture experiments on topographically patterned substrates have explored the effects on cell behavior of a variety of patterned surface features including grooves, pits, ridges, steps, and waves. These experiments have demonstrated the sensitivity of cells to geometric features down to nanoscale dimensions, and have shed light on the mechanisms by which cells are influenced by their surrounding topographies. Neurite extension, for example, can be directly guided along grooved or ridged surfaces, in a manner resembling fasciculation, the naturally occurring process in which axons grow along other pre-existing axons (Rajnicek et al., 1997; Johansson et al., 2006). Other experiments have explored the effects of topographic cues presented in three dimensions. Matrices in the form of permissive gels or porous materials are useful for stimulating cell attachment, and for providing a substrate for physical support and growth. Hydrogels, for example, are composed of a three-dimensional structure of polymer cross-linkages that can be controlled to achieve desired properties such as stiffness and pore size. These parameters can be tailored to create biomaterial scaffolds with similar stiffness to soft-tissues and a low interfacial tension, favorable to cellular in-growth (Woerly et al., 1991; Bellamkonda et al., 1995).

Different types of oriented topographies can be created within three-dimensional substrates using a variety of techniques. For example, gels can be given an aligned orientation by flowing them during gelling. Externally applied magnetic fields have been used to align collagen gels (Ceballos et al., 1999), and a variety of techniques have been used to create aligned subluminal or microchannels within three-dimensional polymer substrates. Oriented three-dimensional substrates have been used to create nerve guidance channels, as well as guidance bridges for treating spinal cord injury gaps. Success has been met in both applications, although in the case of spinal cord repair, additional challenges must be addressed before clinically relevant results are achieved.

Indirect Alignment of Axons

Although topographic cues can be used to directly influence neuronal growth, a potentially more effective strategy is to provide indirect guidance, by targeting the influence of patterned topography towards non-neuronal cells. For example, oriented topography can be used to align glial cells, which in turn can stimulate and support directed axonal growth not only through physical guidance cues, but also through aligned pathways of biochemical guidance cues, such as secreted ECM molecules (Biran et al., 2003; Thompson and Buettner, 2004). Fibroblasts, meningeal cells, astrocytes, and Schwann cells, aligned on topographically defined substrates, have all been demonstrated to promote and direct axonal growth (Figure II.6.14.6) (Miller et al., 2001; Biran et al., 2003; Walsh et al., 2005; Kim et al., 2008).

Techniques for Topographic Patterning. Conventional photolithography techniques are most commonly used to pattern two-dimensional surfaces with microscale features. Silicon is often used as a substrate, due to established patterning techniques developed for the microelectronics industry. Polymeric substrates can also be lithographically patterned, and are typically more suitable due to their definable mechanical properties and/or biodegradability. Another advantage of polymeric substrates is their capacity for direct pattern transfer via casting or embossing (Curtis and Wilkinson, 1997). Polydimethylsiloxane (PDMS) and poly(methyl methacrylate) (PMMA) are two of the most commonly used materials for casting replicas of another patterned substrate.

While standard photolithography techniques can be used to pattern surfaces with microscale features, other techniques are required to pattern nanoscale features (100 nm and below) (Curtis and Wilkinson, 1997). For example, electron beam lithography (EBL) can be used to create arbitrary patterns with feature sizes as small as 3–5 nm (Vieu et al., 2000). However, processing with EBL techniques is time-consuming and requires expensive equipment (Norman and Desai, 2006). To increase speed and reduce cost, patterns initially produced by EBL techniques can be replicated with polymer materials
FIGURE II.6.14.6 Image of a rat dorsal root ganglion (DRG) cultured on a surface of aligned polymer fibers created using electrospinning techniques. (A) Schwann cells (green) migrate from the DRG, following the orientation of the submicron fibers. (B) In this magnified image, axons are additionally labeled (red), and can be seen to grow along the aligned tracts of Schwann cells.

such as PDMS, through techniques such as hot embossing and solvent casting (Figure II.6.14.7) (Dalby et al., 2004; Johansson et al., 2006; Norman and Desai, 2006).

While techniques such as EBL enable arbitrary control over nanoscale surface features, simpler and more
FIGURE II.6.14.7 Scanning electron microscope image of neurites extending along and across patterned ridges, but not within the grooves between the ridges. (Ridges are 100 nm in width and height.) This topography was created by coating a silicon surface with PMMA polymer, and then imprinting the polymer with a master stamp made using electron beam lithography techniques. (Figure reproduced from Johannson et al., 2006, with permission.)

inexpensive techniques are often preferable for patterning nanoscale topography when precise control over individual features is not required (Norman and Desai, 2006). Patterning is discussed in detail in Chapter I.2.13.

Electrospinning techniques, for example, can be used to create polymer fibers with diameters down to the nanoscale range (Figure II.6.14.8A). Aligned nanofibers are thought to mimic fibrous extracellular matrix proteins such as collagen and fibrinogen which have similar dimensions and alignment (Norman and Desai, 2006). The aligned topography of nanofibers can be used to promote directed nerve regeneration by guiding glial migration and axonal growth (Yang et al., 2005; Kim et al., 2008; Clements, 2009). A variety of nerve regeneration scaffolds, employing electrospun nanofibers at their core, have been shown to effectively facilitate nerve regeneration *in vivo* (Figure II.6.14.8B).

Table II.6.14.1 summarizes the use of biomaterial-based topographic cues for neural tissue engineering applications.

Biochemical Cues Can Promote Neural Cell Activity Leading to Repair and Regeneration

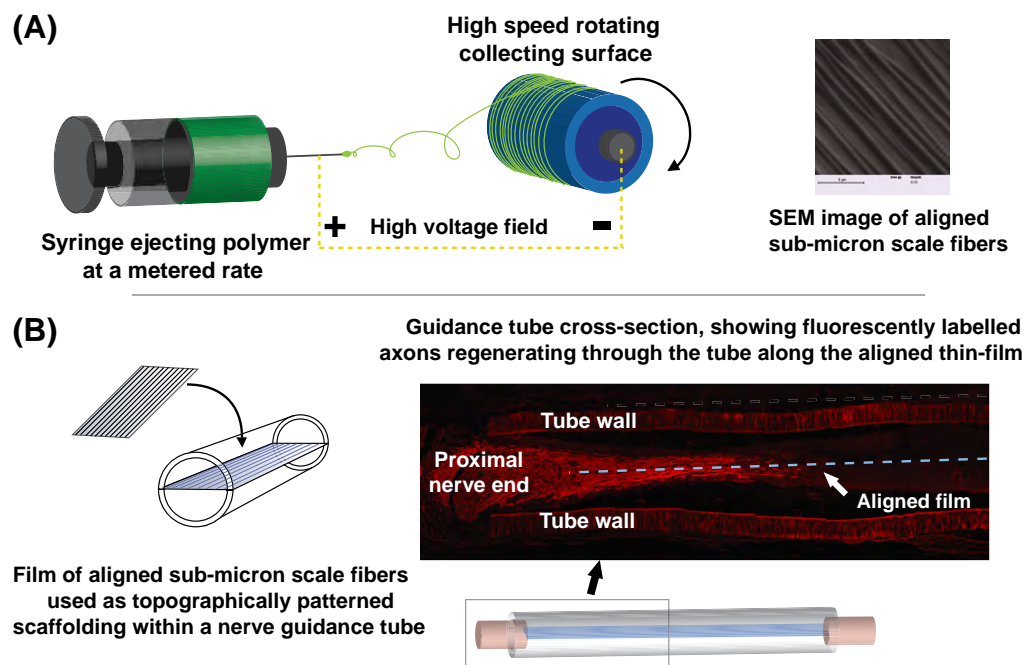
Neural cells are surrounded by a complex sea of biomolecules, many of which the neural cells specifically recognize as biochemical cues. These biochemical cues come


FIGURE II.6.14.8 (A) To electrospin fibers, a liquid polymer melt is introduced to a high voltage field as it is slowly ejected from a syringe. Charge build-up on the drop of polymer at the syringe tip creates repulsive forces that cause tiny streams of polymer to be ejected towards a metal collecting surface. By collecting the ejected fibers over extended periods of time, mats of fibers can be collected. Using a cylinder or disk rotating at high speeds as the collecting surface is one method to collect the fibers in aligned films or sheets. (B) When an empty unpatterned tube is used to repair a nerve gap, the length of the gap across which regeneration will occur is limited. Across long gaps the normal processes of regeneration break down, and glial cells and axons fail to cross the nerve gap. When the guidance tube is supplemented with internal scaffolding of aligned substrates, as in this example, the length across which regeneration will occur can be greatly extended. Aligned topographic cues provided by the scaffolding material enable regeneration across longer gaps, in part by promoting the alignment and directed migration of regenerating cells.

TABLE II.6.14.1	The Use of Biomaterial-Based Topographic Cues for Neural Tissue Engineering Applications			
Type of Topography	**Fabrication Technique**	**Biomaterials**	**Influence**	**Neural Applications**
Roughened surfaces	Reactive ion etching, chemical etching	Rigid materials such as silicon and quartz. Pattern can be transferred onto polymers	Promotes cell adhesion, viability, and activation. Enhances implant/host tissue integration	*In vitro* models (Fan et al., 2002), implanted constructs
Patterned surfaces (e.g., grooves, ridges, steps, etc.)	Photolithography, electron beam lithography. Patterns can be transferred onto other polymers	Silicon, polymers	Promotes cell attachment, alignment, migration, and differentiation. Guidance of axonal/ neurite outgrowth	Influencing and studying cell behavior *in-vitro* and *in vivo* (Goldner et al., 2006)
Three-dimensional solid structures with random or patterned topography (pores, channels, sublumina, etc.)	Freeze drying, injection molding, templating, solvent casting, phase separation, three-dimensional printing, multiphoton excitation, magnetic alignment	Degradable (e.g., PLGA, chitosan) and non-degradable materials (PAN-PVC) can be used to create hydrogels, sponges, and tubes	Promotes cell attachment, alignment, migration, and differentiation. Provides patterned structural support	*In vitro* models, peripheral nerve guidance scaffolds (Chamberlain et al., 1998; Ceballos et al., 1999), spinal cord guidance scaffolds (Yu and Schoichet, 2005)
Random or aligned micro/nano scale diameter fibers	Electrospinning, wet spinning, phase separation, peptide self-assembly	Synthetic polymers (e.g., PLA, PCA), co-polymers (e.g., PLGA), natural polymers (e.g., collagen)	Promotes cell attachment, alignment, migration, and differentiation. Can simulate aligned ECM. Provides aligned structural support.	*In-vitro* cell differentiation models (Yang et al., 2004), peripheral nerve guidance tubes (Ngo et al. 2003; Kim et al., 2008)

PAN-PVC: poly(acrylonitrile)-poly(vinyl chloride)
PCA: poly(caprolactone)
PLA: poly(lactic acid)
PLGA: poly(lactic-co-glycolic acid)
ECM: extracellular matrix

in different forms, and influence cell behavior through a variety of mechanisms.

Surface-Bound Biomolecules Mediate Adhesion.
Surface-bound adhesion molecules are glycoproteins found on cell membranes and within extracellular matrix that provide binding sites able to mediate cellular attachment and growth. Neural cells express several different families of membrane-bound receptors that are able to selectively bind adhesion molecules. In the case of homophilic binding, a given adhesion molecule on one cell binds to the same type of molecule on another cell. This is the case for neural cell adhesion molecules (NCAMs) and cadherins, both of which are important for mediating intercellular adhesion. Neural cell membranes also contain integrins, dual subunit receptors that bind adhesion molecules in the surrounding extracellular matrix, particularly laminin and fibronectin. Other types of bound molecules, including several types found in the terrain of injured CNS tissue, mediate repulsion and inhibition of neural growth (Figure II.6.14.9).

ECM adhesion molecules are frequently used *in vitro* to promote neural cell attachment. Poly-L-lysine, collagen, laminin, and fibronectin are all commonly applied to cell culture surfaces for this purpose. Constructs designed for implantation into the nervous system can be similarly coated with surface bound molecules
FIGURE II.6.14.9 Neurons from chick dorsal root ganglia were cultured on surfaces containing alternating stripes of adhesive laminin and chondroitin sulfate proteoglycans (CSPGs). (CSPGs are growth-inhibitory molecules present within the glial scar following spinal cord injury.) The neurons adhere within and extend neurite along the laminin lanes, but avoid contact with the CSPG-coated lanes.

for the purpose of achieving a more seamless integration between the implant and host neural tissue. For example, anti-inflammatory agents such as dexamethasone can be coated on the surface of an implantable device to modulate scar tissue formation (Zhong and Bellamkonda, 2007).

Surface bound adhesion molecules influence neural cells in a fashion similar to topographic cues. In fact, it is difficult to separate the effects on cellular behavior of surface topography and chemistry, which actually work closely and synergistically together. For example, after peripheral nerve injury, aligned Schwann cells secrete laminin, creating a substrate that is not only topographically oriented, but also rich in growth-promoting adhesion molecules. Tissue-engineered implants are commonly designed with the same combinational strategy, containing topographically patterned surfaces coated with growth promoting biomolecules (Yu et al., 1999; Miller et al., 2002).

Diffusible Biomolecules Activate Intracellular Signaling Pathways. Other biomolecules are released in soluble form, and influence neural cells primarily by activating secondary messenger pathways. Neurotrophins are a family of neurotrophic factors critical in supporting neural cell development, growth, and maintenance. Nerve growth factor (NGF), for example, is the most studied of the neurotrophins and is found throughout the nervous system. NGF and other neurotrophins, including brain-derived neurotrophic factor (BDNF) and NT-3, bind to membrane-bound surface receptors, such as tyrosine kinase receptors, to activate intracellular signaling cascades.

Other biochemical cues mediate different types of effects. Tropic factors, for example, attract or repel extending axons, in a process termed chemotropism. Concentration gradients of chemotropic factors are particularly crucial during development in guiding directed axonal growth towards the appropriate target tissue. Other biochemical cues important in intercellular signaling include molecules known as cytokines. After CNS injury, reactive astrocytes and microglia release inflammatory cytokines, which elicit an increased local immune response that exacerbates the secondary injury process.

Anti-inflammatory drugs can be used to treat CNS injury by modulating the cascade of secondary injury events. Coatings of dexamethasone or α-melanocyte stimulating hormone (α-MSH), for example, have been shown to modulate the local response to neural implants. The anti-inflammatory steroid methylpred-nisolone (MP) has been shown to reduce inflammation after spinal cord injury (Bracken et al., 1990). In one study, sustained release of MP was achieved by encapsulating the drug within degradable PLGA-based nanoparticles, which were suspended with an agarose hydrogel able to conform to the injury site (Chvatal et al., 2008).

Biomaterials Enable the Controlled Delivery of Diffusible Biochemical Cues

Natural biochemical cues are presented in neural tissues according to a precise spatial distribution and time course. For example, tightly localized gradients of biochemicals guide neuronal growth and differentiation during neural development. When neural tissue is injured or diseased, however, the regulation of biochemical cues can be disrupted, resulting in cell death and the establishment of barriers to regeneration.

The controlled delivery of therapeutic drugs can be used to counteract these effects, restoring a balance of biochemical cues able to bring about repair and regeneration. Biomaterials are useful vehicles for mediating this control over drug delivery, because their versatile properties can be tailored to achieve precise spatiotemporal control over drug release. Whereas direct drug injections can be invasive, and injected drugs tend to diffuse away from the target site, biomaterials-based delivery systems can be used to non-invasively deliver drugs in a more controlled and fine-tuned manner. Chapter II.5.16 introduces many different drug delivery modalities.

Classes of Biomaterials-Based Delivery Systems

Drug delivery systems commonly used in neural tissue engineering applications are often polymer-based, and can consist of non-degradable or biodegradable substrates, depending on the requirements of the system and the desired release profiles. In implantable systems that do not degrade, drugs are released by outward diffusion through a porous polymeric substrate. The release profile in these non-degradable systems depends on the porosity and loading of the substrate. A disadvantage is that the polymer remains in the site indefinitely.

In biodegradable drug delivery systems, loaded drugs are released by the degradation of the polymeric matrix (often via hydrolysis), as well as by diffusion through pores. For hydrophobic molecules like steroids, the degradation of the matrix is the primary determinant of delivery time. Commonly used biodegradable polymers for drug delivery into neural tissue include PLLA, PGA, and copolymers such as PLGA. Another synthetic polymer that is widely used is polyethylene glycol (PEG). Naturally derived polymers, like collagen, agarose, and alginate are also available, although natural materials are difficult to modify with peptides or other chemical cues that may be desirable in a regenerating system.

Three major types of drug delivery vehicles used in neural specific applications include solid implantables, scaffolds, and hydrogels. However, as we will see in the following sections, there is significant overlap between these divisions.

Solid Implants for Controlled Presentation of Cues

In its most basic form, a solid implant for drug delivery consists of a biodegradable macrostructure, such as a disk or block. The structure is synthesized externally, and then implanted in a solid form to yield prolonged

and localized release at the target site. Benefits of this type of system include ease of manufacturing, quick administration, and localization of drug release. Prefabricated implants, however, do not geometrically conform to the site of injury, and consequently do not deliver drugs evenly to the surrounding tissues. To illustrate, following surgical removal of brain tumors, a rigid PLGA disk is commonly placed within the site of resection, where it slowly releases chemotherapeutic drug designed to kill remaining tumor cells. However, this non-conformable wafer does not completely contact the surrounding cells in the cavity, and untreated cancer cells can cause tumor recurrence (Fleming, 2002).

Microscale diameter polymer spheres provide an alternative to solid macrostructures (Figure II.6.14.10). Together in high quantities, microspheres can encapsulate large amounts of drug, offering the benefits of a single macroscale implant, while allowing a higher degree of space filling of the target site. Microsphere-based delivery systems are popular in the treatment of degenerative brain diseases, where localized and time-controlled release profiles are critical. For example, microspheres have been used experimentally to deliver Levodopa (L-DOPA) to Parkinson's disease models, and acetylcholinesterase inhibitors for Alzheimer's disease (Arica, 2005; Gao et al., 2007). In these cases, implantable microspheres are delivered via injection to the target site, allowing bypass of the blood–brain barrier. The delivery of drugs using microspheres also protects active compounds, and minimizes diffusion of drug away from the target site.

Due to the small dimensions of individual microspheres, their delivery can be controlled using non-conventional techniques. For example, ferromagnetic alginate microspheres can be moved via external magnetic control to yield a microsphere distribution gradient, and hence a gradient of prolonged NGF release (Ciofani,

FIGURE II.6.14.10 These PCL (polycaprolactone) microspheres were fabricated using a double emulsion solvent extraction/evaporation method. The microspheres are biodegradable and porous, and can release loaded drugs over the timespan of days or weeks. (Figure adapted from Yang et al., 2001, with permission.)

2009). Although still in the early stages of development, these types of advanced delivery techniques might one day enable finely-unable, patient-specific release profiles.

A drawback to the use of freely injected microspheres is that they can move around in the implantation site, and thus do not evenly contact all surfaces of the target tissue. To better adapt to the geometry of the target site, microspheres can be incorporated within three-dimensional systems, such as the hydrogel-based delivery systems described in the next section.

Hydrogel-Based Delivery Systems

Hydrogels can be used as conformable three-dimensional drug delivery systems, able to release embedded drugs while maintaining close contact with the surfaces of the implantation site. Hydrogels can also be tailored to have mechanical properties similar to neural tissue, making them desirable for use in systems of variable geometries that might be sensitive to damage by the implantation of a solid matrix. To conform a hydrogel to a target site, it is first injected in liquid form to fill the site, and subsequently induced *in situ* to gel via cross-linking by a stimulus, such as chemical, temperature or light. Using these techniques, the hydrogel can be chemically controlled to swell to a desired size, and then to degrade at a given rate.

> Photopolymerizable systems cross-link in the presence of light and can include poly(ethylene glycol) (PEG)-based polymers, poly(vinyl alcohol)-based polymers, and polysaccharide derivatives (Nguyen, 2002). Finely-tuned biochemical gradients can be established using photopolymerizable systems (Figure II.6.14.11).

Many natural materials including collagen, agarose, and methylcellulose, serve as excellent hydrogels. These natural substrates can be triggered to gel based on temperature (agarose) and ionic concentrations (collagen). As an example, collagen has been used to successfully deliver the growth factors EGF and FGF to the damaged spinal cord, resulting in increased cell proliferation and reduced cavitation (Hamann, 2005).

Often hydrogels are combined with a drug release system such as microspheres to yield a more even spatial distribution of drug, in addition to a tunable release profile. As an example, lipid microtubules, made of chemically-defined phospholipid derivatives, have been loaded with BDNF and delivered within an agarose hydrogel to target injured spinal cord. The lipid microtubule/hydrogel mixture was delivered to the damaged spinal cord in liquid form, and then cooled *in situ* to conform to the shape of the injury site. This combined release system resulted in enhanced neurite outgrowth and a decreased inflammatory response (Jain, 2006).
Other Scaffold-Based Drug Delivery Systems

Aside from hydrogels, other scaffold-based drug delivery systems are also able to offer structural support and guidance while delivering biochemical cues. Drug delivery scaffolds have been commonly applied to the peripheral nervous system and the spinal cord, where a defined architecture is beneficial in enhancing the longitudinal regeneration of cells across extended injury gaps.

Scaffold-based systems are particularly well-suited for use in multifaceted repair strategies, incorporating combinations of structural, topographical, and biochemical cues. For example, drug-loaded microspheres, embedded within hydrogels, can be incorporated with a physically patterned scaffold to enable finely-tunable drug delivery and to allow for synergistic combinations of physical and biochemical cues. These types of holistic approaches, which seek to provide combinations of cues to influence multiple aspects of healing and regeneration, offer great therapeutic potential in the treatment of neural injury and disease. Table II.6.14.2 provides further examples of biomaterial-based drug delivery systems for neural tissue engineering applications.

Neural Cells are also Sensitive to Electrical Cues. In addition to topographic and biochemical cues, neural tissue is also responsive to other cue types as well. For example, natural electrical cues play a significant role within neural tissue, especially during development and regeneration. Extracellular matrix materials and other
FIGURE II.6.14.11 Chick dorsal root ganglia (DRG) were cultured in agarose hydrogels. (A) This DRG was cultured in a plain agarose hydrogel that was photopolymerized with UV light. Neurites extended from the DRG evenly in all directions. (B) This DRG was cultured in a hydrogel photopolymerized to establish a directional gradient of the adhesive ECM molecule laminin 0.017 (μg/ml/mm). The extending neurites were sensitive to the gradient of biochemical cues, and grew directionally towards the higher concentrations of laminin. (Figure modified from Dodla et al., 2006.)

TABLE II.6.14.2	Examples of Biomaterials-Based Drug Delivery System for Neural Tissue Engineering Application			
Biomaterial	**Biomolecule**	**Types of Implant**	**Applications**	**Benefits**
Nonbiodegradables (e.g., HEMA, EVA, polysulfones)	NGF, NT-3, BDNF, GDNF	Microspheres, scaffolds	PNS injury (Aebischer et al., 1989), Spinal cord injury (Kapur and Shoichet, 2004)	Provide long-term support and extended drug delivery, flexibility of shape/size
Polyesters (e.g., PLGA, PLLA)	GDNF, MP, BDNF, DOPA, AChE, NGF	Microspheres, scaffolds, implants	Neurodegenerative disease (McRae and Dahlstrom, 1994), CNS injury (Saltzman et al., 1999), PNS injury (Piotrowicz and Shoichet, 2006)	Biodegradable, degradation rate is tunable
Poly(ethylene glycol) (PEG)	NT-3, NGF	Hydrogel, scaffolds	Spinal cord injury (Piantino et al., 2006)	Limited immune response, easily modified for cell adhesion, tunable biodegradation
Agarose/alginate	NGF, laminin, CNTF	Scaffolds, hydrogels	PNS injury (Yu et al., 1999)	Can form to injection site (temperature triggered/Ca^{2+} triggered), can vary stiffness
Chitosan	Fibronectin, BDNF, CNTF	Hydrogels, implants, microspheres	CNS degeneration (Mittal et al., 1994)	Can form to injection site (pH triggered), functionalizable
Collagen/fibrin	PDGF, NGF, NT-3	Hydrogels, implants, scaffolds	Spinal cord injury (Houweling et al., 1998)	Promotes cell adhesion, covalently modifiable, reduced immune response

HEMA: 2-hydroxyethyl methacrylate
EVA: ethylene vinyl acetate

components within neural tissue contain charged molecules, and can even exhibit piezoelectric properties (i.e., generate transient electrical currents in response to mechanical deformation) (Valentini et al., 1992).

Influence of Electrical Cues on Cellular Behavior. Naturally occurring electrical cues can impact neuronal behavior in a variety of ways. For example, growth inhibitory CSPG molecules in the CNS are negatively charged, and serve to constrain neuronal growth and adhesion. Patterns of action potential signaling between neurons are critical for establishing and modulating the strength of synaptic connections within developing and neuronal networks (Fields et al., 1990).

A variety of cell culture experiments have been designed to probe the effects of electrical cues on neurite outgrowth. Neurons cultured within electric fields have been shown to alter the direction and rate of neurite extension, based on the parameters of the electrical stimulation. The precise means by which electrical cues influence neural growth are not fully known, but several mechanisms have been proposed. *In vitro* experiments have demonstrated the influence of electric charges and fields on the growth cones of developing neurites. This influence is possibly mediated in part by effects of electrical fields on the distribution of receptors on the growth cone membrane. Electrical cues can also influence voltage-sensitive ion channels on the growth cone membrane, modulating the influx of calcium. Intracellular calcium concentrations have been shown to exert potent effects on growth cone motility (Cohan et al., 1987).

As with other types of cues, electrical cues can also be used to indirectly influence neurons by targeting supporting cells. For example, electric fields have been used to orient astrocytes, which in turn enhanced and directed neurite extension by offering an aligned framework for growth (Alexander et al., 2006).

Biomaterials-Based Electrical Cues. Biomaterials can be used to provide different types of electrical cues for the purpose of influencing cellular growth and differentiation. The most straightforward technique for electrically stimulating neural tissue is to apply current with metallic electrodes. For this purpose, electrodes can be integrated within implantable devices and scaffolds to promote healing and regeneration. Even brief bouts of electrical stimulation applied to peripheral nerves at the time of injury and surgical repair can have long-term effects on the speed and accuracy of regeneration (Figure II.6.14.12) (Brushart et al., 2002; English et al., 2007).

An alternative to metal-based electrodes for transferring current are conducting polymers. Polypyrrole (PPy) and poly(3,4-ethylenedioxythiophene) (PEDOT) are two of the most commonly used conducting polymers for neural tissue engineering applications. Each of these polymers has a reversible electrochemistry, allowing the transfer of ions. Conducting polymers have many advantages over metals, including mechanical properties that are more similar to those of soft tissue.
FIGURE II.6.14.12 These images demonstrate the effects of electrical stimulation on axonal regeneration from transected nerves. The nerve on the right was electrically stimulated for 1 hour at the time of injury. The nerve on the left received no stimulation. Enhanced patterns of regeneration and larger numbers of regenerated axon profiles were present in the stimulated nerve after two weeks. (Experiment detailed in English et al., 2007.)

Piezoelectric biomaterials convert mechanical strain into charge displacement, resulting in the generation of transient local currents. PVDF (polyvinylidene fluoride) is an example of a piezoelectric polymer able to transduce minute vibrational forces into electrical charges. PVDF culturing substrates have been shown to promote neurite outgrowth *in vitro*, and similar piezoelectric materials have been incorporated into nerve guidance channels to promote peripheral nerve regeneration (Valentini et al., 1992; Fine et al., 1991).

These types of studies demonstrate the therapeutic potential of biomaterials-based electrical cues in a clinical setting, although much remains to be learned about the influence of electrical cues on healing and regeneration.

Scaffold-Facilitated Cell Transplantation

A different strategy for treating neural injury and disease is to transplant neural cells to the afflicted site. Transplanted cells can interact spontaneously with host neural tissue in complex ways to restore biochemical deficits and replace lost tissue. For these reasons, cell-based therapies are particularly warranted in cases where the

complexities of injury or disease are such that effective treatment with artificial cues is difficult to engineer.

Candidate cell types for transplantation include glial cells and stem or stem-like neural progenitor cells. Transplanted glial cells have the potential to stimulate neural repair through the natural production of factors such as ECM and biochemical signaling molecules. Stem or stem-like cells have the additional potential to differentiate into neuronal cells to replace lost or damaged tissue.

The conventional technique for transplanting cells is by injection into the injury site. Although this is the simplest technique to implement clinically, it is associated with several disadvantages, including poor survival of transplanted cells, and movement of cells away from the target site.

Biomaterials Allow for More Effective Cell Transplantation Strategies. Biomaterials-based cell transplantation scaffolds may be used to contain transplanted cells within the target site, as well as to control the physical and biochemical environment around the cells. Thus, in the design of a cell transplantation scaffold, consideration must be given not only to the interactions between the scaffold and host tissue, but also to the interactions between the scaffold and the transplanted cells it contains. Topographical and biochemical cues presented by the scaffold should be designed to promote cell viability and desired behavior.

Natural polymers like collagens, agarose, fibrin, and alginate have all been successfully used as substrates for transplanting cells, as have synthetic materials such as the biodegradable polymer PLGA. Component materials of a cell transplantation scaffold should by structured to provide a suitable substrate for cell seeding, and often must be shaped to physically fill gaps left by damaged tissue, and to encourage host cell adhesion to the construct.

Schwann cells, the glial cells of the PNS, can be readily purified and delivered into both PNS and CNS tissues for the purpose of contributing to a pro-regenerative environment (Morrissey et al., 1991). For example, nerve guidance channels can be loaded with Schwann cells suspended in ECM proteins. These cell-loaded guidance scaffolds have been shown to promote axonal outgrowth and myelination more effectively than scaffolds containing ECM proteins alone (Paino et al., 1994; Xu et al., 1997). In the spinal cord, transplanted Schwann cells are effective at promoting the in-growth of regenerating axons, although it is still a major challenge to encourage regenerating axons to then exit the scaffold and continue growth. Notably, combining Schwann cell transplantation with the delivery of anti-inflammatory agents has been shown to help mitigate this obstacle, through the beneficial effects of the drugs on host tissue surrounding the graft (Chen et al., 1996).

Other candidate cell types for encouraging axonal regeneration have been studied to a lesser extent, including CNS glial cells and macrophages. As you remember, astrocytes and microglia become activated after CNS injury, and contribute to the formation of a growth-inhibitory glial scar. Further studies are needed to fully-understand neuronal–glial interactions in the CNS, and how glial cells may aid in regeneration. Macrophages are able to act at the damage site to clear remaining debris. In this way, these cells may indirectly aid in the regeneration of axons by promoting angiogenesis, Schwann cell migration, and clearing of growth-inhibitory molecules (Franzen et al., 1998). Significantly, the future creation of multifunctional cell implant systems, containing multiple cell types within precisely defined scaffolds, may dramatically improve repair and regeneration.

Delivery of Stem Cells and Stem-Like Cells

The implantation of neural progenitor cells (NPCs) and stem cells (SCs) is a more recently developed technique. NPCs are multipotent cells that can develop into neural cell types, while SCs are pluripotent cells that have further differentiation capabilities. This approach is appealing, because these cell types have the potential to differentiate to replace lost or damaged cells. However, there are challenges associated with ensuring the survival, proliferation, and proper differentiation of these multi- or pluripotent cell types. NPCs (more commonly used than SCs because of availability and compatibility) are highly migratory cells that require proper adhesion and signaling interactions with the surrounding ECM, in addition to proper biochemical cues. Thus, the cell transplantation scaffold must be precisely designed in order to signal NPCs to differentiate into the appropriate cell types, while also contributing to cell growth and viability. As an example, exposure of neural progenitor cells to glial growth factor yields differentiation to Schwann cells in the PNS, while exposure to ciliary neurotrophic factor yields differentiation to astrocytes in the CNS. The presence of other growth factors, such as EGF and FGF, furthermore aid in the proliferation and survival of NPCs and SCs (McKay, 1997). These biochemical factors can all be incorporated into biodegradable materials to promote proper differentiation and longevity.

Newer biomimetic materials are tailored with precise control over the presentation of peptides, in order to influence the viability and differentiation of neural progenitor and stem cells. These materials incorporate specific chemical structures that closely mimic endogenous materials, such as collagen and laminin, while allowing finely-tunable degradation time and chemical structure for more reproducible and dependable delivery systems. For example, short peptides can be attached to polymer matrices in order to mimic specific integrin-binding domains. This technique allows the beneficial effects of laminin or fibronectin coatings to be exploited in a highly spatially controllable fashion – without requiring the use of a biological source (Potter et al., 2008; Tate et al., 2009). Similarly, cytokines can also be incorporated and conjugated to biomaterials for cell transplantation. By integrating these types of biochemical and topographical

TABLE II.6.14.3	Use of Transplanted Cells in Neural Tissue Engineering Applications	
Cell Types	**Benefits**	**Examples**
Glial cells: Schwann cells, oligodendrocytes	Deliver growth factors, provide structural support, re-myelinate axons	Schwann cells were transplanted in nondegradable (PVA) scaffolds to enhance spinal cord repair (Xu et al., 1997). A PLGA foam scaffold was seeded with Schwann cells and implanted, yielding enhanced PNS regeneration (Hadlock et al., 2000)
Immune response cells: macrophages, microglia, astrocytes	Contribute to the clearing of dead cells and debris. Other roles not fully understood	Activated macrophages and microglia were transplanted on nitrocellulose membranes in spinal cord to promote regeneration of sensory axons (Prewitt et al., 1997)
Stem cells, neural progenitor cells (NPCs)	Replace damaged neurons and support cells, deliver growth factors, migrate to damaged sites	Neural stem cells were seeded within a PLGA polymer scaffold, which was implanted at the site of spinal cord injury. The treatment enhanced axonal regeneration and functional recovery (Teng et al., 2002)

cues with the control and precision enabled by biomaterials, biomimetic approaches seek to greatly enhance cell transplantation therapies.

In summary, cell-based therapies offer a new dimension to the treatment of neural injury. Transplanted cells offer the potential to deliver ECM-based and diffusible growth factors to indirectly support regenerating neurons, and to replace damaged cells. The use of appropriately selected and structured biomaterials is integral to the success of such scaffold-based cell transplantation therapies. Table II.6.14.3 summarizes the use of transplanted cells in neural tissue engineering applications, and provides some further examples.

CONCLUSIONS

Neural tissue engineering strategies exploit the versatile properties of biomaterials in order to influence cells and tissues of the nervous system, for the purpose of restoring lost function. By delivering topographic, biochemical, and other types of cues, implanted biomaterials can direct cellular growth and behavior in order to overcome biological constraints on neural repair and regeneration. In order to simulate the native architecture of the brain, biomaterials-based cues must be delivered with spatial precision and at controllable timescales. Furthermore, because neural tissues within the CNS and PNS vary widely in both structure and response to disease or injury, unique treatment strategies must be tailored for individual applications. Continuing advances in biomaterials-based neural tissue engineering techniques will enable effective therapies that are increasingly effective in the treatment of neural injury and disease.

INTRODUCTION

Synthetic membranes represent a unique and important class of biomaterials widely used in contemporary medical devices. They provide a means of selective transport, usually by allowing the passage of small molecules while blocking the transfer of larger counterparts. For example, such membranes are the principle enabling biomaterials for hemodialysis, the mainstay treatment for end-stage kidney failure. Synthetic membranes also play a critical enabling role in blood oxygenation during cardiac bypass surgery, as well as in a host of smaller therapies and special purpose devices. Membrane transport and membrane biocompatibility have become highly advanced subspecialties.

The potential role for membrane barriers in tissue engineering derives from their capacity for selective transport. Many of the molecules required by cells for survival, growth, and metabolism, as well as bioactive secretory products of such cells, have much lower molecular weights than the effector molecules of the immune system. Starting in the late 1970s, researchers recognized that foreign cells could survive and function in an immunocompetent host, provided that these non-self cells were contained within, or encapsulated by, a semi-permeable barrier with an appropriate molecular weight cut-off. Since that time, a large body of experimental data has been amassed to confirm that this approach is both feasible, and of potential therapeutic use in a variety of disease conditions. The literature of encapsulation is extensive and contains an estimated 25,000 peer-reviewed publications; many of these describe successful application in animal models for a variety of disease conditions. The technique has been applied experimentally in human clinical trials with a cumulative total of over 250 patients. Encapsulated cell therapy has yet to be approved by the FDA, but regulatory filings are currently under review by the agency.

There are various ways to conceptualize immunoisolation, and to appreciate its potential contributions to cell-based medicine. The first relates to cell sourcing, a major challenge for tissue engineering. Generally, cells are derived from one of three sources: *autologous* (from the patient themself), *allogeneic* (from another human donor) or *xenogeneic* (from another species). All three

sources have major practical limitations. Autologous cells are rarely available in the quantity needed, and may be compromised by the patient's age or disease. In some cases, a small quantity of autologous cells can be harvested from the patient, expanded in tissue culture, and then returned to the body. This approach is technically satisfactory, but very expensive. Allogeneic cells can usually be found in sufficient quantity, but require the recipient to receive life-long pharmacologic immunosuppression. Unfortunately, the side-effects of long-term immunosuppression are severe, and this approach only makes sense in the case of life-threatening disease. Xenogeneic cells also require immunosuppression, and additionally raise a host of vexing safety issues. Encapsulation skirts some of these constraints by allowing allogeneic and xenogeneic cells to be deployed in a contained format, without immunosuppression and often in a retrievable fashion.

Alternatively, encapsulation can be thought of as an advantageous form of gene therapy. Functional genes, usually ones that produce a biologically important protein, can be added to human cells by the established "cut-and-paste" techniques of recombinant molecular biology. The newly designed cell can be expanded to large numbers under controlled conditions, tested carefully, encapsulated, and implanted into a patient. With suitable device design, the encapsulated cell can be recovered from the patient, should it be necessary or desirable. Many consider this approach safer than simply injecting cells or gene constructs into a patient. Finally, encapsulation is sometimes thought of as a method of overcoming the stifling restrictions on the number of human organs suitable and available for transplantation.

All three visions of encapsulation (a method to overcome the limitations on cell sourcing, an improved approach to gene therapy, and a way around the numerical confines of organ transplants) capture the versatility and promise of encapsulation. This chapter explains the mechanisms of immunoisolation in more detail, and provides an overview of the different developed encapsulation formats, along with their advantages and disadvantages. The current status of this technology, and the important challenges for future development, will also be discussed. Of special interest to the student will be the importance of small non-idealities in membrane selectivity, and the difficulties of bringing a therapy clearly effective in large animal models into human clinical practice.

PRINCIPLES OF IMMUNOISOLATION

Traditional cell transplantation strategies utilize pharmacologic immunosuppression to circumvent recipient immune system response to the transplanted allogeneic donor tissue or organ. In the absence of immunosuppression, a recipient's immune system would respond to the presence of foreign cells or proteins from the transplanted tissue or organs via the antibody-mediated

(termed humoral) and cell-mediated response pathways. Humoral response involves the binding of host antibodies (also called immunoglobulins) to foreign substances, called antigens, which elicit antibody responses. Antibody binding triggers a host of complex biochemical pathways that ultimately result in destruction of the foreign cell or protein. Cell-mediated response begins with physical contact between host and graft, and ultimately relies on the activation of killer T-cells and macrophages to secrete antibodies, cytokines, and low molecular weight metabolites, such as free radicals and reactive oxygen and nitrogen intermediates, to attack the transplanted cells. Because the success of a transplant depends on the inhibition of these immune responses, immunosuppressants are a vital part of traditional whole organ transplant strategies. Immunosuppressants are powerful drugs with serious side-effects, and their use is generally limited to life-threatening organ failure. Immunosuppression should not be thought of as a therapy that "shuts down" the immune system. Dosing is complex and requires suppression levels that are neither too low nor too high. Dosages too low will lead to a compromised graft, while dosages too high can have serious or even fatal side-effects.

Immunoisolation does not employ immunosuppression, and instead utilizes selectively permeable membranes to protect allogeneic or xenogeneic transplanted cells and tissue from immunological rejection. As illustrated in Figure II.6.15.1, these membranes serve as a mechanical analog of pharmacological immunosuppression by surrounding donor cells with a membrane whose pores are suitably sized to inhibit the transport of immunologically active molecules and prevent cell–cell contact.

Membranes are often described by a parameter termed nominal molecular weight cut-off (nMWCO) that indicates the approximate maximum molecular weight
FIGURE II.6.15.1 Principles of Immunoisolation. Cells are supported on a synthetic matrix and surrounded by a selectively permeable membrane. The membrane contains pores suitably sized to limit physical contact between the cells within the intracapsular space and immunologically active pericapsular host proteins and cells. Encapsulated cells are able to survive and function since the membrane is permeable to smaller molecules, including dissolved oxygen, nutrients, waste products, and growth factors. In addition, many cell-derived bioactive therapeutic molecules are small enough to diffuse through the capsule wall and into the host.

substance which can pass through the membrane in a given transport mode (Dionne et al., 1996). The molecules needed for cell survival are less than 50,000 Daltons, while immune molecules are generally larger, with molecular weights beginning around 150,000–200,000 Daltons (such as Immunoglobulin E, IgE), and extending to just under 900,000 Daltons (such as Immunoglobulin M, IgM) (Colton 1995; Gentile et al., 1995). For immunoisolation, the ideal membrane should have an nMWCO around 50,000 Daltons, which allows for the passage of both the molecules necessary to sustain the transplanted cells and for any relevant transplant-derived therapeutics, but which prevents entry of lethal numbers of the recipient's immunomolecules.

Transport through immunoisolatory membranes is also described in terms of sieving coefficient, although strictly speaking this term applies to convective rather than diffusive transport. For a given membrane and solute, sieving coefficient represents the ratio of the concentrations of the solute on the filtrate and retentate side, with a value of 1 indicating total permeability of the solute through the membrane. Rejection, on the other hand, is equal to one minus the sieving coefficient, and is a more intuitive parameter. As illustrated in Figure II.6.15.2, an ideal membrane (blue curve) would only allow for the passage of solutes equal to or smaller than its nMWCO. Real membranes (red curve), however, do in fact allow for some transport of molecules above the nMWCO. Determining the tolerable levels of high MW species for a given device and cell–membrane combination is a major part of the development process for an application.

As in the case of immunosuppression, immunoisolation should not be thought of in absolute terms. Low molecular weight metabolites and cytokines generated by the host can still pass through the membranes and attack the grafted tissue. Additionally, because synthetic membranes typically have a Gaussian distribution of pore sizes, a few large proteins well above the nMWCO will be able to pass through the membrane. Together, there is a possibility that these fractional amounts will give rise to a host immune response and inflammation in the graft microenvironment (Hernández et al., 2010). A number of ways to circumvent these effects have been proposed, including the co-administration of anti-inflammatory drugs along with the encapsulated cells (Bunger et al., 2005), using more hypoimmunogeneic donor cells, such as human mesenchymal stem cells (Goren et al., 2010), or co-encapsulating immunoprivileged cells, such as Sertoli cells (Mital et al., 2010), to create a more immunoprotective microenvironment.
FIGURE II.6.15.2 Selective Permeability of Immunoisolatory Membranes. Immunoisolatory membranes are often characterized by two parameters: sieving coefficient (SC) and nominal molecular weight cut-off (nMWCO). Both are determined during filtration, even though most immunisolatory devices operate in the diffusive mode. SC is the ratio of solute concentration in the filtrate to that in the retentate, where a value of 1.0 indicates a membrane freely permeable to the solute in question, and a value of 0.0 indicates an impermeable membrane. The lines on the graph are plots of SC as a function of permeant molecular weight, ranging from 30 to 10^6 Daltons. The blue line signifies ideal membranes for which all solutes less than the nMWCO are passed and all larger are rejected. In practice, however, membranes have a distribution of pore size around a mean leading to the red sigmoid curve. The nMWCO can be thought of as the molecular weight of the largest solute capable of passing through the membrane's mean pore size. For immunisolation, the acceptable level of "leakage" of molecules above nMWCO must be determined empirically for a particular application. Once this is established, graphs like those in this figure are used to perform quality control on membrane production lots. Figure II.6.15.2 is an idealized plot; for actual data, refer to Table 1 and Figure 7 in Dionne et al. (1996). *Biomaterials,* **17**(3), 257–266.

Choice of biomaterial and site of implantation are important considerations during encapsulated cell therapy development.

Additionally, encapsulated cells may be subject to acute inflammation upon implantation. Depending on the biomaterial used, proteins from the host will begin to adsorb upon the capsule surface, which will lead to the activation of macrophages and fibroblasts *in situ* (Zielinski and Lysaght, 2007). After one week, this initial immune response will either result in fibrotic tissue growth around the capsule or will progress to a chronic inflammation and ultimate graft rejection. Either of these situations can result in inhibiting the diffusion through the encapsulating membrane, as a result of which the choice of encapsulating material and the site of implantation remain an important consideration in encapsulated cell therapy development.

DEVICES FOR IMMUNOISOLATION

Devices for immunoisolation vary in design configurations depending upon the intended application. Based on their size and shape, as illustrated in Figure II.6.15.3, devices may be implanted *in vivo* as microcapsules or macrocapsules, or configured as flow-through devices connected to the recipient's circulatory system (Lysaght and Aebischer, 1999). All encapsulation formats have one design constraint in common: cells must be no further than 250 microns from the external supply of nutrients and oxygen (Colton, 1995). Beyond this critical distance cells cannot survive, and this constraint has been demonstrated in numerous unsatisfactory device designs that exhibited central necrosis, a core of dead cells.

Microcapsules (Figure II.6.15.3A), the smallest type of immunoisolatory vehicles, are small spheres with diameters typically ranging from 200–600 μm. Although structurally fragile, microcapsules are easy to produce with readily available laboratory equipment. Microcapsules have a high surface area to volume ratio, a characteristic facilitating mass transfer. Capsules can contain up to a thousand cells, a cell number which typically fills only 1–2% of the capsule volume. Hundreds to several thousand microcapsules can easily be implanted, depending on the requirements for a particular application. Species scaling is not an issue, as the number of capsules can be increased or decreased to adjust therapeutic dose. However, the small size makes explanting microcapsules difficult, and the large number of capsules makes quality control difficult; both represent a significant hurdle to the regulatory approval process.

Macrocapsules (Figure II.6.15.3B) are much larger in size, with a typical length and inner diameter of 1–10 cm and 500 micron – 2 millimeter, respectively. Although flat sheet diffusion chambers have also been employed, these types of capsules are most commonly composed of single hollow fiber capillaries, similar to those used in

(A) Diameter: 100 – 600 μm
Capacity: 10^3 cells per capsule

(B) Length: 1 – 10 cm
Inner diameter: 0.5 – 2 mm
Capacity: $10^6 – 10^8$ cells per device

1cm

(C) Capacity: more than 10^9 cells per device
FIGURE II.6.15.3 Immunoisolatory Device Configurations. (A) is a phase contrast microscopy image of microcapsules containing human fibroblasts formed into clusters, which appear as white dots within the capsules. Scale bar is 200 microns. Microcapsules are not perfectly spherical, nor are they perfectly monodisperse. Capsules can contain a single islet or upwards of a thousand cells. A therapeutic dosage in mice is usually in the range of 500 microcapsules, and scales linearly with the weight of larger animals. (B) is a photograph of a single capillary macrocapsule device and contains an inset micrograph illustrating the cells contained within the device. The length and inner diameter of capillary of such devices typically ranges from 1–10 cm and 0.5–2.0 mm, respectively. Capacity is around a million cells. Unlike microcapsules, macrocapsules are usually easier to retrieve. (C) presents a typical flow-through device, similar to a conventional hemodialyzer, with a capacity of more than 10^9 cells per device. They are typically not implanted, but rather utilized in an intermittent extracorporeal circuit. The device shown is approximately 10 inches long, 1 inch in diameter, and contains several thousand capillaries.

After preliminary design is completed, most new medical devices and virtually all encapsulated cell therapy products are first tested in small rodents, usually mice or rats. Preliminary results may dictate further design iterations, but eventually the candidate products reach the stage where it is necessary to evaluate performance in a larger species, such as a canine, sheep, or nonhuman primate. For drugs and, in this chapter's context, microcapsules, scale-up is directly proportional to the increase in body weight. For example, if a 100-gram mouse is successfully treated with microcapsules containing 500 islets, then a 20-kilogram dog would require 100,000 islets.* Some adjustment may subsequently be required, but linear scaling provides a good starting point. Scale-up of mechanical devices (such as a spinal-fixation cage or joint replacement) is more complex. In the context of encapsulated cell products, scale-up of macrocapsules has proven particularly difficult. The problem arises because at least one dimension of the macrocapsule must remain 500 microns or less, in order to keep cells within reach of nutrient and oxygen supply (see text). In this case, 500 islets for a diabetic mouse would fit into a macrocapsule device smaller than the size of a paper match. However, scaled-up to accommodate a canine model, the device would be equivalent of a string over 15 feet long, and would not fare well after implantation. Because of these issues, to date, macrocapsules have been limited to applications requiring a relatively low dosage of administered therapeutic agent, and thus a small number of cells.

*Although this dosage is correct, the implant itself has proven to be cumbersome. Not only is it difficult to manufacture and control the quality of this many defect-free capsules, but the large volume of capsules needed (approximately 1.4 cm^3 assuming a capsule diameter of 300 μm and one islet per microcapsule) also make it challenging to implant the capsules safely.

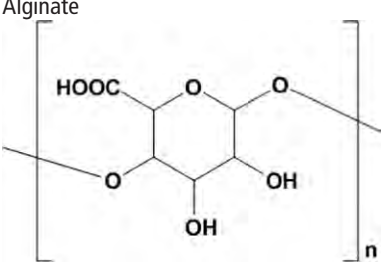
hemodialyzers. Both types of structures are preformed, filled with cells, and then sealed. Elaborate procedures have been developed to confirm the integrity of the seal. Macrocapsules are strong, robust, and have been successfully implanted into a number of locations *in vivo*, including the intrathecal space of the spinal column, and the capsule space of the eye. Their design, validation, and quality control have passed the US Food and Drug Administration (FDA) regulatory scrutiny, at least for human clinical trials. Cell number per implant is based on the size of the device, and can range from 10^6 to 10^8 cells for tubular and flat-sheet diffusion chambers, respectively. Unlike microcapsules, species scaling is an issue with this larger device (see Box 1).

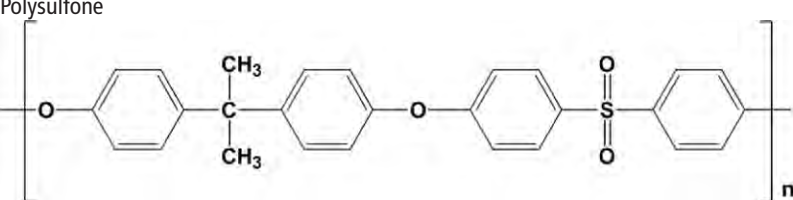
Similar in material properties to macrocapsules, flow-through devices (Figure II.6.15.3C) can be connected via an extracorporeal circuit to the recipient's vascular system, with the device's selectively permeable membrane separating the donor cells in the device from the recipient's blood (Lysaght and Aebischer, 1999). The most common designs employ thousands of hollow fiber membrane capillaries in a configuration similar to that of devices used in conventional hemodialysis and plasma filtration. Devices are much larger than micro- and macrocapsules,

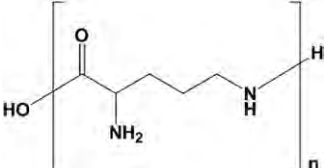
and allow for a capacity of more than 10^9 cells per device. Cells are located either in the lumen of the fiber or in the extra luminal spaces. These devices are intended for use in an extracorporeal circuit, and are typically used for 4–6 hours of treatment and then discarded. Prominent applications include fulminate liver failure or acute renal failure where the goal is to bridge patients to recovery, transplantation or maintenance therapy.

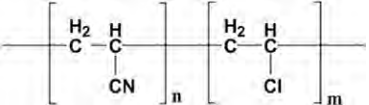
> All encapsulation formats have one design constraint in common: cells must be no further than 250 mm from the external supply of nutrients and oxygen.

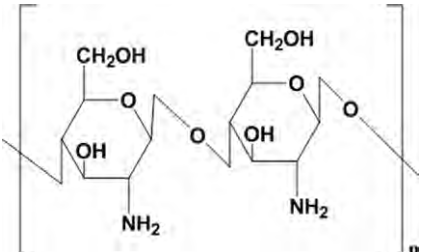
Virtually all immunoisolation devices, regardless of format, employ the same three components: a selectively permeable membrane barrier to isolate the cells; internal matrix scaffolding to physically support the cells within the device; and the living cells themselves (Li, 1998). In the following section, we outline these three components and some of the materials typically used.

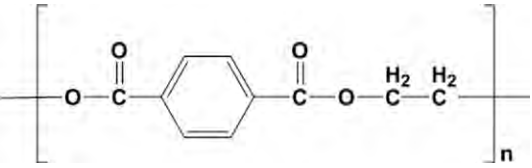
Membranes


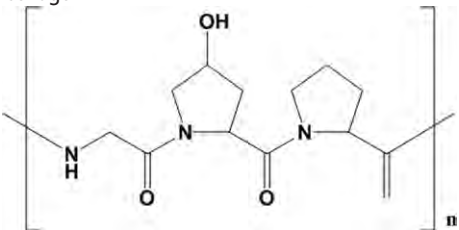


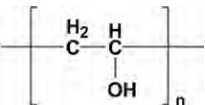












A wide variety of materials have been used in fabricating membranes for immunoisolation therapies, ranging from hydrogel-based polymers, to synthetic thermoplastics and polymer blends. Table II.6.15.1 lists some of the commonly used materials for immunoisolation.

Macrocapsules are generally composed of synthetic thermoplastics in a hollow-fiber design. Membranes are produced via phase inversion, a process by which polymer–solvent solutions are extruded as annular tubes surrounding a core fluid that is miscible with the solvent, but a precipitant for the polymer. Living cells are then loaded into the capsules, which are then sealed prior to implantation.

Most macrocapsules are formed from polysulfone, a material that is widely used in dialysis and which provides a convenient source of medical-grade polymer. Early on, devices were made from copolymers of polyacrylonitrile and polyvinyl chloride, which had previously been favored for the fabrication of specialty dialysis membranes.

Microcapsules are typically comprised of weak polyelectrolyte hydrogels, often coated with an external film formed from oppositely charged electrolytes. Capsules are prepared by suspending cells in dilute aqueous solutions containing a weak polyelectrolyte, and extruding the cell-in-polymer suspension into droplets that fall into a bath containing divalent electrolytes, which bind to and cross-link the charged polymer. Optionally, the capsules may then be overcoated with a layer of oppositely charged polyelectrolytes to provide an outer layer with a lower nMWCO than the uncoated capsule. Equipment for sterile extrusion of uniform droplets is not particularly expensive, and homemade extruders are also an option. The necessary techniques are easy to

learn. Alginate is by far the most widely used encapsulant, and polylysine is the most common outer coating. These materials were among the first to be used, are readily available, and are easy to work with. Furthermore, they have built a successful track record in laboratory and animal experiments, and alternative materials have not shown any clear advantages. Microcapsules can also be fabricated by interfacial precipitation using water-insoluble polymers, such as polyacrylates.

Matrices

Immunoisolation devices typically utilize some internal matrix component that provides the encapsulated cells with a microenvironment similar to that which is found in their natural environment. Analogous to the

extracellular matrix (ECM) found *in vivo*, the matrix provides cells with the appropriate biophysical stimuli that support cell viability and regulate cellular function. The matrix may also play a role in governing cellular proliferation, differentiation, and ECM production. The matrix provides a structural component within the device that ensures cells remain well dispersed throughout the device. Without some matrix, cells tend to aggregate and amass to a size which results in central necrosis.

Matrices can be divided into two categories: hydrogels and solid scaffolds. Hydrogels are typically prepared from a dilute solution of natural polymers (such as collagen, alginate or agarose) to which cells are added to form a cell–polymer suspension. In the case of microcapsules, the cells are extruded into spheres; for macrocapsules and flow-through devices, the suspension is injected

into the preformed capsule and allowed to solidify. Solid matrices may be fabricated from synthetic polymers (such as polyvinyl alcohol or polyethylene terephthalate) or sometimes from cross-linked natural polymers, such as chitosan. These matrices are deployed in a very wide variety of geometries, ranging from solid beads to open cell foams. They tend to be utilized in macrocapsules, and are typically added to the device before the cells. Hydrogels tend to be better for immobilizing suspension cell cultures within a device, while solid scaffolds are ideal for the attachment of adherent cells. Different matrices have different advantages and disadvantages, and as a result, no consensus has emerged in the field as to a preferred matrix material.

Cells

Living cells, encapsulated within the matrix and membrane, make up the final component of an immunoisolatory device. These cells almost always function in a device by secreting therapeutics, thereby making cell choice largely dependent on the application of interest. Every cell has a specific set of metabolic and antigenicity requirements which must be considered during device formulation and implantation. The site of the transplant must also be considered. For example, cells with high metabolic activity will fare better in a nutrient-rich environment. A highly antigenic device may be better suited placed in an immunoprivileged site, such as the eye or behind the blood–brain barrier.

Two broad classes of cells are employed: primary and cell lines. The former are cells which have been isolated and purified from a donor subject, but which are only capable of a limited number of divisions. The number of permissible cell divisions for primary cells is termed "the Hayflick limit," and typically is in the range of 25 divisions, after which cells become senescent. Since cells generally have divided several times prior to harvesting from a donor subject, the extent to which they can be expanded *in vivo* is limited. In contrast, cell lines have gained the ability to proliferate indefinitely through naturally occurring or deliberate mutations. In principle, a single founder population can be used to seed a large number of devices. With appropriate cell banking technology, cell lines become homogeneous, allowing for the functional or safety tests performed on one cohort to be applied to the entire bank. Cell lines are clearly more convenient and cost effective than primary cells. However, not all cell types are available as cell lines; for example, there is no established line for pancreatic beta cells utilized in the bioartificial pancreas. In addition, indefinitely dividing cell lines raise a potential host of regulatory concerns.

Some cells naturally secrete the therapeutic protein of interest for a given application, such as in the case of diabetes treatment using pancreatic beta cells that naturally secrete insulin at a rate responsive to the local glucose concentration. In other instances, cells may be genetically modified using the by-now standard tools of recombinant molecular biology to produce a specific therapeutic. Such modifications are usually, though not always, performed on cell lines. One example where genetic modification is utilized in encapsulated cell therapy is in the treatment of ocular degeneration using recombinant ciliary neurotrophic factor (CNTF) (Tao, 2006). As noted in an earlier section, cells may be autologous, allogeneic or xenogeneic. Allogeneic cell lines or autologous primary cells have been most widely used in human clinical trials. Xenogeneic cells are often used for *in vitro* studies or in early animal studies.

Clinical Trials

Successful human clinical trials represent perhaps the most important step between early development of a new device or therapy format, and its final acceptance into medical practice. The minimum baseline for ethical conduct of a human clinical trial requires that three conditions be met: (1) the overall benefit of the trial must outweigh the risk; (2) the patient must give free and informed consent; and (3) the clinical protocol must be reviewed in advance by a duly constituted independent review board. The gold standards are trials conducted for the purpose of obtaining data to support FDA approval of the device. Whenever practical, such trials have a control group in addition to the study group receiving the new device. Patients are randomized to either the study arm or control arm, thereby eliminating selection bias. Regulatory level trials have a detailed protocol, which is usually discussed in advance with FDA personnel, and is preceded by careful animal trials and studies of material toxicity and biostability. Successful outcomes are defined in advance. Not surprisingly, such trials tend to be expensive, and the total cost may exceed $50,000 to $100,000 per patient. Regulatory level trials are almost always conducted, or at least sponsored, by industry. A second level of trial is that which is performed by an academic investigator. This type of clinical trial usually follows investigations in small and large animal models, and will have been reviewed by the appropriate review boards at the investigator's hospital or academic medical center. These trials are often credible, but frequently are conducted without a control group and without a prospective definition of successful outcomes. Benefits may be technique-dependent and achieved in a fashion that makes the study difficult to reproduce. If the trials are successful they may receive press attention, and further development may be pursued by industry groups who will conduct regulatory level trials. While rarely definitive, academic studies play a very important role in the development of new therapeutic technologies, and bring to bear the brilliance and skills of academic investigators. Less salubrious are "first in man" trials, conducted by the biotech industry and other groups motivated to establish the claim that their products or protocols "reached the stage of successful human clinical trials." Such studies are often conducted in parts of the world with lax regulatory requirements. Control arms are rare, and preclinical studies may or may not be appropriate. While these types of studies occasionally prove to be fruitful, they should generally be taken with a grain of salt.

ENCAPSULATED CELL THERAPY APPLICATIONS

Immunoisolation was first proposed as a therapy for the treatment of diabetes in the late 1970s. Since then, numerous peer-reviewed publications have shown the

		Total Patient Exposure (Study Arm Participants		Principle
Target Disease	**Therapy Format**	**and Controls)**	**Results**	**Investigators**
Acute Liver Failure	Extracorporeal flow-through device (bioartificial liver)	116 patients (85 controls)	Clear benefit in certain patient subsets	A. A. Demetriou B. Solomon
Acute Renal Failure	Extracorporeal flow-through device (bioartificial kidney)	50 patients (18 controls)	Inconsistent results with clear benefit in some, but not all, trials	H. D. Humes
Retinal Pigmentosa and Macular Degeneration	Intraocular implantable macrocapsule releasing human CNTF	166 patients (168 controls)	Study underway with initially promising results	R. A. Bush W. Tao
Chronic Pain	Intrathecal implantable macrocapsule releasing adrenal analgesics	85 patients total	Definitive benefits in some patients	M. Goddard N. de Tribolet
Huntington's Disease	Intracerebral implantable macrocapsule releasing human CNTF	6 patients (no controls)	Improvement in some patients	J. Bloch P. Aebischer

potential utility of immunoisolation in the treatment of a variety conditions, both *in vitro* and in animal models. Furthermore, immunoisolation is one of the few sub-fields within tissue engineering that has successfully pro-vided a platform for evaluation in human clinical trials. Table II.6.15.2 summarizes some of the applications that have been explored in human clinical trials.

In some of these applications, such as liver or kidney failure, encapsulated cells serve as organ replacement therapy, usually as a temporary "bridge to transplant" for patients awaiting whole organ transplantations, as is the case with liver (Demetriou et al., 2004) or renal failure (Tumlin et al., 2008). In other applications, such as Par-kinson's disease (Aebischer et al., 1994), ALS (Aebischer et al., 1996), Huntington's disease (Bloch et al., 2004), and chronic pain (Buchser et al., 1996), encapsulated cells represent destination therapies, intended to be per-manently implanted to synthesize and deliver cell-derived therapeutics *in situ*. This is particularly relevant in cases where conventional drug delivery is inadequate or inef-fective, because the therapeutic agents cannot cross the blood–brain and blood–retina barriers.

While the utility of immunoisolation has been explored in humans for each of the applications listed in Table II.6.15.2, none of these therapies have yet received FDA approval for routine clinical care. Several of the trials demonstrated significant benefit to many of the subjects, but the overall improvements did not rise to the level of statistical difference between the study and control arms as required by the FDA. The studies were relatively small, often with well under 100 patients in the study arm, and underpowered to demonstrate statistical benefit in complex polyfactorial disease states like liver

failure or chronic pain. By way of comparison, even a straightforward drug trial often includes several thou-sand patients. Biotech start-up companies, which have headed the research in the field of immunoisolation, lack the funds to support studies of this size.

> Failure to demonstrate statistical significance with respect to therapeutic benefit is one of the major limitations in translating encapsulated cell therapies to the clinic.

To further illustrate the historical and current context of encapsulated cell therapy as a viable clinical treatment option, the rest of this chapter will expand upon the util-ity of immunoisolation in the treatment of two diseases, diabetes and adult-onset blindness caused by retinal and macular degeneration, with the former being the oldest and most extensively researched application in the field, and the latter being a promising therapy, currently (as of 2011) undergoing FDA-approved clinical trials.

Diabetes

Encapsulated cells in the format of a biohybrid pancreas were first proposed in 1975 by Chick and his colleagues for the treatment of diabetes (Chick et al., 1975). This group went on to demonstrate the reversal of diabetes in a rat model using encapsulated pancreatic islets sourced from healthy rats (Chick et al., 1977). The islets, con-taining pancreatic beta cells, were encapsulated within a hollow-fiber flow-through device, and connected to the vascular system of diabetic rats via an arteriovenous shunt. No immunosuppressive drugs were employed.
FIGURE II.6.15.4 First Report of a Bioartificial Pancreas. Pancreatic islet cells from healthy neonatal rats were encapsulated within a semi-permeable hollow fiber membrane device and connected to the circulatory system of alloxan-induced diabetic rats via an arteriovenous shunt. This "bioartificial pancreas" caused the plasma glucose concentration to drop steadily and stabilize to a normal non-diabetic range. Blood sugar did not continue to decrease below normal (hypoglycemia), suggesting a feedback loop between the encapsulated islets and the circulating plasma. Glucose returned to elevated levels when the device was removed. This experiment was reported in 1977, 35 years ago. Subsequent investigators have optimized the device and simplified its configuration, but have had very limited success in scaling the bioartifical pancreas up for application in dogs or primates. (Adapted from Chick et al. (1977). *Science,* **197**(4305), 780–782.) Reprinted with permission from AAAS.

Insulin was secreted from the encapsulated cells, diffused out of the capsules, and stabilized the diabetic host's plasma glucose concentration to a normal range, as shown in Figure II.6.15.4. This finding began and validated the field of immunoisolation by demonstrating the utility of encapsulated cells as a viable alternative to traditional transplantation and pharmaceutical treatment (Lim and Sun, 1980; Thanos and Elliott, 2009). The transplanted cells produced insulin that was delivered to the host systemically, and thereby eliminated the need for insulin administration orally or via injection. Just as in the case of insulin secreted by the pancreas, secretions from encapsulated cells were responsive to circulating blood level, a feature that has been thoroughly confirmed in later studies.

Since this first demonstration in 1977, diabetes reversal in rats has been reproduced and reported in dozens of peer-reviewed publications using transplantable macro- and microcapsules containing allo- and xenogeneic islets (Thanos and Elliott, 2009). Porcine islets are particularly popular because porcine insulin was the standard treatment in humans until recombinant human insulin became available in the early 1980s. However, reversal of diabetes in larger animal models, as opposed to mice and rats, has proven to be particularly difficult (Pierson et al., 2009). In canine models, only few groups report cell survival and short-term glucose control with allo- and xenogeneic islets with insulin response (Lanza et al.,

1995; Wang et al., 2008). Even fewer reported the success of encapsulated islets in primates, with the majority of these studies assessing encapsulated cell viability in non-diabetic models (Elliott et al., 2005). The reversal and stabilization of glucose levels in these larger animals often required additional insulin administration to supplement the amount that was being delivered by the encapsulated cells.

Reproducing the success of rodent models in larger animals is difficult due to the complexity of species scaling (see Box 1). First, the device requires a large number of cells, making cell harvesting and processing more difficult than in small animal applications. Beta cells cluster into islets that contain about 3000 cells each. About 5000–10,000 islets per kilogram of body weight are believed to be required for successful pancreatic replacement. While the islets for rodent models can be isolated by hand, due to the small number required (about 500 islets), larger animal models require so many cells (300,000–400,000 islets) that automated processing and multiple donor sources are often needed. This results in lower reliability and consistency within the donor cell population. To date, attempts to produce a robust cell line releasing insulin in response to glucose have been unsuccessful. Additionally, the number of cells necessary poses a limitation on the size of the immunoisolatory device used, in that it must be able to house the required number of cells without adversely affecting the

transport properties of the device. Finally, as discussed earlier, encapsulated cells will secrete small amounts of soluble antigens that can diffuse through the immunoisolatory membrane and elicit immune response in the host tissue. This phenomenon is dose-responsive, and so the large number of cells makes it a particular problem for pancreatic replacement in large animals.

Lack of success in reproducible long-term reversal of diabetes in large animal models has not deterred some researchers from exploring the utility of these implants in humans. For instance, in 1994, Soon-Shiong reported insulin independence and tight glycemic control in a single type 1 diabetic patient nine months after an allogeneic transplant of islets encapsulated within alginate microcapsules (Soon-Shiong et al., 1994). However, the patient was never completely taken off supplementary insulin treatment. Over the years, approximately half a dozen other human clinical trials have been conducted around the world (Thanos and Elliott, 2009), many in countries with lax regulation. Some, but not all, involve microcapsules, and have been criticized for the lack of capsule validation through pre-clinical and animal studies, lack of study arm controls, and failure to publish results in appropriate peer-review studies (Grose 2007; Sykes et al., 2007).

The artificial pancreas remains today where it has been for well over a decade. Efficacy has been abundantly demonstrated in small animal models, but despite extensive efforts and impressive incentives for success, this technology has yet to be translated to a clinically relevant device. Development of a practical bioartificial pancreas remains as one of the great bioengineering challenges of the early 21st century.

Ocular Degeneration

Treatment of retinal and macular degeneration, both of which can lead to adult onset vision loss or even blindness, represents an area of research currently (as of 2011) regarded as offering great promise for bringing encapsulated cells to the clinic. An ocular therapy, called NT-501, is currently under investigation in FDA-regulated Phase II human clinical trials for the treatment of retinitis pigmentosa (RP), and has completed a Phase II for the treatment of dry age-related macular degeneration (AMD) (Sieving et al., 2006; Tao, 2006; Emerich and Thanos, 2008). Formulated by the US-based biotechnology company Neurotech Pharmaceuticals, Inc. (Lincoln, RI, USA), NT-501 is an intraocular implantable macrocapsule containing a genetically modified human retinal pigment epithelial cell line that secretes ciliary neurotrophic growth factor (CNTF). The device consists of a polysulfone hollow-fiber membrane which houses the cells, and an internal poly(ethylene terephthalate) yarn scaffold matrix. The entire device is sealed and has a small titanium anchoring loop embedded in one end that is used to tether the device to the sclera after it is placed in the vitreous body of the eye.

CNTF has been shown to be very effective in delaying retinal degeneration in RP animal models, and thus is a promising therapeutic for the treatment of RP and AMD, both of which currently have no available cure or viable treatment options. By delivering CNTF directly *in situ* to the retina, NT-501 circumvents the blood–retina barrier that systemically restricts the retinal tissue, a circumstance which poses a challenge to traditional drug therapies.

NT-501 has fared well in the regulatory process, having been granted "Fast Track" status by the FDA. This status allows for accelerated regulatory review of a drug therapy that exhibits potential to meet the treatment needs of a serious or life-threatening condition that currently has no available treatment options. The randomized, multi-center RP trials (early- and late-stage) each have 60 patients enrolled, while the completed AMD trial had a total of 51 patients. Results from the Phase 2 RP trials, along with the results from the completed AMD trial, reveal a significant increase in retinal thickness with treatment. Additionally, the AMD trials have shown the stability of visual acuity with NT-501 treatment. Together, these results all suggest that the intraocular delivery of CNTF by NT-501 may in fact be effective in decelerating ocular degeneration and loss of vision.

The success of ocular implants in clinical trials, as compared to diabetes implants, is due to a number of factors including the site of implantation, the cell type, and the relatively small population of cells implanted. Unlike the majority of diabetes implants, NT-501 is placed in the eye, which is a more immune-privileged region *in vivo* than the peritoneal cavity. Additionally, NT-501 contains an allogeneic cell line that is easier to source and validate than the xenogeneic or primary human cells utilized in the diabetes implants. Finally, NT-501 contains half a million cells, while most encapsulated cell therapies for treatment of diabetes contain over a billion. The smaller number of cells provides a smaller immune challenge, and significantly simplifies the design and manufacture of the implant.

CONCLUDING PERSPECTIVES

Encapsulated cell therapy remains a promising approach to the treatment of many serious diseases which still lack satisfactory therapies. The technology, especially for macroencapsulation, is well-developed. Clinical trials have been encouraging, although not yet definitive. The remaining challenges relate to more extensive clinical trials, and to regulatory approval.

CHAPTER II.6.16 TISSUE ENGINEERING WITH DECELLULARIZED TISSUES

Stephen F. Badylak, Bryan N. Brown, and Thomas W. Gilbert
McGowan Institute for Regenerative Medicine, University of Pittsburgh, Pittsburgh, PA, USA

INTRODUCTION

Materials for the repair or reconstruction of injured, missing or weakened tissues can be composed of either synthetic or naturally occurring components. The optimal material for each application should be selected based upon criteria such as the structural and mechanical requirements of the intended application, the type of response expected from the adjacent host tissue, and the ability of the material to support normal tissue growth and function over the long-term. Unlike conventional surgical repair procedures, in which a biomaterial mesh simply needs to have sufficient strength to hold adjacent tissues together and avoid an adverse host response, tissue engineering and regenerative medicine approaches utilize "scaffold" materials to facilitate the restoration of the normal structure and function of the tissue or organ of interest. The present chapter will focus exclusively upon the use of decellularized tissues (i.e., extracellular matrix) as scaffold materials in tissue engineering and regenerative medicine applications.

Every tissue and organ is composed of cells and extracellular matrix (ECM). The ECM consists of the secreted products, both structural and functional, of the resident

cells of each tissue and organ. The composition and ultrastructure of the ECM is determined by factors that influence the phenotype of its resident cells, including mechanical forces, biochemical milieu, oxygen requirements, pH, and inherent gene expression patterns. In turn, the ECM influences the attachment, migration, proliferation, and three-dimensional organization of cells, as part of a process of dynamic reciprocity (Bissell et al., 1982; Boudreau et al., 1995; Ingber, 1991). The ECM is essentially an "information highway" between its embedded cells and serves a critical function in tissue and organ homeostasis, as well as response to injury.

For these same reasons, multiple forms of allogeneic and xenogeneic ECM have been isolated, processed into application-appropriate configurations, and investigated as scaffolds for tissue engineering and regenerative medicine purposes in multiple body systems. Tissue engineering and regenerative medicine approaches utilizing ECM scaffolds have been successfully used in both pre-clinical and clinical studies. Examples of ECM scaffold sources, configurations, and tissues that have been reconstructed using ECM scaffolds are listed in Table II.6.16.1, and examples of commercially available ECM scaffold materials, their source tissue, and configuration are provided in Table II.6.16.2.

The success of ECM scaffolds in tissue engineering and regenerative medicine applications may be attributed in large part to their ability to modulate the default mechanisms of tissue repair. In general, the response following implantation of an acellular non-chemically cross-linked ECM scaffold has been described as "constructive remodeling." That is, ECM scaffolds are capable of inducing the formation of new tissue structures that are arranged in a spatially appropriate pattern for the tissue of interest. For example, ECM scaffolds have been shown to be capable of inducing the formation of functionally innervated muscular tissue in a model of abdominal wall reconstruction (Agrawal et al., 2009; Valentin et al., 2010). This is in direct contrast to the default mechanism of mammalian response to injury that involves inflammation and scarring.

The objective of this chapter is to provide a rationale for the use of ECM as a scaffold for tissue engineering and regenerative medicine applications, an overview of the methods used in the preparation of ECM materials, a description of the composition and structure of such scaffold materials, and the mechanisms by which these biologic materials function as inductive scaffolds for tissue reconstruction.

RATIONALE FOR THE DECELLULARIZATION OF TISSUES AND ORGANS AND THE USE OF DECELLULARIZED TISSUES AS SCAFFOLDS IN TISSUE ENGINEERING AND REGENERATIVE MEDICINE

Individual ECM components such as collagen I, laminin, and fibronectin have been isolated, purified, and processed for use in cell culture, as biomaterial coatings, and

as three-dimensional scaffolds for tissue engineering and regenerative medicine applications (Dejana et al., 1987; Macarak and Howard, 1983; Glowacki and Mizuno, 2008). These approaches have typically been successful for such applications. However, an advantage of utilizing ECM materials that have been derived through the decellularization of intact tissues or organs as substrates or scaffolds for cell growth and differentiation is the presence of tissue-specific structural and functional molecules (and their inhibitors) in the same relative amounts that exist in nature, and in their native three-dimensional ultrastructure. The ECM is capable of presenting these factors efficiently to resident or migrating cell surface receptors, protecting growth factors from degradation, and modulating the synthesis of new ECM molecules (Entwistle et al., 1995; Bonewald, 1999; Kagami et al., 1998; Roberts et al., 1988; Freise et al., 2009). If one considers the ECM as a substrate for *in vivo* cell growth, migration, and differentiation, it is reasonable to think of the ECM as a temporary (i.e., degradable) controlled release vehicle for naturally derived functional molecules. Many groups have attempted to create ECM analogs using individual ECM components and/or synthetic materials (Causa et al., 2007; Alini et al., 2003; Koh et al., 2008); however, the diversity and complex structure of the molecules that make up the ECM predict the difficulty of creating such a scaffold *in vitro*. It is for these reasons that the isolation of ECM through the decellularization of tissues and organs is an effective method for the production of materials to be used in tissue engineering and regenerative medicine approaches to tissue reconstruction.

METHODS OF DECELLULARIZATION

The tissues from which ECM scaffold materials are harvested, the species of origin, the decellularization method, and the methods by which the material is sterilized can vary widely. Antigenic epitopes associated with cell membranes and intracellular components of tissues and organs are the primary cause of the adverse immunologic response elicited by allogeneic and xenogeneic tissue transplants (Erdag and Morgan, 2004; Gock et al., 2004; Ross et al., 1993), while the molecules that constitute the extracellular matrix are generally conserved across species lines, and are well-tolerated even by xenogeneic recipients (Bernard MPC et al., 1983; Bernard MPM et al., 1983; Constantinou CDJ, 1991; Exposito JYDA et al., 1992). Therefore, a suitable ECM scaffold material must be effectively treated to remove cellular material or chemically cross-linked to mask the antigens prior to implantation. The most commonly used chemical cross-linking agents are gluteraldehyde, carbodiimide, genipin, and hexamethylene-diisocyanate (Bhrany et al., 2006; Billiar et al., 2001; Harper, 2001). Although a description of the specific effects of chemical cross-linking on ECM scaffold materials is not within the scope of this chapter, the choice to decellularize or chemically cross-link the

material has important effects on the host tissue response, which will be discussed later in the chapter.

Although it seems logical that the decellularization process will by definition affect the structure and composition of the extracellular matrix, the ultimate goal of any decellularization protocol is to remove all cellular material without adversely affecting the biochemical composition, mechanical behavior, topographical ligand landscape, and eventual biologic activity of the remaining scaffold material (Crapo et al., 2011). Decellularization processes generally begin with exposure of the tissue to ionic solutions to disrupt the cell membrane, followed by separation of cellular components from the ECM using enzymatic treatments (e.g., trypsin or nucleases), solubilization of cytoplasmic

and nuclear components using detergents (e.g., most commonly sodium dodecyl sulfate, sodium deoxycholate or Triton™ X-100), and ultimately removal of cellular debris from the ECM scaffold material. Alkaline and acidic solutions are also commonly used to remove nucleic acids from ECM scaffolds, and to disinfect the material prior to sterilization. All of these steps can be coupled with physical treatments (e.g., freezing, direct pressure, sonication, and agitation) to increase their effectiveness. Following decellularization, all residual chemicals must be removed by thorough rinsing to avoid an adverse host–tissue response to the decellularization agents.

Most commercially available biologic scaffold materials are manufactured by first processing the organ of interest into a sheet prior to decellularization. However, due to the density, mass, and three-dimensional architecture of many whole organs such as the heart, liver, and kidney, these approaches are not effective for removing cellular material from these tissues (Crapo et al., 2011). Recent reports have described methodology for decellularizing intact hearts by perfusion of the same reagents described above through the existing vascular network (Ott et al., 2008; Wainwright et al., 2010). Although additional work is still needed, these preliminary reports suggest that the native three-dimensional architecture and biochemical composition of the tissue can be largely preserved, thus providing a promising approach for complex organ engineering (Badylak et al., 2012).

Despite the goal of preserving the intact ECM after the decellularization process, each treatment has an effect on the tissue. Detergents have been shown to disrupt the collagen that is present within certain tissues, thereby decreasing the mechanical strength of the resulting ECM scaffold. The same detergent may, however, have no effect on the collagen present within another tissue (Cartmell and Dunn, 2004; Woods and Gratzer, 2005). This is likely due to the diversity of the types of collagen known to exist within tissues and organs, many of which serve tissue-specific functions (van der Rest and Garrone, 1991). Studies have also shown that removal of glycosaminoglycans (GAGs) from the scaffold can adversely affect scaffold remodeling and the viscoelastic behavior of the scaffold (Cartwright et al., 2006; Lovekamp et al., 2006). Therefore, decellularization methods require optimization for each tissue and organ to remove cellular material without compromising the structural and functional properties of the remaining ECM.

Despite efforts to fully decellularize tissues, most commonly used methods are insufficient to achieve complete decellularization, as most if not all ECM scaffold materials retain some amount of DNA (Derwin et al., 2006; Farhat et al., 2008; Gilbert et al., 2009). In addition, antigens such as the galactosyl alpha 1,3 galactose (i.e., gal-epitope) have been shown to be present in porcine ECM. Fortunately, the gal-epitope in ECM scaffolds does not activate complement or bind IgM antibody, presumably because of the small amount and widely scattered distribution of antigen (McPherson et al., 2000; Raeder et al., 2002). So, while the full removal of cellular content remains the goal of the decellularization process, it appears that there is a threshold below which the amount or integrity of the cellular material is insufficient to invoke immune-mediated rejection. The presence and effects of these molecules will be discussed more fully later in the chapter.

ECM CONFIGURATION

Following the decellularization of a tissue or organ, the resulting ECM may take on a variety of shapes and sizes which are dependant on the particular architecture of the decellularized organ of interest or the methods used in the decellularization process (Gilbert et al., 2006). As mentioned previously, many tissues and organs such as dermis, small intestine, and urinary bladder are typically processed into a sheet-like configuration prior to decellularization. The sheet form may be insufficient in its mechanical properties and/or three-dimensional morphology (i.e., shape and size) depending on the application of interest. Therefore, a number of methods have been utilized for the processing of ECM scaffolds into a variety of application-specific shapes and sizes. Intact ECM scaffolds have been molded and vacuum pressed into shapes that include tubes (Badylak et al., 2005), cones (Nieponice et al., 2006), and multilaminate sheets, among others (Freytes et al., 2004). These scaffolds have been utilized in applications ranging from esophageal repair (tubular) (Badylak et al., 2005) to gastro-esophageal junction repair (cone-shaped) (Nieponice et al., 2006), and orthopedic applications (multi-laminate sheets) (Dejardin et al., 2001). ECM materials have also been comminuted to create a powder form of the scaffold, which is of interest for injectable and space-filling applications (Gilbert et al., 2005). A hydrogel form of ECM has also been produced via enzymatic degradation of whole ECM scaffolds (Freytes et al., 2008). The ability of ECM scaffolds to be formed into varied shapes and sizes further add to their utility as scaffolds for tissue engineering and regenerative medicine applications.

Composition of Extracellular Matrix

Most of the component molecules of the ECM are well-recognized and form a complex, tissue-specific meshwork of proteins, glycosaminoglycans, glycoproteins, and small molecules (Laurie et al., 1989; Baldwin, 1996; Martins-Green and Bissel, 1995). The logical division of the ECM into structural and functional molecules is not possible, because many of the component molecules have both structural and functional roles in health and disease. For example, both collagen and fibronectin, molecules that were once considered to exist purely for their "structural" properties, are now known to have a variety of "functional" moieties,

with properties ranging from cell adhesion and motility to angiogenesis or inhibition of angiogenesis. These "bimodal" or multifunctional molecules provide a hint of the diverse cryptic peptide sequences that exist within certain parent molecules and which, in themselves, have biologic effects that significantly affect the ECM scaffold remodeling process (Agrawal et al., 2010, 2011a,b). This section will highlight a number of the molecules that are known to exist within many of the ECM scaffolds described in this chapter. However, it should be noted that the ECM of each tissue and organ is unique, and the exact composition depends largely on the resident cell population and the function of the organ of interest. Chapter I.2.7 also discusses many natural biomolecules and their use as biomaterials.

Collagen. There are more than 20 distinct types of collagen, each with a unique biologic function. These proteins account for nearly 90% of the dry weight of the ECM of most tissues and organs (van der Rest and Garrone, 1991). Type I collagen is the major structural protein present in tissues, and is found ubiquitously throughout the plant and animal kingdoms. Type I collagen is particularly abundant in ligamentous, tendinous, and connective tissue structures, and provides the strength necessary to accommodate the uniaxial and multiaxial mechanical loading to which these tissues are commonly subject. These same tissues provide a convenient source of collagen for many medical device applications. For example, bovine type I collagen is harvested from Achilles tendon, and is perhaps the most commonly used xenogeneic ECM component intended for therapeutic applications.

Other collagen types also exist in the ECM of most tissues, but typically in much lower quantities. These alternative collagen types provide distinct, tissue-specific, physical and mechanical properties to the ECM, while simultaneously acting as ligands that interact with the resident cell populations. For example, type III collagen is found within the submucosal tissue of selected organs such as the urinary bladder; a location in which tissue flexibility and compliance are required for appropriate function, as opposed to the more rigid properties required of a tendon or ligament supplied by type I collagen (Piez, 1984). Type IV collagen is present within the basement membrane of most vascular structures, and within tissues that contain an epithelial cell component (Piez, 1984; Barnard and Gathercole, 1991; Yurchenco et al., 1994). The ligand affinity of type IV collagen for endothelial cells is the reason for its use as a biocompatible coating for medical devices intended to have a blood interface. Type VI collagen is a relatively small molecule that serves as a connecting unit between glycosaminoglycans and larger structural proteins such as type I collagen, thus providing a gel-like consistency to the ECM (Yurchenco et al., 1994), and has recently been shown to sequester latent forms of matrix metalloproteinases (Freise et al., 2009). Type VII collagen is found within the

basement membrane of the epidermis, and functions as an anchoring fibril to protect the overlying keratinocytes from sheer stresses (Yurchenco et al., 1994). In nature, collagen is intimately associated with glycosylated proteins, growth factors, and other structural proteins such as elastin and laminin to provide unique tissue properties (Yurchenco et al., 1994). Each of these types of collagen exists within many of the ECM scaffolds used in tissue engineering and regenerative medicine applications.

Fibronectin. Fibronectin, second only to collagen in quantity within the ECM of most tissues, was the first primarily "structural" molecule identified to also possess a functional motif. Fibronectin is a dimeric molecule of 250,000 MW subunits, and exists both in tissue and soluble isoforms and possesses ligands for adhesion of many cell types (McPherson and Badylak, 1998; Miyamoto et al., 1998; Schwarzbauer, 1991, 1999). The ECM of submucosal structures, basement membranes, and interstitial tissues all contain abundant fibronectin (McPherson and Badylak, 1998; Schwarzbauer, 1999). The cell-friendly characteristics of this protein have made it an attractive substrate for *in vitro* cell culture. Fibronectin has also been used as a coating for synthetic scaffold materials to promote host biocompatibility. Fibronectin is rich in the Arg-Gly-Asp (RGD) subunit, a tripeptide that is important in cell adhesion via the $\alpha_5\beta_1$ integrin (Yurchenco et al., 1994), and is found at an early stage within the ECM of developing embryos. Fibronectin is critical for normal biologic development, especially the development of vascular structures. The importance of this molecule and its interactions with other matrix components cannot be overstated with regard to cell–matrix communication.

Laminin. Laminin is a complex adhesion protein found in the ECM, especially within the basement membrane (Schwarzbauer, 1999). This protein plays an important role in early embryonic development, and is perhaps the best studied of the ECM proteins found within embryonic bodies (Li et al., 2002). Laminin is a trimeric cross-linked polypeptide that exists in numerous forms dependent upon the particular mixture of peptide chains (e.g., $\alpha 1$, $\beta 1$, $\gamma 1$) (Timpl, 1996; Timpl and Brown, 1996). The prominent role of laminin in the formation and maintenance of vascular structures is particularly noteworthy when considering the ECM as a scaffold for tissue reconstruction (Ponce et al., 1999; Werb et al., 1999). The crucial role of the beta-1 integrin chain in mediating hematopoietic stem cell interactions with fibronectin and laminin is well-established (Ponce et al., 1999; Werb et al., 1999). Loss of the beta-1 integrin receptors in mice results in intrapartum mortality. This protein appears to be among the first and most critical ECM factors in the process of cell and tissue differentiation. The specific role of laminin in tissue reconstruction when ECM is used as a scaffold for tissue engineering and regenerative medicine applications is unclear; however, its importance in normal development suggests that this molecule is essential for self-assembly of cell populations, and for

organized functional tissue development, as opposed to scar tissue formation.

Glycosaminoglycans. A mixture of glycosaminoglycans (GAGs) is present within native ECM, with the amount and relative distribution dependent upon the tissue location of the ECM in the host, the age of the host, and the microenvironment. These GAGs promote water retention, bind growth factors and cytokines, and contribute to the gel properties of the ECM. The heparin-binding properties of numerous cell surface receptors and of many growth factors (e.g., fibroblast growth factor family, vascular endothelial cell growth factor) make the heparin-rich GAGs important components of naturally occurring substrates for cell growth. The glycosaminoglycans present in ECM include chondroitin sulfates A and B, heparin, heparan sulfate, and hyaluronic acid (Entwistle et al., 1995; Hodde et al., 1996). Hyaluronic acid has been extensively investigated as a scaffold material for tissue reconstruction and as a carrier for selected cell populations in therapeutic tissue engineering applications (Chapter I.2.7). The concentration of hyaluronic acid within ECM is highest in fetal and newborn tissues (greater than 20% of total GAGs), and has been associated with desirable healing properties. The specific role, if any, of hyaluronic acid upon progenitor cell proliferation and differentiation during adult wound healing is unknown.

Growth Factors. A characteristic of ECM scaffolds that clearly distinguishes them from other scaffolds for tissue reconstruction is the diversity of the structural and functional proteins that contribute to its composition. The bioactive molecules that reside within the ECM and their unique spatial distribution patterns provide a reservoir of biologic signals. Although the quantity of cytokines and growth factors present within ECM is very small, these molecules act as potent modulators of cell behavior. The list of growth factors found within ECM is extensive, and includes the fibroblast growth factor (FGF) family, vascular endothelial cell growth factor (VEGF), stromal-derived growth factor (SDF-1), transforming growth factor beta (TGF-beta), keratinocyte growth factor (KGF), epithelial cell growth factor (EGF), platelet-derived growth factor (PDGF), hepatocyte growth factor (HGF), and bone morphogenetic protein (BMP), among others (Bonewald, 1999; Kagami et al., 1998; Roberts et al., 1988). These factors exist in multiple isoforms, each with a unique biologic activity. Purified forms of growth factors have been investigated in recent years as therapeutic methods of encouraging blood vessel formation (e.g., VEGF), stimulating deposition of granulation tissue (PDGF), and bone (BMP), and encouraging epithelialization of wounds (KGF). However, this therapeutic approach has been disappointing, because of the difficulty in determining optimal dose and methods of delivery, the ability to sustain and localize the growth factor release at the desired site, and the inability to turn the factor "on" and "off" as needed during the course of tissue repair. An important function of the ECM is its role as a reservoir for latent forms of many growth factors and its ability to release these factors during the process of *in vivo* degradation (Freise et al., 2009).

MECHANISMS BY WHICH ECM SCAFFOLDS FUNCTION AS INDUCTIVE TEMPLATES FOR TISSUE RECONSTRUCTION

The mechanisms by which decellularized tissue (i.e., the ECM remaining following decellularization) scaffolds support a constructive remodeling process and the formation of new functional tissue when appropriately utilized in tissue engineering and regenerative medicine applications are not fully-understood. However, several biologically important events have been clearly associated with positive outcomes. Among these events are: (1) a robust innate immune response consisting of neutrophils at early time points, changing to a predominantly mononuclear cell/macrophage cell population during the 2–3 week period following implantation (Chapter II.2.2); (2) rapid and complete scaffold degradation and the release of bioactive matricryptic peptides from parent molecules within the ECM; (3) abundant angiogenesis which accompanies the deposition of new ECM by the cells that have infiltrated the scaffold; and (4) spatial and temporal remodeling which is clearly respondent to mechanical forces. Each of these events will be discussed separately, but it should be understood that they are occurring simultaneously and are interdependent upon each other for a constructive remodeling outcome following the implantation of an ECM scaffold.

Host Cell and Immune Responses to Implanted ECM Scaffolds

The mechanisms of the host cellular and humoral response to whole organ transplantation are reasonably well-understood. Xenogeneic and allogeneic cellular antigens are recognized by the host, elicit immune activation, and cause the production of pro-inflammatory mediators with downstream cytotoxicity and transplant tissue rejection. The mechanisms of the host immune response to acellular scaffolds derived from ECM, either allogeneic or xenogeneic, are neither as well-studied nor as well-understood as whole organ and tissue transplantation. The preparation of ECM scaffolds for tissue engineering and regenerative medicine applications involves the decellularization of the tissue or organ from which the ECM is to be harvested (Gilbert et al., 2006). The removal of the cellular component produces a different type of "tissue graft" than is typically presented with autogeneic, allogeneic or xenogeneic whole organ grafts. An ECM scaffold consists primarily of the ECM constituent molecules, many of which have been found to be conserved across species (van der Rest and Garrone, 1991), thus mitigating many adverse components of the host immune response (Allman et al., 2001).

Potential Immune Activating Molecules within ECM Scaffolds

Following the removal of resident cells from the tissue of interest, the majority of the components of the remaining ECM scaffold are conserved across species and are, therefore, largely non-immunogenic. However, many ECM scaffolds have been shown to contain a number of components that are thought to induce adverse host immune- and/or rejection-type responses when present in large quantities. These components include the α-Gal epitope and DNA. The α-Gal epitope is known to cause hyperacute rejection of organ transplants (Collins et al., 1994; Cooper et al., 1993; Galili et al., 1985; Oriol et al., 1993). However, studies of α-Gal-positive ECM scaffold implantation have not shown adverse responses that can be attributed to the α-Gal epitope (Raeder et al., 2002; Daly et al., 2009). A recent study investigated the effects of the presence of the α-Gal epitope upon the remodeling of ECM scaffolds in a non-human primate model (Daly et al., 2009). The study compared the host response to ECM derived from allogeneic, xenogeneic porcine, and xenogeneic α-Gal$^{-/-}$ porcine sources. The results of the study showed that although those animals implanted with an ECM scaffold containing the α-Gal epitope exhibited an increase in serum anti-Gal antibodies, there were no adverse effects of the α-Gal epitope upon the remodeling response. Several studies have shown the presence of DNA fragments remaining within ECM scaffolds following the decellularization and sterilization processes (Roberts et al., 1988; Derwin et al., 2006; Zheng et al., 2005). A recent study examined the presence of DNA within a number of commercially available ECM scaffolds (Gilbert et al., 2008), some of which are listed in Table II.6.16.2. The results of the study showed that, although all of the products tested contained small amounts of DNA, the remnants generally consisted of fragments of less than 300 bp. Despite the presence of small amounts of both the α-Gal epitope and DNA within ECM scaffolds, adverse clinical effects have not been observed. This is likely due to the minute amounts of these components present, and the rapid degradation of the ECM scaffold. It has been shown that the presence of large amounts of cellular material within an implanted ECM scaffold lead to scar tissue formation, as opposed to the modulation of the host response towards a constructive remodeling outcome (Brown et al., 2008). Therefore, it is probable that there is a threshold amount of these components required to induce adverse effects upon the remodeling response.

Innate Immune Response to ECM Scaffolds

In general, innate immune cells (neutrophils and macrophages) are the first cells to encounter and respond to implanted biomaterials (also see Chapter II.2.2).

The immediate cellular response observed following the implantation of an ECM scaffold consists almost exclusively of neutrophils, as one might expect, but there is also a significant mononuclear cell component. In the absence of large amounts of cellular debris within the scaffold, chemical cross-linking or an excess of contaminants such as endotoxin, the neutrophil infiltrate diminishes almost entirely within 72 hours and is replaced by a mononuclear cell population. This type of response, characterized by a large infiltration of innate immune cells, has been conventionally interpreted as either acute or chronic inflammation with associated negative implications. However, the presence of these cells, especially mononuclear macrophages, has been shown to be essential to the formation of the type of constructive remodeling response that has been observed following the implantation of ECM scaffolds (Brown et al., 2008, 2012; Valentin et al., 2006, 2009; Badylak et al., 2008).

A histologically similar population of neutrophils and macrophages is observed following the implantation of ECM scaffolds which either have or have not been processed using chemical cross-linking agents such as glutaraldehyde or carbodiimide; however, the tissue remodeling outcome observed following the implantation of chemically cross-linked ECM scaffolds is distinctly different than that observed with the use of non-cross-linked scaffolds (Valentin et al., 2006). The host tissue response typically observed following implantation of an acellular ECM scaffold that has not been chemically cross-linked is characterized by a dense infiltration of neutrophils at early time-points, changing to primarily mononuclear cells thereafter. This infiltrate of innate immune cells is accompanied by rapid degradation of the ECM scaffold, and replacement with organized, site-specific, functional host tissue (Valentin et al., 2006; Badylak et al., 2002; Gilbert et al., 2007c). If the scaffold has been processed using chemical cross-linking agents such as glutaraldehyde or carbodiimide, the host response is characterized by a similar presence of a large number of neutrophils and macrophages, but results in a more typical pro-inflammatory response consisting of dense fibrous tissue encapsulation and the prolonged presence of a multinucleate cell population (Valentin et al., 2006). Although histologically similar populations of neutrophils and macrophages are present in the host response to either scaffold type, studies have linked the differences observed in remodeling outcomes, in part, to differences in the phenotype of the host innate immune cells which participate in the host response to implanted ECM scaffolds (Brown et al., 2008; Badylak et al., 2008).

Mononuclear macrophages are plastic innate immune cells that are capable of changing their phenotype in response to local stimuli during the process of wound healing. The macrophages participating in

the host response following implantation of a biomaterial are exposed to multiple stimuli, including cytokines and effector molecules secreted by cells (including other macrophages) participating in the host response, microbial agents, epitopes associated with the implanted biomaterial, and the degradation products (if any) of the biomaterial, among others. Recently, macrophages have been characterized by differential receptor expression, cytokine, and effector molecule production, and function as having either an M1 or M2 phenotype (Mantovani et al., 2004; Mills et al., 2000). M1 or classically activated macrophages, produce pro-inflammatory cytokines and effector molecules, possess the ability to efficiently present antigen, and are inducer and effector cells in Th1-type inflammatory responses (Gordon and Taylor, 2005; Mosser, 2003; Verreck et al., 2006; Mantovani et al., 2005). M2 or alternatively activated macrophages, are generally characterized by minimal production of pro-inflammatory cytokines, their involvement in Th2-type responses, and their ability to facilitate tissue repair and regeneration. The overall M1/M2 profile of the host macrophage response to an implanted material will fall somewhere along a continuum between the M1 and M2 extremes (Mills et al., 2000). It should be noted that M1 and M2 macrophages are indistinguishable by the routine histologic methods that are generally used to evaluate the host response to a biomaterial. A full description of the activating signals, characteristic surface markers, gene expression, effector molecule production, and biologic activity associated with M1 and M2 macrophages is beyond the scope of this chapter; however, this subject has been reviewed extensively elsewhere (Martinez et al., 2008).

Recent studies of the M1/M2 profile of the macrophages responding to implanted ECM scaffolds have shown that acellular, non-cross-linked ECM scaffolds elicit an enhanced M2-type macrophage response, and result in constructive tissue remodeling (Brown et al., 2008, 2012; Badylak et al., 2008). Chemically cross-linked ECM scaffolds, however, elicit a predominantly M1-type macrophage response and result in a more typical foreign-body-type of response that includes the deposition of dense collagenous connective tissue, and a lack of constructive remodeling. Autograft controls also exhibited a predominance of the M1 phenotype, and resulted in scarring. The exact mechanisms by which acellular non-cross-linked ECM scaffolds are capable of modulating the default host macrophage response are, as of yet, unknown. However, it is increasingly clear that the M1/M2 polarization profile of the macrophages that participate in the host response to ECM scaffolds is related to the downstream outcome associated with their implantation (Brown et al., 2012). Further, characterization and control of the M1/M2 phenotype may provide a tool by which a constructive and functional tissue remodeling outcome can be predicted and/or promoted.

T-Cell-Mediated Immune Response to ECM Scaffolds

In addition to eliciting a robust, but friendly, host innate immune response, acellular non-cross-linked ECM scaffolds have consistently been shown to evoke a Th2-type T-cell response (Allman et al., 2001, 2002). The Th2 response is generally associated with transplant acceptance. One study utilized a mouse model of subcutaneous implantation to examine the T-cell response to xenogeneic muscle tissue, syngeneic muscle tissue, and an acellular ECM scaffold (Allman et al., 2001). Results showed that the xenogeneic tissue implant was associated with a response consistent with rejection. That is, the xenogeneic muscle implant showed signs of necrosis, granuloma formation, and encapsulation. The syngeneic tissue and the ECM scaffold elicited an acute inflammatory response that resolved with time, and resulted in an organized tissue morphology at the remodeling site. Tissue cytokine analysis revealed that the ECM group elicited expression of IL-4, and suppressed the expression of IFN-γ compared to the xenogeneic tissue implants. The ECM group elicited the production of an ECM-specific antibody response; however, it was restricted to the IgG1 isotype. Reimplantation of the mice with another ECM scaffold led to a secondary anti-ECM antibody response that was also restricted to the IgG1 isotype, and there was no evidence of the formation of a Th1-type response. Further investigation confirmed that the observed responses were in fact T-cell-dependent. Finally, it has been shown that, while both T- and B-cells respond to ECM scaffolds, they are not required for acceptance or constructive remodeling of an ECM implant (Allman et al., 2001). This further indicates the importance of the host innate immune response in driving/determining the downstream remodeling outcome following implantation of an ECM scaffold.

Degradation of ECM Scaffolds. ECM scaffolds are rapidly degraded *in vivo*. A recent study showed that 10 layer ^{14}C-labeled ECM scaffolds were 60% degraded at 30 days post-implantation and 100% at 90 days post-surgery in a model of canine Achilles tendon repair (Gilbert et al., 2007c). During this period, the scaffold was populated and degraded by host cells, and resulted in the formation of site-specific functional host tissue. The major mechanism of excretion of the degraded scaffold was found to be via hematogenous circulation and elimination by the kidneys, urine, and exhaled CO_2 (Record et al., 2001). The mechanisms of *in vivo* degradation of ECM scaffolds are complex, and include both cellular and enzymatic pathways. The process is mediated by inflammatory cells, such as macrophages, which produce oxidants as well as proteolytic enzymes that aid in the degradation of the matrix. Another

study utilizing ^{14}C-labeled ECM scaffolds showed that peripheral blood monocytes are required for the early and rapid degradation of both ECM scaffolds, and that cross-linked ECM scaffolds are resistant to macrophage-mediated degradation (Valentin et al., 2009).

ECM scaffolds have also been degraded *in vitro* by chemical and physical methods. Recent findings suggest that the degradation products of ECM scaffolds are bioactive (Brennan et al., 2006, 2008; Haviv et al., 2005; Li et al., 2004; Reing et al., 2009; Sarikaya et al., 2002). Studies have shown antimicrobial activity associated with the degradation products of ECM scaffolds; however, in the absence of degradation, antimicrobial activity was not seen, suggesting that some of the bioactive properties of the ECM are derived from its degradation products, rather than from whole molecules present in the ECM (Holtom et al., 2004). Degradation products of ECM scaffolds have also been shown to be chemoattractants for progenitor and non-progenitor cell populations (Brennan et al., 2008; Haviv et al., 2005; Li et al., 2004; Reing et al., 2009). An ECM scaffold that cannot degrade (i.e., is chemically cross-linked) may not release bioactive degradation products, including those bioactive molecules that may be responsible for modulating the host response towards constructive remodeling. Furthermore, chemical cross-linking may alter ligand–receptor interactions important in determining cell–scaffold interactions.

One of the biologic effects of ECM degradation is the recruitment of host stem and progenitor cells to the site of degradation. A study of ECM scaffold remodeling in a mouse Achilles tendon model examined the ability of ECM scaffolds and autograft tissue to recruit bone marrow-derived cells (Zantop et al., 2006). Bone marrow-derived cells were observed in the sites of remodeling associated with both ECM scaffolds and autograft control tissue, among what appeared to be predominantly mononuclear cells at early time points (1 and 2 weeks) post-surgery. Both scaffold types remodeled into tissue resembling the native Achilles tendon; however, by 16 weeks the presence of bone marrow-derived cells was observed only in the ECM treated group. Another study, also utilizing a model of mouse Achilles tendon, examined the ability of ECM scaffold explants to cause the chemotaxis of progenitor cells after 3, 7, and 14 days of *in vivo* remodeling (Beattie et al., 2009). The results of the study showed greater migration of progenitor cells towards tendons repaired with ECM scaffolds, compared to tendons repaired with autologous tissue and uninjured normal contralateral tendon. The mechanisms by which ECM scaffolds recruit progenitor cell populations during *in vivo* remodeling and the specific phenotype of the cells recruited remains unknown, and the effects of the recruited cells upon the scaffold remodeling process is also not well-understood.

Angiogenesis and New ECM Deposition

Angiogenesis is implicit to the success of many tissue engineering and regenerative medicine strategies involving biomaterials. The in-growth of vessels into a tissue-engineered construct provides a means for nourishing the tissue growing on or within the implanted material. In the absence of angogenesis, many implanted biomaterials may fail to integrate with the surrounding tissue, and/or fail to support cell populations that have been seeded onto or migrate into the material. The process of angiogenesis within the native extracellular matrix of tissues and organs has been studied in-depth. The mechanisms by which ECM scaffolds facilitate angiogenesis are not clear. Angiogenesis has, however, been shown to be a prominent feature of ECM scaffold remodeling, and is commonly observed within the first 1–3 days following scaffold implantation. These vessels remain within the implantation site, and continue to provide a blood supply to the remodeling tissue throughout the remodeling process. It has been shown that certain ECM scaffolds contain bioactive VEGF (a potent angiogenic factor) and basic fibroblast growth factor (bFGF) (Chun et al., 2007). Factors such as these may account, in part, for the ability of ECM scaffolds to promote angiogenesis at early time points following implantation.

Response to Mechanical Stimuli

Several studies have shown that early site-appropriate mechanical loading facilitates the remodeling of ECM scaffold materials into site-specific tissue (Boruch et al., 2009; Hodde et al., 1997). In a recent pre-clinical study, partial cystectomies repaired with an ECM scaffold material were exposed to long-term catheterization and prevention of bladder filling, with an associated lack of cyclic distention and decrease in maximal bladder distention, compared to bladders that experienced an early return to normal micturition following ECM scaffold implantation (Boruch et al., 2009). The presence of physiologic amounts of mechanical loading in the early timeframe promoted remodeling of the ECM scaffold material into tissue that had a highly differentiated transitional urothelium, vasculature, innervation, and islands of smooth muscle cells. Delayed return of normal mechanical loading was insufficient to overcome the lack of early mechanical signals, and resulted in degradation of the ECM scaffold material without constructive remodeling.

Similar results were observed in a study of Achilles tendon repair in rabbits, with and without post-surgical immobilization (Hodde et al., 1997). With early mechanical loading, the SIS was rapidly infiltrated by mononuclear cells and new, highly aligned host collagenous connective tissue eventually replaced the ECM scaffold. In contrast, after a period of immobilization, cell infiltration into the scaffold was limited to the periphery of the

graft, and little or no ECM remodeling was observed. The lack of cellular infiltration in the immobilized Achilles tendon differed from the abundant mononuclear cell population observed in the early catherization group in the study described above, possibly due to the inadvertent pressure on the bladder from surrounding tissues. It is possible that non-specific mechanical loading may have contributed to the cell infiltration, but site-appropriate mechanical loading is necessary for site-specific remodeling.

When ECM was used for vascular reconstruction, the host remodeling response was different in the arterial system than in the venous system (Lantz et al., 1993; Sandusky Jr. et al., 1992). In the arterial system, a smooth muscle layer developed in the adventitia of the remodeling ECM, while the remodeling response after repair of the superior vena cava led to the formation of primarily collagenous tissue (Lantz et al., 1993; Sandusky Jr. et al., 1992). These differences in the remodeling response are thought to be due to the different mechanical environments present in the high pressure arterial circulation and low pressure venous circulation.

The mechanisms by which ECM scaffolds promote site-specific remodeling in the presence of site-appropriate mechanical loading have been partially elucidated. Static and cyclic stretching of cells seeded on an ECM scaffold *in vitro* modulated the collagen expression by the cells, enhanced the cell and collagen alignment, and improved in the mechanical behavior of the scaffold (Almarza et al., 2008; Androjna et al., 2007; Gilbert et al., 2007b; Nguyen et al., 2009; Wallis et al., 2008). In addition, during *in vivo* remodeling, it is thought that the progenitor cells that are recruited to the site of ECM remodeling by matricryptic peptides formed during scaffold degradation will differentiate into site-appropriate cells in the presence of local mechanical cues (Reing et al., 2009; Zantop et al., 2006; Badylak et al., 2001; Beattie et al., 2009; Crisan et al., 2008). Several *in vitro* studies have shown that mechanical loading can induce progenitor cells to differentiate into fibroblasts, smooth muscle cells, and osteoblasts (Altman et al., 2002; Matziolis et al., 2006; Nieponice et al., 2007).

CONCLUSION

ECM scaffolds have been isolated from a number of tissues and organs for the purpose of tissue engineering and regenerative medicine. The methods by which these scaffolds are derived are highly dependent on the structure of the organ of interest, and may include both chemical and physical methods. Decellularization processes should be designed such that the majority of the antigenic cellular components are removed while attempting to maintain the highly complex, tissue-specific combination of structural and functional molecules present within the ECM. Following decellularization, ECM scaffolds can be processed into application-specific configurations. These scaffolds have been used successfully in a wide variety of clinical and preclinical settings. The success of ECM scaffolds in these applications is due, in large part, to their ability to modulate the default mammalian host response from scar tissue formation to constructive remodeling. The ability of an ECM scaffold to promote constructive remodeling has been related to a number of biologic events that occur during the remodeling process. Among these are the ability of the scaffold to elicit a friendly host innate immune response, degrade rapidly and fully while releasing bioactive peptides from ECM parent molecules, promote angiogenesis at early time-points following implantation, and respond to the mechanical microenvironment in which it is placed. These processes occur concurrently through the course of scaffold remodeling, and are likely interrelated. Failure of an ECM scaffold to undergo any one of these processes may result in degradation of the scaffold without constructive remodeling, fibrous encapsulation of the implanted material and a lack of scaffold degradation or the formation of scar tissue within the implant site.

Implants, Devices, and Biomaterials: Special Considerations

CHAPTER III.1.1 INTRODUCTION: IMPLANTS, DEVICES, AND BIOMATERIALS: SPECIAL CONSIDERATIONS

Frederick J. Schoen
Professor of Pathology and Health Sciences and Technology (HST), Harvard Medical School, Executive Vice Chairman, Department of Pathology, Brigham and Women's Hospital, Boston, MA, USA

Section III.1 addresses some special concerns about the use of biomaterials in surgical implants and medical devices. The themes of this section are that implant retrieval and failure mode analysis provide information that improves the design and use of medical devices and thereby patient outcomes, and that the characteristics of biomaterials surfaces play a critical role in determining the tissue reactions to implants. Moreover, in this respect, sterilization of implants, as discussed by Lambert et al. in Chapter III.1.2, is not only critical to preventing infection, but this procedure can also alter the surface chemistry of biomaterials (and indeed potentially their bulk properties), and thereby inadvertently affect implant performance. A central concept of this section is that following contact of biomaterials with tissues, careful and detailed analysis of implants, the biomaterials that comprise them, and the surrounding tissues, can be a powerful tool in understanding the mechanisms and causes of tissue–biomaterials interactions, both desired and adverse, and in ensuring the efficacy and safety of medical devices.

Although most surgical implants serve their recipients well by performing their desired function (i.e., *functionality*), the outcome of biomaterials and medical device implantation is not always optimal, in large part owing to suboptimal tissue–biomaterials interactions (i.e., *biocompatibility*). Implants can be retrieved after *in vitro* studies or at either reoperation or necropsy/autopsy of animals or humans, and they may or may not be failed. In order to understand tissue reactions, described in Section II.2, the correlation of biomaterials surface chemistry with performance is a critical step (as by detailed by Ratner in Chapter III.1.3). The literature contains numerous instances where problem-oriented evaluation and analysis of medical implant research has yielded important

insights into both deficiencies and complications limiting the success of implants, and understanding why certain implants are successful. The approaches to implant analysis (for both individual cases and for cohorts of implants of similar type) and numerous instances where such analyses have been useful are summarized in Chapter III.1.4 by Schoen, and Chapter III.1.5 by Anderson et al. Implant research has guided development of new and modified implant designs and materials, assisted in decisions of implant selection and management of patients, and permitted *in vivo* study of the mechanisms of biomaterials–tissue interactions, both local and distant from the device.

Preclinical studies of modified designs and materials are crucial to developmental advances. These investigations usually include *in vitro* functional testing (such as fatigue studies at accelerated rates) and implantation of functional devices in the intended location in an appropriate animal model, followed by noninvasive and invasive monitoring, specimen explantation, and detailed pathological and material analysis. Relative to clinical studies, animal investigation may permit more detailed monitoring of device function and enhanced observation of morphologic detail, as well as frequent assay of laboratory parameters, and allow *in situ* observation of fresh implants following elective sacrifice at desired intervals. In addition, specimens from experimental animals can minimize the artifacts that can occur inadvertently when specimens are harvested under clinical circumstances. Furthermore, advantageous technical adjuncts may be available in animal but not human investigations, such as injection of cells or radiolabeled imaging markers or fixation by pressure perfusion that maintains tissues and cells in their physiological configuration following removal. Animal studies often facilitate observation of specific complications in an accelerated timeframe, such as calcification of bioprosthetic valves, in which the equivalent of 5–10 years in humans is simulated in 4–6 months in juvenile sheep (Schoen and Levy, 2005). Moreover, in preclinical animal studies, experimental conditions can generally be held constant among groups of subjects, including nutrition, activity levels, and treatment conditions, and concurrent control implants are often possible. This is clearly not possible in clinical studies. However, animal models that faithfully duplicate the relevant human anatomy, physiology and pathology are not often available.

Nevertheless, clinicopathologic analysis of cohorts of patients who have received a new or modified prosthesis type evaluates device safety and efficacy to an extent beyond that obtainable by either *in vitro* tests of durability and biocompatibility or preclinical investigations of implant configurations in large animals. Moreover, through analysis of rates and modes of failure, as well as characterization of the morphology and mechanisms of specific failure modes, retrieval studies can contribute to the development of methods for enhanced clinical recognition of failures. The information gained should serve to guide future development of improved prosthetic devices, to eliminate complications, and to develop and validate diagnostic and therapeutic management strategies to reduce the frequency and clinical impact of complications. Furthermore, since patient-specific factors could impact performance, demonstration of an individual propensity toward certain complications (see below) could impact greatly on further management. Moreover, history has shown that some medical devices demonstrate important but rare complications only during clinical trials or postmarket surveillance (complications that were not predicted by animal investigations). Subsequent study of clinically important device failure mechanisms may yield prevention strategies; such strategies may then be screened *in vivo* in animal studies; favorable therapies are then tested in clinical trials. Thus, an important future goal is the effective integrated use of data derived from implant retrieval investigations (along with other clinical and experimental data) to inform regulatory decisions and device improvements in an ongoing, incremental and iterative fashion throughout the product lifecycle.

Clinical implant retrieval and evaluation can yield additional benefits. Implant retrieval studies have demonstrated that success of a material or design feature in one application may not necessarily translate to another. Although analysis of implants and medical devices has traditionally concentrated on failed devices, important data can accrue from implants serving the patient well until death or removal for unrelated causes. Indeed, detailed analyses of implant structural features following implantation can yield an understanding of not only predisposition to specific failure modes, but also structural correlates of favorable performance. Implant retrieval and evaluation may also provide specimens and data that can be used to educate patients, their families, physicians, residents, students, engineers, and biomaterials scientists, as well as the general public. As a basic research resource, the process of implant retrieval and evaluation yields data that can be used to develop and test hypotheses, and to improve protocols and techniques.

For investigation of bioactive materials/devices, and combination and potentially tissue-engineered medical devices in which the interactions between the implant and the surrounding tissue are complex, research based on implant retrieval and evaluation continues to be critical.

In such instances, novel and innovative approaches must be used in the investigation of *in vivo* tissue compatibility. In such implant types, the scope of the concept of "biocompatibility" is much broader, and the approaches employed in implant retrieval and evaluation require identification of the phenotypes and functions of cells, and the architecture and remodeling of extracellular matrix (Mendelson and Schoen, 2006; Hjortnaes et al., 2009). These are circumstances in which individual patient characteristics (for example, genetic variation in molecules important in matrix remodeling) could have a profound influence on the outcome in some patients (Ye, 2000; Jones et al., 2003). This potentially yields a new area of study: "biomateriogenomics," conceptually analogous to the emerging area of pharmacogenomics (Wang et al., 2011). Indeed, individuals with genetic defects in coagulation proteins may be unusually susceptible to thrombosis of prosthetic heart valves (Gencbay et al., 1998). Thus, a critical role of implant retrieval will be the identification of patient and characteristics and post-implant tissue responses (as assessed by *biomarkers*) that will be predictive of (i.e., surrogates for) success and failure. A most exciting possibility is that such biomarkers may be used to non-invasively image/monitor the maturation/remodeling of tissue-engineered devices *in vivo* in individual patients (Sameni et al., 2003; Mendelson and Schoen, 2006; Hjortnaes et al., 2009).

CHAPTER III.1.2 STERILIZATION OF IMPLANTS AND DEVICES

Byron Lambert[1] and Jeffrey Martin[2]

[1]Sterilization Science, Abbott Vascular, Temecula, CA, USA

[2]Director of Corporate Quality Technology, Alcon® a Novartis Company, Fort Worth, Texas, USA

INTRODUCTION

Successful sterilization of biomaterials used in implants and devices is a critical prerequisite for their successful clinical application. It requires knowledge of sterility concepts and sterilization technologies that render products sterile. Understanding the effect of sterilization processes on the biomaterials themselves is also increasingly important. These topics are the focus of this chapter.

Delivering a sterile product is the responsibility of a hospital, a manufacturer of an aseptically processed device or a manufacturer of a terminally sterilized device. This chapter is largely focused on the latter: industrial terminal sterilization. Equipping the biomaterials scientist to find a terminal sterilization solution for a product, if possible, and thereby avoiding aseptic processing of the product, is a desired outcome of the chapter.

The current regulatory expectation of the term "sterile" for blood-contacting medical devices and implants is to produce only one non-sterile device out of one million. If you think about it, this is an extreme target. Fortunately, it is normally attainable, and clearly a patient heading to the hospital appreciates this high safety target. The patient, however, would cease to be pleased if that sterile device failed during treatment because the sterilization cycle was so rigorous in killing microbes that it also damaged the product. The challenge for the biomaterials scientist responsible for defining a terminal sterilization process is an optimization problem – to determine and define a cost effective sterilization process window where sterility is achieved, and yet deleterious material effects are minimized. Many traditional medical devices are made with materials that are compatible with multiple sterilization modalities. In this scenario, finding a terminal sterilization solution is straightforward. However, the optimization problem is much more complex for biologics and combination devices, both of which are important and rapidly growing markets.

To navigate these challenges, it is useful for the biomaterials scientist to have a concrete understanding of common terminal sterilization technologies (see below, Sterilization Technologies), which are the basis of both achieving sterility and any product material effects. Material compatibility constraints often drive the choice of sterilization modality. The next section of the chapter, therefore, provides an overview of sterilization material compatibility challenges and guidance (see below, Material Compatibility). Robust sterilization validation methods embodied in national and international standards are the foundation for the strong patient safety record of terminal sterilization. However, some materials, especially biologics, may have undesirable responses to the techniques used, and then may require special sterilization methods. Sterility assurance concepts are, therefore, reviewed in sufficient detail to give the biomaterials scientist confidence in evaluating all options for finding a sterilization solution (see below, Sterility and Patient Safety). The chapter closes with a view toward exciting challenges on the terminal sterilization horizon. The combination device market offers compelling patient benefits, and equally compelling challenges for terminal sterilization. Awareness of these challenges and knowledge to meet them will serve the biomaterials scientist well (see below, Summary and Future Challenges).

STERILIZATION TECHNOLOGIES

How is microbial contamination on fully packaged devices reduced by 9, 12 or even greater orders of magnitude? This section provides a concrete understanding of industrial sterilization technologies that deliver these enormous microbial reduction levels. Two terminal sterilization modalities, radiation sterilization and ethylene oxide sterilization, dominate the industrial (non-hospital) terminal sterilization market. These robust workhorse terminal sterilization technologies utilize well-established validation processes (see below, Sterility and Patient Safety) that, in most instances, far exceed regulatory requirements for a one in a million sterility assurance level. Under well-controlled and validated conditions, neither of these modalities inflicts significant material degradation damage on many traditional devices. In addition, both are capable of processing high volumes of product at low cost. These important technologies are reviewed in some detail, along with a brief overview of a number of other methodologies that are less frequently utilized.

Radiation Sterilization

Safety First. Radiation sterilization doses are lethal. Terminal sterilization doses typically range from 8 to 35 kGy. An acute lethal dose to man is approximately 0.01 kGy, requiring an exposure time of only a fraction of a second in some processes. To ensure worker safety in these high radiation environments, significant shielding, robust interlocks, and the utmost care are required in radiation processing facilities. Another safety concern is exposure to ozone, a toxic gas, produced by radiation as it passes through air. Appropriate ventilation and ozone monitors are required to provide fresh air, and ensure the safety of personnel prior to entering a processing cell.

Technology Overview. Terminal sterilization by radiation sterilization is elegantly simple. Fully packaged medical devices are exposed to a validated dose from

a radiation source that emits electrons or photons that penetrate through the final packaging and inactivate the device's microbial load. One parameter, radiation dose, correlates directly with microbial kill, and this is easily measured to provide process control. The microbial kill mechanism involves radiation-induced scission of DNA chains to stop microbial reproduction. While radiation destroys the ability of most microorganisms to reproduce, the resistance of viruses such as HIV-1 remains a concern (Smith et al., 2001).

International radiation sterilization standards (ISO 11137-1; see Table III.1.2.1) call out three radiation sterilization modalities: gamma, electron beam, and X-ray. Gamma and electron beam dominate the radiation sterilization market, and are described in enough detail below to provide a working knowledge of the technologies. Sources of the radiation, processing facility layouts, mechanism of radiation energy deposition into materials,

and key processing parameters are described. Cycle times range from minutes to half a day. Technologies available for R&D, pilot, and low volume processing are also described. These small-scale systems will play an increasingly important role in qualifying materials and providing special processes to meet demanding material compatibility needs of combination devices.

Gamma Sterilization. Cobalt-60 gamma sterilization accounts for approximately 80% of the radiation sterilization market, 40% of the overall terminal sterilization industrial market. ^{60}Co is a radioactive element that undergoes nuclear decay producing useful gamma radiation. Note: while the gamma source itself is radioactive, the product sterilized by the exposure to the radiation does not become radioactive in the slightest measure.

High product volume ^{60}Co processing plants are relatively simple. Small ^{60}Co pellets are doubly encapsulated in rods, which are arranged into racks and stored in

a pool of water, with some 20 feet of water acting as shielding to keep the constantly emitted gamma radiation away from the processing room when product is not being processed. When the room is cleared, interlocks satisfied, and the facility is ready to process product, a mechanical elevator system raises the radiation source from the pool into the room. A conveyor system moves many totes of fully packaged product into the room and around the racks of ^{60}Co, often passing by multiple times, as seen in .

^{60}Co gamma particles have no charge and penetrate uniformly through a very long distance of material. This is a significant processing benefit. Configurations of product within shipper boxes and processing load configurations are rarely a limitation due to the high gamma penetration. Product is then brought back out of the processing room. Product is released for distribution after dosimeters are read and documented to confirm that the product received the proper dose.

The beneficial sterilization effects of ^{60}Co gamma rays (along with any deleterious material effects) come as a result of the energy of the photons being deposited into the microbes and materials. By definition, the energy deposited per unit weight is the radiation dose (typical units are kJ/kg, i.e., kilogray or kGy). Energy deposition from a gamma ray into a material occurs through a Compton Scattering interaction that generates high energy electrons (0.5 MeV). These primary electrons travel through the material and deposit their energy in 60–100 electron volt bundles as they generate secondary electrons. It is these secondary electrons that cause all microbial kill. They do so by forming oxidizing free radicals. In addition to causing scission of DNA, the radicals can also cause scission or crosslinking of polymer chains (see Material Compatibility).

Electron Beam Sterilization. Electron beam (e-beam) sterilization accounts for approximately 20% of the radiation sterilization market, 10% of the overall terminal sterilization industrial market. High energy electrons for e-beam sterilization are generated by a variety of technologies that take 200 volt electrons from the power grid and accelerate them to 0.2 million to 10 million electron volts (0.2–10 MeV, typically 5–10 MeV). At these energy levels, no part of the e-beam processing plant (or the product irradiated) is or becomes radioactive; e-beam accelerators turn off like a light bulb. Before turning on the accelerator, however, the processing room must be cleared and safety interlocks satisfied to avoid human exposure to the high doses of radiation and ozone that are generated. Accelerated electrons for device sterilization are typically magnetically focused into a 1–5 cm diameter beam, and magnetically scanned at high frequency across the conveyor width, typically 12–48 inches.

The conveyor system transports product through the shielding and in front of the beam. Typically, one product, one shipper box or one thin tote of product at a time passes by the beam's scan horn. Electrons from accelerators do not penetrate nearly as far as photons from gamma sources. A rule of thumb is that the maximum penetration (in centimeters) from a two-sided e-beam process is 0.8 times the beam energy (in MeV) divided by the density of product (in g/cm^3). Resulting maximum penetration distances are only a fraction of a meter, with higher beam energies resulting in higher penetration. Limited penetration can lead to inefficient processing and/or large distributions of delivered dose. In practice, this requires significant dosimetry work to develop load configurations that ensure an appropriate range of e-beam doses. Due to the limited penetration
FIGURE III.1.2.1 High volume production gamma irradiation facility (courtesy of MDS Nordion, Canada).

of accelerated electrons, products need to be carefully "dose-mapped," as their size and shape provide shielding, scattering interfaces, and incident angles which impact dose distribution. These differences provide a less homogeneous dose profile than that of ^{60}Co.

Product is then brought back out of the processing room. Product is released for distribution after dosimeters are read and documented to confirm that the product received the proper dose. E-beam processing facilities can either be in a processing room as described above for a gamma facility or be of a self-shielded design, as shown in Figure III.1.2.2.

The mechanism of energy deposition from e-beams is that the high-energy electrons journey through the material and deposit their energy in 60–100 electron volt bundles as they generate secondary electrons. Like gamma processing, the resulting secondary electrons cause microbial kill, as well as all product material effects. The main advantage of e-beam relative to gamma in terms of material compatibility is that the dose is delivered very quickly. Products being treated in gamma sterilization processes often have dwell times of several hours, whereas products typically dwell in an e-beam process for only minutes. The short processing time limits oxidative degradation, since oxygen does not have time to diffuse into the product. The main disadvantage of e-beams versus ^{60}Co is that the negatively charged electrons do not penetrate deeply into a material compared with neutral gamma rays, which penetrate through the product being sterilized.

X-ray Sterilization. X-ray sterilization accounts for a small fraction of the radiation sterilization market. It is a hybrid between gamma sterilization and e-beam sterilization. Radiation is generated from high-energy electrons from accelerators, typically 5 MeV electrons, impinging on a high atomic number ("z") target, often tungsten, to generate X-rays. The X-ray photons behave nearly identically to photons from gamma sources in terms of energy deposition and high penetration capabilities. Like e-beam plants, no part of the X-ray processing plant is or becomes radioactive if X-rays are generated by electrons with energies no greater than 5 MeV.

Important Processing Parameters

Radiation sterilization processing parameters that are of practical importance to the biomaterials scientist are those that affect the maximum dose to the product, and those that affect the throughput of product through the process. The maximum dose to the product is dependent on:

- sterilization dose (minimum dose to the product);
- dose uniformity during the radiation sterilization process; and
- number of sterile cycles for which the device will be qualified.

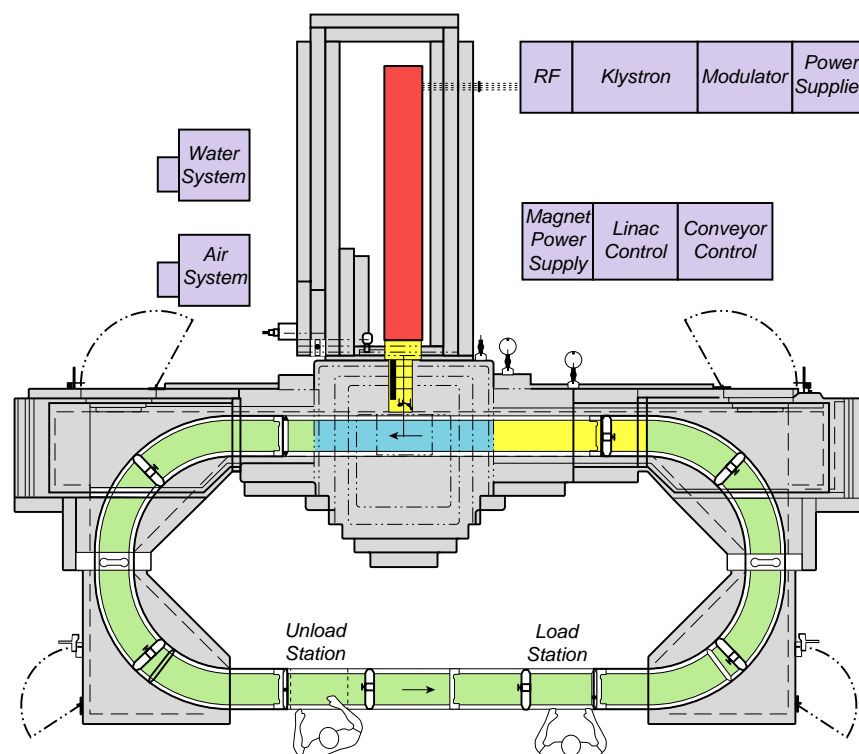
New Electron Beam Sterilization Systems:
Surebeam® On-Site System


FIGURE III.1.2.2 Medium volume self-shielded production electron beam irradiation facility.

Dose uniformity ratio (DUR) is a measure of the range of doses delivered to product by a given radiation sterilization process. DUR is defined, for a given load configuration and density, as the ratio of the maximum to the minimum dose received by any one product. The DUR of a radiation sterilization process is always greater than 1.0; radiation sterilization does not provide a single dose, but a distribution of doses delivered throughout any one product. Dose uniformity is dependent on the radiation source (gamma is typically significantly more uniform than e-beam), product density, product shipper box or pallet size, sterilizer configuration, and for e-beam, energy of the electrons. High density products with large boxes, resulting in large distances through which the radiation must travel, result in a high distribution of doses, e.g., a DUR greater than 2.

Throughput for a radiation sterilization process is primarily dependent on the radiation source intensity, i.e., for gamma sterilizers the number of curies of ^{60}Co, and for e-beam and X-ray sterilizers the number of electrons, the current. Secondarily, throughput is a function of product density and quantity of product processed at a given time. For example, while it may be beneficial to reduce the quantity of product processed at a given time to reduce the dose distribution, and hence the overall dose to product, this change also reduces throughput efficiency.

R&D, Pilot, and Low Volume Technologies

Small radiation sources are very powerful tools for the biomaterial scientist and his/her team. An R&D gamma cell like that shown in Figure III.1.2.3 provides a narrow dose range, very close to a DUR of 1.0. Along with delivering precise doses for the sterilization validation process (see below, Sterility and Patient Safety), the biomaterials scientist will be well-served by these narrow dose ranges during material qualification exercises, especially if the source is easily accessible to provide fast iterations during the product development process.

FIGURE III.1.2.3 Low volume self-contained R&D gamma cell manufactured by MDS Nordion (courtesy of IAEA, STI/PUB/1313).

In addition, small self-shielded low energy e-beam accelerators are available to process single units. The low energy of the beam, typically 0.5–2.0 MeV, may only penetrate a single product or a sample portion of a product at a time. This low energy keeps the accelerator to a manageable size and cost, and allows for rapid product development iterations.

Ethylene Oxide (EO) Technologies

Safety First. Ethylene oxide gas is toxic, carcinogenic, and very explosive. EO sterilization cycles must be designed to avoid conditions or parameters that may be explosive. Precautions must be taken to avoid any equipment, tools, etc., that may spark in the vicinity of EO chambers. Explosions can be horrific in magnitude, and extreme care must be taken. After an EO process is complete, employees must take appropriate precautions to avoid exposure to EO gas, e.g., use of respirators when working in the vicinity of product that has not been fully aerated to dissipate the gas. Finally, the manufacturer of EO sterilized product is responsible for following international standards to ensure that product is allowed to aerate in order to get EO residual levels below permissible limits for distribution (ISO 10993-7; see Table III.1.2.1).

Technology Overview. Ethylene oxide sterilization accounts for approximately 50% of the industrial terminal sterilization market, and is another conceptually simple terminal sterilization process. Fully packaged devices are placed into an ethylene oxide chamber and exposed to a validated combination of humidity, ethylene oxide gas, temperature, and time. Microbial-resistant sterile barrier packaging must be used, to allow ingress and egress of EO and water vapor within a defined load configuration. Following the sterilization process, EO levels are brought below acceptable levels through completion of a validated in-chamber vacuum purge process or a post-sterilization aeration process. Product is released for distribution following review and documentation of routine monitoring parameters and, in many instances, biologic indicator test results. Total cycle times range from six hours to several days.

The international ethylene oxide sterilization standard, ISO 11135-1 (see Table III.1.2.1) refers to the use of both ethylene oxide, and mixtures of ethylene oxide and a diluent. Diluents were commonly used as a deterrent to explosions, but are less common today since many common diluents are HCFCs and their use has been curtailed. Instead, nitrogen blanketing and other cycle design features are used to reduce the presence of air/oxygen and keep EO non-flammable. Diluents do not affect the principles of operation and validation of an EO cycle.

EO sterilization principles and practical aspects are described below in enough detail to provide a working knowledge of the technology. Chamber dynamics, processing plant layout, mechanism of microbial kill, and key processing parameters are described. Cycle times range from

several hours to several days. Technologies available for R&D, pilot, and low volume processing are also described.

Ethylene oxide is a highly reactive cyclic ether with two carbons and one oxygen, CH_2CH_2O (Figure III.1.2.4). It is a gas at room temperature, with a boiling point of 11°C. It is pressurized and stored as a liquid for use in EO processing plants. The mechanism of microbial kill is alkylation of the amine groups of DNA. Moisture facilitates microbial kill; product has to be exposed to a humid environment before EO exposure. EO kill rate is a function of temperature and concentration of EO gas.

In practice, approximately three cubic meters of product is placed on pallets in well-defined configurations. Product is humidified, either in a dedicated preconditioning area (typically 6–24 hours at 50–80% relative humidity (RH) and mild temperatures) or within the EO processing chamber with dynamic vacuum/steam pulsing. One to 40 pallets of product are placed into industrial EO chambers. A three-pallet chamber is shown in Figure III.1.2.5.

Along with humidification, early phases often include evacuation to remove oxygen, and injection of nitrogen to keep the cycle non-explosive. Evacuation levels can be down to 2 torr in some cycles, with very fast evacuation rates. EO gas is injected into the chamber with the humidified product, and allowed to dwell for a validated period of time, EO concentration, temperature, and humidity. Typical in-chamber exposure times are 6–24 hours at processing temperatures of 40–65°C and RH of 30–90%. The EO is then purged, for example, with dynamic vacuum/steam pulsing followed by vacuum/nitrogen pulsing.
FIGURE III.1.2.4 Ethylene oxide molecule.

FIGURE III.1.2.5 Medium volume ethylene oxide production sterilization chamber manufactured by Getinge (Courtesy of Getinge Inc.).

If EO residual levels do not meet regulatory requirements for product release at the end of the cycle, product is placed into a dedicated forced air heated aeration room.

Important Processing Parameters

Ethylene oxide sterilization processing parameters that are of practical importance to the biomaterials scientist are those that can affect the product and package, and those that affect throughput. Deep vacuum levels, rate of vacuum cycles, chamber temperature and concentration, and time of exposure to humidity, EO gas, and any diluents utilized can all potentially affect packaging and/or device material components, especially pharmaceuticals and biologics. The size of the chamber, the length of the cycle, and any preconditioning and/or aeration steps affect cycle times and therefore product throughput.

R&D, Pilot, and Low Volume Technologies

Small ethylene oxide sterilizers are very powerful tools for the biomaterials scientist and his team. As well as providing a vehicle for well-controlled microbial kill challenge testing, they can be used to facilitate finding material compatibility solutions and qualifying product at most challenging parameters. Special low temperature and/or low humidity EO cycles can be developed and validated to avoid material compatibility concerns. A well-controlled eight cubic foot R&D EO chamber is shown in Figure III.1.2.6. Small EO chambers are also used extensively within the hospital setting.

Other Terminal Sterilization Technologies

Moist heat, i.e., steam, sterilization has long been a workhorse technology for reusable devices in hospitals and certain industrial applications. The high temperatures limit its use for most devices with plastic materials, including most single-use devices. Moist heat sterilization, like other major industrial and hospital processes, is well-characterized in national and international sterilization standards (see Table III.1.2.1). Gas phase hydrogen peroxide sterilization has, in the last decade, come into broad application in hospitals, but has limited industrial applications. This was the first technology to drive the generic ISO 14937 "General Criteria" sterilization standard (see Table III.1.2.1). A number of additional gas chemical sterilization technologies have been developed, but have not found significant industrial terminal sterilization application, including chlorine dioxide, ozone, nitrogen dioxide, supercritical carbon dioxide, and propylene oxide. In addition, dry heat sterilization has limited applications.

Liquid chemical sterilization is sometimes used for sterilization, in applications either with animal or human tissues that are not compatible with terminal sterilization options or as a high level disinfection for reuse of

FIGURE III.1.2.6 Low volume ethylene oxide R&D sterilization chamber (Courtesy of Getinge Inc.).

certain devices, such as blood dializers. The process involves the immersion of the device into formulations of either an aldehyde or an oxidizing agent (e.g., gluteraldehyde, hydrogen peroxide or peracetic acid), sometimes with buffers, anti-corrosive agents, and detergents. The method does not provide the process control or sterility assurance levels of terminal sterilization processes (Chamberlain et al., 1999). Automation of the process, however, has led to significant success in providing safe tissue product.

MATERIAL COMPATIBILITY

The attention of this chapter will now shift to the response of the materials being terminally sterilized, especially the molecular effects which in turn can affect physical, chemical, and mechanical properties of the material. Specific guidance is provided for the two major industrial sterilization technologies: radiation and EO. Many of the principles and processes outlined, however, are applicable to all sterilization technologies. In addition, there are material compatibility resources available in the literature for some of the less utilized technologies, for example, for hydrogen peroxide and ozone (AAMI, 2008), nitrogen dioxide (Kulla et al., 2009), and supercritical carbon dioxide (White et al., 2006).

To reap the high patient safety benefits of robust terminal sterilization technologies, the biomaterials scientist

needs to manage potential material compatibility concerns. This is necessary in order to ensure a high quality product, and to claim compliance to international sterilization standards that require assessment of material compatibility with terminal sterilization.

Requirements in Sterilization Standards to Assess Material Compatibility

International sterilization standards require the assessment of material compatibility under worst case sterilization conditions. For radiation sterilization, ISO 11137-1 (see Table III.1.2.1) requires the following:

> *8.1.1 When treated with **the maximum acceptable dose**, product shall meet its specified functional requirements throughout its defined lifetime.*

For ethylene oxide sterilization, ISO 11135-1: 2006 (see Table III.1.2.1) requires the following:

> *7.2.1 It shall be confirmed that the product and its packaging meet specified requirements for safety, quality, and performance following the application of the defined sterilization process at **the most challenging process parameters** for the product/ package. The influence of the tolerances for the process parameters shall be taken into consideration.*

Effect of Terminal Sterilization Modalities on Materials

Knowledge of a sterilization modality's processing parameters and how they interact with materials (see above, Sterilization Technologies) is a key element in assessing the compatibility of materials with a given terminal sterilization process. A summary of material effects with six sterilization modalities is given in AAMI TIR17 (see Table III.1.2.1); radiation and ethylene oxide sterilization are reviewed below.

Radiation Sterilization. Radiation chemistry initiated by secondary electrons (see above, Sterilization Technologies) produces material effects during radiation sterilization. These effects include generation of free radicals that can cause polymer chain scission or cross-linking, as well as interaction with oxygen that can do further damage to the synthetic polymer or biologic product being sterilized. The radiation chemistry of polymeric materials and industrial applications have been studied and extensively reviewed (e.g., Forsythe and Hill, 2000; Clough, 2001; AAMI, 2008). Many device materials are essentially inert to the relatively low doses applied during radiation sterilization. Some of these materials are actually cross-linked by the radiation, e.g., polyethylene (PE), with a neutral or positive effect on functional properties. Some polymers of medical device interest, however, tend toward scission and are mechanically degraded to a significant extent following radiation sterilization, in particular

polytetrafluoroethylene (PTFE), fluorinated ethylene pro-pylene (FEP), polyacetals, and natural polypropylene (PP). In some cases, the presence of air can accelerate chain scis-sion via a radiation-induced oxidation process. Degrading materials may be acceptable in certain applications, but must be evaluated carefully after exposure to a maximum dose to ensure clinically acceptable performance over the shelf-life of the device. In glassy polymers like polymeth-ylmethacrylate (PMMA), low energy electrons may be trapped within the polymer, causing yellow or brown-ish discoloration, a challenge for radiation sterilization of contact lenses. Also, in cross-linking materials like PE (UHMWPE [Ultra High Molecular Weight Polyethylene] in orthopedic implants) it may be important to anneal out the trapped free radicals, to avoid undesirable, long-term free radical-induced reactions. Bioabsorbable polymers, e.g., polylactide (PLA) and PLGA or poly(lactic-co-glycolic acid), show significant molecular weight (MW) reduction as a function of sterilization dose. This change in initial MW of the polymer may affect *in vivo* polymer degrada-tion dynamics, leading to a change in device performance, such as drug release kinetics from degradable PLGA mic-roparticles. In special cases, it may be possible to account for this MW decrease by increasing the initial pre-sterile molecular weight. In such cases, radiation would be the sterilization modality of choice, since irradiations can be done in a refrigerated state to maintain structural integrity by keeping well below the glass transition temperature of the polymer.

Secondary effects in material may arise from or be avoided by managing the radiation sterilization process. The temperature of a device will be elevated during irra-diation, for a few seconds for e-beam sterilization (typi-cally to 50°C with polymeric materials) or for a few hours for gamma sterilization (typically 30–40°C). For low glass temperature bioabsorbable materials, this may be signifi-cant. If so, it can be managed by processing the device at a reduced temperature. If oxygen and humidity contrib-ute to deleterious material interactions with radiation, the device can be packaged in an inert packaging environment to manage the problem.

Biologics and Human-Based Tissue: Compatibility with Radiation Sterilization. Progress has been made achieving compatibility of tissue products with radiation sterilization. Sterilization process concerns are addressed in AAMI TIR37: *Sterilization of health care products – Radiation – Guidance on sterilization of human tissue-based products* (see Table III.1.2.1). Low dose radiation sterilization validation methods (see Sterility and Patient Safety) offer promise of expanded use of radiation ster-ilization with tissues and other biologic products. There are also other interesting cases where biologics are ter-minally sterilized with radiation after special processing to produce sterile biologics, e.g., sterile liposomal vac-cines and human insulin. Special processing may include lyophilization, cryoprotection, and addition of free radi-cal scavengers or radio-protectors (e.g., the anti-oxidant,

ascorbic acid) (Mohammed et al., 2006; Terryn et al., 2007). Processes have also been developed using radical scavengers and other tools to improve radiation com-patibility of tissue products. These developments offer promise for the expanding market of tissue engineering scaffolds.

Ethylene Oxide Sterilization. Alkylation chemistry, the microbial kill mechanism for DNA, may produce other material effects, but in general the effects are small. Other EO process parameters, i.e., temperature, humidity, and evacuation cycles, can also affect device materials. Materials must be able to withstand the most challenging range of conditions used in a given EO cycle. As described previously, this may include humidity pre-conditioning before, and aeration cycles afterwards, for several days at 40°C; EO cycles for 6–24 hours at pro-cessing temperatures of 40–65°C; RH in the range of 30% to 90%; and evacuation levels down to 2 torr in some cycles with very fast evacuation rates.

Bioabsorbable polymers may be difficult to process under these conditions, in particular if structure integ-rity is required. Both the temperature and the humidity can degrade bioabsorable material properties. Packaging materials need to be able to withstand the evacuation rates and pressures. Materials with known deleterious responses to typical single EO sterilization cycles include polyacrylates, e.g., polymethylmethacrylate (PMMA), and some styrene resins, e.g., polystyrene (PS) and styrene acrylonitrile (SAN). These materials may be acceptable in certain applications, but must be evaluated carefully after exposure to worse case cycle ("most challenging parameters") to ensure clinically acceptable performance over the shelf-life of the device. It is not expected that EO sterilization will affect device performance over time.

Pharmaceuticals and Biologics: Compatibility with EO Sterilization. In the pharmaceutical/biologics and human-based tissue industries, the issue of sterilization can take on a variety of special conditions and concerns. In the pharmaceutical industry, the predominant use of EO (and radiation) sterilization is used for packag-ing components that enter the aseptic processes (bottles, plugs, caps). EO is also used to sterilize some dry phar-maceutical active components. Liquids and tempera-ture-sensitive drugs will likely *not* be compatible. Few biologics are compatible with EO sterilization due to concerns regarding temperature and EO residues, as well as the ability for EO to alkylate chemically reactive spe-cies such as amines or proteins. This is analogous to the reaction of EO with DNA to sterilize product.

Other Sterilization Modalities. For heat sterilization modalities, material compatibility challenges arise from the temperatures to which the devices are exposed and, for moist heat, from hydrolysis reactions. For oxida-tive sterilization technologies, e.g., hydrogen peroxide, ozone, and chlorine dioxide, the oxidative mechanism of microbial reduction is also the mechanism by which devices are damaged.

Optimizing Chances for Finding Material Compatibility Solutions

Starting with the best candidate materials is the surest way to optimize material compatibility with terminal sterilization. Guidance on selecting material compatible with six terminal sterilization modalities is available (AAMI, 2008). The most challenging material selection scenario is the combination of a difficult-to-sterilize primary material, which is central to the clinical use of the device, with secondary materials that are also sensitive to sterilization, e.g., an active agent (pharmaceutical or biologic), a bioabsorbable material, and/or active electronics. The best approach is to select a sterilization modality that is compatible with the primary material, and then try to select secondary materials that are compatible with the selected sterilization modality.

It is also important to avoid material processing errors that lead to performance failures caused by sterilization. Both extrusion and molding processes can build in significant polymer stresses, leading to product testing failures post-sterilization. This can be identified by testing product pre-sterilization as a control to compare with post-sterilization testing.

Choosing or developing clinically relevant test methods is also important. It can be tempting to use easily available test methods to demonstrate material performance before and after sterilization. If the test method does not correlate well with clinical performance, the test may not be an appropriate indicator of material compatibility. Clinically-relevant device attributes and test methods vary enormously depending on the device. Physical, analytical, and microbiological tests need to be considered. To characterize drug release kinetics and other combination device properties, micro- and nano-characterization of drug–polymer matrices may be required (Ding et al., 2009). Material biocompatibility can change as a function of sterilization modality and process. Device endotoxin levels are typically not sensitive to the sterilization modality, and testing may often be performed before or after sterilization. The effect of sterilization on the surface of biomaterials should also be considered. Radiation typically has a minimal effect on biomaterial surfaces, while EO, oxidative gases, and liquid chemical sterilants can have either a positive or negative surface effect depending on the application of the biomaterial (Chamberlain et al., 1999).

Ensuring adequate device performance throughout its intended shelf-life is the final material compatibility challenge for the biomedical scientist. The most conservative route is to age the materials in the final product format at room temperature, and confirm the desired functionality throughout the desired shelf-life. If the product is designed to be stored in refrigerator or freezer conditions, this approach can require exceptionally long development timeframes, and can limit the availability of important technologies to the market. As a result, accelerated aging models have been developed to safely and conservatively estimate device performance over time. The cornerstone of all models, however, is confirmation of the model with aging at storage conditions.

Arrhenius (semi-logarithmic) temperature-based accelerated aging models have been used extensively in the medical device industry for product (AAMI, 2008) and packaging (ASTM, 2007). Practical methods have been developed that can accelerate aging by two-fold to greater than ten-fold. Basic conservative aging models that are simple and cost-effective have been shown to be appropriate for most materials (Lambert and Tang, 2000). With additional resources, more sophisticated correlations between accelerated and real-time conditions can be developed to provide more aggressive aging factors.

For devices combined with pharmaceutical materials, regulatory agencies expect to have accelerated stability protocols based on ICH (International Conference on Harmonisation) guidelines. Distinguishing between accelerated device-aging models and pharmaceutical stability requirements is both challenging and important.

STERILITY AND PATIENT SAFETY

For a device with significant sterilization material compatibility challenges, a robust understanding of sterility concepts and associated patient safety issues may be the key to discovering a cost-effective sterilization solution. At one end of the spectrum of sterilization options is overkill terminal sterilization. This approach has for decades served the industry well for devices with limited material compatibility concerns. The other end of the spectrum includes liquid chemical sterilization of biologics, and aseptic processing of combination devices, relatively costly options from many perspectives. Between these extremes are creative terminal sterilization validation methodologies, and terminal sterilization to non-traditional specifications. Without the ability to skillfully navigate this continuum of options, the biomaterials scientist may not be able to cost-effectively bring a product to market.

This section begins with a review of sterilization-related product and patient safety issues. This is followed by an overview of basic terminal sterilization principles related to logarithmic microbial reduction, validation of sterility, and maintaining sterility over time through sterile barrier packaging. The end of the section reviews efforts to provide creative sterilization validation methods to reduce material compatibility concerns, and differentiates terminal sterilization from sterilization achieved by aseptic processing.

PRODUCT AND PATIENT SAFETY ISSUES

Review of the US Food and Drug Administration (FDA) product recalls and the Center for Disease Control (CDC) publications indicates very few instances related to inadequate industry terminal sterilization practices (Favero, 2001). Therefore, it appears the existing standards and

medical device manufacturers, and associated contractors, are providing safe and effective devices in terms of product sterility. In the following case studies we will take a look at where the industry safety concerns may lie by examining a few sterilization-related incidents with subsequent patient infections or injury.

Three case studies described here in the text illustrate how small changes in product design and/or the materials used, in combination with the sterilization protocols used, caused significant medical problems. The cases are examples which had significant patient safety issues. Case 1 involved a highly respected major device and pharmaceutical manufacturer utilizing a moist heat terminal sterilization process with cooling water. Case 2 is from a medical supply company totally unaware of the requirements related to the GMP (Good Manufacturing Practice) and aseptically processed products or drugs. Case 3 highlights an instance where a sterilizer and sterilization technology was sold to hospitals without regulatory approval. Sterilization technologies need to be evaluated by the manufacturers as being suitable for their devices and the materials used. Hospitals should not use sterilization technologies that are not indicated in the device manufacturer's directions for use. These instances, although significant, are relatively rare.

Case 1

From October 1970 until March 1, 1971, eight US hospitals encountered 150 cases of bacteremias associated with *Enterobacter cloacae* or *Erwinia*, a genus of *Enterobacteriaceae* which is gram-negative. All hospitals had used the same intravenous (IV) fluids provided by a major manufacturer. The CDC studies for IV systems indicate that at least 6% of all IV tubing or bottles are contaminated after the system has been in use. A higher risk of contamination is attributable to systems that are not changed after 48 hours. However, in these cases the incidence was much higher. CDC sampling and culturing of fluids directly indicated no contamination. Bottles that were opened by unscrewing the bottle cap and closing again revealed contamination. After further investigation, it was determined that the manufacturer was in the process of implementing a new closure system and that the contamination was associated with the new cap design. The older cap design contained a red rubber disc and a Glisonite wafer which was pressed against the bottle opening. It was discovered that the red rubber had antibacterial properties against the contaminating organisms. The new cap design allowed these organisms to be drawn up into the lined cap while cooling after being autoclaved, but the red rubber had been eliminated and no longer provided an antibacterial effect. The organisms were prevalent in the manufacturing environment due to spillage of solutions during manufacturing. Recalls were initiated for all affected products. Ulitimately, the epidemiological studies estimated the total outbreak of bloodstream infections to be between 2000 and 8000 episodes caused by these contaminated IV fluids. Approximately 10% of the case patients in the hospitals studies died while bacteremic or shortly thereafter (CDC, 1997).

Case 2

From December 12, 2004 until February 15, 2005, local health departments and the CDC identified 36 cases of *Pseudomonas fluorescens* infections in patients that were previously administered a heparin-saline flush from prefilled syringes. The majority of the patients had central venous catheters and lines which required removal and treatment with antibiotics. Prefilled syringes cultured by a few of the hospitals involved all grew the contaminating organism. In almost all cases blood cultures from the patients grew *Pseudomonas fluorescens.* The investigation performed by the CDC indicated that seven of nine product lots tested were contaminated. The company filling the syringes had contracted a pharmacy to prepare a heparin concentrate which was returned to the manufacturer and then added to saline bags, and was subsequently used to fill the syringes. Although preparation of drug products to fill prescriptions is considered pharmaceutical compounding and not manufacturing, in this instance the supplier was acting like a manufacturer and subject to the FDA Good Manufacturing Practices. This manufacturer did not perform final product sterility testing of the finished products, which could have detected the contamination and prevented the product distribution (CDC, 2005).

Case 3

April 13, 1998, the FDA issued a safety alert regarding the use of the AbTox Plazlyte™ sterilization system. The Plazlyte™ sterilizers utilized a proprietary, low temperature gas plasma, along with vaporized peracetic acid. Although the system provided sufficient lethality, the FDA had not cleared the safety, performance or instructions for use of this sterilizer. The sterilizers were sold directly to hospitals seeking alternatives for ethylene oxide sterilizers. The warning was initiated due to serious eye injuries to corneal endothelial cells which resulted in corneal transplantation in some patients. The problem occurred when surgical instruments were sterilized, and copper and zinc salts formed on the surfaces of the sterile instruments. The copper compound residues were toxic to corneal endothelia and resulted in blindness (FDA, 1998). During the time period of January 8–14, 1998, six of eight patients undergoing intraocular surgery incurred corneal edema and opacification of the cornea (CDC, 1998).

The majority of patient safety issues do not come from non-sterile, aseptically-processed product, or from improperly sterilized products, regardless of the delivered Sterility Assurance Level (SAL). Patient safety issues develop from the introduction of foreign materials into the body during patient treatment at hospitals. There is a relatively high incidence of surgical site infections (SSI), estimated to be at 2% for all procedures. In 2002 there were approximately 1.7 million hospital-acquired infections (HAIs). Of these, 22% were urinary tract infections, 14% were bloodstream infections, 15% were pneumonia, 22% were surgical site infections, and 17% were related to other issues (Klevens et al., 2007).

As can be seen from these examples, patient safety goes well beyond the ability to provide a sterile product. Nonetheless, the validation of product sterility is an absolute must, and part of the regulatory submission and approval process. Principles of terminal sterilization validation are the next topics covered.

TERMINAL STERILIZATION VALIDATION PRINCIPLES

Logarithmic Microbial Reduction

An amazing feature of terminal sterilization processes is the ability to enormously reduce microbial contamination levels on fully packaged product, with exceptionally high process control to meet regulatory requirements for sterility. The word sterile is defined as "free from viable microorganisms." Sterilization is defined as a "validated process used to render product free from viable microorganisms" (ISO/TS 11139, 2006). These definitions are problematic, as they imply an absolute condition. Sterilization processes are based on microbial inactivation which is exponential in nature, in most cases, and follows first order kinetics. Therefore, the sterility of a product is expressed in terms of probability. While the probability can be reduced to a very low number, it can never be reduced to zero. The probability of a non-sterile unit associated with inactivation of a microbial population is quantified by the term Sterility Assurance Level (SAL).

Logarithmic microbial reduction to achieve various sterility assurance levels is illustrated in Figure III.1.2.7. The SAL required for regulatory purposes is 10^{-3} or 10^{-6}, the probability of one in one thousand units as non-sterile or one in one million units as non-sterile, respectively. The SAL of 10^{-6} is a lesser number, but provides a greater assurance of sterility.

Sterilization Validations and Consensus Standards

If at all possible, regulators require a terminal sterilization process over the risk associated with aseptic processing. The strong track record of terminally sterilized product in regards to patient safety owes much to robust sterilization validation methods. It is, therefore, important to understand the basic principles surrounding terminal sterilization validations. The terminology of international sterilization validation standards is provided in this section to equip the biomaterials scientist to interface effectively with regulatory and sterilization vendor personnel.

Sterilization is a special process where the results of the processing cannot be demonstrated by routine testing. For instance, in order to demonstrate an SAL of 10^{-6} it would require the sterility testing of approximately one million products with only one positive. This is neither possible nor practical. Therefore, sterilization processes are validated. EN 556-1 2001 indicates the following:

Evidence that a medical device is sterile comes from: (1) the initial validation of the sterilization process and subsequent revalidations that demonstrate the acceptability of the process; and (2) information gathered during routine control and monitoring which demonstrates that the validated process has been delivered in practice.

The achievement of sterility is predicted from the bioburden level on products, the resistance of the micro-organisms comprising that bioburden, and the extent of treatment imposed during sterilization.
FIGURE III.1.2.7 Sterility Assurance Levels: Illustration of logarithmic microbial reduction.

How are these sterilization validations attained? The medical device and pharmaceutical industries, in conjunction with regulatory authorities, have cooperatively developed industry standards. Device manufacturers, contract sterilization providers, regulatory authorities, and academic resources are all part of the process of developing a consensus standard. These standards provide requirements and guidance for the performance of the sterilization validation. Table III.1.2.1 provides a listing of standards documents utilized for validating and controlling a particular sterilization process.

Sterilization equipment and the process must be qualified and validated. The following paragraphs provide the general steps outlined in the standards for the validation of the sterilization process. Terminology used in the standards is introduced as it is recognized by regulatory bodies around the world. The first considerations are termed "Product Definition" and "Process Definition." For a radiation process this includes defining product families, establishing the maximum acceptable dose (the highest dose the device can withstand and still function properly), and establishing the sterilization dose (the validated minimum dose the device can receive to ensure sterility). The considerations for an ethylene oxide process include defining product families, confirming that the product design allows EO and humidity to penetrate the product and package, defining the hardest to kill location within the product, and determining the microbial rate of inactivation.

Sterilization equipment and systems go through an Installation Qualification (IQ). The IQ entails the calibration of measurement equipment. Utilities and services are verified that they are provided and capable of supporting the equipment requirements. The system software and control hardware are tested and qualified as appropriate for the process. In the case of contract sterilization services, the IQ and Operational Qualification are generally performed by the contract facility, and must be reassessed on a regular basis for inadvertent changes and degradation of equipment performance.

The IQ is followed by an Operational Qualification (OQ). The OQ tests the installed equipment to determine that it operates and performs within predetermined specifications. Procedures for the operation of equipment are established. For example, the OQ for a gamma irradiator would entail dose distribution studies in varying density loads, for all possible modes of operation, and determining the impact of system restarts. The OQ for gaseous sterilization systems (e.g., EO, steam, dry heat) include empty chamber temperature distribution studies, rates and depth of evacuation, injection rates and temperatures of gases, etc.

The next element of the sterilization validation is the Performance Qualification (PQ). ISO 14937 (see Table III.1.2.1) defines the PQ as the: "process of obtaining and documenting evidence that the equipment, as installed and operated in accordance with operational procedures, consistently performs in accordance with predetermined criteria, and thereby yields product meeting its specification." For radiation processes this entails the demonstration of the dose distribution for the product-specific loading configuration, establishing the minimum and maximum dose location(s), and demonstrating that the product can be routinely processed within the range of the minimum and maximum allowable doses. In the case of ethylene oxide sterilization, the PQ would include a microbial qualification under subnominal conditions, and measurement of product temperature and humidity distributions. The reduction or dissipation of sterilant residuals in full cycle worse case conditions (highest gas concentration and longest exposure time) is also required.

Maintaining Sterility Over Time: Primary Package Validation

If the sterilization process is controlled to the extent that the standards require, e.g., such that the process delivers to the product a 9 to 12 or greater log reduction in microbial load, then what do we have to worry about? The package. The product packaging and sterile barrier system is critical to maintaining the safety and integrity of the sterilized product. Device packaging must maintain the product sterility throughout the expected shelf-life. As indicated previously in the section Material Compatibility, this would require accelerated and real-time aging studies. Packaging failures (i.e., open seals, pinholes in materials, material degradation, etc.) represent one of the most common reasons for product recalls. Compromised packaging jeopardizes the safety and integrity of the sterile product, and becomes a patient safety issue. The standards for packaging validation provide the industry with the requirements for validation of device packaging (ISO 11607-1; see Table III.1.2.1).

> Packaging failures represent one of the most common reasons for product recalls. Examples of possible causes of such failures include pinholes worn into the sterile barrier from device protrusions, cracks in rigid packaging components, dislodged devices from the packaging fixtures, product damage or wear, and dust generated by device components rubbing against other materials.

Packaging materials used for the sterilization of gaseous sterilants must allow for the ingress of the sterilant to the device surfaces, while packaging for irradiated products can be a vapor barrier. A breathable package may be desirable for irradiated products, as some materials (polyethylene, PVC, and polyurethane used in tubing, drapes, and gowns) tend to generate gases during radiation sterilization. If the gases are trapped within the package, they may present potentially offensive odors when opened. Odor generation may be reduced incorporating antioxidants or by using higher

molecular weight materials and breathable packaging materials (Hemmerich, 2000). For product material compatibility purposes, and to protect the product from the environment (i.e., water vapor, oxygen, etc.), one may have to provide packaging with a very low rate of gas transmission.

Product and packaging are subject to an accelerated aging program, and a simulation of the transportation environment. The shipping simulation can be performed according to one of several approaches, either ASTM D4169-05 *Standard practice for shipping containers and systems*, or by an appropriate International Safe Transit Association (ISTA) procedure such as ISTA 2A – Packaged-Products 150 lb (68 kg) or less. Following performance of the shipping simulation and aging, the packaging and products are inspected for packaging failures. Examples of possible failures include pinholes worn into the sterile barrier from device protrusions, cracks in rigid packaging components, dislodged devices from the packaging fixtures, product damage or wear, and dust generated by device components rubbing against other materials.

Alternative Sterilization Validation Methodologies and Specifications

Where does the biomaterials scientist go if standard terminal sterilization processes and validation methodologies do not meet the product need? Straight to liquid chemical sterilization or aseptic processing? These are relatively expensive options that may not provide as high a level of process control as terminal sterilization. It is, therefore, hoped that the biomaterials scientist will explore creative sterilization validation methods, and ensure that the sterility assurance specification being used is appropriate.

Validation Considerations for Minimizing Process Impact. In the majority of sterilization validations, the sterilization process delivers a significantly greater amount of lethality than is actually required. Typically, for devices composed of materials and packaging that are compatible with the sterilization process, the sterilization scientist uses a sterilization process that is easy to validate, such as substantiation of a standard sterilization dose of 25 kGy or an "overkill" approach. EO processes often use half-cycle overkill approaches that deliver SAL values of at least 10^{-12}, and often values of 10^{-20} to 10^{-40}, an overkill of enormous proportions. If product and or package functionality are a potential issue, one should explore options of minimizing the conditions of the terminal sterilization process in order to overcome material compatibility challenges.

EO sterilization process optimization can be achieved by exploring the possibilities of using a bioburden-based validation process and minimizing the conditions of exposure to the process (Annex A of ISO 11135-1). Figure III.1.2.8 illustrates the benefit of simply using actual product bioburden (orange line; assuming a
FIGURE III.1.2.8 Microbial contamination level versus EO processing time: High and very high initial contamination levels.

realistic but high bioburden of 1000) as opposed to using the overkill method where an initial bioburden of 1,000,000 is assumed (purple line). The times required to achieve the desired SAL are considerably less. Using the overkill assumption, a 12 log reduction down to an SAL of 10^{-6} is achieved at about 120 minutes, whereas with an initial population of 1000 a 9 log reduction to attain the 10^{-6} SAL is achieved in approximately 95 minutes. If the microbial resistance of the actual product bioburden is not as robust as the severe biological indicator challenge assumed in the overkill method, and the slope of the actual bioburden line (orange line) decreases, the time to achieve an SAL of 10^{-6} is reduced even further.

Even though radiation sterilization validation processes are based on natural product bioburden, as opposed to an overkill method, the sterilization validation may not be optimized to deliver the lowest dose, but an acceptable or convenient dose. New radiation sterilization validation methods have recently been developed (See Table III.1.2.1: Method VD_{MAX}, AAMI TIR33; Modified Method 2, AAMI TIR40) that allow for the lowest possible doses to be achieved for a given product. Along with optimizing the minimum sterilization dose, the biomaterials scientist may want to reduce the range of doses provided in the radiation process. An unnecessarily high distribution of doses throughout one product leads to high product doses and, therefore,

significant overkill and potential damage to product. Achieving a low sterilization dose and a narrow distribution of doses may lower the overall product dose to allow for successful radiation sterilization of a sensitive product. In addition, as mentioned in the section Material Compatibility, cold processing and processing with an inert environment within the product packaging may also help reduce material degradation even further.

Application of Sterility Assurance Level (SAL)

The typical SAL for most devices distributed in Europe and the US is 10^{-6} (EN 556-1; see Table III.1.2.1). Historically the US permitted a greater SAL value of 10^{-3} for items such as surgical drapes and gowns (ST67; see Table III.1.2.1). However, with the requirement for CE marking at the start of 1998, and in recognition of certain Pharmacopeia requirements, the SAL value decreased to a greater assurance of sterility, 10^{-6}. This is not to say that a device cannot be submitted and approved by the regulatory authorities with an SAL value greater than 10^{-6}. Regulatory approval for these lower sterility assurance levels, such as 10^{-3}, may be granted if it is shown that the device functionality cannot be achieved with a SAL of 10^{-6}. Alternatively, if the biomaterials scientists, the microbiologists, and sterilization personnel cannot demonstrate that the device is compatible from a product performance perspective with any sterilization process, they may need to move the product to an aseptic process where contamination rates may not be greater than 0.1%. With either of these scenarios, it must also be shown that the benefits of the device for the target population outweigh the risks (potential harms and severity of these harms to the patient) associated with the use of the device. Another major perceived concern for a greater sterility assurance level such as 10^{-3} is the potential use of the device on elderly patients, immuno-compromised patients, those with HIV, transplant patients, burn patients, newborns, and children. This perception is countered by the fact that these high risk patients routinely are treated with aseptically processed products.

Terminal Sterilization Versus Aseptic Processing

In order to put terminal sterilization and sterility assurance levels in perspective, it is useful to compare terminal sterilization with aseptic processing. In aseptic processing there is no inactivation of the product bioburden. These products are not exposed to a sterilization process in their final packaging. Aseptic processing is defined as "handling of sterile product, containers, and/or devices in a controlled environment, in which the air supply, materials, equipment, and personnel are regulated to maintain sterility" (ISO 13408-1, 2008). Aseptic processing includes compounding, filtration, and filling.

Through simulations or media fills of the aseptic process, the manufacturer must demonstrate the effectiveness of the controls over the risks of contamination associated with each step of the process. The control over potential contamination in an aseptic process results in a frequency of a non-sterile unit occurring of less than one in one thousand (0.1%). The sterility of the final product is based on the filter efficiency and integrity, the lack of available contamination in the surrounding environment, and controlling a series of operations in order to "maintain" sterility.

Since better process control and patient safety is achieved through terminal sterilization processes, the current regulatory environment requires medical device manufacturers to demonstrate that a product cannot be terminally sterilized before they can convert to an aseptic process. The extent of this demonstration is not well defined. To serve the needs of the industry when a terminal sterilization option is not achievable, there is current activity within the ISO TC198 Working Group 9 on development of a standard for solid medical devices (ISO/Committee Draft 13408-7, *Aseptic processing of health care products – Part 7*: *Aseptic qualification of solid medical devices and combination medical devices*). It is hoped that the creative terminal sterilization options provided in this chapter will permit some biomaterials scientists to avoid this option.

SUMMARY AND FUTURE CHALLENGES

The medical device industry has been well served by robust workhorse terminal sterilization technologies, radiation and ethylene oxide, in addition to many other technologies that meet lesser needs. The important processing parameters and mechanisms of microbial kill are well established. This information provides foundational insights into the interactions of the sterilization modality with a device's materials. This information, along with available guidance on the compatibility of materials subject to sterilization, allows for the biomaterials scientist to overcome material compatibility challenges in order to reap the benefits of terminal sterilization relative to aseptic processing. Patient safety is ensured by terminal sterilization, as a result of the very high assurance of sterility specifications utilized, strong process control, and robust sterilization validation methodologies that have been incorporated into national and international standards.

The challenge for the biomaterials scientist is to skillfully apply terminal sterilization technologies to as many products as possible, especially the more recent combination devices. There are many material compatibility challenges that will make this a formidable challenge. Examples include drug delivery systems with active biological agents, bioresorbable temperature-sensitive polymers, and radiation-sensitive electronics. The ability to find terminal sterilization solutions to avoid aseptic processing will allow the device industry to provide these

innovative therapies at the lowest price, and with the highest associated process control and patient safety.

The solution to these challenges will be an effort from a combination of disciplines. Material scientists and engineers need to develop increasingly robust materials that can withstand terminal sterilization processes. Even so, biomaterials scientists will need to carefully choose a sterilization modality that is compatible with key primary materials; this may require the utilization or development of novel sterilization technologies. Once a technology is defined that is compatible with the most sensitive materials of the device, supporting materials must be selected, processed, and tested to optimize chances for success with the sterilization modality. Optimal accelerated aging techniques to ensure product functionality over time are also required. In addition, to optimize chances of success with sensitive materials, the sterilization community needs to continue to develop and publish creative and gentle sterilization validation methodologies (e.g., minimizing radiation dose; ethylene oxide concentration, humidity, and temperature). Finally, regulatory authorities, industry forums, and international bodies involved in writing standards need to continue to challenge the bases for sterility assurance levels to assure that the terminal sterilization requirement for combination devices is not being set to an arbitrarily high standard.

CHAPTER III.1.3 CORRELATION, MATERIALS PROPERTIES, STATISTICS AND BIOMATERIALS SCIENCE

Buddy D. Ratner
Professor, Bioengineering and Chemical Engineering,
Director of University of Washington Engineered Biomaterials
(UWEB), Seattle, WA, USA

INTRODUCTION

In chapters prior to this one, this textbook has presented much on the characterization of biomaterials, assessment of biological reaction to biomaterials, and medical applications of biomaterials. What are the prospects for physical and chemical measurements for predicting the performance of new materials in complex medical applications? In other words, can we find relationships between the composition and structure of a biomaterial and its biological interactions, particularly in complex systems like living organisms? This chapter will address this question.

The reality is that physical or chemical measurements which can reliably predict *in vivo* biocompatibility are at this time unavailable for most biomaterials. It would be ideal, when considering a new material for medical applications, to use a spectroscopic technique to measure the properties and, from that physical measurement, predict how well the material will work in a particular application. Animal experiments are expensive, of questionable value for predicting performance in humans, and raise ethical issues (see Chapters II.3.7 and III.2.7). Human clinical trials are very expensive, and also raise ethical issues (Chapters III.2.7 and III.2.9). Can we predict or prescreen *in vivo* or *in vitro* performance from measurements of surface and other physical and chemical properties? This chapter, addressing correlation, will examine this question, and offer suggestions for future exploration.

Correlation implies *dependence* of one set of data on another. Correlations can take many forms. For biomaterials, some possibilities are:

1. Measure specific surface physicochemical properties (for example, contact angle), and correlate that with a biointeraction response such as a protein adsorption or blood cell interaction.
2. Measure protein adsorption or cell adhesion and predict *in vivo* performance.
3. Measure mechanical properties and predict the wear of an implanted hip prosthesis.
4. Measure an animal response to materials (for example, blood platelet consumption by the material), and predict clinical performance.

This chapter will primarily focus on those correlations that fit within number 1 above, but the comments made will have relevance to many correlations that can be envisioned for biomaterials.

BIOCOMPATIBILITY AND MEDICAL DEVICE PERFORMANCE

A re-examination of the definition of biocompatibility presented in the Introduction to this textbook and in Chapter II.3.2 is appropriate at this point.

Biocompatibility is the ability of a material to perform with an appropriate host response in a specific application (Williams, 1987).

The "biocompatibility" of a medical device can be defined in terms of the success of that device in fulfilling its intended function. Thus, the blood filtration module of a hemodialysis system might be defined by its ability to appropriately fractionate soluble blood components, its robustness over its intended lifetime, and its non-damaging interaction with the patient's blood. Alternately, we can define a "blood compatibility" for the membrane, a "blood compatibility" for the silicone rubber header, a "blood compatibility" for the tubing, and a "blood and soft tissue compatibility" for the percutaneous connection between the apparatus and the patient's bloodstream. Similarly, for a hip joint prosthesis, we can discuss the fatigue resistance of the device, the corrosion resistance of the device, the distribution of stresses transferred to the bone by the device, the solid angle of mobility provided, and the overall success of the device in restoring a patient to an ambulatory state. Again, the hip joint prosthesis performance might also be couched in terms of the tissue reaction to the bone cement, the tissue reaction to an uncemented titanium prosthesis stem, and the tissue reaction to the acetabular cup. In both of these examples, two cases are offered: in the first case, a whole system (device) performance is assessed, and in the second case, the biological reaction to specific components of the device (the biomaterials) is examined. The difference between the consideration of the whole device and the materials that comprise it is a critically important point. In certain contexts, only the performance of the complete device can be labeled as biocompatible. This distinction can be inferred from the US Food and Drug Administration (FDA) policy that only complete devices, and never materials, receive "approval." Yet biomaterials scientists and engineers refer to the performance of the individual materials as "biocompatibility." The materials performance can also be described as a "bioreaction" or "bioresponse." This is a textbook on biomaterials, so it is appropriate to focus on the materials. "Bioreaction" is a much more straightforward descriptor than "biocompatible," and this term will largely be used here and defined by example.

Toxicology assays, at times imprecisely referred to as biocompatibility assessment, were presented in Chapter II.3.3. These assays deal with measurement of substances that leach from materials, most of which will induce some cell or tissue reaction. Such assays will be discussed here, because the published correlations are clear, interpretable, and measurable. In contrast, if we

concentrate on bioreactions to implanted materials that *do not* leach substances (i.e., most "biocompatible" biomaterials) the surface properties immediately assume a high profile as the prime candidate to control bioreaction. However, hardness, porosity, shape, movement, and specific implant site are also important. These issues will be addressed in working through important concepts in correlating material properties to bioreaction.

Using words such as "correlation" and "dependence" requires some appreciation of data and statistics. This topic will be briefly addressed before the discussion of biomaterials and correlation.

DATA, INFORMATION, AND STATISTICS

Laboratory experiments generate data that comes from the measurement of the properties (biological and physical) of materials. Frequently we are given that data as a column of numbers (maybe a spreadsheet). Staring at these numbers is often unhelpful in understanding the system under study. What we really desire is not *data*, but *information*, about our system. This idea is illustrated in Figure III.1.3.1, proposing how clinical performance data and physicochemical measurement data

might lead to the development of an improved implant device. Correlation is one way to process data so that it yields information.

Correlation is a statistical tool useful for analyzing data so as to appreciate its variance, significance, and interrelationships. A general introduction to statistics is not presented here, but every biomaterials research and engineer should be versed in these mathematical tools. A few useful, general books on statistics as applied to scientific problems are Bevington and Robinson (2002), Mosteller and Tukey (1977), Anderson and Sclove (1986), and Urdan (2010). A book that can be useful in interpreting the meaning of statistics is Huck (2000). A search of Amazon.com found over 10,000 textbooks on statistics and probability.

CORRELATION

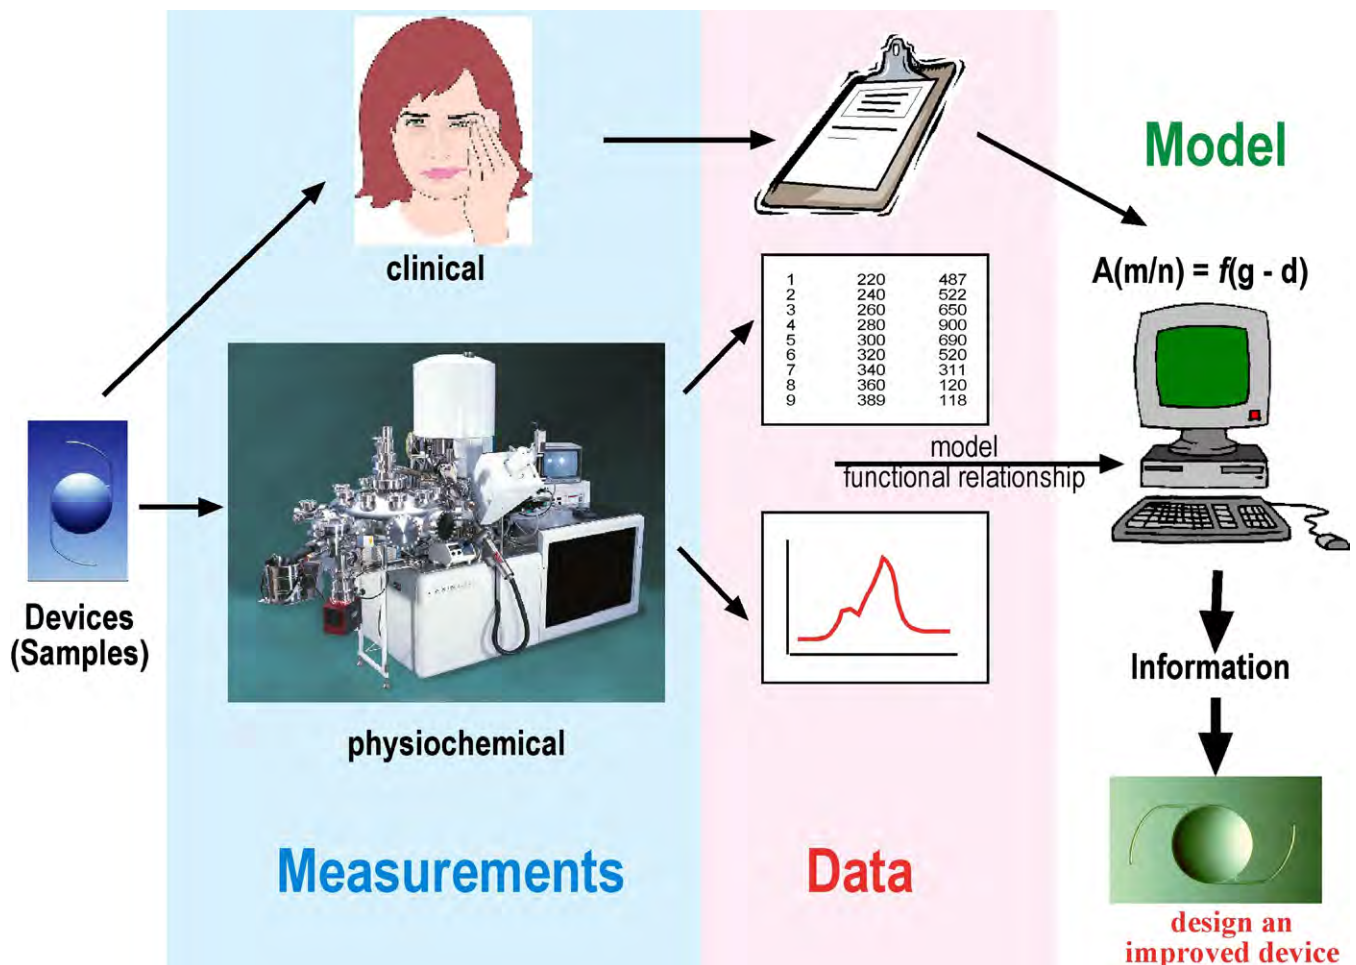
Correlation is a relationship (dependency) between two or more variables. Correlation does not necessarily mean cause and effect. For example, most people walking with open umbrellas in the rain will have wet feet. But, in this situation, it is obvious that umbrellas do not cause wet feet. We have a high correlation, but it misses the controlling factor (causative factor) in this example – the


FIGURE III.1.3.1 Clinical and physicochemical data are converted to useful information to optimize the performance of an implant device.

rain. Thus, we can propose that A (the umbrella) causes B (wet feet), B causes A, they cause each other or they are both caused by C (the rain). We cannot prove causation, but it can be strongly suggested. Often, where correlations are observed, the causative factor is obscured, and so we have data but little useful information. Where relationships are established between a dependent variable and an independent (or explanatory) variable, this is referred to as regression analysis.

It may be more productive to look at this problem in terms of calibration and prediction. Calibration in a practical (e.g., analytical) sense has been defined by Martens and Naes as the use of empirical data and prior knowledge for determining how to predict unknown quantitative information Y from available measurements X, via some mathematical transfer function (Martens and Naes, 1989). This could be as simple as plotting Y versus X and using a least squares fit to deal with modest levels of random noise or as complex as a multivariate calibration model to accommodate noisy data, interfering agents, multiple causes, non-linearities, and outliers. Multivariate methods will be elaborated upon toward the end of this chapter.

ASPECTS OF THE BIOREACTION TO BIOMATERIALS

Bioreaction, a process related to, but more readily understood than "biocompatibility," can have many manifestations. Some of these are listed in Table III.1.3.1. A bioreaction is most simply defined as an observed response upon interaction of a material with a biological system or system containing biomolecules. Can simple measured physical properties of materials be correlated with bioreactions? There are many examples where this is indeed the case. Table III.1.3.2 lists some of the surface physical measurements for materials that one might hypothesize as influencing bioreaction or biocompatibility.

THE CASE FOR CORRELATION: A BRIEF REVIEW OF THE LITERATURE

In the 1970s and 1980s there was widespread interest in using correlation to predict biomaterial performance. The lessons learned provided insights, but also tempered the enthusiasm for establishing such relationships. Still, papers continue to explore correlation and a few modern efforts will be described here.

An early and influential paper demonstrating that physical measurements might be correlated with observed reactions to biomaterials concerned extractables from biomaterials (Homsy, 1970). Many biomaterials were examined in this study. Each was extracted in a pseudoextracellular fluid. The extract was examined by infrared absorbance spectroscopy for hydrocarbon bands that are indicative of organic compounds. A positive correlation was observed between the strength of

TABLE III.1.3.1	Some Bioreactions
• protein adsorption	• macrophage adhesion
• protein retention	• neutrophil attachment
• lipid adsorption	• cell spreading
• bacterial adhesion	• phagocytosis
• platelet adhesion	• biodegradation
• hemolysis	• angiogenesis
• platelet activation	• apoptosis
• expression of new genes	• cell differentiation
• downregulation of genes	• mRNA production
• cytokine release	• fibrous encapsulation

Note: These reactions are commonly observed with implant materials; however, their relationship to "biocompatibility" is not direct.

TABLE III.1.3.2	Physical Parameters of Biomaterial Surfaces that Might Correlate with Bioreactivity
• wettability	• sub-surface features
• hydrophilic/hydrophobic	• distribution of functional groups
• polar/dispersive	• receptor sites
• surface chemistry	• modulus
• specific functional groups	• hydrogel (swelling) character
• surface electrical properties	• mobility
• roughness/porosity	• adventitious contamination
• domains (patterns) of chemistry	• trace levels of functional groups
FIGURE III.1.3.2　A hypothesis for a minimum biointeraction for surfaces with critical surface tensions around 22 dynes/cm.

the IR absorbances and the reaction of the materials with a primary tissue culture of neonatal mouse heart cells (Figure III.1.3.2). This paper was important in scientifically justifying *in vitro* cell culture analysis for screening the toxicology of biomaterials, and for developing the principle that biomaterials should not unintentionally leach substances.
FIGURE III.1.3.3 A correlation between baboon platelet consumption as measured in an *ex vivo* shunt system and hydrogel water content. (From Hanson et al., 1980.)

In the late 1960s, Robert Baier and colleagues offered an intriguing hypothesis concerning surface properties and bioreaction that continues to stimulate new experiments (Baier, 1972). This hypothesis is based upon interfacial energetics of surfaces as approximated from contact angle measurements, and suggests that materials with critical surface tensions (see Chapter I.1.5) of approximately 22 dyne/cm would exhibit minimum bioreactivity (Figure III.1.3.3). Support for this hypothesis has been generated in a number of experiments spanning different types of biointeractions (Dexter, 1979; Baier et al., 1985). However, in a larger number of cases, this minimum has not been observed, raising questions about the generality of this concept (Lyman, 1970; Mohandas et al., 1974; Chang et al., 1977; Yasuda et al., 1978; Neumann, 1979).

Some of the clearest biointeraction correlations have been observed in simple, non-proteinaceous media. Linear trends of cell (mammalian and bacterial) adhesion versus various measures of surface energy have been noted (Mohandas et al., 1974; Chang et al., 1977; Yasuda et al., 1978; Neumann et al., 1979). For example, Chang and co-workers (1977) found that the adhesion of washed pig platelets to solid substrates increased with increasing water contact angle, a parameter that generally correlates well with solid surface tension. It is interesting that these simple linear trends often vanish or diminish if protein is present in the attachment medium (Chang et al., 1977; Neumann et al., 1979; van der Valk et al., 1983). More complex surface energetic parameters have also been explored to correlate bioreaction to surface properties (Kaelble and Moacanin, 1977).

Correlations between material properties and long-term events upon implantation are less frequently seen in the literature. However, some important examples have been published. The baboon A–V shunt model of arterial thrombosis has yielded a number of intriguing correlations (Harker and Hanson, 1979). Using an *ex vivo* femoral–femoral shunt, this model measures a first order rate constant of platelet destruction induced by the shunt

material (the units are platelets destroyed/cm^2/day). The values for this surface reactivity parameter are independent of flow rate (after the flow rate is sufficiently high to ensure kinetically limited reaction), length of time that the reaction is observed, blood platelet count, and surface area of the material in contact with the blood. In one experiment, a series of hydrogels grafted to the luminal surfaces of 0.25 cm i.d. tubes was studied (Hanson et al., 1980). The platelet consumption (see Chapter II.3.5) was found to increase in a simple, linear fashion with the equilibrium water content of the hydrogels. This correlation, illustrated in Figure III.1.3.4, is particularly intriguing because the hydrogel materials studies were amide-, carboxylic acid-, and hydroxyl-based. The only clear, correlating parameter was equilibrium water content. In another study, the platelet consumption of a series of polyurethanes was observed to decrease in a linear fashion as the fraction of the polyurethane C1s ESCA surface spectrum that was indicative of hydrocarbon moieties increased (Hanson et al., 1982).

There have been many attempts to correlate specific protein adsorption with biological reaction. A 1975 study showed that the number of platelets adsorbed to polyurethanes correlated inversely with the amount of albumin adsorbed in competition with fibrinogen and IgG (Lyman et al., 1975). For a series of polyurethanes, platelet attachment was shown to correlate with the amount of fibrinogen adsorbed (Chinn et al., 1991). However, two surprising outlier points could not be explained – two materials that adsorbed high fibrinogen levels adhered low levels of platelets. Bailly et al. (1996) used a direct ELISA method to measure adsorbed fibrinogen on catheters, and found that *in vitro* platelet adhesion and *in vivo* catheter thrombogenicty correlated with the amount of adsorbed fibrinogen. Hu et al. (2001) have isolated specific domains within fibrinogen that help to explain their observation that the level of adsorbed fibrinogen correlates with the magnitude of the foreign-body reaction at short (~3 day) implantation times.
FIGURE III.1.3.4 Four very different surfaces with similar average roughness (R_a).
FIGURE III.1.3.5 Cross-sectional views of four surfaces with similar average roughness (R_a).

These studies all implicate levels of adsorbed fibrinogen with complex biological reactions.

A material parameter that lends itself to correlation is roughness or surface texture. Roughness is readily measured using a scanning electron microscope, a profilometer or an atomic force microscope (see Chapter I.1.5). Relationships between roughness and blood hemolysis (Wielogorski et al., 1976) or thrombogenicity (Hecker and Scandrett, 1985) were reported. Textures and roughness are also extremely important to the fixation of materials into hard tissue, and to the nature of the foreign-body response observed (Thomas and Cook, 1985; Schmidt and von Recum, 1991; Brauker et al., 1992) (see Chapter I.2.15). A complication in the use of the roughness parameters is differentiation between porosity and roughness, and also an appreciation of the difference between the average feature amplitude (often call R_a) and the nature of the roughness (e.g., are rolling hills and jagged rocks of the same height also of the same roughness; see Figure III.1.3.5)? Specific porosities, which might be measured as rougher or smoother surfaces, profoundly impact biological reactions (Brauker et al., 1992; Bryers et al., 2012).

Clinical results correlated with material properties are infrequent, in part because materials used in clinical studies are generally not characterized to measure the parameters appropriate to make such correlations, and also because of the complexity of interpreting data from humans. However, a few such studies have been published. In the 1970s, a contact angle measurement criterion was established as a quality control paramater for qualifying the clinical success of processed umbilical cord vascular grafts (Shapiro et al., 1978). In another example, rigid gas permeable contact lens wettability was correlated with subject discomfort, and a predictive trend was noted (Bourassa and Benjamin, 1989). Catheters that are used in humans were evaluated in a test system closely simulating clinical application (Wilner et al., 1978). Catheters were classified into three groups related to their probable success, but clear relationships to surface properties were not discerned. Studies by Bailly et al. (1996) were more successful at establishing relationships between catheter properties and *in vivo* thrombogenicity. The complications in performing control studies, the difficulties in assembling a sufficiently large experimental

population, the complexity of the materials (devices), and the human biology make clinical correlation challenging.

ISSUES COMPLICATING SIMPLE CORRELATION

Correlations should allow us to take readily measured physical properties and use that information in the design of improved biomaterials. Although many studies suggesting intriguing possibilities are cited here, this textbook does not present these correlations as rules that can be used in biomaterials design. It should be clear by now that, although many correlations have been noted, there is often contradictory evidence about what the correlating factors are, and the nature of the correlations. Also, in many systems, no obvious correlations have been noted.

The most widely-used correlating factor has been surface energetics, possibly because contact angles can be readily measured in any laboratory (Chapter I.1.5). Surface energetic parameters relate back to the second law of thermodynamics, and it is well-established that the interactions of simple colloid particles can be modeled using thermodynamic and electrostatic arguments. If living cells are treated as simple colloid particles with fixed mass, charge density, polar forces, and hydrophobic interactions, thermodynamic (energetic) modeling may be appropriate (Gerson and Scheer, 1980; Fletcher and Pringle, 1985). However, living cells most often cannot be viewed as "hard, charged spheres." Living cells can change their surface characteristics in response to surfaces and other stimuli. Also, specific (e.g., receptor) interactions do not lend themselves to this simple thermodynamic modeling. For example, two surfaces with similar (but not the same) immobilized oligopeptides, and hence essentially the same surface energy, may interact very differently with cells, if one of the oligopeptides represents a minimal recognized sequence for the cell surface receptor. This was observed with fibroblast cell attachment where an immobilized peptide containing an RGD unit (arginine-glycine-aspartic acid) and a closely related immobilized peptide containing an RGE segment (where the E indicates glutamic acid) were compared (Massia and Hubbell, 1990). The RGD peptide was highly active in inducing cell spreading, while the RGE peptide was not (see Chapter I.2.17 for details on this experiment). Finally, the nature of the correlations may be multivariate rather than univariate. This concept will now be discussed.

MULTIVARIATE CORRELATION

Cause and effect observations are widely used by scientists and engineers to develop generalizations valuable for predicting and modeling phenomena. For example, if the temperature of a solution is increased (the cause), the reaction rate between two chemicals in the solution will increase in a well-defined manner (the effect). There is a simple univariate correlation between temperature and reaction rate. However, many systems, particularly multicomponent systems that are so often important to biomaterials science, have competing reactions that are dependent upon each other (e.g., the product of one reaction may influence the rate of another reaction). Thus, we do not see a simple relationship, but rather many changes occurring simultaneously. Our eye cannot discriminate the key trend(s) in this "stew" of changing numeric values. Multivariate statistics is a class of statistical methods that looks for trends, patterns, and relationships among many variables. Also, where contemporary analytical instrumentation produces large amounts of complex (e.g., spectral) data, multivariate statistics can assist in examining the data for similarities, differences, and trends. Where large data sets overload our ability to discern relationships, multivariate methods thrive on large amounts of data and, in fact, become more accurate and useful. This class of statistical methods has come into its own only with the introduction of powerful computers, since the methods are computation-intensive. Many general introductions to multivariate statistics are available (Sharaf et al., 1986; Massart et al., 1988; Martens and Naes, 1989; Wickens, 1995; Brereton, 2003; Manly, 2004). Multivariate statistics applied to problems involving chemistry are often referred to as "chemometrics."

An important general principle in multivariate analysis is dimensionality reduction. A plot of x versus y requires us to think in two dimensions. A "three-dimensional" plot of x, y, and z can still be easily visualized. Where we have w, x, y, and z as the axes, we lose the ability to absorb the information in graphical form and visualize trends to the data. However, if we take our three-dimensional example, we can visualize a projection (shadow) of the three-dimensional data cluster in two dimensions. We have reduced the dimensionality from 3 to 2. Similarly, our four-dimensional data set can be projected (by a computer) into a three-dimensional space. Thus, we have a data representation we can visualize in order to look for trends. This dimensionality reduction is readily performed by computers using linear algebra methods. The projection of a five-dimensional data set is a four-dimensional shadow, a structure in space our minds cannot visualize. But a computer has no such limitations in looking for relationships in complex multidimensional data sets. The number of dimensions that the computer can work with is, for all practical purposes, unlimited.

There are many multivariate statistical algorithms useful for analyzing data. They are sometimes divided into classification methods (also called cluster analysis methods) and factor analysis methods (Mellinger, 1987). Classification methods find similarities in groups of data points, and arrange them accordingly. Factor analysis methods take data and transform them into new "factors" which are linear combinations of the original data. In this way the dimensionality of the problem is reduced. Factor analysis methods useful for multivariate correlation with data sets such as are acquired in

biomaterials research include principal component analysis (PCA) (Wold et al., 1987) and partial least squares (PLS) regression (Geladi and Kowalski, 1986). Review articles oriented to the issues in biomaterials science are Wagner et al. (2006) and Park et al. (2009). Two important points about these methods are that they do not require a hard model (rarely do we have such a quantitative model), and that they make use of all the data (i.e., we do not have choose which data we want to put into the correlation model). There are numerous examples of the application of these methods to biomaterials research (Wojciechowski and Brash, 1993; Perez-Luna and Ratner, 1994; Kempson et al., 2010; Barnes et al., 2012). The power of these statistical methods is being recognized, and they will become standard data analysis tools. This is because they make efficient use of all data, thrive on large amounts of data produced by modern instruments, are objective in that we do not have choose which data to use, are congruent with biomaterials studies that typically have many interrelated variables, and reduce the influence of noise and irrelevant variables, thereby effectively increasing the signal-to-noise ratio.

Multivariate statistical methods can be a great boon to data analysis, but they will not solve all problems in biomaterials science. They should be considered as powerful hypothesis generators. The correlations and trends noted using such analysis represent a new view of the significance of data that we cannot appreciate by staring at spectra or tables. New hypotheses about the importance of materials variables can be formulated, and then they must be tested. Multivariate statistical methods also provide powerful tools for experimental design, but these will not be discussed here.

CONCLUSIONS

Perhaps the reader expected this chapter to provide instruction on the importance of wettability, or roughness or carboxyl group concentration on biological reaction? Unfortunately, biomaterials science is not yet at the state where we can assemble a handbook of design data about the relationships between surface structures and biological reactions. We do not fully-understand the controlling variables from the biology or the materials science sufficiently well to generalize many of our observations. What this chapter does do is to suggest that such relationships probably exist, and to point out that there are powerful mathematical methods that have the potential to help us generalize our data into correlations and trends useful in biomaterials and medical device design.

CHAPTER III.1.4 DEVICE FAILURE MODE ANALYSIS

Frederick J. Schoen[1] and Allan S. Hoffman[2]
[1]Professor of Pathology and Health Sciences and Technology (HST), Harvard Medical School, Executive Vice Chairman, Department of Pathology, Brigham and Women's Hospital, MA, USA

[2]Professor of Bioengineering and Chemical Engineering, UWEB Investigator, University of Washington, Seattle, WA, USA

The design of implants, the biomaterials selected for them, their fabrication, and the protocols used to test them before use in humans, are all intended to mini-mize the possibility of device failure. Indeed, the major-ity of such devices serve their patients well, alleviating pain and disability, enhancing quality of life, and/or increasing survival. Nevertheless, some medical devices fail, often following extended intervals of satisfactory function. Problems involving medical device technol-ogy are often called "medical device error" (Goodman, 2002). Unraveling a cause of failure in an individual case usually requires systematic integration of clinical and laboratory information pertaining to the patient, and careful and protocol-driven pathological analyses. Anal-ysis of a cohort of failed devices, often called "failure mode analysis", involves many such cases and sometimes additional investigation, such as review of corporate quality assurance and/or other documents. Irrespective of implant site or desired function of the device, the over-whelming majority of clinical complications produced by medical devices fall into several well-defined categories, which are summarized in Table III.1.4.1.

TABLE III.1.4.1	Patient–Device Interactions Causing Clinical Complications of Medical Devices

Thrombosis

- thrombotic occlusion
- thromboembolism
- anticoagulation-related hemorrhage (owing to the therapy to prevent thrombosis)

Infection

Inappropriate healing

- too little/incomplete
- excessive tissue overgrowth

Structural failure due to materials degeneration

- wear
- fracture/fatigue
- calcification
- tearing

Adverse local tissue interactions

- inflammation
- toxicity
- tumor formation

Migration

- whole device
- embolization or lymphatic spread of materials fragments

Systemic and miscellaneous effects

- allergy
- heart valve noise

Unraveling a cause of failure in an individual case usually requires systematic integration of clinical and laboratory information pertaining to the patient, and careful and protocol-driven pathological analyses. Analysis of a cohort of failed devices, often called "failure mode analysis", involves many such cases and sometimes additional investigation, such as review of corporate quality assurance and/or other documents.

Medical device failures have some features in common with medical errors in general, in that they result from an alignment of "windows of opportunity" in a system's defenses (Carthey et al., 2001). In general, demographic, structural, functional or physiologic factors relating to the patient (e.g., age, anatomy of the implant site, activity level, genetic predisposition to complications to thrombosis, allergies) and the implantation procedure (e.g., implant selection, technical aspects of the surgery, potential damage to the implant), are superimposed on the biomaterials and device design, which collectively induce vulnerabilities to particular failure modes (Figure III.1.4.1). Thus, we will see that failure of a device in the clinical setting often involves multiple contributing factors. For example, a material or design inadequacy that could potentially cause excessive wear or fracture in an orthopedic prosthesis (hip or knee joint) may only come

All implants of type
- design,
- materials
- pre-clinical testing
- clinical testing

HAZARDS

Individual implant
- component mismatch
- defects in manufacturing, packaging, shipping or storage
- contamination
- damage/error during implantation
- poor patient/prosthesis matching
- usual/idiosyncratic patient-prosthesis interactions
- inadequate patient management
FIGURE III.1.4.1 Analysis of implant failure using systems approach to understanding multiple factors (including latent factors, i.e., those relating to any implant of a particular type, and active factors, i.e., conditions affecting a particular implant), useful in critical incident and near-miss reporting in other high technology industries. When potential risks "line up" a failure can occur. (Concepts modified from Carthey, J., de Leval, M. R. & Reason, J. T. (2001). The human factor in cardiac surgery: Errors and near misses in a high technology medical domain. Ann. Thorac. Surg. **72**, 300–305. Reproduced by permission from The Society for Thoracic Surgeons)

to light in a young, athletic patient. Moreover, a tendency toward thrombosis of a new design of prosthetic heart valve may only cause a problem in a patient whose anti-coagulation effectiveness drops below a critical point, who has a genetic hypercoagulability disorder or who has local blood stasis owing to atrial fibrillation. The determination of the cause(s) and contributory mechanism(s) of implant or other device failure is accomplished by a process called *implant retrieval and evaluation* (see Chapter II.1.5).

> In general, demographic, structural, functional or physiologic factors relating to the patient (e.g., age, anatomy of the implant site, activity level, genetic predisposition to complications to thrombosis, allergies) and the implantation procedure (e.g., implant selection, technical aspects of the surgery, potential damage to the implant), are superimposed on the biomaterials and device design, which collectively induce vulnerabilities to particular failure modes.

The fundamental objective of incident investigation is to identify the root cause of an incident, and eliminate or decrease the risk (based on the probability and severity) of recurrence (Baretich, 2007). The results of implant failure analysis have several potential implications for quality care in individual patients or cohorts of prior and potential recipients, and thus the US Food and Drug Administration (FDA) Medical Device Reporting regulations require investigation and reporting of certain device-related incidents (Shepherd, 1996). Analysis of an isolated failed implant or of multiple implants that have suffered a consistent failure mode can provide important information for individual patient care. For example, such information can:

- Impact on implant selection and patient–prosthesis matching.
- Mandate altered management of a specific patient, such as a change in the type or dose of drug therapy, such as anticoagulation, and/or closer monitoring of the patient with the at-risk type of prosthesis by echocardiography for a heart valve or X-ray or bone scan to monitor a hip joint.
- Reveal a vulnerability of a sub-group of patients (often called a *cohort*) with a specific prosthesis type to a particular mode or mechanism of device failure. This can both lead to closer scrutiny of that group of patients with such a device already implanted, and/or stimulate the need for a prospective change in design, materials selection, processing or fabrication, or potential action by regulatory agencies such as further testing or withdrawal from use.

The results of failure analysis can also influence product liability litigation, either in an individual case or in a class action proceeding involving multiple patients who have received a device with a specific real or potential failure mode.

The purpose of this chapter is to define a conceptual approach to the determination of the factors responsible for a device or implant failure. The aim is to provide a basis for using failures to guide patient management and enhance high-quality design, biomaterials development, selection, and implantation of implants.

> Analysis often reveals considerations which relate to the development, testing or manufacturing processes, and thereby potentially affect all devices in a cohort, or conditions germane primarily to a particular failed device and the patient who received it.

Questions to be addressed in a specific case might be:

- Was the device chosen the correct type and size for the patient?
- Was it optimally implanted or was there a technical error in placement?
- Was the implant damaged during fabrication or implantation by the surgeon or interventionalist?
- Did the patient have an idiosyncratic pathophysiologic response to the implant, such as allergy or an inherited heightened tendency toward blood clotting on the component biomaterials?
- Was there a design flaw in this prosthetic device type or a poor choice of materials in using an appropriate design?
- Did failure arise because the pre-clinical testing phases of the device did not (or were unable to) reveal some defect of design or materials which only became apparent following use of the device in a large number of patients or for longer duration following large-scale clinical utilization?

The array of potential causes is summarized in Table III.1.4.2 and conceptualized in Figure III.1.4.2. This chapter is not meant to describe the detailed mechanisms of either deterioration or biological responses of materials, although they may be contributory to complications (which are covered in Sections II.2 and II.4 of this book).

Multiple recent instances of medical device cohort failures have occurred in the last decade; particularly notable are the metal-on-metal hip replacements implicated for excessive wear (Browne et al., 2010), late thrombosis in drug-eluting endovascular stents (Holmes et al., 2010), and some implantable cardioverter-defibrillators with defective leads, making them unable to provide life-saving heart rhythm corrections (Becker, 2005; Maron and Hauser, 2007).

TABLE III.1.4.2	Potential Contributory Causes of Implant or Device Failure
Inadequate materials properties	
Inadequate materials testing	
Design flaw	
Inadequate pre-clinical animal test models	
Components missized/mismatched during fabrication	
Defects introduced during manufacturing, packaging, shipping, and storage	
Damage or contamination during sterilization	
Damage or contamination during implantation	
Technical error during implantation	
Poor patient–prosthesis matching	
Unavoidable, physiologic patient–prosthesis interactions	
Inadequate patient management	
Unusual/abnormal patient response

FIGURE III.1.4.2 Potential causes of implant or device failure.

ROLE OF BIOMATERIALS–TISSUE INTERACTIONS: EFFECT OF MATERIALS ON THE PATIENT AND THE EFFECT OF THE PATIENT ON THE MATERIALS

Biomaterials Selection

Mechanical failure of biomaterials and adverse biomaterials–tissue interactions are often implicated as the key factors in a device failure. The wide range of different material "breakdown" mechanisms which can cause an implant or device to fail is summarized in Table III.1.4.3. A device or implant can fail simply because the component biomaterials did not have, and/or were not tested for, the requisite physical, chemical or biological properties for the intended application. For example, the poor resistance of Teflon® (polytetrafluoroethylene) to abrasive wear, and its unsuitability for use in both hip joint

prostheses (Charnley et al., 1969) and artificial heart valves (Silver and Wilson, 1977) was appreciated only following extensive clinical use. Similarly, the inadequate durability of a carbon-reinforced Teflon® in temporomandibular joint replacement was encountered in clinical usage (Trumpy et al., 1996). In addition, the earliest silicone ball poppets in the Starr–Edwards caged-ball heart valves frequently absorbed lipids from blood during function, and consequently swelled and became brittle, and sometimes fractured (Chin et al., 1971). "Ball variance," as this complication was known, caused valve dysfunction and/or downstream embolization of fragments. This problem stimulated development of an improved processing protocol for curing medical silicone elastomers that enhanced their mechanical properties, mitigated the lipid absorption, and thereby effectively eliminated ball variance. Conversely, a material used to form the femoral stem of a hip joint prosthesis which is too stiff can cause "stress-shielding," leading to structurally poor surrounding bone remodeling and consequent loosening of the prosthesis (Huiskes, 1998).

Design

Device design is critical to performance. Design of the femoral stems of hip joint prostheses has evolved from clinical experience with fractured stems in human implants to computer-aided design and manufacturing techniques. The design of a heart valve affects the pattern of blood flow and associated platelet damage, and/or the presence of regions of blood stasis, both of which can lead to thrombosis (Yoganathan et al., 1978; Yoganathan et al., 1981).

Device design is critical to performance. Design of the femoral stems of hip joint prostheses has evolved from clinical experience with fractured stems in human implants to computer-aided design and manufacturing techniques. The design of a heart valve affects the pattern of blood flow and associated platelet damage, and/or presence of regions of blood stasis, both of which can lead to thrombosis.

However, redesigning a medical device to eliminate one complication can have unintended, potentially serious consequences. When a widely used tilting disk heart valve was redesigned to allow more complete opening, and thereby enhance its hemodynamic function as well as reduce the incidence of thrombosis, a large number of mechanical failures occurred (Walker et al., 1995). Nearly all failures had similar characteristics; they resulted from fracture of the welds anchoring the metallic struts (which confine and guide the motion of the disk) to the housing, with consequent separation of the strut and escape of the disk. Pathology studies revealed that the underlying problem was metal fatigue resulting from design-related high-velocity over-rotation of the disk during closure, excessively stressing the welds, potentially coupled with intrinsic flaws in the welded regions (Schoen et al., 1992). Interestingly, many such failures occurred in young patients during exercise, when cardiac forces and thereby valve closing velocities, are enhanced (Blot, 2005). Another example was a specific design of a bileaflet tilting disk heart valve which developed fractures that were initiated in various locations along the contacts of the disks with the housing (Baumgartner et al., 1997). In this case, the likely cause was a design flaw which led to the formation of cavitation bubbles during function as the disk moved away from the housing during the earliest phases of valve opening. The hypothesis was that implosion of these bubbles initiated microscopic cracks in the pyrolytic carbon components which then precipitated gross fractures.

TESTING OF BIOMATERIALS–DESIGN CONFIGURATIONS

In some cases, the pre-clinical *in vitro* or *in vivo* evaluation studies that were carried out on the material itself, or on the design and device prototype, either did not adequately simulate the range and/or nature of conditions which are encountered in actual clinical use or were "under powered" (did not have enough replicates) to reveal relatively low-frequency complications, especially where those complications are potentiated by infrequent patient-related factors. For example, some patients have genetic conditions that predispose to hypercoagulability; such individuals would be particularly vulnerable to clotting in cardiovascular devices (Valji and Linenberger, 2009). Individuals taking high

therapeutic doses of (cortico) steroid medications for inflammatory/autoimmune disease may not heal implants properly. The inability to reveal certain complications in pre-clinical studies may be a result of the necessarily limited numbers of animals used, or differences in animal versus human anatomy or physiology. In the case of a new bileaflet tilting disk heart valve design which suffered clinical failures due to thrombosis initiated at the points where the hemidisks contacted and pivoted in the housing, the testing of implants in sheep failed to reveal a tendency toward thrombosis (Gross et al., 1996). Furthermore, appropriate tests are not available for some physiologic responses, especially but not exclusively where those problems potentially arise from immunological interactions of xenograft (animal) or allograft (from another person) tissues with humans. For example, the potential for a significant immunological response, such as has been suggested but not proven in some patients with silicone gel breast implants, and is always a possibility in tissue-based biomaterials, is difficult to evaluate adequately in pre-clinical studies. It is also possible that available tests were overlooked because the specific problem types that occurred later were not anticipated.

A particularly illustrative example points out not only the need for improved and comprehensive pre-clinical testing regimes, but also that a change in biomaterial implemented to alleviate one complication may precipitate another problem if corresponding design changes are not considered. Specifically, bioprosthetic heart valves were fabricated from photooxidized bovine pericardium to mitigate the well-known potentiating effect of glutaraldehyde on calcification. However, many of these valves failed by abrasion-induced tearing of the pericardial tissue against the cloth which covered a portion of the stent (Schoen, 1998). The issue in this case was that photooxidized pericardium has a higher compliance than the glutaraldehyde-preserved pericardium used, but the design was unchanged from that of a valve which had been clinically successful. Higher tissue compliance led to greater excursion of the cuspal material during valve closing; the greater tissue movement of the more compliant material caused the tissue to contact and thereby abrade against the cloth. However, this was not revealed during extensive pre-implantation *in vitro* bench fatigue testing, most likely owing to the markedly accelerated rate of *in vitro* durability testing which limits tissue movements used owing to a high rate of cycling (generally approximately 20 times or more actual). Moreover, animal testing done in sheep was not (and is typically not) extended more than approximately five months, except in a few specimens which in this case did not exhibit gross failure.

BIOLOGICAL TESTING OF IMPLANTS

After prototype devices have been designed and fabricated, biologic tests *in vitro* and in animals are normally

used to gain more information for eventual regulatory approval and introduction of such a device into the clinic. However, as with the *in vitro* tests on the materials or designs, *in vivo* tests on the final device or implant could be poorly chosen, key tests could be overlooked, and/or the animal model selected or permitted may not be the most appropriate one available. For example, there have been continuing arguments over the past several decades among biomaterials scientists as to whether the dog is an appropriate animal model for evaluating blood–surface interactions, especially since dog platelets are considered to be much more adherent to foreign surfaces than human platelets. Furthermore, there is no adequate animal model to study the intense inflammatory reaction to wear debris and other particulates which can accumulate adjacent to a hip joint (Holt et al., 2007). Another case in point highlights a problem that arose owing to differences in healing in some animal models versus humans with a caged-ball mechanical prosthetic heart valve type which had a ball fabricated from silicone and cloth-covered cage struts (Schoen et al., 1984). This design was intended to encourage anchoring and organization of thrombus in the fabric, and thereby decrease thromboembolism. Pre-clinical studies of this valve concept utilized mitral valve implants in pigs, sheep, and calves; in such models the cloth-covered struts were rapidly healed by endothelium-coated fibrous tissue (Bull et al., 1969). However, subsequent clinical implantation of these valves was complicated by cloth wear and embolization before healing occurred. This vivid "case history" illustrates and reinforces the concept that human implantation may reveal important problems not predicted by pre-clinical animal testing. The more vigorous healing that occurred in the preclinical implants in this case is typical in animals compared to humans; this sometimes makes prediction of such problems very difficult. This reinforces the need for closely monitored clinical (human) trials during the introduction of a new implant type, and continued post-market surveillance following widespread general availability and implantation thereafter (Blackstone, 2005).

Animal models also must be used thoughtfully in the study of calcification of tissue valves (Schoen and Levy, 1999), another problem that results from an adverse biomaterial–tissue interaction (see Chapter II.4.5). Two animal models are generally used: (1) subcutaneous implants of valve materials in weanling (approximately three-week-old) rats, which achieve clinical levels of calcification in eight weeks or less; and (2) mitral valve replacements in juvenile sheep, which calcify extensively in 3–5 months. However, when older animals are used (in either model), calcification is vastly diminished. Use of inadequately severe models could lead to overestimation of the efficacy of an anticalcification strategy. This raises a more generic problem: that demonstration of the absence or prevention of specific pathologic features by a therapeutic option in a study requires proper controls to ensure that the model used is capable of provoking the pathology being investigated.

RAW MATERIALS, FABRICATION, AND STERILIZATION

In unusual circumstances, a batch of raw material may become defective or damaged. The fabrication process used to manufacture a device can introduce defects or contaminants which can lead to failure of a device, even though the biomaterials and design are well-matched and appropriate for the application and otherwise intact at the start of device assembly. The fracture in the weld of the tilting disk heart valve mentioned above illustrates well the introduction of defects and vulnerabilities during the fabrication process that can contribute to failure.

Incomplete sterilization of the implant (potentiating infection) or damage to the material by the sterilization process also can occur. Indeed, the use of certain materials places serious limitations on sterilization conditions. For example, PMMA intraocular lenses cannot be heat sterilized because the shape (and thereby optics) of the rigid poly(methyl methacrylate) (PMMA) lens would change above the glass transition temperature of the PMMA (100°C). Sterilization by ethylene oxide (EO) gas cannot be used with some biomaterials, because of EO solubility within and/or reactivity with the biomaterial.

These limitations are sometimes so severe that a sterilization protocol is used which is inadequate to sterilize the device. Incomplete sterilization, of course, can lead to infection, as exemplified by cohorts of porcine aortic valve or bovine pericardial bioprostheses contaminated with *Myobacterium chelonei*, an organism related to that causing human tuberculosis (Rumisek et al., 1985; Strabelli et al., 2010). The problem is that the antibacterial and antifungal efficacy of low concentrations of glutaraldehyde may be poor. The use of combined sterilization agents (e.g., alcoholic glutaraldehyde solutions) has been used to solve this problem without damaging the valve tissue.

PACKAGING, SHIPPING, AND STORAGE

Contamination or degradation can occur not only during fabrication and sterilization of devices, but also can be introduced during packaging and shipping. In all medical devices and implants, inadequate packaging or improper storage can contribute to limited shelf life. Transdermal drug delivery patches have to be carefully protected so that the drug does not leak out of the device. Tissue-derived heart valves and other devices may be degraded by excessive heat or freezing, and so are packaged with temperature indicators. Packaging and storage are also critical issues for condoms, made from natural rubber, which is sensitive to oxidation, a process that can degrade the rubber chains during storage on the shelf. Moreover, any drug delivery implant or device (e.g., skin

patch, stent, degradable microparticles) could become saturated with the drug while the device is stored, and deliver a burst of drug until the steady-state concentration gradient is reached after contact with the body.

CLINICAL HANDLING AND SURGICAL PROCEDURE

Given an implant made of appropriate materials, properly designed, fabricated, sterilized, tested, manufactured, packaged, shipped, and stored, the "moment of truth" occurs at the instant when the package is opened, and the device is handled and implanted or contacted extracorporeally with the patient's "biosystem." Key issues here relate to the technical aspects of the surgery and the skill of the surgeon, the possibility of infection due to pre-implantation contamination or mechanical damage caused by improper handling by surgical personnel and/or their instruments. An example is the kinking of a tubular vascular graft, during implantation, thereby impeding its flow and potentially inducing thrombosis.

THE RECIPIENT

Although patients are generally well-matched to their prostheses, factors related to the particular recipient, but infrequent in the population at large, may cause or contribute to some failures. For example, since young patients exhibit accelerated calcification of tissue heart valves, such devices are generally avoided in children and adolescents, in whom calcification is accelerated (see Chapter II.4.5). Moreover, appropriateness of prosthesis selection (type or size) can play a role. For example, it would not be appropriate to use a mechanical valve (which requires anticoagulation therapy) in a patient with a known bleeding problem, such as a stomach ulcer. Moreover, some patients are allergic (i.e., exhibit hypersensitivity) to nickel or other metallic elements, and patients with implants containing nickel have had hypersensitive reactions that necessitated reoperation with removal. Thus, a prosthesis containing nickel should not be implanted in a patient with a known allergy to nickel. In addition, a prosthesis inappropriately sized can be deleterious, such as a heart valve with an insufficiently sized orifice (Rahimtoola, 1998). Finally, a patient can abuse or misuse an implant, or can exhibit an unexpected "abnormal" physiologic response. For example, a hip implant recipient who over-exercises before adequate healing has occurred could cause implant loosening.

Abnormal responses may be related to normal or disease-altered physiology. All individuals with implants are vulnerable to infection (see Chapter II.2.8), and they often receive prophylactic antibiotics when undergoing procedures that may introduce bacteria into the bloodstream. However, individuals with cancer or who have received organ transplants, who are often immunosuppressed, are particularly vulnerable to infection at any tumor, transplant or implant site; they may be at even higher risk to develop implant-related infections. Moreover, "abnormal" or "skewed" pathophysiologic responses may also occur in any large population of patients. For example, some patients have genetic or acquired abnormalities of coagulation which render them particularly vulnerable to thrombosis. They are at heightened thrombotic risk for cardiovascular implant or device therapies (De Stefano et al., 1996; Girling and de Swiet, 1997). This general issue of patient heterogeneity in biologic processes may become even more critical in the future with cell-based and other tissue engineered medical devices, in which biological processes play a critical role in both efficacy and safety (Mendelson, 2006).

Failure can also be related to use, independent of patient factors. Implanted interposition grafts (called fistulas) linking artery to vein in the arm are often used for the access to the vasculature required by hemodialysis. Use requires frequent puncture by needles. Repetitive puncture can lead to graft fragmentation, local hemorrhage or aneurysm formation (Georgiadis et al., 2008).

CONCLUSIONS

In this chapter, we have described the wide range and diversity of factors that can contribute to the failure of a medical device or implant, and an approach to thinking about them in a particular case. It is important to emphasize that inadequate properties or behavior of the biomaterials or poor design features are not always responsible for failure, and other factors may be superimposed on particular inherent vulnerabilities of the biomaterial and/or design. Moreover, a well-meaning and heavily tested modification of biomaterials and/or designs to solve an important complication can lead to unintended and unpredictable consequences. Indeed, abnormal physiological responses of a patient due to an implant or treatment with a therapeutic device can be expected in some, but is not always predictable in a random subgroup of patients. It is up to the biomaterial scientists and engineers to alert and educate the public and their representatives, as well as the corporate community, to these possibilities. In this way, the biomaterials scientist or engineer can play a major role in ensuring the success of medical devices and implants.

INTRODUCTION

Implant retrieval and evaluation is a term used to describe a method of scientific analysis designed to determine the efficacy and safety or biocompatibility of biomaterials, prostheses, and medical devices *in vivo*. A key objective of this process is to determine if a medical device and its constituent biomaterials present potential harm to the patient. Implant retrieval and evaluation addresses the effects of both the recipient on the implant, and the implant on the recipient, especially biocompatibility, in the context of existing pathology. Implant retrieval and evaluation methodology is used to analyze an individual implant in the context of surgical removal or autopsy from a particular patient, or as an analysis of a collection of implants of a given generic type or a specific model of a device. When properly done, comprehensive analysis of cohorts of implants of similar types reveals paradigms of success as well as failure.

Implant retrieval and evaluation, both preclinical (animal) and clinical (humans), provides the opportunity to identify the modes, interactions, and mechanisms that lead to the success or failure of medical devices under end-use conditions. Appropriate implant retrieval and evaluation requires the development of a multilevel strategy to address device-specific parameters, the role of the patient, and device–patient interactions that lead to implant failure. Implant retrieval and evaluation is at its best highly structured and multidisciplinary, requiring the expertise and experience of scientists, engineers, and clinicians.

In this chapter, implant retrieval and evaluation are considered from the perspective of ultimate human clinical use. Therefore, this chapter draws upon many important perspectives presented in chapters dealing with materials science and engineering, biology, biochemistry, and medicine, host reactions and their evaluation, the testing of biomaterials, the degradation of materials in the biological environment, the application of materials in medicine and dentistry, the surgical perspective of implantation, the correlation of material surface properties with biological responses of biomaterials, and failure analysis (as discussed in Chapter III.5.3). Although this chapter focuses on implant retrieval and evaluation in the clinical environment, many of the goals and perspectives presented are important, and largely identical, to those used in preclinical (i.e., animal) investigation. Emphasis will be on the appropriate rationale and overall contributions of hypothesis-driven explant analysis applicable to failed as well as nonfailed and, in some situations, unimplanted devices. In this chapter, implants are considered to be composed of one or more biomaterials that are part of a specific design for a specific application. For these purposes, implants are prostheses, medical devices, or artificial organs.

GOALS

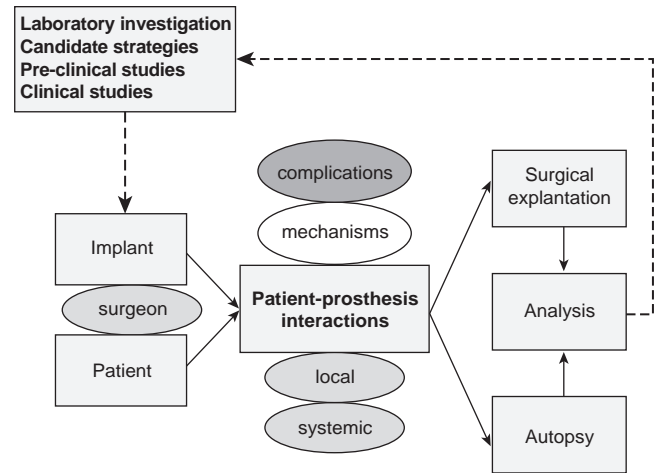
The general concept of implant retrieval in the context of clinical device use is presented in Figure III.1.5.1. Key factors determining the outcome of a medical device are the biomaterials and device design, patient-specific functional anatomy and pathology, and technical aspects of the implantation. An implant is placed in a patient by a surgeon. The term "surgeon" is broadly used here to include also "interventionalists" such as cardiologists or radiologists, etc., who implant devices through catheters or cannulas. Through device selection, implantation technique, and implant manipulation during the insertion procedure, the surgeon potentially has considerable impact on the success or failure of a device. This feature constitutes a key difference between devices and drugs (the efficacy and safety of the latter generally are not affected by the process of insertion *per se*). All implants have interactions of the constituent biomaterials with the surrounding tissues. These interactions may be local at the


FIGURE III.1.5.1 Role of implant retrieval and evaluation in the development and use of clinical devices.

TABLE III.1.5.1	General Goals of Implant Retrieval and Evaluation
Determine rates, patterns, and mechanisms of implant failure	
Identify effects of patient and prosthesis factors on performance	
Establish factors that promote implant success	
Determine dynamics, temporal variations, and mechanisms of tissue–materials and blood–materials interactions	
Develop design criteria for future implants	
Determine adequacy and appropriateness of animal models	

site of implantation or distant from the device, and their mechanisms may be elucidated by careful and appropriate study. Clinically important deleterious biomaterials–tissue interactions manifest in a patient as *complications*. Implants are retrieved after successful function or failure by either surgical removal (at reoperation) or autopsy (by consent of the next-of-kin obtained after the patient's death). However, conventional autopsy permission and procedures generally do not permit destructive examination of the extremities or face. The information derived from implant retrieval and evaluation is frequently used to guide development of new, and modification of existing, implant designs and materials, to assist in decisions of implant selection, and to otherwise alter the management of patients (such as anticoagulation drug regimens for prosthetic heart valves, activity limitations for patients with prosthetic joints, or periodic imaging of an operative site).

The general goals of retrieved implant evaluation are presented in Table III.1.5.1. While many implant failures can be characterized as implant- or material-dependent or clinically- or biologically-dependent, many modes and mechanisms of failure are dependent on both implant and biological factors (Schoen and Levy, 2005; Goodman and Wright, 2007; Burke and Goodman, 2008; Revell, 2008a,b).

To appropriately appreciate the dynamics and temporal variations of tissue–materials and blood–materials

interactions of implants, a fundamental understanding of these interactions is important. Appropriately conceived, structured and implemented, implant retrieval and evaluation should elucidate materials, design, and biological factors in implant performance, and enhance design criteria for future development. Finally, implant retrieval and evaluation should offer the opportunity to determine the adequacy and appropriateness of animal models used in preclinical testing of particular types of implants and biomaterials.

The goals of routine hospital surgical pathology or autopsy examination of a prosthetic device are generally restricted to essential documentation that a specific device has been removed at reoperation or that the patient died with the device, and diagnosis of a clinical abnormality that required the original therapeutic intervention or was a major complication of the device. Detailed correlation of morphologic features with clinical signs, symptoms, and dysfunctional physiology is usually not performed. Indeed, few pathologists have appropriate training, motivation and necessary resources to do complete and sophisticated analysis of retrieved implants. Nevertheless, directed and informed pathological examination of prostheses retrieved during preclinical animal studies or at reoperation or autopsy of human patients can provide highly valuable information. First, preclinical studies of modified designs and materials are crucial to developmental advances for technological innovation in biomaterials and medical devices. These investigations usually include implantation of functional devices in the intended location in an appropriate animal model, followed by noninvasive and invasive monitoring, followed by specimen explantation, and detailed pathological and material analysis. Second, for individual patients, demonstration of a propensity toward certain complications (e.g., a genetic propensity toward thrombosis) could have great impact on further management. Third, clinicopathologic analysis of cohorts of patients who have received a new or modified prosthesis type evaluates device safety and efficacy to an extent beyond that obtainable by either *in vitro* tests of durability and biocompatibility or preclinical investigations of implant configurations in large animals. Moreover, through analysis of rates and modes of failure, as well as characterization of the morphology and mechanisms of specific failure modes in patients with implanted medical devices, retrieval studies can contribute to the development of methods for enhanced clinical recognition of failures. The information gained should serve to guide both future development of improved prosthetic devices to eliminate complications, and diagnostic and therapeutic management strategies to reduce the frequency and clinical impact of complications. Emphasis is usually directed toward failed implants; however, careful and sophisticated analysis of removed prostheses that are functioning properly is also needed. Indeed, detailed analyses of

implant structural features prior to, and their evolution following, implantation can yield an understanding of structural correlates of favorable performance, and identify predisposition to specific failure modes, which can be extremely valuable.

Device retrieval analysis has an important regulatory role, as specified in the US Safe Medical Devices Act of 1990 (PL101–629), the first major amendment to the Federal Food, Drug, and Cosmetics Act since the Medical Device Amendments of 1976. The user requirements of the 1990 legislation require health care personnel and hospitals to report (within 10 days) to the US Food and Drug Administration (FDA) or manufacturers or both (depending on the nature of the occurrence) all prosthesis-associated complications that cause death, serious illness or injury. Such incidents are often discovered during a pathologist's diagnostic evaluation of an implant in the autopsy suite or the surgical pathology laboratory.

Implant retrieval and evaluation programs may also provide specimens and data that serve as a teaching or research resource. The information gained can be used to educate patients, their families, physicians, residents, students, engineers, and materials scientists, as well as the general public. As a research resource, implant retrieval and evaluation yields data that can be used to develop and test hypotheses, and to improve protocols and techniques.

COMPONENTS OF IMPLANT RETRIEVAL AND EVALUATION

Implant retrieval and evaluation is a structured, multifaceted, and interdisciplinary effort by scientists with expertise in materials science, materials engineering, biomechanics, biology, pathology, microbiology, radiology, medicine, and surgery (Table III.1.5.2).

TABLE III.1.5.2	Important Components and Features of an Implant Retrieval and Evaluation Program
Entire activity is hypothesis-driven	
Specimens are appropriately accessioned, cataloged, and identified	
Known and potential failure modes are thoughtfully considered	
Patient's medical history and laboratory results are reviewed	
Data are collected on well-designed, study-specific forms	
Careful gross examination, photography, and other basic analyses are always done	
Advanced analytical techniques done by specialists are considered in selected cases	
Analytical protocols and techniques for assessing host and implant responses are rigorously followed	
Correlations and cause-and-effect relationships among material, design, mechanical, manufacturing, clinical, and biological variables are sought	
Quantitative data are collected wherever possible and appropriate	
Statistical and multivariant analyses are used	

The first component is the appropriate accessioning, cataloging, and identification of retrieved implants. Patient anonymity* is required in any implant retrieval and evaluation program, and this can be achieved through appropriate accessioning, cataloging, coding of demographic information, and restriction of access. At most institutions, implant retrieval is carried out through the Surgical Pathology and Autopsy Services of the hospital.

As an example the Implant Retrieval and Evaluation Program at University Hospitals of Cleveland Case Medical Center uses the general accessioning and cataloging scheme for surgical pathology specimens. Gross and microscopic diagnoses in a standardized format are provided for patient's charts, for the appropriate clinicians and surgeons, and for the database for the Implant Retrieval and Evaluation Program. The Department of Surgery provides specimens to the Division of Surgical Pathology, with the patient's name and hospital identification number, clinical diagnoses, and notes on the patient and/or implant history.

An in-depth evaluation of a retrieved implant requires a review of the patient's medical history and radiographs, and other studies (e.g., echocardiograms, MRI scans), where pertinent. Table III.1.5.3 provides a partial list of anatomic and physiologic conditions that may influence the failure or success of orthopedic and cardiovascular implants. The identification of acute and chronic problems presented by the patient often will provide guidance on how the evaluation of a specific implant should be carried out. For example, a clinical diagnosis of infection necessitates that biohazard precautions, sterile handling and microbiologic cultures should be used in the evaluation. In addition, gross examination and photography play an important role, and must be carried out before specific techniques are used to evaluate implants.

It is critical to use a strategy that will allow optimal information yield using appropriate analytical protocols and techniques to assess host and implant responses. This strategy is directed toward developing correlative and cause-and-effect relationships among material, design, mechanical, manufacturing, clinical, and biological variables (Chapter III.1.3). Finally, whenever possible, analytical protocols and techniques should produce quantitative information that can be analyzed statistically. These analyses may also include clinical information.

Osteonecrosis	
Recipient activity level	

Procedures used to evaluate devices and prostheses after function in animals and humans are largely the same. However, subject to humane treatment considerations, enumerated in institutional and federal guidelines and legislation, animal studies permit more detailed monitoring of device function and enhanced observation of morphologic detail (including blood–tissue–biomaterials interactions), as well as frequent assay of laboratory parameters (such as indices of platelet function or coagulation), and allow *in situ* observation of fresh implants following elective sacrifice at desired intervals. In addition, specimens from experimental animals can often be obtained rapidly, thereby minimizing the autolytic changes that occur when tissues are removed from their blood supply. Furthermore, advantageous technical adjuncts may be available in animal but not human investigations, including *in vivo* studies, such as injection of radiolabeled ligands for imaging platelet deposition, fixation by pressure perfusion that maintains tissues and cells in their physiological configuration following removal, and injection of various substances that serve as informative markers during analysis (such as indicators of endothelial barrier integrity). Animal studies often facilitate observation of specific complications in an accelerated time frame, such as calcification of bioprosthetic valves, in which the equivalent of 5–10 years in humans is simulated in 4–6 months in sheep (Schoen and Levy, 2005). Moreover, in preclinical studies, experimental conditions can be held constant among groups of subjects, including nutrition, activity levels, and treatment conditions. Consequently, concurrent control implants, in which only a single critical parameter varies, are often available in animal but not human studies.

Most implant retrieval involves examination of failed implants that have been surgically removed from patients or have been encountered at autopsy. Nevertheless, critical information can accrue from examination of "successful" implants removed after either fulfilling their function (e.g., a bone fixation device) or death of the patient resulting from an unrelated cause

---

*In the US The Privacy Rule provides federal protection for personal health information held by health care providers, and gives patients an array of rights with respect to that information. At the same time, the Privacy Rule is balanced so that it permits the disclosure of personal health information needed for patient care and other important purposes. The Privacy Rule was a component of The Health Insurance Portability and Accountability Act of 1996 (HIPAA), Public Law 104-191, which was enacted on August 21, 1996 (http://www.hhs.gov/ocr/privacy/hipaa/understanding/index.html).

(e.g., heart valve prosthesis in a patient who dies of cancer). However, such studies may present difficulties, including but not limited to, access to the anatomic site, timing of the explantation following excessive postmortem interval, and family permission (Jacobs et al., 1999).

APPROACH TO ASSESSMENT OF HOST AND IMPLANT RESPONSES

Evaluation of the implant without attention to the tissue will produce an incomplete evaluation, and no understanding of the host response. Table III.1.5.4 provides a partial list of techniques for evaluating implants and tissues. We anticipate that novel implants and materials may dictate further techniques to be used in evaluating host–biomaterials interactions, and new analytical techniques will likely be developed.

Adequate and appropriate implant retrieval and evaluation require the quantitative assessment of host and implant responses using analytical protocols and non-destructive and destructive testing procedures. Techniques utilized for implant and tissue evaluation should be both device-designed and material-specific, permitting the collection of quantitative data that, in turn, can provide correlations and cause-and-effect relationships between material, design, mechanical, manufacturing, clinical, and biological variables. The evaluation techniques appropriate for a particular sample may be mutually exclusive, and the choice of a subset of techniques for evaluation may be dictated by the key clinical questions, and the availability and condition of the retrieved implant and tissue specimens. While a multilevel strategy is necessary for implant evaluation, analytical protocols and techniques are only utilized following a thorough understanding of the patient's medical history, laboratory results, and associated information, and known and potential failure modes and mechanisms are considered.

In general, analytical protocols and techniques for assessing host and implant responses can be divided into two categories: nondestructive and destructive testing procedures. Only after appropriate accessioning, cataloging, and identification, and a complete review of the patient's medical history and radiography, can the analytical protocols and techniques for implant evaluation be specified.

It should be noted that the techniques for implant evaluation are most commonly destructive techniques, that is, the implant or portions of the implant and the surrounding tissues must be destroyed or altered to obtain the desired information on the properties of the implant or material. The availability of the implant and tissue specimens will dictate the choice of technique.

Detailed analysis of the implant–tissue interface often necessitates that both a piece of tissue and a piece of the implant which it contacts be sectioned and examined in

TABLE III.1.5.4	Techniques for Implant Evaluation

continuity (i.e., as one unit). This may necessitate special procedures, especially for polymer and ceramic implants in hard tissue (see below), which generally precludes any other analysis of that specimen. Similarly, chemical analysis of a piece of tissue for metal ion concentration requires acid digestion, and thus precludes morphological analysis. Thus, consideration must be given to either selection of multiple specimens or division of a specimen before processing, in order to permit part to be used for morphological and part for chemical analyses. Each of these portions may need to be further subdivided to be processed according to the requirements of specific tests. Moreover, since many of the procedures include cutting or sectioning a portion of the retrieved device, one must consider the legal aspects of device ownership, and destruction of what may become evidence in a court of law. Strict institutional guidelines need to be adhered to, and permission for use of destructive methods may be necessary. For clinicopathologic correlation studies that

involve utilization of both patient data and pathological findings, approval of the local institutional review board (IRB) in the US is required. This is largely to ensure that the confidentiality and other interests of the patients from whom the implants were removed will be maintained, especially for purposes of publication or other dissemination of information.

Technical Problems of Metallic Implants, Bone, and Calcified Tissue

Evaluation of an implant and the surrounding host tissue when the implant was placed into bone, bone has formed around it, local tissue has calcified, or teeth presently pose unique problems. Dental implants and orthopedic implants are usually associated with hard tissue, but other implants may have contact with calcified tissue. Material containing calcified tissue, bone or teeth should be identified before the laboratory begins processing it or there may be harm to some of the equipment used for sectioning soft tissue. In addition some consensus standards, such as ASTM F561 and ISO/FDIA 12891-1, have been developed that address these special issues. Bone is a dynamic tissue, and analysis of bone formation and bone resorption may be a critical part of the study. Selection of techniques for evaluation must be undertaken carefully. Consideration needs to be given to what questions are being addressed before anything is cut or any harsh solutions are used.

If the implant and tissue are handled correctly, the techniques listed in Table III.1.5.4 are applicable to the study of hard tissue and associated implants. As stated earlier, some techniques are mutually exclusive. For example, histologic analysis of particle size and quantity, and chemical digestion and analysis for metal ions cannot be done on the same sample. Following routine fixation to preserve cellular detail, either of two generic approaches may be taken with implants adjacent to hard tissue: preparation of undecalcified sections or decalcification prior to embedding. Fully decalcified bone can be embedded and sectioned using methods common to soft-tissue pathology. To prepare undecalcified sections, hard tissue and the associated implant component or section are dehydrated and embedded in a hard plastic (usually methyl methacrylate) and thick (approximately 500 μm) sections are cut with a diamond saw and ground down to form the final thin section (approximately 50 μm). The advantage of undecalcified sections is that areas of mineralization and newly formed bone can be clearly distinguished from soft tissue. Specimen X-rays can also be taken to identify sites and extent of mineralization. Assistance with techniques for evaluation of specimens containing bone is available from the Society of Histotechnology and elsewhere (McNeil et al., 1997; Sanderson and Bachus, 1997; Callis and Strerchi, 1998).

Other special techniques may need to be developed and/or adapted to study particular issues. For example, stents composed of metallic wires are now commonly used in many clinical applications, including peripheral vascular disease intervention, biliary obstruction, endovascular repair of aneurysms, and percutaneous coronary interventions. In the examination of vascular stents, it is particularly important to determine if the stent is open or has become obstructed, and identify specific biomaterial–tissue interactions, without disturbing the key interfaces during dissection. A rapid and cost-effective method was recently described to dissolve most metallic stents, leaving the vascular and luminal tissues intact, in order to facilitate this type of analysis (Bradshaw et al., 2009).

Other Special Issues

Because implant retrieval programs may obtain data that will be used in regulatory or litigation procedures, it is important to document the disposition and appearance of the tissue, and of the implant, at each stage in the evaluation. Ample use of photography will greatly help in the description of the tissue and implant condition at each step of analysis. Careful labeling that is recorded during photography is helpful in later reviews of the evaluation procedure.

Concerns relative to the safety of laboratory personnel arise in the examination of retrieved materials and tissues, especially with respect to infection. If the device and/or tissues arrive in the laboratory without having been adequately disinfected or treated, special precautions need to be observed with the use of barrier clothing and gloves, and the use of biosafety cabinets. All safety regulations of the institution need to be known and followed. Procedures for disposal of hazardous chemicals also need to be carefully observed. If untreated devices or tissues are to be packaged and shipped from the clinical setting to the laboratory, care must be taken to follow the rules and regulations of the shipping agency and the Department of Transportation for transportation of biohazardous material. ASTM Committee F04 has a draft standard WK13292, Standard Guide for Shipping Possibly Infectious Materials, Tissues, and Fluids. This document contains guidelines and references for all the regulatory issues involved in shipping explant related materials.

An additional and very complex matter relates to implant ownership (Beyleveld et al., 1995). Several parties may have (and claim) rights to possession of a removed device under various circumstances: the patient, the surgeon, the pathologist, the hospital, an entity such as an insurance company, and attorneys representing both the plaintiff and the defendant in product liability or malpractice litigation. Moreover, ownership may not automatically entail the right to test. These issues are both controversial and unresolved.

The Multilevel Strategy to Implant Evaluation

Implant retrieval and analysis protocols often utilize a multilevel approach along the spectrum of essential documentation to the use of sophisticated research tools. Some investigators have advocated a basic two-level approach (Table III.1.5.5). Level I studies include routine evaluation modalities capable of being done in virtually any laboratory, and that characterize the overall safety and efficacy of a device. Level II studies comprise well-defined and meaningful test methods that are difficult, time-consuming or expensive to perform, require special expertise or yield more investigative or esoteric data. Since some level II analyses may be mutually exclusive, some material might routinely need to be accessioned, set aside (during level I analyses), and prepared for more specialized level II studies, in the event that they should be indicated later. Level II evaluation is usually undertaken with specific investigative objectives directed toward a focused research question or project. Prioritized, practical approaches using these guidelines have been described for heart valves, cardiac assist devices and artificial hearts, and other cardiovascular devices (Schoen et al., 1990; Borovetz et al., 1995; Schoen, 1995, 2001; Schwartz and Edelman, 2002, 2004).

Both ASTM and ISO implant retrieval standards (F561 and ISO 12891, respectively) have utilized a three-stage approach to implant analysis. Stage I analysis consists of routine device identification and description. Stage II is more detailed, time-consuming, and expensive, and includes photography and non-destructive failure analysis. Since stage I and II protocols are the same for all material types, they are combined in F561. Stage III protocols include destructive analytical techniques, many of which are specific to particular material types, and thus separate guidelines are provided for metallic, polymeric, and ceramic materials. Combinations of these protocols provide guidelines for analysis of the various components of composites and tissue engineered materials.

THE ROLE OF IMPLANT RETRIEVAL IN DEVICE DEVELOPMENT

For implants placed into many anatomic sites, prosthesis-associated pathology is a major determinant of quality of life and prognosis of patients. Implant retrieval and evaluation plays a critical role in the evolution of medical devices through development and clinical use (Figure III.1.5.1). Implants are examined as: (1) fabricated but unimplanted prototypes, to reveal changes in device components induced by the fabrication process that can predict (or lead to an understanding of) failure modes observed subsequently; (2) specimens that have been subjected to *in vitro* tests of biocompatibility or durability; (3) specimens removed from animal models following *in vivo* function, usually as actual devices; (4) specimens that accrue in carefully controlled clinical trials; and (5) failed or functioning specimens that are explanted in the course of ongoing surveillance of general clinical use of a device following regulatory approval. In each case, implant retrieval is concerned with the documentation of device safety and efficacy, and problems that dictate modification of design, materials or use of the implants in patients (e.g., patient–device matching or patient management). Devices are explanted and analyzed with attention directed toward all complications, but especially those that may be considered special vulnerabilities engendered by the device type. Efforts are made to retrieve and evaluate as many such implants as possible, both failed and nonfailed. Evaluation of retrieved animal implants plays a special role in the documentation for the FDA-Investigational Device Exemption (IDE) required for a clinical trial and for the FDA-Premarket Approval (PMA) required for general marketing. The literature contains numerous instances where problem-oriented implant evaluation studies have yielded important insights into the deficiencies and complications that have limited the success of various implants. Implant retrieval has also contributed to the assessment of the safety and efficacy of implant modifications intended to be improvements. The conceptual approach to the analysis of a failed implant is explored in Chapter III.1.3.

Common failure modes of cardiovascular implants include thrombosis, embolism, calcification, and infection, whereas those of orthopedic and dental implants are loosening, wear, and infection. Implant retrieval studies have, and will continue to have, significant clinical, as well as research and development, utility. Specific implant designs can lead to specific types of complications and failure. Implant retrieval and evaluation with the identification of failure modes and mechanisms have played a significant role in the evolution of medical devices and will continue to be crucial for the evaluation of "next" generation devices.

WHAT CLINICALLY USEFUL INFORMATION HAS BEEN LEARNED FROM IMPLANT RETRIEVAL AND ANALYSIS?

Cardiovascular Implants

Cardiovascular implants commonly involve both blood and soft-tissue interactions with materials. The complications most commonly found with these implants, i.e., heart valve prostheses, vascular grafts, cardiac assist devices/artificial hearts, and vascular stents are listed in Tables III.1.5.6 and III.1.5.7. Perspectives, approaches, and techniques for evaluating cardiovascular implants have been described (Schoen et al., 1990; Borovetz et al., 1995; Schoen, 1995, 2001; Schwartz and Edelman, 2002, 2004). Specific examples from the field of cardiovascular prostheses are summarized next and in Table III.1.5.8, to illustrate the scope and utility of this activity.

Experience with caged-ball mechanical prosthetic heart valves in the 1960s demonstrated both thrombus and degradation as complications. Degradation of silicone due to lipid absorption (called ball variance) was virtually eliminated by improved curing of silicone poppets (Hylen et al., 1972). Subsequently, a cloth-covered caged-ball mechanical prosthetic heart valve that had a ball fabricated from silicone and a metallic cage covered by polypropylene mesh was introduced. The cloth-covered cage struts were designed to encourage tissue ingrowth, and thereby decrease thromboembolism. Preclinical studies in pigs, sheep, and calves demonstrated rapid healing by fibrous tissue of the cloth-covered struts. However, subsequent clinical studies of these valves showed abundant cloth wear in some patients, sufficient to cause escape of the ball through the spaces between the cage struts, a circumstance that was usually fatal without emergency surgery (Schoen et al., 1984). This analysis demonstrated the general concept that valve prostheses used in humans may have important complications that were not predicted by animal investigations, in this case because the vigorous healing that occurred in animals, but not in humans, obscured the potential problem.

Modification of a tilting-disk valve design intended to permit enhanced opening and thereby reduce thromboembolism also led to a new complication – strut fracture with escape of the disk. Careful studies of retrieved valves made a critical contribution to understanding and managing this serious clinical problem (see Prosthetic Heart Valve Case Study). Multiple coordinated studies of retrieved experimental and clinical implants have characterized and facilitated therapeutic approaches toward elimination of calcification-induced failure modes in bioprosthetic tissue heart-valve replacement (Schoen and Levy, 1999, 2005).

Such studies have identified the causes and morphology of failure, patterns of mineral deposition, nature of the mineral phase, and early events in the mechanisms of calcification. Calcification of valve tissue in both circulatory and subcutaneous animal models exhibits morphological features similar to that observed in clinical specimens, but calcification is markedly accelerated in the experimental explants. Such studies have provided the means to test approaches to inhibit bioprosthetic valve calcification by modifying host, implant, and mechanical influences. These studies serve to emphasize that biological, as well as mechanical, failure mechanisms can be understood using specifically chosen and controlled animal model investigations, guided by and correlated with the results of careful studies of retrieved clinical specimens. Furthermore, they show how implant retrieval studies can be used as a critical component of a program to ensure efficacy and safety of potential therapeutic modifications.

An additional use of retrieval studies is exemplified by a case in which a change in biomaterials was shown

TABLE III.1.5.8	Clinical Utility of Retrieval Studies: Heart Valve Substitutes
Implant Type	**Knowledge Gained/Lessons Learned**
Caged ball valves	• Poppets fabricated from industrial silicone absorbed blood lipids, and became swollen and brittle
	• Fragments of degraded heart valve material may embolize to other organs
	• Thrombosis can occur at stasis points downstream of the ball
Cloth-covered caged ball valves	• Cloth wear can cause hemolysis and cloth emboli
	• Cloth wear accompanied by silicone poppet wear can precipitate poppet escape
	• Healing of fabric may be more vigorous in animals than in humans
	• Quantitation of data (e.g., polymeric poppet weight and dimensions) may facilitate the understanding of a failure mode
Caged disk valves	• Teflon® has poor wear resistance as a valve occluder
	• Poor design features may potentiate thrombosis
Tilting-disk valves	• Thrombosis may initiate downstream to the edge of a partially open disk at a region of stasis
	• A "minor" change in valve design can result in a new propensity toward failure
	• Animal implants instrumented with strain gauges can be used to test a hypothetical mechanical failure mechanism
	• Understanding a failure mode can lead to both new methods for noninvasive diagnosis (e.g., X-ray and acoustic), and modified patient management strategies (e.g., drugs to depress cardiac contractility)
Bileaflet tilting-disk valves	• Cavitation may cause critical materials damage in some valve designs
	• Thrombosis may be initiated in regions of microstasis at component junctions
	• Microscopic areas of stasis may be predicted by computer-assisted computation
	• Animal implant models may fail to predict vulnerability to thrombosis in humans
Bioprosthetic heart valves	• Tissue calcification is a major failure mode
	• Calcification is most pronounced in areas of leaflet flexion, where deformations are maximal
	• Calcification is accelerated in young recipients, especially children
	• Heart valve calcification can be studied outside of the circulation (e.g., subcutaneous implants in rats)
	• Calcification is initiated principally at cell remnants deep in the tissue
Cryopreserved allograft valves	• These valves are not viable and cannot grow
	• Failure is not immunologically mediated and, therefore, immunosuppression is inappropriate
Substitution of new materials	• Pyrolytic carbon has favorable clinical durability
	• Detailed examination of functional (not failed) prostheses may yield worthwhile data

Case Study	Prosthetic Heart Valve Case Study

Often cited as the prototypical device failure analysis that contributed important clinical information, the problem of the Björk-Shiley tilting disk mechanical valve prosthesis provides an instructive case history. The prosthesis of original design, initially in which a Delrin® polymer disk and later a pyrolytic carbon disk was held in place by a wire superstructure composed of inflow and outflow struts, was associated with an unacceptable late failure rate owing to thrombotic occlusion (Figure III.1.5.2). The inflow strut was an integral part of the valve base while the outflow strut was welded to the base ring.

In order to reduce the risk of thrombosis by improving valve flow, the company manufacturing the valve (Shiley, Inc.) redesigned the prosthesis to achieve opening angles of the disk of 60° or 70° from the plane of the valve base and rounded the surfaces of the disk ("convexo-concave" or "C-C"). However, clinical use of the redesigned Björk-Shiley C-C heart valve led to an unusually large cluster of cases in which the metallic outlet strut fractured in two places, leading to disk escape (Figure III.1.5.3). The complication was fatal in the majority of patients in whom it occurred. In 2005, strut fracture was reported in at least 633 of the 86,000 valves of this type implanted worldwide during 1978–1986. Clinical studies identified large valve size, mitral site, young recipient age, and valve manufacture date as risk factors for this failure mode (Blot et al., 2005). The mechanisms of this problem were elucidated through careful analysis using retrieved implant analysis, coupled with other methods.

Pathologic studies of retrieved Björk-Shiley valves, enhanced by scanning electron microscopy, demonstrated a pronounced wear facet at the tip of the outlet struts, and localized pyrolytic carbon wear deposits at sites where the closing disk contacted the strut (Schoen et al., 1992), providing a fatigue fracture mechanism that began on the inflow side of the outlet strut often initiated within a weld joint (Figure III.1.5.4). The analysis suggested that the first strut leg fracture typically initiated at or near the point of maximum bending stress, was traced to a site of weld shrinkage porosity and/or inclusion in most cases, and was followed by fracture of the second leg. Occasionally, valves with only a single strut fracture were encountered. This showed that the underlying problem in catastrophic failure was metal fatigue failure, probably initiated by over-rotation of the disk during valve closure in this design, leading to excessive bending stresses at or near the welds joining the outlet struts to the housing, and potentially coupled with intrinsic weld flaws.

Moreover, in subsequent animal studies in which Björk-Shiley 60–70° C-C valves were implanted in sheep and instrumented with strain gauges showed that impact forces varied greatly with cardiac activity, and that loads occurring during exercise were significantly elevated. This correlated with clinical data that showed that fracture often occurred during exertion.

The Björk-Shiley heart valve case demonstrates that elucidation of a failure mode by detailed materials failure analysis can have

potential impact on patient management. Understanding this mode of failure has enabled development of non-invasive testing modalities (via high-definition radiography (O'Neill et al., 1995) or acoustic characterization of strut status (Plemons and Hovenga, 1995)) to establish when one strut has fractured prior to the onset of clinical failure, to

caution patients with these valves against vigorous exercise, and to consider re-replacement of properly functioning valves at high risk of fracture. Moreover, this case has reinforced certain principles of valve testing which should occur before widespread clinical use of a new or modified prosthesis design (Blackstone, 2005).
FIGURE III.1.5.2 Björk-Shiley mechanical heart valve prosthesis. Left: Original model with pyrolytic carbon disk, unimplanted. Right: thrombosed prosthesis. (B) from Schoen F.J., Levy, R.J., Piehler, H.R. (1992). Pathological Considerations in replacement heart valves. Cardiovascular Pathology 1:29–52.
FIGURE III.1.5.3 Modified Björk-Shiley mechanical heart valve prosthesis with convexo-concave disk and 70° opening. Left: Unimplanted valve. Right: Explanted valve with outflow strut fracture at welds (arrows). Disk had escaped from housing and the outflow strut piece was not located. (B) from Schoen F.J., Levy, R.J., Piehler, H.R. (1992). Pathological considerations in replacement heart valves. Cardiovascular Pathology 1:29–52.

to be beneficial. Implant retrieval studies of a low-profile disk valve composed of a disk and cage fabricated from Teflon® demonstrated poor wear properties of the disk. After a new model of the valve with disk and struts fabricated from pyrolytic carbon was introduced, clinical experience suggested that the use of carbon contributed to a major advancement in the durability of prosthetic heart valves. Retrieval studies of carbon valves recovered at autopsy or surgery, and analyzed by surface scanning electron microscopy and surface profilometry indicated that, compared with valves composed of Teflon®, carbon valves exhibited minimal abrasive wear (Schoen et al., 1982). This study revealed that although analysis of implants and medical devices has traditionally concentrated on those devices that failed in service, important

data can accrue from implants serving the patient until death or removal for unrelated causes. Thus, detailed examination of the properly functioning prostheses removed from patients after a long duration of implantation may yield worthwhile data, provided that a focused question is asked of the material.

Other retrieval studies have revealed: (1) the cause of excessive thrombosis of a new bileaflet tilting-disk design (Gross et al., 1996); (2) the cause of mechanical failure of a new pericardial bioprosthesis fabricated from photofixed bovine pericardium that had different mechanical properties than conventional glutaraldehyde-fixed tissue (Schoen, 1998a); and (3) the cause of failure and characteristic changes that occur in cryopreserved allograft aortic heart valves transplanted from one individual
FIGURE III.1.5.4 Analysis of retrieved Björk-Shiley convexo-concave mechanical heart valve prosthesis. Upper left: Elliptical wear flat on tip of outlet strut resulting from contact with disk during closure. Upper right: Worn and abraded surface of first strut leg to fracture. Origin of the fatigue fracture is at bottom center. Lower left: Fracture surface of second leg to fracture; stigmata of fatigue fracture are absent. Lower right: Residual weld fracture at the base of valve showing weld porosity and secondary cracking (arrows). From Schoen F.J., Levy, R.J., Piehler, H.R. (1992). Pathological Considerations in replacement heart valves. Cardiovascular Pathology 1:29–52.

to another (Mitchell et al., 1998). Studies of ventricular assist devices have demonstrated the importance of valves or biomaterial junctions in initiating thrombosis (Fyfe and Schoen, 1993; Wagner et al., 1993), and several studies have described the failure modes of specific types of vascular grafts in different locations (Canizales et al., 1982; Downs et al., 1991; Guidoin et al., 1993), and the morphology of vascular stents (Anderson et al., 1992; van Beusekom et al., 1993; Farb et al., 2002).

Oxidative biodegradation and environmental stress cracking of polyether polyurethane pacemaker lead insulation have been identified as failure mechanisms of pacemaker leads (Wiggins et al., 2001). Reactive oxygen radicals, released by adherent macrophages and foreign-body giant cells in the foreign-body reaction oxidize the polyether component of the polyurethane, leading to oxidative chain cleavage of the polymer and subsequent failure. These findings have lead to the development of new polyurethanes that are oxidation-resistant or inhibit the adhesion and activation of adherent cells in the foreign-body reaction at the tissue–material interface (Anderson et al., 2007).

Orthopedic and Dental Implants

Complications most commonly found with orthopedic and dental implants are presented in Table III.1.5.9 and Table III.1.5.10, respectively. The clinical utility of hard-tissue (orthopedic and dental) implant retrieval and evaluation is summarized in Table III.1.5.11.

TABLE III.1.5.9	Complications of Orthopedic Implants	
Bone resorption	Loosening
Corrosion	Mechanical mismatch
Fatigue	Fracture
Fibrosis	Motion and pain
Fixation failure	Particulate formation
Fracture	Surface wear
Incomplete osseous integration	Stress riser
Infection	
Interface separation	

TABLE III.1.5.10	Complications of Dental Implants	
Adverse foreign-body reaction	Loosening
Biocorrosion	Foreign-body reaction
Electrochemical galvanic coupling	Corrosion
Fatigue	Particulate formation
Fixation failure	Wear
Fracture	
Infection	
Interface separation	
Loss of mechanical force transfer	

Early studies were concerned primarily with metallic devices used for internal fixation of fractures. Examination of some early designs showed failure at regions of poor metallurgy or weak areas due to poor design (Cahoon and Paxton, 1968). Other studies (Wright

TABLE III.1.5.11	Clinical Utility of Retrieval Studies: Hard-Tissue Implants
Implant Type	**Knowledge Gained/Lessons Learned**
Plates, screws, and rods used for fracture fixation	• Do not mix metal alloys in same device
	• Match the hardness (degree of cold-work) and stiffness with the application
	• Metallic implant wear and corrosion may lead to problems associated with allergic reactions
Tooth root implants	• Careful surgical technique avoids thermal tissue necrosis of the implant–tissue interface
	• Implant surface finish is a critical determinant of outcome
Femoral stems of total hip replacements (fracture analysis)	• Cobalt alloys require high-quality casting
	• High-strength superalloys may be advantageous
	• Welded regions may fail in tensile-loaded locations
	• Part numbers should not be etched in tensile-loaded locations
Femoral stem, modular interface	• Corrosion at an interface is dependent on metallurgical and mechanical design factors
Polymeric component to total joint replacements (excluding one-piece flex hinge joints, such as finger)	• Teflon® performs poorly in wear applications
	• Reinforcement of UHMWPE (ultra-high molecular weight polyethylene) with chopped carbon fiber is ineffective
	• Laboratory simulation should be done using clinically realistic implant wear motion and loading patterns
	• Mechanical designs that produce high localized stresses may cause delamination
	• Radiation sterilization to produce cross-linking is useful, but can lead to molecular-chain scission, oxidation, and aging
Analysis of tissues surrounding total joint replacements	• Wear particles derived from breakdown of the implant–bone interface or wear of the articulation (bearing) material cause inflammation and loosening
Titanium and titanium-alloy implants	• A good material in one implant application may not necessarily be good in another
	• Commercially pure titanium is appropriate for tooth root implant or fracture fixation devices
	• Titanium alloys may yield severe wear in some total joint applications

et al., 1982; Cook et al., 1985) reinforce the importance of material and design, such as the pitfall of stamping the manufacturer's name in the middle of the plate where stresses are high. Modern total hip replacements have also had fatigue fractures initiated at labels etched at high-stress regions (Woolson et al., 1997). Galvanic corrosion due to mixed metal alloys was also demonstrated in early retrieval studies (Scales et al., 1959). Analyses of fixation devices have shown a correlation between corrosion and biological reactions, such as allergic reactions to metallic elements in the implants (Brown and Merritt, 1981; Cook et al., 1988; Merritt and Rodrigo, 1996).

The development of the low-friction total hip arthroplasty by Charnley is a classical example of how implant retrieval can yield important clinical information which impacts implant materials and design (Charnley et al., 1969). The initial choice for the low-friction polymeric cup (replacing the acetabulum) was a Teflon®-like PTFE. As described above for heart valves, this relatively soft material had a very high wear rate, and within a few years many hip replacements had been removed due to severe wear and intense inflammatory reactions. The analysis of the retrievals has also demonstrated the relationships between large head diameter, and the wear debris and excessive wear that have served as the basis for our understanding of joint bearing design. Clinical and retrieval studies are now examining the performance

of metal-on-metal total hip bearing couples (Kwon et al., 2010; Ebramzadeh et al., 2011).

Teflon® was replaced by ultra-high molecular weight polyethylene (UHMWPE) as the acetabular cup bearing surfaces, and retrieval studies have continuously stimulated changes in the methods of processing UHMWPE. Retrieval studies have demonstrated that reinforcing UHMWPE with carbon fibers did not sufficiently improve its strength (Wright et al., 1988). Heat pressing to improve surface hardness was not effective with some total knee designs (Bloebaum et al., 1991; Wright et al., 1992).

The physical and mechanical properties of UHMWPE are altered by ionizing radiation, due to the generation of free radicals. Oxidative degradation of UHMWPE components radiation sterilized in air-permeable packaging occurs during sterilization, during shelf-storage prior to implantation, and *in vivo*. Oxidation has a detrimental effect on UHMWPE, leading to a decrease in the elongation to failure, an increase in elastic modulus, and a decrease in fatigue crack propagation resistance (Kurtz, 2009), and has resulted in the premature failure of some UHMWPE components *in vivo*. Contemporary radiation sterilization practices (e.g., sterilization in an inert gas or vacuum) for UHMWPE have largely eliminated the potential for shelf aging; however, *in vivo* oxidation occurs and remains a concern (Kurtz et al., 2006).

Case Study	**Orthopedic Hip Prosthesis Case Study**

One of the most dramatic examples of effective implant retrieval and analysis is that of the zirconia femoral ball head made under the trade name of Prozyr® by Saint-Gobain Ceramiques Desmarquest. By mid-1998 they had made thousands of these with very low failure rates. However, in 1998 they changed a processing step from batch furnace sintering to a continuous flow "tunnel furnace" (Clarke et al., 2003). In 2001 reports of catastrophic head fracture were being reported by the primarily European manufacturers. On August 10, 2001, the French Agency of Health Security of Health Products issued a recall on all TH batches from the tunnel furnace. On August 16, 2001, the British Therapeutic Goods Administration issued a similar recall. The major manufacturers involved were European and Australian divisions of Biomet, DePuy, Smith & Nephew, Zimmer, and Stryker Howmedica Osteonics.

What followed was an intense international study of device failure. The company organized a committee of experts. They met with the national regulatory authorities to discuss the issue. Failed and non-implanted devices were studied. As of April 2003 (http://www.prozyr.com/PAGES_UK/Biomedical/breakages.htm), Saint-Gobain was reporting on their web site that six TH batches had fracture problems;

the two major failure batches had failure rates of 33% (227 out of 683) and 8.7% (60 out of 692).

So what was learned? Zirconia is a metastable ceramic which will undergo a phase transformation at room temperature (Chevalier et al., 2004) which is partially stabilized by the addition of Yttria. With proper sintering, the material obtains maximum density, and the result is a very strong material (Clarke et al., 2003; Chevalier et al., 2004) which was thus considered a better ceramic than its more brittle alternative, alumina. However, some of the batch furnace runs produced balls which were not fully densified in the center of the ball. This unstable material was exposed by boring out the center for taper fit to the metallic femoral stems. Very careful analysis of failures, non-implanted balls, and the "carrots" produced by the hollow core drills used to drill out the balls revealed that this material was subject to environmental degradation, phase transformation, and fracture (Clarke et al., 2003; Chevalier, 2006). While subsequent batches had better thermal controls and the carrots were fully dense, the global impact of such a large failure rate and recall resulted in the company's decision to pull Prozyr® off the market (Chevalier, 2006). Subsequent analysis of other Y-TZP products may well restore clinical confidence in this material.

Highly cross-linked UHMWPE formulations have been in clinical use for a decade as a means to improve wear resistance of acetabular hip components. Clinical studies of highly cross-linked acetabular hip components support reduced wear within the first decade of use (Muratoglu et al., 2004; Bragdon et al., 2007). However, cross-linking adversely affects uniaxial ductility, fracture toughness, and fatigue crack propagation resistance (Rimnac and Pruitt, 2008; Sobieraj and Rimnac, 2009). Due to the changes in mechanical properties of first-generation highly cross-linked UHMWPE materials, there has been concern regarding the potential propensity of *in vivo* fracture of highly cross-linked UHMWPE joint replacement components. In fact, *in vivo* fractures of highly cross-linked UHMWPE hip components have been reported, though the numbers are small (Tower et al., 2007; Furmanski et al., 2008). Also, when UHMWPE is cross-linked via ionizing radiation, free radicals are generated that can lead to oxidative degradation; thus, post-processing above (remelting) or below (annealing) the melt temperature is usually conducted. Remelting effectively eliminates free radicals, but also alters crystallinity, which affects mechanical properties. Annealing preserves the original crystal structure better, but is not as effective at reducing free radicals as remelting so that oxidation is possible with annealed cross-linked UHMWPE formulations (Rimnac and Pruitt, 2008). More recently, sequential radiation/annealing and incorporation of vitamin E (as a free-radical scavenger) have been introduced (the second-generation highly cross-linked UHMWPE materials) as methods by which to more effectively reduce or eliminate free radicals while preserving crystallinity (Oral et al., 2006; Sobieraj et al., 2008).

Implant retrieval and analysis has provided critical information toward understanding the anchoring of implants in bone. Branemark and associates demonstrated that direct bone–metal osseointegration of titanium tooth-root implants was possible with carefully controlled surgical technique and implant surface preparation (Albrektsson et al., 1982). Porous coatings may be applied to implants to facilitate bony ingrowth; relationships between pore size and bony ingrowth have come from retrieval studies (Cook et al., 1988).

Examination of the interface between the bone and the acrylic bone cement in long-term implant recipients examined at autopsy demonstrated the presence of inflammation with macrophages, thus providing the initial description of bone resorption due to particulate debris (Charnley, 1970). The relationship between the amount of particulate wear debris generated and bone resorption due to inflammation, i.e., osteolysis, was graphically demonstrated by the retrieval and tissue studies of Willert and Semlitsch (1977). Extensive research has been conducted over the years looking at osteolysis or "particle disease," and characterization of the polymeric debris, as correlated with implant type and design (Schmalzried et al., 1997). Studies on tissue reactions to particulates and wear debris require special histologic evaluation, as described by Wright and Goodman (1996), in the various consensus standards, in other references cited earlier, and in many other studies readily available in the orthopedic or histotechnology literature (see Goodman and Wright, 2007; Burke and Goodman, 2008; Purdue, 2008; Revell, 2008a,b).

Implant retrieval studies have demonstrated that the success of a material in one application may not necessarily translate to another. For example, titanium does

well as a bone–implant interface, but it may be subject to severe wear as a bearing surface (Agins et al., 1988). An alternative approach in the hip was to use titanium alloy stems with modular press-fit heads made of a more wear-resistant cobalt alloy. However, some of these designs demonstrated significant corrosion, which was first attributed to use of mixed metals (Collier et al., 1991), and later to microgalvanic corrosion of the cast heads (Mathiesen et al., 1991), and to micromotion and fretting corrosion between components (Brown et al., 1995).

As with orthopedic devices, complications of dental implants may be related to the mechanical–biomechanical aspects of force transfer, or the chemical–biochemical aspects of elements transferred across biomaterial and tissue interfaces, or both. The complex synergism that exists between tissue and biomaterial responses presents a significant challenge in the identification of the failure mechanisms of dental implants. Since many dental devices are percutaneous, in that they contact bone but are also exposed to the oral cavity, the problems of infection are also significant (Moore, 1987; Sussman and Moss, 1993). Lemons (1988) and others have provided appropriate perspectives to be taken in the evaluation of dental implants.

CONCLUSIONS

Although the focus of this chapter has been on the retrieval and evaluation of implants in humans, the perspectives, approaches, techniques, and methods may also apply to the evaluation of new biomaterials, preclinical testing for biocompatibility, and premarket clinical evaluation. Each type of *in vivo* or clinical setting has its unique implant–host interactions, and therefore requires the development of a unique strategy for retrieval and evaluation.

Indeed, for investigation of bioactive materials and tissue engineered medical devices, in which interactions between the implant and the surrounding tissue are complex, novel and innovative approaches must be used in the investigation of *in vivo* tissue compatibility. In such cases, the scope of the concept of "biocompatibility" is much broader, and the approaches of implant retrieval and evaluation require measures of the phenotypes and functions of cells, and the architecture and remodeling of extracellular matrix and the vasculature (Mizuno et al., 2002; Peters et al., 2002; Rabkin et al., 2002; Rabkin and Schoen, 2002). Moreover, a critical role of implant retrieval will be the identification of tissue characteristics (biomarkers) that will be predictive of (i.e., surrogates for) success and failure. A most exciting possibility is that such biomarkers may be used to noninvasively image/monitor the maturation/remodeling of tissue engineered devices *in vivo* in individual patients (Mendelson and Schoen, 2006).

Voluntary Standards, Regulatory Compliance, and Non-Technical Issues

CHAPTER III.2.1 INTRODUCTION: VOLUNTARY STANDARDS, REGULATORY COMPLIANCE, AND OTHER NON-TECHNICAL ISSUES

Frederick J. Schoen[1] and Jack E. Lemons[2]
[1]Professor of Pathology and Health Sciences and Technology (HST), Harvard Medical School, Executive Vice Chairman, Department of Pathology, Brigham and Women's Hospital, Boston, MA, USA
[2]University Professor, Schools of Dentistry, Medicine and Engineering, University of Alabama at Birmingham, Birmingham, AL, USA

This section highlights some of the key non-technical considerations in the development of medical devices that depend so importantly on biomaterials. Several principles underlie the approach presented in this section. The major driving force to technological innovation in biomaterials, implants, and medical devices is to improve the quality of life and survival of patients. The early phase of the process includes these steps: (1) identification of a clinical problem that needs solving ("clinical pull"); (2) determination that a viable market exists for it; and (3) the judicious and sophisticated application of existing, or development of, novel technology to solve this problem. In this sense, hospitals and clinics provide a "problem-rich" environment, and a laboratory for testing and translating the latest technologies and materials into clinical successes. An invention, by itself, is of little value; the value of the idea represented by an invention is through innovation, i.e., the validation and implementation of that idea or embodiment thereof to affect individuals and populations through its utilization and acceptance by others.

In addition, it is important to recognize that the future of a new biomaterial associated with a device- and/or implant-based treatment utilizing a biomaterial usually depends on the successful commercialization and implementation of a medical product (Chapter III.2.2). For any product, such as an implant or medical device, the needs of commercialization (involving development, design optimization, a viable fabrication process, financing, regulatory approval, reimbursement,

manufacturing and scale-up, a suitable and profitable business model, marketing, etc.) are vital, and the scientific development, fabrication, clinical trials, and subsequent regulatory approval must occur in the context of, and concurrent with, business considerations (Figure III.2.1.1). Indeed, medical device innovation is complex; the generic process and the requisite skills in technological innovation in medicine, including identification, invention and implementation phases, have been recently described, both systematically and in detail (Zenios et al., 2010). Moreover, although demonstration of clinical effectiveness and safety are vital to clinical translation of any new medical product, today's economic pressures demand serious consideration of cost-benefit and cost-effectiveness, i.e., the relative gain in health from a measure (years of life, pain-free gained) and the relative costs of different ways to achieve an equivalent gain in health, respectively (Sculco, 2010; Lammers et al., 2011; Moreno et al., 2012). Finally, as embodied by the total collection of chapters in this book, progress in biomaterials and their implementation in clinically-useful medical devices requires multidisciplinary collaboration, thinking, and communication, where engineers, physical scientists, biologists, and clinicians are on an equal footing, and share a common language and objectives – an approach generally termed "convergence" (Sharp and Langer, 2011).

The chapters that comprise this section summarize the key principles enumerated above and provide a "toolkit" for medical device innovation. Specifically, the chapter by Lemons (Chapter III.2.3) describes consensus standards for biomaterials and devices. Consensus standards in general can be separated into categories of specifications, test methods, terminology (nomenclature and definitions), provisional, and guidances (Chapter III.2.3). Related to biomaterials, standards have been developed and repetitively tested for metallics, ceramics, polymerics, and combinations of these classifications. In broad terms for biomaterials of synthetic origin, biomaterials may also be classified in terms of biological responses such as bio-tolerant, -active, and -degradable.

FIGURE III.2.1.1 Key steps in technical development (flow chart on left) and non-technical considerations (box on right) must be integrated to achieve successful innovation in biomaterials and medical devices.

Also, since regulatory processes consider devices (rather than biomaterials, per se, grouping can also be made in terms of the clinical application. Consensus standards have provided an opportunity to document biomaterial charateristics needed for biocompatibility, the methods for testing and presentation of results (precision and accuracy), terminology including basic definitions, and importantly, guidelines for evolving device systems and the properties of new or modified biomaterials. Over past decades, as the device disciplines have evolved from synthetic origin bio-tolerant biomaterials to surface bio-active biomaterials, naturally-derived biomaterials, and to biodegradable and biointeractive biomaterials, the focus has shifted to Tissue Engineered Medical Product Standards (TEMPS). This shift has resulted in reconsideration of standards needed for evaluations, including a move from *in vitro* to *in vivo* testing methods. Also, consensus standards have become more harmonized throughout developed countries, especially as device products have expanded throughout the world. Many consensus standards for medical devices have now been evaluated and accepted for regulatory processes and approvals. Thus, in many submissions device developers only need to list "meets standard x." This process has enhanced considerably the value of standards, especially when harmonized internationally.

Anders and Tolkoff (Chapter III.2.2) provide aspiring entrepreneurs a basic introduction to the considerations they can use to size up an idea in the context of clinical utility and commercial potential. Most medical and dental device applications are regulated by government agencies charged to ensure patient health and welfare. Thus, agencies evaluate safety and efficiency of devices and related treatments. In the USA, most devices constituted to include biomaterials are regulated by the US Food and Drug Administration (FDA) Center for Devices and Radiological Health (CDRH). As biomaterials, devices and treatments have evolved to combination products (comprising mixtures of materials, drugs and cells (and their products) many must be considered by combining expertise from the FDA centers regulating biologicals (including cells) and drugs. Duncan (Chapter III.2.4) summarizes the key concepts that govern the regulation of medical devices by the Food and Drug Administration in the USA; regulation abroad follows generally similar principles although not exactly the same approaches. Cahn and Erickson (Chapter III.2.5) discusses reimbursement, the process by which medical devices and any other medical services are paid for; this chapter emphasizes that reimbursement is often critical to market success and that those inventing, developing or marketing new medical devices have an understanding of how their products will be reimbursed. The integration of regulatory and reimbursement considerations is emphasized by several case histories of actual products presented by Baura (Chapter III.2.6). This is followed by related discussions of pertinent ethical and legal issues by Bianco et al. (Chapter III.2.7) and Mayesh and Vicari (Chapter III.2.8), respectively. Grunkemeier et al., in the following chapter in this section, addresses the special challenges associated with clinical trials of biomaterials and medical devices (Chapter III.2.9) that necessitate very different approaches than those used in the development and implementation of drugs. Langer and colleagues (Chapter III.2.10) write with considerable experience about the approach to creating small start-up companies to develop medical devices born in the university setting. In the last chapter in this section, Feigal (Chapter III.2.11) addresses the special regulatory aspects of the post-market period, when a product is in the marketplace, is no longer investigational and is available for commercial use.

CHAPTER III.2.2 COMMERCIALIZATION: WHAT IT TAKES TO GET A PRODUCT TO MARKET

Joshua Tolkoff[1] and Richard Anders[2]

[1]Accelerator Executive, CIMIT, Boston, MA, USA

[2]Senior Lecturer, Massachusetts Institute of Technology, Cambridge, MA, USA

INTRODUCTION

Previous chapters of this book cover technical and biological issues relating to biomaterials. Transforming a biomaterial into a commercial product with clinical utility is extraordinarily difficult. There are two major routes to commercializing a product: licensing it to an established company or creating a company to move it to market. In this chapter we focus on the latter pathway, but our discussion will also include the key elements involved in a successful license.

A business starts with an idea. And, like the mythical Pygmalion, those who come up with ideas have a tendency to fall in love with them. In the world of promising ideas, there are some which when brought to fruition make a significant difference, and those that have little impact. We urge the entrepreneur to test their idea against a list of important success factors to determine if it will have real impact. It is, after all, easy to find ideas that appear to have good business prospects, but ultimately very few have the potential for real market success.

A medical product must meet many criteria: it must be well-designed; fulfill complex regulatory requirements; obtain reimbursement; be appealing to one group of (often conservative) medical practitioners while able to withstand the attacks of other practitioners who may be working against its adoption. Failure of any of these is usually fatal to the product.

In this chapter we give aspiring entrepreneurs a basic introduction to the considerations they can use to size up an idea. But the subject is vast, and this introduction is merely a brief survey. Still, we hope that if you are seeking to commercialize a product, what follows will give you an entry point to the hard work you will need to do to honestly assess, modify or even discard your idea. We also hope that by giving you insight into how to increase your own chances of success, more clinically useful products will get to market, which will help us all.

Life science businesses fail for many reasons, including lack of financing and poor execution. But in our experience they most often fail because the idea driving the business premise does not provide sufficient value to the prospective customer or market. The chasm between an interesting idea and an idea with significant new value arises for many reasons, some of them quite predictable: an uncompelling need; the market size doesn't justify the cost to bring the product to market; the idea infringes on other's patents; there is no reimbursement. At the beginning of an enterprise, the team is setting out the blueprint for the next five-to-ten years of the company's work. They have an obligation to carefully evaluate every facet of the future company. Problems such as those listed above can be identified at this early planning stage and, ideally, avoided. Then, the team should again evaluate the key risks to business success. This continuing circle – considering risks, evaluating them in light of the best available data and opinions, strengthening the plan, and doing it again – is critical if the team is to hit key milestones and be successful. Elucidating shortcomings early is a useful (though painful) task. It can save the adept practitioner from literally years of work chasing unproductive blind alleys to their inevitable, fruitless, conclusion.

THE NEED YOU PROPOSE TO SOLVE

There are techniques for developing ideas for medical products. One, based on the so-called Biodesign Process, was evolved by Paul Yock, Josh Makower, and others at Stanford (Zenios et al., 2009). The subject of an excellent textbook, their technique starts with fieldwork – observing real-life clinical procedures, and using those observations to uncover important needs and formulate novel solutions. This process from the start is designed around finding needs to solve, not ideas to solve them.

But that's not what usually happens. More often, a scientist or inventor makes a discovery and starts thinking about how and where it can be applied. Many applications are considered, and chosen as much for whether the idea can be applied to them as whether they are worth solving. As a result, although it may seem too obvious to state, one must keep in mind that a new medical product must solve a clinical problem.

Developing something innovative and useful is not the same as solving an important need. For example, a new treatment for smallpox, while undoubtedly an achievement, is not the solution of an important clinical need (the possibility of bioterrorism notwithstanding), since the disease has largely been eradicated.

Although it is hard to give absolute rules, a solution to an important need might typically have some of the following characteristics:

- Provably decreases mortality or serious morbidity in an identifiable patient group;
- Substantially lowers the cost of treatment relative to the standard of care;
- Meaningfully improves an existing treatment by such things as filtering out patients who will be unresponsive or will have serious adverse effects;
- Makes an earlier diagnosis of an illness for which an earlier diagnosis means substantially better outcomes.

Less significant solutions often include the following:

- Early detection of conditions for which early detection confers no benefit or even worse, early detection of things that are not even provably connected with the condition;
- Improvement of patient comfort but not patient outcomes. Since payors typically will not pay for comfort, it will be hard to find a market;
- Small decreases in surgery time, especially when this comes at significantly increased cost.

Determining whether one solves an important need is difficult to do in a vacuum. It will typically require extensive research of the literature. One will likely wish to speak with clinicians to have them validate the idea's value. Depending on the degree of protection, this may need to be done under non-disclosure agreements (NDAs), but to maximize the chances someone will speak with you. NDAs should be avoided if at all possible. Your goal, when all this has been done, is to very succinctly – ideally in a paragraph or so – write down the need you proprose to solve, explain why its solution is important, and in what ways your idea solves it.

MARKET SIZE AND GROWTH

Although it is possible to develop a product for a small market, the size of the opportunity has an obvious impact on the amount of money that should be spent to develop it. Thus, it is essential to understand how large the potential market for your product/technology is, and how ready the clinical users will be to adopt it. This can be evaluated at the earliest stages of a project, and again when prototypes are available, when animal testing is done, at early clinical trials, etc. Important considerations include:

- The projected growth of the patient population (i.e., diseases of aging are likely to increase in aging populations);
- The number of procedures currently performed and the number of units sold;
- The current solutions, including how they are applied, their outcomes, their cost (especially reimbursed cost), length of time they take to use, and the tools and training they require;
- Whether your solution is incremental or a path-breaking replacement;
- The companies selling the existing solutions and whether your device complements their product line (i.e., appeals to the same markets without replacing their product) or competes with it;
- The path of innovation, and what the most likely new devices will be in one, five or ten years;
- The number of patients who COULD BE and are LIKELY to be served by your solution;
- The specialty that will use your solution, and whether this is a change from current practice.

Before an entrepreneur moves to exploring the numerous tactical business considerations, which we will outline in the section entitled "Business and Commercialization Issues," they should gain insight into one more aspect(s) of the market: how the various constituencies will align in support of or against the proposed new product.

EFFECT ON VARIOUS CONSTITUENCIES

New products displace old ones, and disruptive new products upset complex webs of relationships and interests. In a business as complex and conservative as the healthcare industry, it is important to understand that introducing solutions also creates problems. For example, the arrival of percutaneously introduced vascular stents caused a dramatic shift in power between cardiac surgeons and interventional cardiologists, with surgeons being less than completely enthusiastic advocates of the new technology. In developing a new medical product, it is – perhaps surprisingly – not enough to simply improve patient care. You should also pay attention to how the new product will affect the interests of each constituency. For example:

- *Patients*: who balance ultimate results against recuperation time, likelihood of success, risks, and many other factors;
- *Clinicians*: whose concerns include patient safety, difficulty of learning to use the new product, and whether they – or a different specialist – control the patient workup;
- *Insurers*: who worry about the additional cost of new technologies, and risks to their competitive position if they fail to reimburse the technologies.

CLINICAL TRIALS

It is never too early to begin to understand the clinical trials a company will need to perform. Here is a short list of some of the reasons:

- Regulatory approvals often require clinical data;
- Reimbursement often requires proof of economic performance that can only be obtained through clinical trials;
- Marketing claims can often only be made after clinical trials have substantiated them;
- Investors are usually much more interested in investing in companies that have proven their product works. Additionally, investors are loath to invest in companies where the expected clinical trials will be long, large, and extremely expensive;
- Clinicians are much more interested in products for which there is clinical validation;
- Some products that would undoubtedly be valuable simply cannot be brought to market because the cost of the trials would be too high.

Clinical trials are generally the costliest initiatives undertaken by a life science company. But because a clinical trial needs to accomplish so many disparate objectives (viz. the list above) it is extremely important to design them as efficiently as possible, and to understand their purpose as early as possible.

Intellectual Property

A start-up's most significant asset is usually its intellectual property (IP). Therefore, every start-up needs a strategy for developing, increasing, and protecting this key asset. Understanding competitive IP, and the strengths and weaknesses of your IP, are critical for fundraising and prioritizing all other expenditures.

Patents are expensive and slow to obtain. It can cost $10,000 or more to have a law firm file a US Patent. Even a provisional patent, which gives you the right to file an actual patent within a year, can run upwards of $2000. Initial responses ("office actions") from the United States Patent and Trademark Office can take two years or more, and there is a long road to a patent following that. As a result, there is often a substantial gap between the time one starts a company and the time patents are in hand. During that time, founders must convince savvy investors that the company's patent applications are likely to lead to issued, strong patents. The company must clearly understand the strength of their patent applications, and have an in-depth understanding of how they are superior to the competitive IP.

Selecting a strong patent attorney is crucial. Use advisers, investors, and the company board to get recommendations of at least three patent firms, and interview each to assess their expertise in the company's scientific domain, their ability to be prudent advisors to the company, and the personal chemistry you will have in working with them. A good patent attorney will be a source of strategic IP advice regarding patents, including IP budget priorities. In some cases, IP attorneys will defer their fees for start-ups until the company has obtained funding.

There are alternatives to using patent attorneys, for example, filing a provisional patent is often straightforward work for a technical person. Another source of expertise is the patent agent, a technical person with additional training analyzing and preparing patents. An economical and effective approach is to draft the initial application oneself or with the help of a patent agent, and then have an attorney do a final review prior to submission.

It is also important to understand the patents close to your IP to ensure you have "freedom to operate," meaning that you are able to build your device without infringing anyone else's patents. Again, patent lawyers and patent agents can assist you. Much of this work can be done by the company founders, as long as they have good advisors.

Regulatory Strategy

It is far beyond the scope of this chapter to provide a detailed view of the regulatory process. Our purpose instead is to provide a basic understanding of the regulatory complexities, and an appreciation of the need to plan the regulatory strategy early. There are few things more critical to a life science company than its regulatory strategy and choices, and the better you understand the regulatory framework, and the earlier you understand your strategic choices, the greater your chance of success.

In the United States, the Food and Drug Administration (FDA) is committed to ensuring a product is safe and effective for its intended purpose. The level of FDA review is determined by the nature of the product, its indication for use, and the manner in which it is to be used.

Broadly speaking, in the U.S. medical products for human use are regulated under one of three divisions: drugs (Center for Drug Evaluation and Research or CDER); devices (Center for Devices and Radiological Health or CDRH); and biologics (Center for Biologics Evaluation and Research or CBER). Most biomaterial-based products will fall within CDRH. The device pathway through CDRH (or at times, CBER) is usually simpler, cheaper, and faster than the drug pathway.

CDRH regulates how a device can be brought to market, and what controls are placed on the marketing and manufacturing of the device. The manner in which a device can be brought to market depends first on the device classification (I, II or III), and to a lesser extent on the CDRH medical specialty panel that will be reviewing it. This, and a great deal more about the regulatory framework, is explained in further detail at the FDA website, www.fda.gov.

Class I devices – such as bandages, adjustable beds, many surgical instruments, and manual stethoscopes – are deemed to pose minimal risk to patients and are therefore regulated most lightly. Such products can usually (count on exceptions in the complex regulatory world) be brought to market without any advance approvals or clearances from the FDA. Additionally, the company will be subject only to a set of general rules ("general controls") about how the product must be labeled, registered, and manufactured.

Class II devices – e.g., mercury dental amalgam, electronic stethoscopes, most catheters, needles, and monitoring devices – pose higher risks than Class I devices. They must usually be cleared in advance by the FDA before they can be brought to market. This is done by the 510(k) premarket notification process, the overwhelmingly dominant path to the US market for complex medical devices. A 510(k) clearance can often be completed in months, usually without clinical trials, and is relatively inexpensive.

To receive a 510(k) clearance, one must usually show that the device is "substantially equivalent" in safety and effectiveness to one or more "predicate" devices.

There is a great deal of misunderstanding about what are true predicates, and substantial art and skill in selecting appropriate predicates and preparing a submission under the 510(k) rules. Thus, this is usually done with the help of experts.

Class III devices – including devices that are life-sustaining, such as cardiac assist pumps and also most implants such as bone grafts, heart valves, orthopedic implants, arterial grafts, and pacemakers – are regulated most strictly. The FDA requires Class III devices to undergo a more elaborate approval before allowing them on the market. This so-called Pre-market Approval (PMA), requires a minimum of 180 days, and often a year or more, to issue after submission of significant amounts of data, and typically will require many millions of dollars in preclinical and clinical trials. One of the hurdles to surmount is that the device must typically be tested in a pivotal human trial of effectiveness, and this trial must be conducted under an Investigational Device Exemption (IDE).

Many other countries have their own regulatory approval bodies. In the European Economic Area (EC), a manufacturer can market a device when it has received a CE ("Conformité Européenne" or "European Conformity") mark, meaning that the manufacturer's product conforms to applicable EC directives. Many other countries, including China, piggyback on the United States regulatory system, and in such countries, US FDA approval is sufficient for a manufacturer to bring their product to market.

Entrepreneurs should keep the following regulatory considerations in mind:

- In the US, a company must carefully plan its regulatory strategy and be sure the FDA is comfortable with corporate marketing strategies. In particular, before approval do not be vague about product claims in your product manuals or literature. Instead be transparent in your intent, document your work meticulously, and work with the FDA to make them comfortable with your approach.
- Don't cut corners with the rules. For example, if you believe your device can be shoehorned into Class I as a wound cover, but your intent is to use it in brain surgery, you are likely at some point to face significant regulatory problems and delays, and your business may be shut down. It is far better to confront the issue head on and seek an advance determination that your product is, indeed, Class I.
- As elaborate as the regulatory infrastructure is, it is not algorithmic. Often regulatory consultants or even FDA insiders will disagree on how something is regulated. Thus, there can be significant value to managing your approach intelligently and carefully.
- Understand the regulatory framework around your product as completely as you can. Among many reasons for this, investors expect that entrepreneurs will

have thought a great deal about this critical aspect of a product.
- FDA regulations are enabled by law, but evolve by agency action. They are in constant flux (currently the most notable example being the 510(k) regulations), so keep abreast of these changes through trade organizations, current FDA news, and by working with experienced consultants.

Because of the aforementioned complexities, companies are increasingly introducing their products outside the US where regulations are easier to comply with and approvals are faster.

Reimbursement

In the United States, most medical expenses are paid by healthcare insurance, and so insurance carriers are a crucial part of the medical market infrastructure. Business plans from companies in the 1990s rarely discussed reimbursement because it was assumed that a superior product desired by the clinician would be paid for. But this has changed dramatically as medical costs have escalated. While drugs, once approved, have a very favorable reimbursement profile, medical devices, even when approved, often face a complex and uncertain reimbursement process. Nevertheless it is never too early to obtain an understanding of the reimbursement landscape, because without adequate reimbursement a product will be doomed.

Very generally, reimbursement within the US falls into one of four bins:

- Unreimbursed "self-pay" procedures, such as cosmetic surgery, typically paid for by the patient;
- Physician services, described using CPT (or its synonym, HCPCS level I) codes and reimbursed by the insurer (Medicare or others) based on how they wish to pay for these services;
- Hospital admissions to treat a condition, typically reimbursed by Medicare (and often other insurers, though with different payment amounts) as part of a single fixed payment to the hospital (which of course in the complex world of reimbursement can change subject to various factors) under a diagnosis-related-group or DRG, and a separate CPT-based payment to the physician;
- An outpatient-based procedure performed in a hospital or ambulatory surgical center, reimbursed by Medicare (and often other insurers) using one or more ambulatory procedure codes (APCs) which are like DRGs with the notable exception that several APCs can be stacked together for a single patient visit.

Subject to insurance regulations and its own commitments to its clients, a private insurer has great latitude to set its own reimbursement levels for any particular product or to not reimburse it at all. However, broadly speaking, private insurers follow Medicare, and therefore

obtaining Medicare reimbursement is critical for a new product.

There are several general business considerations to keep in mind which will make the reimbursement environment easier to negotiate.

- Some devices are used in a self-pay indication. In such a case, with no insurer, there is no reimbursement issue (although of course self-payers also care about cost).
- Products used as integral parts of existing DRGs or APCs – for example, an improved heart bypass pump for cardiac surgery – have narrowed reimbursement concerns. Perhaps the biggest risk is that the new device fundamentally changes the procedure, thereby bumping it into a different DRG or APC, or worse, transmuting it into something no longer covered under any DRG or APC. Assuming this is not the case, customers will care about the value the new product adds to the process – reduced procedure time, lowered co-morbidities or hospitalization time, perceived importance of the product by clinicians and even patients, and so forth – compared to its cost.
- For new services and procedures which require a CPT code, the code may already exist and be reimbursed. But keep in mind, a CPT code *is not a guarantee* your product will be reimbursed. For example, if a product dramatically changes how a procedure is applied, perhaps by substantially enlarging the pool of patients who will receive it or allowing a different specialist to perform it, insurers may reconsider reimbursement. That is one reason why experienced investors look carefully when device entrepreneurs claim their new product fits into an existing code.
- Each country has its own reimbursement process, and different payers within countries have their own processes.

When a product is unreimbursed, in many cases the entrepreneur may need to obtain a CPT or DRG code. This alone can be an extended multi-year process, often longer than the regulatory approval process. And unlike the regulatory process, with its established (mostly followed) timelines, there are no such schedules for the reimbursement process. In the current cost-constrained environment, there is negative pressure to add expensive new procedures. Some of the things required to obtain reimbursement include:

- Determining who makes reimbursement decisions at each payer;
- Describing the clinical and economic value of the proposed product/procedure, including key economic benefits and consideration for the proposed new reimbursement;
- Indicating how this procedure will affect total costs;
- Collecting clinician feedback on the proposed product/procedure;

- Performing clinical trials of the new product, including the economic issues as part of the study;
- Publishing the clinical results showing the economic value produced by the new product;
- Getting regulatory approval of the new product;
- Having the new product used by many practitioners in the use indicated;
- Getting support from clinicians, key opinion leaders, and medical societies;
- Obtaining relevant codes from the American Medical Association (AMA) or Medicare.

For these reasons, obtaining anything remotely close to national reimbursement (i.e., from Medicare and most insurers) for an unreimbursed product can take years. The process is quite expensive for two reasons: first, the actual cost of obtaining reimbursement; and second, the difficulty in convincing practitioners to use a product without an automatic reimbursement. Thus, it is critical for small companies to work with experienced reimbursement experts. And if a company needs to obtain new reimbursement codes, the experts may well need to be retained full-time on staff.

BUSINESS AND COMMERCIALIZATION ISSUES

Once you have confirmed a compelling unmet need in a large market, understood the regulatory and reimbursement issues, and considered the clinical trials your company will need to perform, you have done your basic due diligence. If your idea has passed muster, congratulations! But running a business brings a number of other issues to the fore which you should consider (Figure III.2.2.1).

Funding

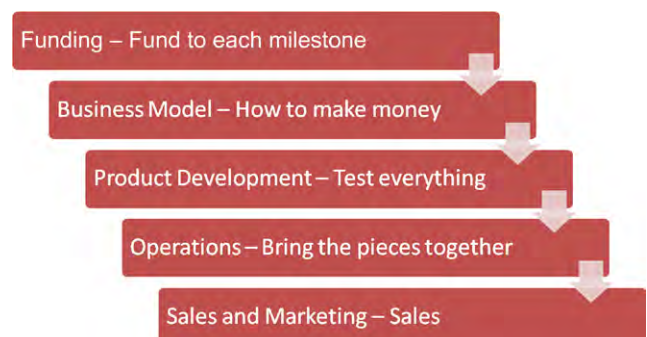
Developing a new product employing a biomaterial technology is an expensive and time-consuming process. Table III.2.2.1 shows an example of a typical timeline for development of a PMA product within the United States. Many start-up companies do portions of this work outside the US to save time and money. Nevertheless, the steps, approximate times, and rough budgets are good guidelines for 2012.


FIGURE III.2.2.1 Steps to commercialization.

TABLE III.2.2.1	Sample Timeline & Budget for Development of a PMA Product within the US							
Year	**1**	**2**	**3**	**4**	**5**	**6**	**7**	**8**
Feasibility	▬							
Preclinical development		▬						
Preclinical testing			▬					
IDE				▬				
IRB					▬			
Clinical trial						▬		
PMA								▬
Monthly expenses ($MM)	0.08	0.15	0.25	0.4	0.65	0.75	0.85	
Total funding ($MM)	1	3	6	11	18	27	38	

IDE: Investigational Device Exemption.
IRB: Institutional Review Board.
PMA: Pre-market approval.

During the development stages of a company, moving quickly and meeting the key milestones of the project plan within budget are critical to having adequate resources to succeed. Since a medical business rarely has revenues during the development stages, raising capital is essential. Below are the three major sources of capital you are likely to encounter. Keep in mind that the earlier investors typically incur the highest risk, and therefore rightly expect the highest potential returns.

- Friends and family (sometimes jokingly referred to as "three f" financing: friends: family: and fools). This includes unpaid "sweat equity" put in by founders. Typical amounts are tens to hundreds of thousands of dollars;
- "Angel Investors," often wealthy individuals who have made money in business and enjoy the chance to make money or become involved in new start-ups. They will typically invest hundreds of thousands to low millions of dollars in a venture;
- Professional investors or Venture Capitalists (VCs) who manage large pools of money, and are often seeking companies of a stage and type able to use millions of dollars, which of course requires an eventual payback of tens to hundreds of millions of dollars.

A business without funding will not likely survive. Therefore, an entrepreneur should learn about the funding process early. This is an extremely intricate topic, and we offer one hopefully useful tip: call potential funders before you are actually looking for money to solicit their advice and get to know them. Then when you are actually looking, they can calibrate your progress, and also you are a known entity. Three more tips:

- If possible, do not cold call these funders. Network first to clinicians and scientists in the field. Many of them may know investors and can arrange introductions. Use the initial investor's introductions to obtain other introductions.

- Use care before approaching professional venture capitalists. If your idea has major holes or you lack experience, it would be better to hone your approach a bit first.
- Spend time understanding, as deeply as possible, the various factors described in this chapter. Savvy potential investors will care about all of them, and will be reassured when they meet a CEO who has really thought through the business.

Business Model

A business model refers to the method a company will use to make money from its product. Although it may seem straightforward, there are usually many ways to bring a product to market, and it usually takes a great deal of effort to determine the best one.

Considerations that can affect the model include: resources available to the company; relevant experiences of the team; buying patterns of customers; rate of product adoption in the marketplace; and the value of the product to each stakeholder. Some of the approaches used in medical device business models include the following.

Direct Sales. The company sells its products directly to end-users. Although this typically captures more value for a company than licensing, it is very expensive and can be slow to ramp-up to levels sufficient to support the company. Additionally, products must generally be expensive with high margins to warrant the cost of direct selling, as even a single sales call – which is often unsuccessful – can cost hundreds to thousands of dollars.

Recurring Revenue. In a recurring revenue model, the company has a continuing stream of revenue from a product. There are numerous ways to do this, including disposables, service contracts, leases, and tolls. Most innovative medical devices use some method of obtaining recurring revenues.

Disposables. Some products, such as surgical instruments, are purchased once and used multiple times. Others, such as hypodermic needles, are purchased, used,

discarded, and replaced. Still others are purchased once and require additional components every time they are used. For example, many diagnostic instruments require reagents or special disposable sample holders. Such recurring revenue can be very attractive to a small company, amplifying the initial sale many times over a product's life.

Service Contracts. Another source of recurring revenue is to add a service component to expensive capital equipment. Such service costs can be in the range of 10–15% per year.

Leases and Tolls. One way of lessening a customer's cost for a product or converting it from a capital expenditure to an expense is to lease it or rent it on a per use basis or for a fixed number of prepaid uses. This model is especially suited for expensive imaging equipment, monitoring equipment, complex pumps, dialysis equipment, and the like.

Licenses. Companies that cannot or do not want to bring a product to market themselves can license it to another company for commercialization. A license agreement often includes an upfront licensing fee with recurring royalties for product sales. This can be a good way to create revenue, particularly in markets and geographies that the company will be unlikely to enter for an extended time. One danger is that a license necessarily involves a company giving up certain rights (such as exclusivity) to others. By doing so, it may diminish its value to potential acquirers or prospective partners who desire these foregone rights.

Development Strategy

Operations

"Operations" often refers to manufacturing, but also includes a wide variety of other tasks involved in running a business. These include purchasing materials, delivering products to customers, managing employees, and keeping track of product costs and capital expenses. For capital equipment product sales, "operations" generally includes managing installation, warranty, and ongoing service updates, and for software products it would include installation, assurance of compatibility, training,

and ongoing support and upgrades. The comments below refer specifically to issues related to the manufacture of biomaterials products and implants.

Key Operations: Keep them in House or Outsource? One of the critical questions a start-up faces is whether to keep operations in house or outsource them. This can have day-to-day implications, but also larger strategic ones. For example, if a business expects to eventually be acquired by a larger company, generally the acquirer will have their own operations expertise, and therefore will not pay more for a start-up's operations. Developing operational capacity and expertise for biomaterials and implants requires significant effort, capital, and management attention. These are the reasons that most small companies find a partner to manufacture their products. However, in spite of these costs and complexities, start-ups with novel biomaterials often find it important to create unique processes for efficient manufacturing and repeatable product performance. Developing these finicky processes may take significant expertise and multiple iterations to assure a stable, repeatable, predictable, and affordable outcome, and the novel processes themselves then become part of the IP of the company, covered either by patents or trade secrets. In such cases, developing operational expertise internally builds a valuable asset of the company, and often is necessary for the success of the venture.

Even in companies that have outsourced the bulk of their operations, it is critical to have adequate and experienced oversight. Materials suppliers must be qualified, and contracts and oversight must be in place to ensure consistent quality, traceability, and delivery. Failure at any point in the supply chain with these partners will result in product problems for the start-up company. For a summary of these basic considerations, refer to Table III.2.2.2.

Sales and Marketing

"Sales" is the process of offering the product to a purchaser. This includes: finding the initial leads; setting up meetings; demonstrating the product; enlisting users to speak with potential purchasers; working with purchasing

TABLE III.2.2.2	**In-house or Outsource: Basic Considerations**	
	Advantages	**Disadvantages**
Outsourced development	• More resources • Resources available • Infrastructure in place • Flexibility: can cut or add resources quickly • Acquirers don't value infrastructure • Novel processes available	• More expensive • Less motivated/slower • What they have may not be what you need • You may not be their top priority • Acquirer may need more capacity • No control over access to novel processes
Internal development	• Founders' dedication overcomes obstacles • Control is optimized • Technology may need unique infrastructure • Processes kept as trade secrets	• Alternatives may be overlooked • Formal systems may be limited • Small company systems may not scale-up • May miss better processes

departments and committees; and doing whatever else it takes to get the sale made! Marketing involves developing the value proposition for a product – that is, the economic and other benefits to be gained by using it – and communicating that inside and outside the company. The marketing department performs the product management function – identifying strategies for locating customers, preparing literature and other support materials for the sales department, and helping develop new product ideas based on the market feedback it obtains. One important thing to keep in mind is that a marketing department is very limited in the claims it can make about a regulated device, unless it can prove those claims are true. The best way to do that is by clinical trials; therefore, it is very important to involve the marketing department in clinical trial design early in the process to ensure they can make the claims they require.

Although sometimes people confuse sales with marketing, the function of marketing is to lay the groundwork of building tools to communicate what the product does and locating customers so the sales department can sell to them. Experience from large companies demonstrates the value of using dedicated salespeople to call on potential customers and build long-term relationships with them as a prelude to selling them products. But it is a rare start-up that can afford both a dedicated marketing department and full-fledged internal sales effort. Therefore, start-ups should consider a number of alternatives for selling.

The most obvious sales model uses employees as salespeople. Unfortunately, this can be very expensive, requiring management, salary, expenses, training, and additional sales resources. Additionally, the company must be prepared to wait for possibly a long period of time before it will see significant revenues from a salesforce.

Manufacturer's representatives (or "reps") are independent business people who sell products made by different manufacturers. A rep typically works in a defined geographical region and works on commission. Reps generally know their customers well, know the buying processes in the healthcare entities they visit, and get paid when products are sold. They provide affordable selling outreach and greatly expand the sales territory a company is able to cover. But reps, who need training and management in the product, have divided attentions because they usually sell multiple products from many companies. Thus, they rarely provide the "missionary" effort required for acceptance of a novel product, and can lose confidence if a product does not catch on quickly. Finally, in the event a company wishes to restructure a sales effort, rep contracts can sometimes make that difficult.

Stocking distributors purchase products directly from a company at a significant discount, typically 30–40% of the expected sale price. Distributors tend to specialize in particular medical areas, creating extensive catalogs of products which they sell. The distributor maintains an inventory of products, and handles the shipping and billing to the customer. The distributor will have its own sales staff, with each salesperson responsible for various accounts and/or various product lines. In the United States, a distributor will often have sales people in an entire state or region, giving them a strong sales footprint. Because distributors may carry even more products than sales reps, they can be even harder to motivate, and one complaint companies have about distributors is that they don't sell, but "merely" take sales orders from customers who call them.

Due to the increasingly difficult regulatory environment in the United States, companies are increasingly looking to introduce their products abroad. Because the cost and complexity of selling a product in another country can seem even more daunting to a start-up than selling in the US, international sales almost always begin with international distributors. There are substantial, experienced, and knowledgeable distributors in many countries. Even so, a start-up will likely need to dedicate a full-time experienced professional to finding and managing the international distributors.

Team

Founding a company is an intensive process that takes dedication, perseverance, and a dogged determination to overcome innumerable obstacles. A company includes a number of individuals, each with different skills. The first people to come on board are, by definition, founders. Usually founders of a biomaterials start-up will have either a technical or marketing background. This is because the key assets in a start-up are typically IP (technical), understanding of the unmet market need/value proposition (marketing), and the ability to inspire others to invest in the company (often marketing, sometimes technical).

The Chief Executive Officer (CEO) has the most critical job in a company. The CEO plans and explains the company's strategy, obtains (often through investors) the money and other resources the company will need, and hires and manages the team who implements the strategy. An experienced, charismatic CEO can plan on spending the equivalent of a full-time job raising money and working with the investors for the first two or three years of the company's active life. Unfortunately it is not uncommon for the first CEO to initially be, or eventually become, an inappropriate fit for the company. In part that is due to the fact that many CEOs are brought into a company by "being there" as a founder or an acquaintance of the founder. Such accidents of proximity by no means insure that such a person has the appropriate skills to run a company, especially as the company's needs evolve.

Assuming adequate financial resources, the CEOs key job is to hire the best team possible to implement the strategy. This will include consultants and employees. Early strategic experts in areas such as regulatory will likely be consultants. Working part-time they can develop the regulatory requirements for product development, bench

and animal testing, and clinical trials. The first hires will be in key positions critical to the company's success, such as R&D. Later hires will include marketing, regulatory, clinical, reimbursement, and operations staff. The CEO is constantly balancing the budget with the timing for adding other personnel.

A board of directors is not only statutorily required for companies in most states, but is also required by many investors, who will often demand one or more seats on the board (and investors should strive to balance this with an equal number of independent directors). But a good board does more than just fulfill these obligations. It also provides a pool of connections and expertise for the CEO to draw on as needed, and provides needed oversight to ensure the company stays on track. Generally the best board members have deep experience in the field, and significant operational expertise as CEOs or general managers. Investing board members often receive no stock, but independent board members typically receive 1–4% of the company for their service.

A board of scientific or clinical advisors validates the company's science and product. For a company with a superb idea, it is not difficult to recruit a top-notch board. Often, clinicians and scientists are extremely approachable and interested in new products for patient care. These boards usually meet three or four times per year, are available for advice to the team at other times, and often are the first users of new devices in animal or clinical tests. Advisors will typically receive a small amount of stock in return for their services.

THE STAGES OF LIFE SCIENCE: FROM CONCEPT TO ADOPTION

As a company grows, it will need ever increasing amounts of capital, and for this to occur with minimal pain for all concerned, investors will expect to see the value of the company continue to climb as new investments are brought in. Generally this means the company must continually be reducing the chance of failure. To be clear: successful management of a medical device company is about progressively eliminating risk. There are various reasonably well-defined risk-reduction stages in a medical product's life cycle (Figure III.2.2.2), each with its own considerations. They are set out below.

Idea

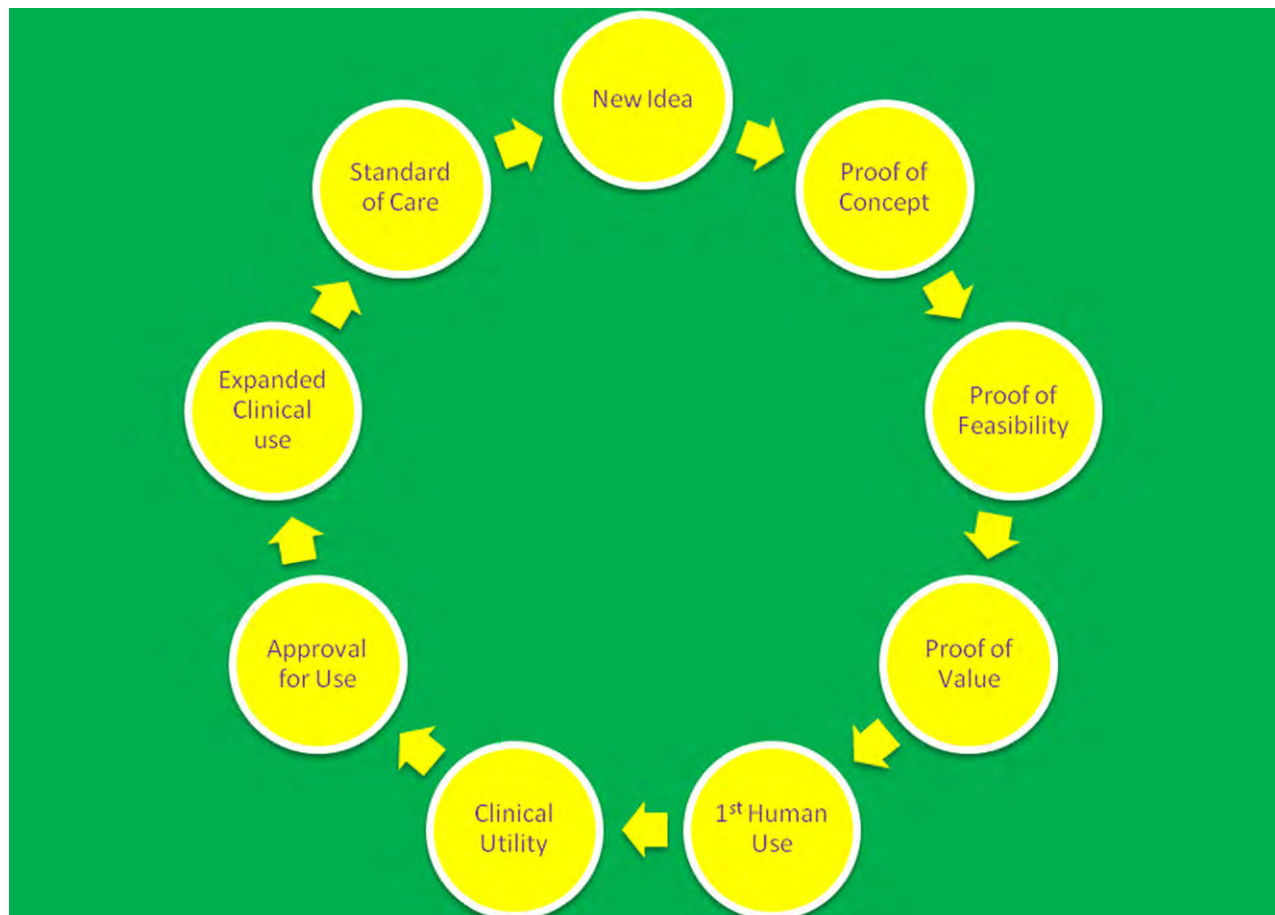
In the idea stage, the entrepreneur is first and foremost dedicated to ensuring their idea solves a real problem.


FIGURE III.2.2.2 The Circle of Life in a Life Science Company.

Assuming so, this is the stage to read and absorb the medical literature, learn about patients and treatments, and investigate the competitive products and the IP around those products. It is also a good time to start expanding on the idea to understand how it will: work in practice; actually be turned into a product; and provide clinical value. This is the time when the successful entrepreneur will be starting the never-ending process of stress-testing the idea against the considerations put forth in the beginning of this chapter: need; market; clinical trials; intellectual property; regulatory; reimbursement. Before in-vivo or even in-vitro testing, this is the time for the successful entrepreneur to start the "in-cerebro" work, that is, the never-ending process of stress-testing the idea against the considerations put forth in the beginning of this chapter: need; market; clinical trials; intellectual property; regulatory; reimbursement.

As the idea progresses to an invention, it is important to follow best-practices such as capturing the idea as clearly and completely as possible in writing and with sketches and three-dimensional computer models for use when filing, and perhaps defending, patents.

Proof of Concept

This milestone is achieved when the entrepreneur can demonstrate to themselves and their advisors that the invention can work. One should select the fastest, most cost effective, and elegant tests sufficient to convince a critical but friendly expert of the validity of the idea. The demonstration will involve science, but selecting the appropriate demonstrations is certainly an art.

For example, in a percutaneously delivered cardiac valve replacement, making a structure that can be folded sufficiently small and then expanded in place is doubtless a critical test. For anti-microbials, demonstrating that their presence in agar plates prevents bacterial growth may be compelling. Be creative and wide-ranging: consider crude prototypes in cadavers; animal parts purchased from butcher shops; bench simulations; mechanical testing; and so forth. As the saying goes, one dumb experiment is worth ten expert theories, so build things that can be tested. No matter how crude your prototypes, you will learn from these tests.

Sometimes one can develop very clever ideas for testing something. For example, it may be possible to try an early prototype product implant in a patient who is going to have an amputation. A device to treat morbid obesity could be placed for a short while in patients who are being prepared for stomach reduction surgery. In general, the better a concept is tested in simulated yet valid tests, the more compelling the value proposition becomes.

Proof of Feasibility

Proof of concept is achieved by convincing your "insiders." Proof of feasibility, by contrast, is achieved by

convincing multiple, skeptical, outsiders. To do this, a product must be fabricated in small quantities and tested in a controlled biological model. Although the product should be reproducible, it will not likely be fabricated in any sort of production environment. The emphasis should not be on reducing cost or manufacturing complexities, or improving shelf-life or human factors. Instead, the point is to develop the most expeditious, inexpensive ways to make small quantities so preliminary clinical testing may begin.

Animal Models. If there is an available predictive animal model, it can be an excellent vehicle for feasibility testing. One should spend time learning the intricacies, strengths, and shortcomings of various models. For example, porcine (pig) models are often favored for cardiovascular testing due to the similar reactions pig and human blood vessels have with biomedical devices. Canine models may not be good for testing thrombogenicity since dogs have more aggressive clotting mechanisms than humans.

Short-Term Results. If there is no animal model suitable to test your invention, it may be possible, as described above, to perform short-term human testing to get valid data on device performance.

Proof of Value

This milestone ties the theoretical functioning of a product to the practical requirements for using it. A device or technology may work, but may take so long to use or be so difficult to deploy that only the most skilled practitioners can use it effectively. For example, if a new knee replacement requires more precise alignment in the receiving bones, most practitioners may be unwilling to use it. Proof of value involves an exploration of whether, all things considered, the product adds value. Considerations include time to perform the procedure, expertise required, practice patterns, patient comfort, and time for rehabilitation, likelihood of adverse outcomes, and so forth.

Although it may still be possible to fine-tune the product and procedure to enhance value and manage the risks and unintended consequences, this is the time for an honest, unflinching look by the team and their advisors, to determine whether the product is likely to be useful, and therefore successful in the market.

First Human Use

This is a really big milestone, with significant implications. It means the company has managed to persuade an Institutional Review Board (IRB) to allow the device to be used on patients, and has received an Investigational Device Exemption (IDE) from the FDA. The company has also persuaded one or more clinicians to use it and will soon see how it performs, in the target population, under the intended procedure.

First human use is often performed outside the United States, since other countries typically have a shorter review and approval cycle, lower costs, and faster patient recruitment. In addition, in the event a start-up must make modifications to its device or protocol after these trials, there will often be less adverse publicity than if the trials occurred in the US.

Validation of Clinical Utility

Validation of clinical utility occurs upon early statistical confirmation of what had heretofore been anecdotal evidence of product and procedural value.

Trial results from the initial human use site provide the first data used for this validation. This data – including description of device, protocol, clinical outcomes, economics, post-procedure recovery, and other parameters of the trial – is measured, captured, and made available for others to review. While early clinical adopters may be willing to use devices that have limited human use, the average practitioner will wait for test results from numerous users at several institutions. And the more serious the indication, the more conservative the average practitioner will be.

The difficulty is that some devices – especially biomaterials-based ones – can require extensive time and large numbers of patients for true validation. A new drug-eluting stent will take at least 6–12 months (perhaps more) of patient follow-up in hundreds or thousands of patients before most clinicians will have confidence in its performance. A new orthopedic implant may take many years before the true story is known.

Approval for Use

This occurs upon clear and unequivocal receipt of notice from a regulator that the company is cleared for commercial launch. For more information, see the "Regulatory Strategy" section above.

Expanded Clinical Use

The product is in general market release, in use by mainstream clinicians. It has been estimated that 5–10% of clinicians can be characterized as "early adopters" willing to use a product before it is widely accepted. But mainstream users need more. They rely on things such as testimonials from one or more early adopters, discussion at medical conferences, and journal articles. The product still requires user training and sales, but there is much less "missionary" selling; most potential users are aware of the new technology, and it requires just a little bit of persuasion to give them the confidence to try it.

Standard of Care

By this phase, the product is in widespread use by mainstream clinicians as part of their standard patient practice. By the time a product has achieved this market-leading milestone, it usually will have large competitors making knock-offs with incremental or substantial improvements. One sure indication that a device or technology has reached this milestone is when the device and related procedures are taught in medical schools and residency programs. But by then, the start-up is no longer a start-up. It will have typically sold the business or licensed the product to a large medical device company or in rare cases will be a large company itself.

The Next Phase

A new idea or invention! And the cycle begins anew.

CHAPTER III.2.3 VOLUNTARY CONSENSUS STANDARDS

Jack E. Lemons
University Professor, Schools of Dentistry, Medicine and Engineering, University of Alabama at Birmingham, Birmingham, AL, USA

WHAT ARE STANDARDS?

Consensus standards are documents that have been developed by committees to represent a consensus opinion on test methods, materials, devices or procedures. Most standards organizations review their documents within five years to ensure that they are up-to-date. The mechanisms by which they are developed are described in subsequent sections. Development of standards is an ongoing process, and the latest publications should be consulted for new standards.

A test method standard describes the test specimen to be used, the conditions under which it is to be tested, how many specimens and what controls are to be tested, and how the data are to be analyzed. Many methods are validated by "round-robin testing," meaning that several laboratories have followed the method and their results are analyzed to determine the degree to which they agree to a specified degree of precision and accuracy. Once a test method has been standardized, it can be used in any other laboratory; the details are sufficient to ensure that different facilities will obtain similar results for the same samples. Stating that a test was "conducted in accordance with…" ensures that the results can be duplicated. Some representative test methods are listed in Table III.2.3.1.

A material or specification standard describes the chemical, mechanical, physical, and electrical properties of the material. Any test method standards cited are to be used to ensure that a significant sample meets the requirements of the standard. Some representative material standards are listed in Table III.2.3.2.

For implant materials, there is also a requirement that the materials meet general biocompatibility test criteria. There are two formats for the biocompatibility language

in the material standards of the American Society for Testing and Materials (ASTM). For materials that can be well-characterized by chemical, mechanical, and physical tests, and have demonstrated a well-characterized biological response, reference to the published biological testing data and clinical experience is often sufficient. For materials that are not well-characterized, for example, the wide class of materials called epoxy resins, biological test methods are cited, and each particular formulation must be tested independently. This area is evolving for combination biological and synthetic (tissue-engineered) products.

A device standard describes the device and its laboratory-based performance. General design aspects, dimensions, and dimensional tolerances are given using schematic drawings. The materials to be used are described by reference to materials standards. Methods for testing the device are also cited. Since test methods only describe how to do a test, it is in the device-related standards that performance is addressed. For example, the fatigue life requirements of biocompatibility requirements of the device and its materials would be stated in a device standard. Some representative device standards are listed in Table III.2.3.3.

TABLE III.2.3.1	Some Representative ASTM Standard Test Methods
A. Mechanical testing standards	
ASTM D412 Test methods for rubber properties in tension	
ASTM D638 Test method for tensile properties of plastics	
ASTM D695 Test method for compressive properties of rigid plastics	
ASTM D790 Test methods for flexural properties of unreinforced and reinforced plastics and electrical insulating materials	
B. Metallographic methods	
ASTM E3 Preparation of metallographic specimens	
ASTM E7 Terminology relating to metallography	
ASTM E45 Determining the inclusion content of steel	
ASTM E112 Determining the average grain size	
C. Corrosion testing	
ASTM G3 Conventions applicable to electrochemical measurements in corrosion testing	
ASTM G5 Reference test method for making potentiostatic and potentiodynamic anodic polarization measurements	
ASTM G59 Conducting potentiodynamic polarization resistance measurements

AAMI ST19 Biological indicators for saturated steam sterilization process in healthcare facilities	
AAMI ST21 Biological indicators for ethylene oxide sterilization processes in healthcare facilities	
ASTM F86 Surface preparation and marking of metallic surgical implants	
ASTM F561 Retrieval and analysis of implanted medical devices and associated tissues	
ASTM F565 Care and handling of orthopedic implants and instruments	
ASTM F983 Permanent marking of orthopedic implant components	

AAMI: Association for the Advancement of Medical Instrumentation
ASTM: American Society for Testing and Materials

WHO USES STANDARDS?

The term "voluntary standards" implies that the documents are not mandatory; anyone can use them. This terminology also refers to the way that standards are developed. Standards are used by manufacturers, users, test laboratories and, in many instances, college professors and their students. One's use or compliance with a standard is voluntary. Using them is often to everyone's advantage. At this time, standards can also be utilized as a part of the regulatory (US Food and Drug Administration (FDA)) approval process.

Manufacturers often use standards as guidelines in making and testing their materials and devices. Manufacturers also cite standards in their sales literature as a concise way of describing their product. Stating that a device is made from cast cobalt-chromium-molybdenum alloy in accordance with ASTM F75 tells the user precisely what the material is. Conformance to standards is also a way to expedite device review by the FDA.

On a more personal level, for example, after purchasing a piece of plastic pipe at the hardware store labeled with "ASTM D1784," one could go to ASTM Volume 8.02 and find that this is a specification for rigid poly (vinyl chloride) compounds. If you have "DIN" stamped on the bottom of your ski boots, you know they conform to the standards of the Deutsches Institut für Normung, and the ski shop will have standards for adjusting your bindings.

As an example of why one would want device standards used for medical devices, consider screws for fixing bone fractures. There are device standards for bone screws, plates, taps, and screwdrivers. The physician can purchase a screw and a screwdriver, and be confident that the components will fit as intended. A surgeon about to remove a plate implanted at another hospital can evaluate radiographs and see that the device has 4.5 mm bone screws of a specific design. Knowing this, a standard 4.5 mm screwdriver can be used to remove the screws.

Standardized test methods should simplify life. For example, many who teach undergraduate and graduate biomedical engineering courses use standards. In a mechanical testing laboratory, several ASTM standard test methods for mechanical testing, such as D790, "Flexural properties of plastics and electrical insulating materials," might be used. This method describes the samples, test apparatus, test speeds, and equations used to calculate the results. During a laboratory session, the students follow the test directions. In writing the methods section of their reports, all they had to write is "the test was done according to D790."

WHO WRITES STANDARDS?

In the United States, voluntary consensus standards are developed by a number of organizations. In the medical electronics, sterilization, vascular prosthesis, and cardiac valve areas, most standards are developed by committees within the Association for the Advancement of Medical Instrumentation (AAMI). In the implant materials and implants area, most standards are set by ASTM Committee F04 on Medical and Surgical Materials and Devices. These documents may then be reviewed and accepted by the American National Standards Institute (ANSI). ANSI is the official US organization that interacts with other national organizations in developing international standards within the International Standards Organization (ISO), such as TC 150 on Medical Materials and Devices, and TC 194 on Biological Evaluation of Medical Devices. The USP provides information on minimal biocompatibility testing for materials intended to be used in medical devices.

Dental material standards are written by the American Dental Association (ADA). Similar committees exist in other countries: the Canadian Standards Association (CSA); the British Standards Institute (BSI); the Association Française de Normalisation (AFNOR) in France; and the Deutsches Institut für Normung (DIN) in Germany, which is a voluntary organization.

The initiation, development, and process for the completion of national ASTM F04 consensus standards for medical and surgical materials and devices has evolved significantly within recent years. In part, this has been a result of multiple interactions among those involved with the basic sciences, applied research and development, business marketing and sales, clinical applications, regulatory agencies, professional societies, legal and insurance professions, device recipients, and associated advocacy groups. To establish consensus opinions satisfactory to all of these interest groups is far from a simple process.

History and Current Structure of ASTM F04

The ASTM was organized in 1898, whereas Committee F04 on Medical Devices and Surgical Materials and Devices was founded in 1962. The committee has grown to include a current membership of approximately 600 individuals, representing a variety of disciplines and interests. The ASTM F04 Committee has more than 100 active standards, and is structured into more than 30 technical subcommittees. The overview structure includes five divisions divided according to responsibilities specific to organizational activities (process) or the development of specific types of standard document e.g., full consensus standards include six types: (1) classification; (2) guide; (3) practice; (4) specification; (5) terminology; and (6) test methods, plus a provisional status. The divisions are: (I) resources; (II) orthopedic devices; (III) medical/surgical devices; (IV) tissue engineered products; and (V) administration. Each division is subdivided into subcommittees and task groups according to areas of interest and activities. This structure is intended to be flexible and can be rearranged to suit new or more efficient operations at any scheduled meeting of the executive committee. The divisions, subcommittees, and task groups have an

appointed chair and vice-chair, whereas the executive is nominated and elected on a two-year cycle.

Standards Development Process

After a request for a new standard is received by a member or group (task group or subcommittee) and accepted by the executive committee, a task group activity is initiated. An appropriate chair is recommended and approved by the administrative committees, and the process is started. Consensus standards development follows a reference document for content, form, and structure. An assignment of an appropriate document number is made for records purposes, and a staff manager confirms that the committee and subcommittee representation associated with this activity is classified and balanced with respect to producers and non-producers. A first draft of the proposed document is reviewed (usually three to five times) before the task force reaches a consensus.

Critical to these proceedings is the necessity that adequate information is available within the public domain in order to substantiate the requirements listed with the final standard. If data are limited or unknown, round-robin tests or new test methods must be developed, and then confirmed to be applicable and valid. Sometimes, documents are held until basic (necessary) information for the standard is developed. Again, a standard must be based on known results, and documents are not intended to represent areas of new research.

As a part of the process, once a draft document has been circulated within the task group and consensus is reached, the task group chair may recommend initial voting at the task group level. At this time, the opinions gained could lead to further improvements and no formal voting rules are required within the task group interactions. At the next stages, the subcommittees and main committees of ASTM F04 must ensure a balance among the various voting interests, with adequate representation from the general interest, user, consumer, and producer segments of the membership. The total of the user, consumer, and general interest votes must equal or exceed the number of producer votes. To prevent domination by any one interest group, only one vote per voting interest is permitted. The ASTM staff confirms the numerical status (adequate response and balance) for each formal vote, and all members are permitted to vote on any ballot within their committee and membership. If approved or approved with editorial (no substantive) changes at the subcommittee level, the document proceeds to main committee ballot and society review. If, however, a negative vote is received during formal voting, the task group and subcommittee chairs must resolve the negative to the satisfaction of the negative voter or must provide rational and justification to find the negative voter nonpersuasive. This opinion must be accepted by the task force and approved at the subcommittee and main committee levels by a formal recorded vote based on written documentation and associated discussions. The staff manager works with the committee to confirm the validity of the vote, and to document the action.

The general experience has been that it requires three to five years (six to ten meetings) to go from a first draft to a full standard accepted at the main committee level. Several procedural steps are also required in the process, including approval of a rationale statement, use of standardized units (SI) and terminology, and acceptance by the editorial and precision and bias subcommittees. At the stage of society acceptance, the final document is reviewed by the Committee on Standards prior to publication by ASTM.

After approval, a given standard may remain "active as published" for up to five years. At five years, that standard must be reaffirmed or revised to suit the information available at that time. For records purposes, the date of last formal approval is included as a part of the standards designation.

BIOCOMPATIBILITY STANDARDS

There is a wide range of tests that may be used to determine the biological response to materials. Short-term uses require only short-term tests. Long-term uses require tests applicable to the particular device and tissue type. Since not all tests are necessary for all applications, national and international standards organizations have developed matrix documents that indicate what methods are appropriate for specific applications. These documents can be used as guidelines in preparing a submission to the US Food and Drug Administration (FDA) and other national regulatory agencies for approval of a new material or device. Similar matrix documents have been standardized by the CSA, BSI, and ISO. Test method documents have also been developed by the National Institutes of Health (NIH) and the US Pharmacopeia (USP). Guidelines for dental materials have been developed by the ADA and ISO.

Much of the standards activity is now associated with the International Standards Organization (ISO) with biological evaluation of medical devices under the consideration of TC 194 and presented in the developing documents of ISO 10993. There are various parts to this document. Part 1 is definitions and the guidance on selection of evaluation test categories that should be done. The other parts of ISO 10993 give more discussion and detail on the selection of individual tests that should be done for a particular biological interaction or biological effort (e.g., contact with blood, systemic toxicity, genotoxicity). Often, the details of test methods are not given in the ISO documents, and reference is made to other documents such as ASTM and USP standards for procedures and methodology.

Material selection and evaluation of biological risk are integral components of the design process for medical devices being considered by TC 194. This evaluation

is a component of the risk management plan in line with ISO/IEC 14971 – Application of Risk Management to Medical Devices, encompassing identification of all hazards and the estimation of their associated risks. Criteria to define the acceptable biological (toxicological) risk must be established at the start of the risk assessment and design management processes. The biological safety evaluation must be designed and performed to demonstrate the achievement of the specified criteria for safety. Adequate risk assessment requires characterization of toxicological hazards and exposures. Following the risk management structure described in ISO 14971, a major component in hazard identification is material characterization.

In the following section we review some of the steps taken to establish the biocompatibility of a new material for a specific application, in this case a long-term orthopedic implant. We use ASTM standard F748 "Practice for Selecting Generic Biological Test Methods for Materials and Devices" as a guideline. The standard test methods described are those used within ASTM.

In Vitro Tests

F619. Practice for Extraction of Medical Plastics. A method for extraction of medical plastics in liquids that simulate body fluids. The extraction vehicle is then used for chemical or biological tests. Extraction fluids include saline, vegetable oil (sesame or cottonseed), and water.

F813. Practice for Direct Contact Cell Culture Evaluation of Materials for Medical Devices. A cell culture test using American Type Culture Collection (ATCC) L929 mouse connective tissue cells. This method or this type of cell culture method can be used as the first stage of biological testing. It is also used for quality control in a production setting. There are other ASTM standard cell culture methods, and others not standardized by ASTM that could also be used.

F756. Assessment of Hemolytic Properties of Materials. An *in vitro* test to evaluate the hemolytic properties of materials intended for use in contact with blood. Procedure A is static; procedure B is done under dynamic conditions.

Short-Term *In Vivo* Testing

F719. Testing Biomaterials in Rabbits for Primary Skin Irritation. A procedure to assess the irritancy of a biomaterial in contact with intact or abraded skin. This test would be indicated for surgical glove material or skin dressing.

F720. Practice for Testing Guinea Pigs for Contact Allergens: Guinea Pig Maximization Test. A two-stage induction procedure employing Freund's complete adjuvant and sodium lauryl sulfate, followed two weeks later by a challenge with the extract material. Ten animals per test material.

F749. Practice for Evaluating Material Extract by Intracutaneous Injection in the Rabbit. Extraction vehicles (as per F619) of saline and vegetable oil are injected intracutaneously and the skin reaction graded for erythema, edema, and necrosis. Two rabbits per extraction vehicle.

F750. Practice for Evaluating Material Extracts by Systemic Injection in the Mouse. Intravenous injection of saline extracts and intraperitoneal injection of oil extracts. Animals are observed for evidence of toxicity. Five mice per extract and five mice per extract vehicle controls.

F763. Practice for Short-Term Screening of Implant Materials. This method provides for several implant types and sites for short-term screening *in vivo*. This method is essentially the first stage of animal testing of solid pieces of the implant material.

F1983. Assessment of Compatibility of Absorbable/Resorbable Biomaterials for Implant Applications. This material type presents unique features for tissue evaluation, in that the materials are not inert, and a chronic inflammatory reaction may be observed during the degradation period. The time periods at which reactions are examined are based on the anticipated rates of degradation of the test material.

Additional tests for special issues are also included in ASTM standards, such as examination and reactions to particles, immunotoxicity, and retrieval and analysis of implants and tissues.

These are additional *in vivo* tests that have not yet been standardized by ASTM:

Thrombogenicity. Tests for the propensity of materials to cause blood coagulation have not been standardized. Guidelines for such tests have been developed by the NIH Heart Lung and Blood Institute.

Mutagenicity. There are a number of *in vitro* and *in vivo* tests to determine if chemicals cause cell mutations. Although not specifically developed for implants, guidelines do exist as part of the OECD (Organisation for Economic Co-operation and Development) guidelines for testing of chemicals, and within ASTM, e.g., E1262, Guide for the Performance of the Chinese Hamster Ovary Cell/Hypoxanthine Guanine Phosphoribosyl Transferase Gene Mutation Assay; E1263, Guide for Conduct of Micronucleus Assays in Mammalian Bone Marrow Erythrocytes; E1280, Guide for Performing the Mouse Lymphoma Assay for Mammalian Cell Mutagenicity; E1397, Practices for the *In Vitro* Rat Hepatocyte DNA Repair Assay; and E1398, Practices for the *In Vivo* Rat Hepatocyte DNA Repair Assay, which are in Vol. 11.05 of the ASTM *Annual Book of Standards*.

Pyrogenicity. A pyrogen is a chemical that causes fever. The USP rabbit test is a standard *in vivo* test. One can also test for bacterial endotoxins, which are pyrogenic, using the Limulus amebocyte lysate (LAL) test.

The oxygen carrying cell (amebocyte) of the horse-shoe crab, *Limulus polyphemus*, lyses when exposed to endotoxin.

Long-Term *In Vivo* Testing

There are two aspects to the long-term testing issue. One is the response of tissue to the material; the other is the response of the material (degradation) to implantation.

F981. Practice for Assessment of Compatibility of Bioma-terials for Surgical Implants with Respect to Effects of Materials on Muscle and Bone. Long-term implan-tation of test materials in the muscle and bone of rats, rabbits, and dogs. Two species are recommended. For rabbit muscle implants the standard calls for four rabbits per sacrifice period, with one control and two test materials placed in the paravertebral muscles on each side of the spine. For bone implants in rabbits the standard calls for three implants per femur.

A general necropsy is performed at the time of sac-rifice. Muscle and bone implant sites are removed at sacrifice and the implants left *in situ* until the tissue has been fixed in formalin. Implants may be removed prior to embedding and sectioning.

No standards have been established for any long-term testing of devices. However, for a device intended for a particular application, it is essential to conduct a func-tional device test. For a fracture fixation plate, it could be proposed to use plates to fix femoral osteotomies in dogs. This study would consider the effects of the implant on the tissues, as well as the effect of implantation on the properties of the device, i.e., material degradation.

The methodology for long-term carcinogenicity test-ing of implants also has not yet been standardized by the ASTM, although F1439 (Standard Guide for Perfor-mance of Lifetime Bioassay for the Tumorigenic Poten-tial of Implant Materials) does provide guidelines for test selection. This is normally a life survival and tumor production test, typically in rats. ISO 10993-3 provides considerations for genotoxicity, carcinogenicity, and reproductive toxicity testing with reference to some test methods.

TISSUE-ENGINEERED MEDICAL PRODUCTS

A rapidly evolving area for standards has been tissue-engineered medical products (TEMPs). This area was identified early in the product development cycle, and focused initially on terminology and guidance standard-ization. Combination products, including synthetic and biologic origin biomaterials within bioactive and bio-degradable device designs, required very different types of test for product safety and efficiency. Key within this activity was testing of biocompatibility and meth-ods for sterilization of substances with biologic type

properties. Examples of some standards from the ASTM F04 Division IV documents are provided below.

NANOTECHNOLOGY

The continued expansion of nanotechnology-based medi-cal and dental devices has now evolved as an area in need of standardization. In this regard, higher resolution microscopy and spectroscopy instruments and methods are required, thereby resulting in a focus on test methods and round-robin testing to ensure precision and accuracy. It is anticipated that this area and the need for standard-ization will increase significantly over the next few years.

WORKSHOP AND SYMPOSIA

Planning for a new standard often results in identifica-tion of areas where data are needed prior to developing a consensus standard. As an example, the ASTM F04 annual meetings normally initiate with a workshop or symposium within a pre-identified focus topic. Work-shops include invited short papers with abstracts, usu-ally as half-day sessions where participants are asked to participate in the following subcommittee group meet-ing for standard development. Symposia often follow and require a two-year planning cycle. The meeting is based on peer-reviewed papers and the proceedings are published as a Standard Technical Publication (STP) as a component of the ASTM Journal (ASTMI) or a co-sponsoring professional society document.

Importantly, these meetings, which are open to all stakeholders, provide interactions for acceptance or not of basic data on existing or new surgical implant prod-ucts. Examples of some previous and scheduled ASTM F04 and co-sponsored workshop and symposia titles are listed in Table III.2.3.5.

INTERNATIONALIZATION OF STANDARDS

The various USA-based standards organizations harmonize the consensus standards within the world communities through a number of different interactions. The American National Standards Institute (ANSI) represents many of the standards groups, such as ASTM and AAMI, for the International Standards Organization (ISO). The various committees within the USA act through Technical Advisory Groups (TAGs), and participate within the ISO committees as formal voting participants. Where applicable, considerable similarities exist between AAMI, ASTM, and ISO standards. Although processes are

TABLE III.2.3.5	Examples of ASTM and Collaborative Workshop and Symposia Held Using a Consensus Standard Format

11. Fretting Fatigue of Metallic Medical Devices and Materials, ASTMI E8/F04, Nov. 2009.
12. Symposium on Mobile Bearing Total Knee (MBK) Replacement Devices, May, 2010.
13. Static and Dynamic Spinal Implants: Are We Evaluating Them Appropriately? 2010.
14. Workshop on Metal on Metal Total Hip Replacement Devices, ASTM F04/AAOS, May, 2011.

different within ISO, the outcome is published standard documents.

Organizations such as the ASTM also maintain international structures (ASTMI), where international participation results in an ASTMI standard and in some cases a memorandum of understanding (MoU) for utilization of the standard as applicable to specific products. In many situations, regulatory organizations such as the FDA seek and accept the most applicable standard(s) related to procedures for product acceptance.

CHAPTER III.2.4 REGULATORY OVERVIEW FOR MEDICAL PRODUCTS USING BIOMATERIALS

Elaine Duncan
Paladin Medical, Inc. Stillwater, MN, USA

INTRODUCTION

Assessment of the safety and effectiveness of new (and the ongoing evaluation of approved) medical devices is challenging. The US Food, Drug & Cosmetic Act amendment in 1976 extended the powers of the US Food and Drug Administration (FDA) over medical devices. The key areas of the FDA that are responsible for the

regulation of therapeutic medical products are the Center for Biologics Evaluation and Research, the Center for Devices and Radiological Health, and the Center for Drug Evaluation and Research. The FDA's Center for Devices and Radiological Health (CDRH) is responsible for regulating firms who manufacture, repackage, relabel, and/or import medical devices sold in the United States. In addition, CDRH regulates radiation-emitting electronic products (medical and non-medical) such as lasers, X-ray systems, ultrasound equipment, microwave ovens, and color televisions. Thus, CDRH plays an essential role in promoting and protecting the public health by ensuring that medical devices marketed in the United States provide a reasonable assurance of safety and effectiveness and confer a favorable risk–benefit

profile for their intended use population. Many subsequent amendments have continued to refine and broaden the agency's control to include many other specialties, such as veterinary drugs, biologics, and combination products.

It is important to emphasize that the agency does not specifically regulate biomaterials, by choice. Rather the agency prefers to see regulatory constraints on the use of a biomaterial follow the intended use of the device (drug, biologic, or combination product, i.e., a product comprised of two or more regulated components, i.e., drug/device, biologic/device, drug/biologic or drug/device/biologic, that are physically, chemically or otherwise combined or mixed, and produced as a single entity) of which the biomaterial is a component. This section provides a broad regulatory overview with a few specific requirements incumbent upon an engineer developing a medical device incorporating a biomaterial. General references describing the details of the regulatory review process and strategies are available (Maisel, 2004; Muni and Zuckerman, 2007; Ergina et al., 2009; Zenios et al., 2010; Sweet et al., 2011).

GLOBAL REGULATORY STRATEGY ACCORDING TO INTENDED USE

In most countries the regulation of the use of a biomaterial depends primarily on the risk associated with the intended use of the product into which the material is incorporated. For example, a biomaterial may be the major component of an implanted artificial joint, a surface in contact with blood or tissues (such as an intravenous line) or a material within a free-standing device (such as a dialysis membrane). The inherent risk intrinsic to the intended use of the device establishes the requirements on the biomaterial and thereby the level of performance validation required.

This section will focus on how compliance with US FDA regulations (21 CFR Part 820: Quality Systems Regulations) and the commonly adopted quality system standard: ISO 13485:2003 standard for "Quality Management Systems – Medical Devices – System Requirements for Regulatory Purposes" defines the responsibilities of the developer of a medical device incorporating a biomaterial.

The European Union adopted the Medical Device Directives (MDD) and the Active Implantable Medical Device Directive (AIMDD), and also continues to evolve both the directives and supporting requirements. The general construction of the European directives builds on recognized international standards and Essential Requirements. The Essential Requirements specifically require that the chemical, physical, and biological properties guarantee characteristics and performance of the product. Demonstration of conformance to the Essential Requirements is directly tied to demonstration of meeting a recognized European or international-level

standard. Although these directives have regulated the "safety" of a device, only in a few instances is the efficacy of a device brought under scrutiny. Changes, which took effect in 2010, update the Directives to now require that the Conformity Assessment process for active implantable medical devices as well as for class III and implantable medical devices include a clinical investigation unless it is duly justified to rely on existing data (section 1.2 of Annex 7 of directive 90/385/EEC and section 1.1a of Annex X of directive 93/42/EEC). Any such justification will have to be based on a proper clinical evaluation. This requirement further harmonizes the European requirements with the FDA regulations to demonstrate a device is not only safe but also the the device performs as intended.

As a result of global harmonization, it is generally fair to say device regulations are divided into two main groups: (1) development and manufacturing regulations; and (2) premarket entry requirements. Internationally or nationally recognized standards, as discussed previously in this chapter, play a major role in defining the requirements for conformity in both of these regulatory theaters. Premarket entry requirements vary more broadly between countries, but because of the harmonization of the quality standards, the development and manufacturing controls for devices using biomaterials enable most devices to be developed and manufactured for the global market.

Despite various premarket regulatory requirement differences, the strategies are fairly uniform in segmenting medical device regulatory thresholds around the perception of relative risk (and perception of benefit.) Thus a low-risk device generally carries the requirement to be manufactured in a proper environment and promoted only for the well-established intended use. A moderate-risk device typically requires some intermediary to review the technical documentation of the product prior to its reaching the marketplace, to ensure that the device is safe for the intended use. The highest risk category thus require the greatest scrutiny of the performance of the device prior to market, which may include extensive animal trials or human clinical trials to establish not only safety, but also efficacy. In the US, these classifications are Class I, Class II, and Class III, respectively.

A well-constructed Device Master Record will go a long way in satisfying the regulatory requirements of most countries, even though it may need to be presented in various regulatory formats. Documentation of conformity to international standards and essential requirements will become an increasingly important function for all medical device developers. Harmonization efforts may soon do away with the historic "me too" practice of the 510(k) submission, which requires the applicant to compare the properties and performance of the candidate product to a previously cleared device. Instead, perhaps an FDA submission for a low- or medium-risk device may certify conformity to standards or FDA published guidance documents, and equivalence analysis

may be less crucial. As this textbook goes to press, the FDA continues to reassess the premarket clearance procedure and the implementation of other 30-year old regulations to improve the methods without endorsing a wholesale change in practice. An example of continuing updates of policy and practice are published through public guidance documents such as draft guidance "510(k) Device Modifications: Deciding When to Submit a 510(k) for a Change to an Existing Device": http://www.fda.gov/medicaldevices/deviceregulationandguidance/guidancedocuments/ucm265274.htm

The regulatory environment is volatile, so the premarket regulatory scrutiny of a new medical device may vary with changing perceptions of risk-to-benefit. Some commonly known products which enjoy high confidence of regulators may be "down-classified" (requiring less oversight), whereas a sudden outbreak of failures of a device with comparable risk factors may suddenly enjoy increased testing prior to market release or even post-market surveillance. These trends are a natural by-product of changes in our understanding of biomaterial interactions (systemically and locally), changes in expectations for device performance, and are possibly the result of devices functioning longer in a more diverse population. Unfortunately, a textbook cannot stay current with such variations in regulatory enforcement, so it is best to stay up to-date by viewing the latest information on www.fda.gov.

A device previously cleared by the FDA, but which must undergo a significant change, may also require regulatory review or approval prior to market introduction of the change. It is the responsibility of the manufacturer to document that the changes do not affect the safety and efficacy of the device. The nature of the change, and the potential for new risk due to the change, will determine the level of regulatory scrutiny required prior to introducing the modified product to market. At the present time, guidance documents which describe methodology to assess the safety and efficacy of such changes can be found on the web at: http://www.fda.gov/downloads/MedicalDevices/DeviceRegulationandGuidance/GuidanceDocuments/ucm080243.pdf or http://www.fda.gov/downloads/MedicalDevices/DeviceRegulationandGuidance/GuidanceDocuments/ucm089612.pdf (FDA website addresses are subject to change).

Regulations and design requirements for biomaterials in medical devices typically focus on concerns for the safety and efficacy of biomaterials when the medical device is used as intended. The potential harm derived by using an unsafe biomaterial is viewed in the context of the device application. Therefore, more stringent testing of biomaterial safety and efficacy is required for devices with longer exposure, those used in life-supporting or life-sustaining devices, or where repeated exposure to the biomaterial component could engender greater risk. Increasing concern for the safety of a device when it is mishandled or fails to meet user's expectations (or level

of understanding) has seen increased attention on human factor engineering and usability testing of devices. Usability testing of device design and labeling can span the range of testing to ensure a surgical instrument's use does not damage a delicate implant during surgery, to the ability of a patient to "self-diagnose" adequately "over-the-counter" (OTC) biomaterial-based devices ranging from wound dressings to anti-snoring mouth guards.

In general, all regulations that govern medical devices place the burden of proof upon the manufacturer to document the quality of the biomaterials from which the medical devices may be fabricated. Biomaterial suitability for use determinations are strongly influenced by the FDA's guidance documents, which usually describe the level of testing the FDA expects to see in an application for market. The FDA also publishes a list of "recognized standards" which may also influence the material selection process, and the testing required. The voluntary standards and guidance documents, plus what the FDA calls "general control" create boundaries or expectations for performance, but are inadequate to ensure the biomaterials selected will perform as intended within the given device for the stated intended use for all circumstances.

DESIGN CONTROL AND RISK ANALYSIS

The FDA Modernization Act of 1990 introduced the requirement for preproduction design validation of medical devices. Finally, in October 1996, the FDA issued the resultant regulations that enhanced the good manufacturing practice regulations (GMP) to include, among other provisions, the requirement that a device's development would also be subject to written procedures. The new regulation adapted principles for design processes initiated in ISO 9001 known as "design controls." The FDA's regulations of design control are not voluntary for most Class II and Class III devices. Furthermore, design control requirements were excluded from the "exemption" in the Investigational Device Exemption regulations (21 CFR Part 812) which had previously exempted investigational devices from GMPs. After the effective date of the regulation, almost all new medical devices involving a biomaterial would be subject to design control and review according to Quality System Regulations (21 CFR Part 820).

Design Control and Review, as described in §820.30 and §820.40, lay out the fundamental requirements for development of a new medical device. Implementing these requirements as early as possible in the development of a new medical device ensures early documentation of critical "design inputs" that often heavily influence the success of a new medical device. Any new medical device involving a biomaterial has intrinsic "input requirements" which may prove difficult to elucidate. For example, it's obvious that a biomaterial would need to be "biocompatible," but design engineers must attempt to clarify the meaning of that requirement. Is the "input"

that the material must be biocompatible for a few hours, a few days or will the device be a long-term implant? When the duration for biocompatibility is defined we have more information with which to establish performance requirements. Is "biocompatibility" to be judged as how well the material creates an interface with bone, how well it tolerates contact with another synthetic material which might induce a chemical interaction or is there long-term blood contact? These "input" details are critical information necessary to accurately describe the user's expectation for the service of the biomaterials within the device.

One of the first tasks to meet the Design Control regulations is the establishment of Design Inputs (§820.30(c)). Typically a robust project must define "user requirements," and then further refine this information to "engineering design requirements," because the "user requirements" may be too vaguely expressed to be sufficiently useful for materials selection and evaluation. Even this process of refining the input requirement can lead to design drift as the engineer attempts to interpret the user's statements into quantitative and measurable design parameters.

Design "outputs" are often an area of confusion for beginning medical device designers, because the regulation allows a broad interpretation of what constitutes an "output." It is generally agreed in the industry that "outputs" are the sum total of the finished design, inclusive of design documentation, design testing results, and the device itself. Nevertheless, the regulations require that any device subject to Design Control must demonstrate that the Design Outputs meet the Design Inputs (see §820.30(d)).

Each new medical device requires the systematic Design Review (§820.30(e)) of the device performance and documentation through each defined phase of development. Proof that the device design (outputs) meets the device inputs may require iterative reviews of test results conducted over a range of design phases. These phases or stages should be identified in a Design Plan (§820.30 (b)) which is reviewed repeatedly to confirm that design development is on track, and that requirements are being met in a systematic manner throughout the development project.

Setting up a Design Plan for a new biomaterial can be especially difficult, because the performance of the biomaterial within the device is intrinsically linked to the performance of the device. Qualifying a new biomaterial in a new, unproven medical device may require iterative qualification cycles, as the biomaterial, then the device, then the biomaterial is repeatedly tweaked and evaluated. Possibly the only way to evaluate and define performance is through repetitive animal and/or bench models, which are perhaps themselves not yet validated. Critical to success in these circumstances is accurate, thorough, and relentless documentation of changes as the development progresses, and written justification of compromises made to input requirements.

Certainly a more straightforward scenario is substituting a new biomaterial in an existing and well-established medical device where performance is well-characterized. In this situation the new biomaterial would be evaluated against the performance of the current biomaterial to determine if the new material performs as well, without compromising overall device performance. Even this can be challenging if the relationship of material properties to device performance was never elucidated.

Biomedical engineers often find that the prior biomaterial performance requirements were not well-characterized for the intended use when the material was originally adopted. Many older medical devices have undergone design or materials "creep," whereby the performance requirements of the components and/or biomaterials were never separately qualified for the specific role played within the device function, yet change after change has slowly moved the device performance along to keep up with customer requirements. Qualifying a substitute biomaterial in these circumstances can be time-consuming and expensive. Gradually as principles of Design Control and Review infiltrate the medical device industry, biomaterial characterization associating material properties more succinctly to intended use may streamline biomaterial substitutions.

Fundamental to establishing the suitability of the biomaterial within the medical device is the task of assessing risks and how to mitigate these risks. ISO 14971:2007 describes methods for conducting and documenting risk analysis, but this standard also describes the concept of Risk Management. Risk Management begins at the design level, but continues through the lifecycle by continuous risk assessment and management during development and marketing phases, including how to incorporate risk assessment into corrective and preventative action and management oversight. For this present discussion, Design Level Hazard Analysis and Risk Assessment are of immediate interest.

In the design level hazard analysis the exercise is to evaluate the potential hazard that may exist if the device (biomaterial) failed to meet the user requirement (or engineering requirement). A hazard is the "potential" to do harm (either to the patient, the user or even device performance). A difficult chore is assessment of risk posed by the potential hazard, because one must understand the "likelihood" or "potential" for the hypothetical hazard to actually occur in the defined circumstances. This exercise can lead to excessive speculation or contrarily, a denial that there is any risk at all. Despite the often awkward and painful process of listing and evaluating these potential hazards, the resultant laundry list of potential hazards and mitigations (usually testing, labeling, and defining release criteria) should help to reduce the potential for the identified risk to occur. This list ideally creates the road map for a "risk-based" approach to the verification and validation plan for the new product (§820.30(f) and (g)). From here designers can document

that device outputs, including risk mitigations, have met user inputs.

Complex new medical devices, particularly those with innovative biomaterials, may require iterative testing, and protracted design phases and multiple reviews prior to final release of the device to manufacturing (Design Transfer §820.30(h)). Design review stages for such products may require bench and standardized testing on early prototypes, then animal testing on prototypes maximized for the test subject, then still more sophisticated and possibly different "prototypes" for limited clinical trials.

In each design phase the device, as embodied by the prototypes, may be fabricated differently, use different formulations of biomaterials or other components, and may have different physical shapes or sizes. Processes such as packaging and sterilization may also differ. As the design evolves there must be Design Control that documents the many Design Changes (§820.30 (h)). All of the design changes, the results of testing, and the myriad design specifications must be maintained in the Design History File (§820.30(j)). Early design documentation may begin in a laboratory notebook and evolve to state-of-the-art electronic documentation systems, but in every circumstance the development engineer is charged with the responsibility of providing documentation that the device is properly validated for intended use. Good documentation will prove invaluable if it should be necessary to justify why the test results using early prototypes are still valid as supporting evidence of the suitability of the final design. Even with such support, most medical device manufacturers will conduct a final design validation on devices produced from final production runs prior to full market release. For Premarket Approval (PMA)-regulated devices, this is necessary prior to FDA establishment that the device is safe and effective, and thereby can be released to market.

BIOCOMPATIBILITY ASSESSMENT FOR BIOMATERIALS IN MEDICAL DEVICES

Standardized biocompatibility assays are conducted prior to clinical evaluation of the device or for those not requiring a clinical trial, prior to clearance to market the product. Regulatory requirements based upon the risk of the device will typically dictate the extent of standardized biocompatibility testing. These recommendations, such as those mapped in ISO 10993: Part 1, reflect the perceived risk associated with the use of the product. Many of the standardized biocompatibility screens focus on the chemical toxicity of leachable components or degradation by-products. These exposure-based categories have for years been seen as a logical (although sometimes awkward) structure for determination of which testing protocols best evaluate the potential toxicity of the material/device. It is tempting to make the list of tests a "tick-list" without considering the value of the test and its appropriateness to the product. Ethical use of animals

and considerations for cost-control compel the biomedical engineer to prudently and judiciously take advantage of published literature, internal corporate databases, and commercial databases offering technical information on materials. Biomaterials suppliers are more frequently establishing "Device Master Files" (MAF) which may serve as a reference library of prior testing, held confidential at the FDA for use by reviewers when a biomaterial is included in a new medical device. Such historic testing may not eliminate the need for additional testing in the specific application or due to differences in processing, but the device developer should attempt to take every advantage from well-characterized materials that are offered for use in medical devices, rather than incur excessive costs and potential setbacks due to selecting industrial-grade materials not intended for use in medical devices.

Despite the goal to conduct biocompatibility assays on finished devices, most test regimens cannot make use of the entire, finished device. It may be necessary to evaluate a biomaterial separate from the finished device, with consideration for the exposure of the materials in the finished device by including exposure to effects from manufacturing and sterilization processes. Such "environmental" stressors may be important in determining the potential that the material may have toxic and accessible process by-products. The standardized biocompatibility screens are not without limitations. For example, these screens are not designed to evaluate the long-term effects of any structural forces on the device which might affect the biomaterial once incorporated into an implant. As an example, osteolysis, due to the presence of wear particulates, has been identified as a cause for implant loosening, yet the materials responsible for osteolysis routinely pass all of the biocompatibility screens.

For new biomaterials or new formulations of historic materials, developers may wish to consider a risk-based approach to establishing allowable limits for leachable substances. ISO 10993-17 provides a method by which maximum tolerable levels can be calculated from available data on health risks that can be systemic or local, immediate or delayed, and range in severity from minor to life-threatening. The derivation of the allowable limits should be conducted by an individual knowledgeable and sufficiently experienced to form a qualified opinion based upon scientific data and knowledge of medical devices. Such an effort may be useful in establishing whether or not expensive and long-term chronic studies on animals to rule out carcinogenicity are warranted.

Medical device regulatory authorities recognize that many, if not most, of the standardized biocompatibility assays were not designed to assess performance of combination devices, tissue-derived products, and devices designed to be modified by the body after implantation. New standardized testing protocols are necessary, but are unlikely in the short-term. In the interim, biomaterials

development companies must contend with the cost of these standardized assays, despite their lack of practical value to predict the performance of the new biomaterial in a new medical device application. Acceptance of a new biomaterial continues to rely heavily on the results of animal trials in each device application, with the hope that the biomaterial can be transitioned to additional new uses as the material gains a reputation. Unfortunately, this migration of a biomaterial from one use to the next has historically resulted in the material's eventual use in an application for which it is ill-suited, with the resultant whiplash against the material in all applications. The best immunization against fad-material adoption is training engineers in the requirements of Design Control and Review, but in particular, the necessity for defining the input requirements for the biomaterial in the device, in the intended use.

MANUFACTURING CONTROLS AND POST-MARKET OVERSIGHT

Most regulatory authorities require that medical device manufacturers demonstrate acceptable manufacturing practices, although the specific obligations and criteria required may vary from country to country. In the US, the law of the land is found in 21 CFR Part 820: Quality System Regulations. These regulations are more or less harmonized with ISO 13485:2003, but different details still keep manufacturers on their toes when different auditors come to call.

An emerging threat to the safety of medical devices is the potential for counterfeit or tainted materials to make their way into a device after initial design qualification. Medical device manufacturers must increase vigilance with vendors of raw materials and components to ensure purity of the material supply. It is no longer sufficient to call out a material by a "name brand" in a specification. Component and material purchasing must be accompanied by trustworthy integrity testing which gives evidence that the source has delivered materials to the agreed specification. "Certification" to a standard should only be trusted when there is an active and robust auditing program in place. "Certified" vendors may help secure the supply chain, but periodic testing of materials is still critical to ensure only qualified biomaterials are used in critical medical devices.

Post-marketing oversight of medical devices in the marketplace is increasing as the sophistication of medical devices increases. Conventional clinical trials designed to prove efficacy seldom establish the long-term performance of the product. More importantly, the interaction of the medical device with the patient in their normal environment, with other devices and drugs or as the patient may age, is not typically assessed during a clinical trial. The FDA has regulations concerning recalls, product removals, and corrections, and heavily stresses the importance of corrective and preventive action (CAPA)

programs for marketed products. The FDA's enforcement and oversight will continue to increase in an effort to monitor device performance in the hands of the user, not just as-manufactured in the factory.

Post-approval limitations to the distribution of the medical device typically include restrictions to be placed on the claims for the product, and on the content of labeling. Restrictions on the content of labeling and advertising medical devices are increasing as the FDA seeks to avoid creating undue expectations by patients for the performance of a medical device. Some "off-label use" of a device by a physician has been tolerated in the past, but promotion by industry of new use or "performance claims" for a device requires a new application to support a different indication for use or claims of performance not previously reviewed by the FDA.

Most regulatory authorities around the world now require the reporting of adverse effects. The degree of hazard that must be reported to the governing agency will vary from country to country. Tracking of implantable or life-supporting devices is limited, but is still a common regulatory constraint for high-risk implantable devices, such as defibrillators.

PREMARKET CLEARANCE (510(K)), PREMARKET APPROVAL (PMA) OR "CE MARK"

For the European market, once a developer of a medical device has demonstrated conformance with the Essential Requirements of either the MDD or AIMDD, the company can often file a Certificate of Conformance or request that a Notified Body conduct an examination to ensure conformance. The route to conformity assessment is spelled out in the Directives, and is determined by the classification of the device and the applicable rule, which is primarily a risk-based stratagem. Higher risk devices require clinical data and review of a Design Dossier by a Notified Body. The CE Mark must be applied, based upon assessment of conformance, prior to the sale of any medical device in a country within the European Union, and in other countries that have voluntarily adopted the recognition of the CE Mark. Canada, Australia, and many Asian countries follow a similar pattern for device review and market approval, but their market entry requirements may differ significantly from those of the EU.

The US FDA requires that the manufacturer demonstrate safety and efficacy of the product, unless the device can be shown to be substantially equivalent to a predicate product that is legally marketed in the United States (via the 510(k)). For most new products, those without predicates, and certain high-risk products (typically Class III), a PMA is required. Certain Class I and exempted Class II medical devices are permitted to be marketed without the FDA's prior authorization, although manufacturing (Quality System Regulations) and/or documentation controls may still apply.

Premarket applications for medical devices containing biomaterials may take a variety of regulatory pathways, but for most new or innovative biomaterial-based, implantable devices, the PMA is required. The FDA has continued to permit some Class III devices to enter the market after clearance by 510(k), although the US Congress has now mandated that FDA down-classify any remaining "transitional" devices or show cause why the products should remain Class III and require a PMA. The FDA database can provide information for comparative analysis of predicate devices, and help to identify the device classification and regulations for new products, but finding the "keywords" and how to most effectively "mine" the database for information can take time. The best place to start is to review the information on: http://www.fda.gov/MedicalDevices/DeviceRegulationandGuidance/Databases/default.htm. (Zuckerman et al., 2011)

For devices subject to the PMA process, the culminating step in the lengthy and expensive regulatory review process may be the presentation to the FDA's clinical advisory panel (this is known as "panel track"). Panels of medical experts focused in a medical sub-specialty convene at the FDA's request to make recommendations on the acceptance of a new medical device. These sessions typically focus on whether, in the opinion of the panel, the clinical evaluation of the product has demonstrated efficacy. Proof of efficacy is highly dependent upon statistical analysis of prospective data collected under tightly controlled clinical evaluation protocols. These recommendations often impact the FDA's decision to allow a new device to be marketed, and limitations on labeling claims.

The FDA has sought to take some of the uncertainty and time out of the approval process by offering manufacturers collateral review steps. The modular-PMA is finding favor with medical device companies, because they can submit sections of testing as completed. This does not, however, eliminate the potential that the clinical panel may fail to recommend the product for approval based upon the lack of convincing performance data produced during the Investigational Device Exemption (IDE) studies.

The FDA has issued a revised draft guidance: The 510(k) program: Evaluating Substantial Equivalence in Premarket Notifications [510(k)] http://www.fda.gov/MedicalDevices/DeviceRegulationandGuidance/GuidanceDocuments/ucm282958.htm, which seeks to clarify how to compare a new product to an existing device and its associated technology for the purposes of filling an application for premarket clearence [510(k)]. The speed at which a medical device technology can become obsolete mandates that the FDA's review process for moderate and low-risk devices be equally swift. But Congress has expressed concerns that device safety may be compromised due to antiquated regulatory strategies which may allow inadequately tested devices to become broadly marketed or allow undue industry influence over the review process. It is obvious that requiring every new medical device to undergo full premarket approval would guarantee stagnation of the industry and escalating costs for new products, not to mention overwrought FDA reviewers. It is already common for new medical devices to reach the European market years before the same device is available in the USA. A delicate balancing act between the needs of the stakeholders will continue to affect the economic impact of medical device regulations, the availability of new technology for patients, and ultimately the cost of healthcare.

CLINICAL AND ANIMAL TRIALS OF UNAPPROVED DEVICES

Clinical evaluations for significant-risk devices containing biomaterials are cleared for study in human patients by the FDA under an IDE (Investigational Device Exemption regulations – 21 CFR Part 812.) A protocol (study plan) and informed consent form must be approved by an institutional review board (IRB). The patient must give prior consent before enrollment in the investigational study. Investigators must be trained in the use of the product, and sign an agreement to conduct the study according to regulations and according to the approved protocol. Investigators must now disclose certain levels of financial involvement with the study sponsor. Case report forms and data collection methods must be carefully crafted in order to document data required to support the claims for the product under study. Software used to capture or evaluate data must be validated, and any electronic-capture systems must be compliant with 21 CFR Part 11.

When the study constitutes a "significant risk," the sponsor must submit and wait for approval of an IDE application prior to commencing the trial. US clinical studies must now be posted on the internet at www.clinicaltrial.gov. This is an effort to make the trials more accessible to more potential patients. The public disclosure of the existence of the clinical trial also reduces the potential that trials with less than sterling results will go unreported to the FDA.

Clinical trials for medical devices containing biomaterials must develop objective evidence of safety of the device, and indirectly the safety of the biomaterial as applied in the device. Any safety problem encountered with the use of a biomaterial during the study is reported as a part of the adverse effects of the clinical trial. Any special performance claim attributed to the biomaterial, such as tissue in-growth, needs to be evaluated both as a part of a preclinical animal study, and if possible, in the clinical study. In the United States, only claims for a biomaterial supported with statistically valid evidence will be permitted in the device labeling.

Basic requirements for the conduct of human clinical trials continue to be harmonized internationally, although significant differences in trial monitoring and regulatory

oversight remain. Clinical trials of US-developed medi-cal devices outside of the US, prior to starting investiga-tional trials in the US, are likely to remain the quickest and least expensive way to obtain clinical experience and market approval for a new medical device. The poten-tial ethics of this practice are not challenged by the US FDA, and indeed seem to be encouraged. Ironically, ethi-cal constraints on testing devices in animals in Europe often motivate European medical device manufacturers to come to the US for animal studies.

Specific clinical performance claims of a biomate-rial must be supported by clinically significant objective evidence. Obviously it can be difficult on a clinical level to isolate biomaterial performance from device perfor-mance. This further complicates assessment of the iso-lated performance characteristics of a biomaterial for any future marketing benefits. Often, indirect or nonin-vasive clinical assays, such as X-rays, prove inadequate to demonstrate biomaterial performance. As a result, understanding long-term biomaterial performance usu-ally depends upon high-quality animal studies to demon-strate interfacial characteristics between the tissues and biomaterial. Often these studies have contextual limita-tions and are not published, due to proprietary concerns. Even though animal study protocols strive to provide the basis for predicting behavior of the material in the human application, their objectives are typically tightly focused and not entirely relevant to applications beyond the spe-cific intended use. Impediments to success include the dif-ferences in animal anatomy, animal metabolism, healing characteristics and behavior, when compared to humans.

Despite these limitations, pivotal animal studies are crucial to developing the confidence that a material is safe for human clinical trials. Pivotal trials support-ing a device submission must be conducted under the Good Laboratory Practices Regulations (CFR Part 58). These regulations establish the quality standards for the research data that may be used in support of an FDA application, and help the sponsor of the study to have confidence that the study has been monitored for conduct according to the protocol.

STERILIZATION, SHELF-LIFE, AND AGING

Physical properties and durability of the biomaterial in its intended use are critical parameters to establish. If failures begin to occur in the field, differences from base-line parameters can provide crucial evidence to assist in establishing the root cause. Data demonstrating the shelf-life aging profile of medical device materials is required for an increasing number of new device applications to the FDA. The device manufacturer can expect increasing demands by the FDA for evidence that the device will perform to specification, at least to the expiration date placed on the labeling. Such data are already required if a medical device manufacturer incorporates drugs and/or biologics as a surface treatment or as enhancements

to device performance. Most sterilization processing can affect biomaterial performance in a product to some degree, even though the effects may not be immediately evident. It is known that effects, such as those from irra-diation, may not be immediately apparent but can accel-erate over time. The exact parameters of a sterilization cycle must be defined and documented, and the informa-tion maintained for future reference. The FDA requires that validation of materials performance requirements and safety testing of the device is conducted after the same sterilization cycle that will be applied to the mar-ket-released product. Long-term shelf-life aging studies, which include a variety of sterilization processes, should begin on any new biomaterial as soon as possible so that potential effects of environmental stressors (heat, gas, radiation, oxidation, etc.) can be quantified as early as possible. Such materials aging studies should begin using standardized specimens and well-defined test methods as early as possible, to ensure the candidate material can remain stable within the device under development.

INNOVATIVE TECHNOLOGIES REQUIRE SPECIAL CONSIDERATIONS

Silo-style regulations of drugs, biologics, and devices have proven inadequate to the challenges from novel biomaterial technology. In October 2002, Congress passed the Medical Device User Fee and Modernization Act of 2002 that established the Office of Combination Products. Combination products use device, biologics or drugs in combination to enhance or deliver the desired treatment (or diagnostic). The premarket review juris-diction of such combination products is predetermined by interagency agreement. The FDA has now created a Combination Products website (http://www.fda.gov/CombinationProducts/default.htm) to serve as a portal to various guidance documents and performance reports. As new biomaterials incorporate biologic functions, inte-grate within organ systems to replace lost function, and evolve engineered performance requirements as tissue scaffold devices, more biomaterials will likely fall into the category of combination products. Manufacturers may request the FDA to make a determination of the review authority if the Center with authority is uncer-tain. Early determination of the regulatory pathway for a combination biomaterial application can help developers avoid setbacks due to inadequate scientific assessments. Determining the "mode of action" dictates the regula-tory pathway for a combination product. For combina-tion products, joint review between two FDA Centers is commonly required, and more than one type of premar-ket application may be necessary.

Continued concerns for the safety of biomaterials derived from human or animal products have increased the regu-lations associated with these medical products. The FDA has issued guidance for the use of animal materials used in medical devices. The guidance titled "Medical Devices

Containing Materials Derived from Animal Sources (Except for *in Vitro* Diagnostic Devices") has provided details on the FDA's concerns, and how the FDA expects manufacturers will control the sources of the materials.

Tissue-engineered products designed to replace major organ function are in clinical research, thus the FDA is exploring methods for predictably characterizing the materials that support these novel technologies. The FDA sponsors studies that help to understand the processes surrounding cell maturation, cell signaling, differentiation and formation of organs, and functional tissue. This research will help to contribute to methods for predicting behavior and perhaps quality control testing.

The FDA has formed a taskforce to evaluate how nanotechnology may impact device safety. The taskforce released a report (Nanotechnology Task Force Report released July 2007) which made the case to continue to develop innovative and safe FDA-regulated products, such as "tiny sensors to detect disease markers in the body" to imaging tools, and even packaging that can extend shelf-life. While recognizing the potential for the technology to impact all aspects of medical product assessment, the FDA recognizes that nanoscale biomaterials can have chemical or physical properties that are different from those of the bulk material, including altered magnetic, electrical or optical activity. Nanobiomaterials could have altered structural integrity, and differences in biological activity. Because of their special properties, nanobiomaterials may pose different safety issues, and conventional testing methods may not identify the potential risks.

SUMMARY

Development engineers must document conformance of the product to requirements, and be able to show that the established specifications result in a product that meets user needs. By following the basic steps for Design Control and Review, biomaterials which serve as device components can be demonstrated safe and effective for sale in the global medical device market. Medical device regulations and best practices for evaluating biomaterials in new medical products change faster than book chapters can be updated. This is a broad outline of

the regulatory structures. Consult the FDA website and numerous published resources for the most up-to-date regulations.

CHAPTER III.2.5 PRINCIPLES OF REIMBURSEMENT FOR MEDICAL DEVICES

Fred Cahn
BioMedical Strategies, La Jolla, CA, USA

SIGNIFICANCE OF REIMBURSEMENT

"Reimbursement" is a term used to describe the process by which medical products are paid for. In most cases medical devices are not chosen and purchased by the patient who receives them; instead, they are purchased by a hospital or physician (the "provider") as a necessary component of a medical service that is provided to the patient. Also, in most cases the patient does not pay either the hospital or physician directly for that service; instead, the provider is "reimbursed" for providing the service by a health insurance company or a Government program, such as Medicare in the United States (the "payer"). Thus, if the provider is paid adequately by the payer for providing a medical service, the provider will be willing and able to purchase from the manufacturer the medical devices that are required to perform the service.

There is considerable complexity in the reimbursement processes, and there are many considerations that can go into reimbursement policies for existing and new products. It is important that those responsible for inventing, developing or marketing new medical devices have an understanding of how their products will be reimbursed, because reimbursement is often critical to market success. Thus, reimbursement should be treated as an input to be addressed repeatedly during the design control procedures of a new medical product, beginning with marketing feasibility in the initial design plan. Reimbursement considerations should be addressed in the regulatory strategy, and in the clinical study planning, since these are the stages at which the foundation of a successful reimbursement plan is laid.

BACKGROUND

Health Plans

In the United States, at this time, there is no universal healthcare plan or policy. Patients usually fall into one of the following categories:

*   Private insurance (usually provided by, and mostly paid by, employers for their employees and their families). Private insurance plans generally fall into two basic types:
    *   Fee for service, in which the provider is paid on a per patient visit basis;
    *   Health maintenance organization (HMO) in which the provider is paid on a "capitated" basis (a fixed payment per patient per month), and the provider is responsible for providing all necessary care to the patients in the plan.
*   Medicaid administered by state governments on a fee for service or HMO basis, for residents who are classified as poor or who fall into a special needs category.
*   Medicare, a US Government program for the elderly and certain others. Medicare has both fee for service ("Part A" and "Part B") and HMO (Medicare Advantage) options.
*   Veterans and Military.
*   "Self-pay," representing patients who are not covered by any health plan, and who are expected to pay for services themselves. Self-pay also includes patients in a healthcare plan who wish to obtain services not included ("covered") in the plan (e.g., cosmetic surgery).

Usually, a manufacturer trying to understand the likely reimbursement policies for their product will initially be concerned with trying to understand the policies of Medicare fee for service, which is not only one of the largest plans, but also one in which the policies are relatively transparent because they are defined by public law and by published administrative policies. Many of the policies of large private fee for service plans are also published and easily obtained from the Internet, and frequently they are based on Medicare policies. These fees for service plans usually represent the majority of the market for medical devices, at present.

Because Medicaid policies are different in each state, it is usually too difficult to assemble comprehensive information on them and on veterans or military, unless the product is of special interest to these groups.

Self-pay is a special case that can affect the marketability of certain products. While self-pay may also be practical for routine medical care by some "middle income" patients, very few of these patients have the financial resources to pay for hospitalization. In this case, in the United States, providers can be required to provide emergency care, and they attempt to collect their "charges" (retail prices) from the patient. Most self-pay patients cannot afford to pay all or most of the charges, and their care is subsidized by the provider and by government subsidies to the providers. The result of this situation is that there are certain types of care for which hospital providers frequently lose money, for example, emergency trauma care, which affects younger and often less responsible patients who are frequently not covered by health plans. Hospitals tend to resist the purchase of products that are disproportionately used for these patients.

On the other hand, there are a few products specifically supplied to patients who are willing and able to pay for them, and reimbursement is not an issue (e.g., for cosmetic surgery).

POINTS OF SERVICE

In fee for service plans, reimbursement methods for medical devices depend on the "point of service" where they are used:

*   Physicians' offices
*   Inpatient hospital
*   Outpatient hospital
*   Ambulatory Surgical Center (ASC)
*   Laboratories (for diagnostic devices)
*   Other institutions (skilled nursing facilities, long-term care, etc.)
*   Durable Medical Equipment ("DME," for home use, by prescription)
*   Pharmacy, by prescription (e.g., diabetic supplies)
*   Over-the-counter.

Over-the-counter products are not reimbursed by health plans. Pharmacy fees for service reimbursement are covered under Medicare "Part D" or private pharmacy benefit plans, but very few medical devices are paid for in this way. The "other institutions" are usually not significant users of advanced medical devices, with the exception of chronic wound care. Thus, for the reimbursement of most medical devices, we are concerned primarily in

the reimbursement of physicians, hospitals, laboratories, and DME.

THE "HOSPITAL BILL" AND THE "CLAIM"

In the US, physicians and hospitals are paid separately. Internally, a hospital maintains a "chargemaster," which contains the (retail) prices of all services, goods, and procedures for which a separate charge exists. It is used to generate an itemized patient bill. Similarly, physicians also bill patients for each service they perform. These are the bills that would be presented to a self-pay patient. However, for reimbursement from health plans, the reimbursement is based on negotiated contracts (private plans) or Government rules (Medicare), and the reimbursement process begins with claims from the providers.

There are two basic types of claim, an institutional (hospital) claim and a professional claim (physicians, also used for DME and laboratory). When a physician provides services in his or her office, there will be only a professional claim, but for a service provided in a hospital there will be two separate claims for the same services, one from the physician for his professional services, and one from the institution for use of facilities and supplies. While these claims will include summaries of the hospital or physician charges, these are not the amounts that will be paid. Instead, the procedures and diagnoses are identified on the claims by combinations of codes, which form the basis of the reimbursement system. The format and rules for coding the claims are mandated by the Government for Medicare claims, but in general all payers use the Medicare formats and rules.

CLAIMS PROCESSING

Processing of claims can be divided into three basic components: coding; coverage; and payment.

Coding

All physician and hospital claims include one or more diagnosis codes (Table III.2.5.1). Currently, the ICD-9-CM diagnosis coding system is used, but it is scheduled to be superseded by the ICD-10-CM system in October, 2012.

Hospital inpatient claims also include one or more procedure codes that represent the services performed. Currently, the ICD-9-CM procedure coding system is used, but it too will be superseded soon by the ICD-10-CM procedure coding system. Hospital outpatient and physician claims do not use the ICD-9-CM procedure codes; instead they use two other methods to code procedures and related services:

- CPT procedure codes (published by the American Medical Association, AMA) are five digit numeric codes that identify procedures performed on the physician's claim at all points of service (inpatient, outpatient, ASC, office). CPT codes also identify these procedures on claims by hospital outpatient departments and ASCs.
- HCPCS codes, which are alphanumeric codes issued by the Centers for Medicare and Medicaid Services (CMS (Centers for Medicare and Medicaid Services), the Government agency that administers the Medicare Program), extend the CPT system to identify services not included in the CPT codes, including certain drugs, biologics, and devices.

Another type of code appears on institutional claims: the "revenue code." These codes are used to summarize hospital charges by department; Medicare uses this charge information for statistical purposes to determine payment rates in subsequent years.

Coding Implications for New Devices and Technologies

Codes are the only way the payer can recognize the performance of a procedure or the use of a device in the procedure. Thus, the proper use of existing codes or the creation of new codes can be essential for the use of the device. For physician procedures, the AMA CPT Editorial Panel is the sole determiner of whether existing codes can be used with new technology, as well as whether new codes will be created. The members of the editorial panel are physicians who generally represent their professional societies. Manufacturers do not directly participate in these decisions.

The AMA, following the advice of specialty medical societies that participate in the CPT editorial process, makes these coding decisions; criteria include clinical coherence and the amount of physician time and skill required to perform

TABLE III.2.5.1	Procedure Coding			
Point of Service	**Physician Claim**	**Institutional Claim**	**DME Claim**	**Laboratory Claim**
Physician office	CPT and HCPCS	N/A	HCPCS	CPT and HCPCS
Hospital inpatient	CPT	ICD-9-CM Procedure codes	N/A	N/A
Hospital outpatient or ASC	CPT	CPT and HCPCS	HCPCS	CPT and HCPCS

ASC: Ambulatory Surgical Center.
CPT: Current Procedural Terminology.
HCPCS: Healthcare Common Procedure Coding System.

the procedure (measured by relative value units (RVUs), discussed below), whether the procedure is commonly performed, and whether it provides equivalent or superior clinical results. AMA has a procedure for requesting new codes and for confirming the correct use of existing ones.

For a new product that will be used in a medical procedure, there are several possibilities:

- AMA can decide that it can be used under an existing CPT code. For example, a device improves patient outcomes, but still meets the code description and requires the same amount of skill and work.
- The description of an existing code could be modified or a new CPT code could be created. Generally, creation of a new CPT code takes at least two years.
- Physicians can use a "miscellaneous code;" however, payment is unlikely from Medicare and other payers.
- The AMA can assign a "Level III" code to track its use. No RVUs are assigned; Medicare or other payers nearly always use a level III code as proof that the procedure is "experimental," and thus ineligible for payment.

Resistance to the creation of a new code or to the use of an existing one can arise when a new technology enables a less skilled physician or surgeon, or one in a different specialty, to carry out a procedure.

PAYMENT

Medicare's payments are established by law and Federal regulations. Medicare has different payment systems, depending on the type of claim and the point of service.

Physician Payments for Office Procedures

Physician professional payments are based on "relative value units" (RVUs) that the AMA assigns to each CPT code. The RVU consists of three components: a Work RVU, representing an estimate of the physician skill and time required to carry out the procedure; a "practice expense" RVU; and a malpractice RVU. In the case of Medicare, each of these RVU values is subject to a geographical adjustment, and the sum of the adjusted RVU is multiplied by an annual conversion factor. For private plans, the same logic is frequently used, but the conversion factor would be negotiated.

Most medical supplies, drugs, and devices used in an office procedure are "bundled" into the practice expense. Some relatively expensive drugs and devices are paid for separately, in addition to the RVU-based payment. These are identified by the HCPCS codes, which are reported along with CPT codes on the physician's claim.

Physician Payments for Hospital Procedures

If the procedure is carried out in an institution, a different, lower, practice expense RVU is used, reflecting the lower expenses a physician experiences by carrying out the procedure in an institution. Also, there would be no payment to the physician for HCPCS codes, since the institution purchases those items.

Hospital Payments for Outpatient Procedures

Hospital outpatient departments perform procedures for which the patient is not expected to stay overnight. Under Medicare, outpatient visits are paid by a system called the Hospital Outpatient Prospective Payment System. (Procedures carried out in Ambulatory Surgical Centers (ASC), which perform similar procedures but are private facilities that are independent of hospitals, are paid under a different, but similar system.)

CPT and HCPCS codes identify procedures on outpatient claims. The principle of the outpatient payment system is to group all of the procedures into a single payment amount, called the Ambulatory Payment Classification (APC). The procedure codes, and the diagnosis codes, are used to group procedures that are considered clinically similar, and also similar in terms of the cost to the hospital of the resources (e.g., operating room type and time, staff, supplies, drugs) required, into an APC. Each APC has a payment rate; both the grouping into "similar" resource requirements and the payment amounts are determined by statistical analysis of the codes and charges from prior years' claims. Depending on the services provided, hospitals may be paid for more than one APC, and they may also be paid separately for certain "expensive" drugs and devices (identified by HCPCS codes). Some services, such as clinical laboratory, are not bundled into the APCs; they are paid separately under the laboratory fee schedule.

It is important that companies developing new technology that will be used in hospital outpatient departments have a thorough understanding of the outpatient payment system. Some procedures are disadvantaged because they are relatively expensive compared with the rest of the group, and products used in those procedures may be uncompetitive. There are provisions with rigorous requirements for CMS to recognize and classify entirely new procedures, to pay for certain devices separately, and to provide transitional add-on payments for new technologies. Critical to obtaining favorable classifications or add-on payments is data that shows substantial clinical benefits for the technology, as well as economic data proving the expense to the hospital of employing a new, relatively expensive technology. On the other hand, cost-saving technologies can often be marketed successfully to hospitals.

Hospital Payment for Inpatient Procedures

Hospitals are paid for inpatient discharges according to the Inpatient Prospective Payment System. This system follows the principle of bundling services more

rigorously than the outpatient system. The payment for all of the hospital resources used between admission and discharge, including laboratory, are grouped into a single MS-DRG ("modified severity adjusted diagnosis related group") by a computer algorithm known as the "grouper;" each MS-DRG has a payment amount associated with it. Adjustments are made for geographical and other hospital-specific factors, and there is an additional payment for "outlier" cases, but there are no separate payments for drugs or devices.

An exception is the "new technology transitional add-on payment." This payment pays a portion of the additional cost of using a new technology in an existing MS-DRG. New technologies can qualify for this payment for two to three years; after that, the historical statistical data exists for properly classifying the procedure into the existing MS-DRGs. Requirements for the add-on payment are FDA premarket approval (or rarely, 510[k] clearance), an expected increase in the charges associated with one or more MS-DRGs above a threshold, and demonstration of "substantial clinical improvement." To demonstrate that the charges exceed the threshold, claims data is required. Sponsors can collect these claims during clinical studies, and/or historical charge data can be used to support their claim. If the technology is considered to be eligible for the add-on payment, a new ICD-9-CM procedure code is created by CMS so that the use of the technology can be identified on claims.

As with devices used in hospital outpatient departments, manufacturers developing products that will be used in hospital inpatient departments should have a thorough understanding of how the inpatient payment system will affect the economics of using their product, and the criteria and procedures for obtaining add-on payments.

Private payers pay for inpatient stays in various ways, as specified in contracts between payer and provider. These are not publicly available. They could be a multiple of Medicare's payment, or they may be based on *per diem* rates or a percentage of charges.

Payment for Outpatient Clinical Laboratory Tests

Laboratory tests are identified by one or more CPT codes and paid for by Medicare by a fee schedule. Private payers usually pay laboratories a multiple of the Medicare fee. In many cases, multiple CPT codes identify a single test, and a payment is made for each; for example there could be a code for sample preparation, codes for each analyte tested.

The existence of codes representing components of a test often means that a new test can be coded and paid for immediately under the existing fee schedule. This ability to fit new tests into the existing structure is advantageous for new tests that have similar cost structures to existing ones. However, the introduction of more expensive technologies can be complicated by the time and uncertainty for obtaining a new CPT code, and by the "gap

filling" and "cross walking" methodology that CMS uses to price new tests, which restricts the price that a manufacturer can charge.

Payment for Durable Medical Equipment (DME)

DME represents equipment that can withstand repeated use, primarily serves a medical purpose, and generally is not useful to a person without an illness or injury. DME also includes prosthetics, orthotics, and some medications considered necessary to use the equipment. DME is identified on claims by HCPCS codes. DME is paid under a fee schedule for each state. Medicare is in the process of implementing a competitive bidding process for DME.

COVERAGE

Coverage determines whether a provider will be paid at all. Even if there are codes to identify the procedure, and payment amounts in the fee schedules or prospective payment systems, the combination of procedure and diagnosis must meet the payers' criteria for being "reasonable and necessary," which lacks a common definition.

Usually, coverage is not an issue for inpatient procedures, since the assignment of a procedure code to an MS-DRG includes recognition of its medical necessity. However, physician and hospital outpatient payments identified by CPT and HCPCS codes are usually covered only under limited circumstances. Many are considered to be bundled into the physician or hospital payments for procedures which are covered. Many have no coverage under any circumstance.

Each payer has their own coverage policies and, within Medicare, each regional contractor has its own coverage policy; however, some procedures are covered under National coverage policies. For common procedures, coverage policies of Medicare and most large payers are published on the Internet.

Coverage decisions are made by medical directors, who are usually physicians employed by the payers. The medical directors claim that their coverage decisions are based on principles of "evidence-based medicine" which, however, is loosely defined and inconsistently applied. In practice, evidence-based medicine represents a compilation of peer-reviewed publications, but only studies from controlled randomized multicenter trials are given serious consideration.

It is common for coverage decisions to consider new CPT or HCPCS codes to represent "experimental" procedures (thus not reasonable and necessary), and to demand published peer-reviewed clinical data from large-scale multicenter clinical studies conducted under "real world" conditions that are not practical to conduct on new technologies. Furthermore, essentially all studies on new technology are sponsored by the company developing it, which can bias the results in favor of the technology.

However, publications based on the clinical data submitted to obtain premarket approval from the FDA can be convincing to some or most medical directors.

Frequently, coverage decisions use reports from independent "technology assessment" organizations that compile and assess the published literature and sell these assessments to health plans. However, these reports are of varying quality and may be biased against genuinely new technologies; furthermore, these organizations do not have the resources for thorough and impartial investigations.

A recent development is government financing of "comparative effectiveness" studies sponsored by organizations such as the Agency for Healthcare Research and Quality. Comparative effectiveness studies are directed towards major public health problems, those which affect large patient populations with significant mortality or morbidity, and to treatments that are well-established. Such studies are believed to avoid company bias, and they are able to compare the products of different companies. Company sponsored clinical studies rarely compare their products with the most effective alternatives. (Clinical studies designed to demonstrate "safety and effectiveness" to the FDA frequently compare products with placebo or a "standard of care," which may not be the most effective alternative.)

It can be important for manufacturers introducing new technologies to be aware of the concerns of medical directors. Technologies that add to the payers' expense and also may be used by a large patient population receive special, critical attention. Technologies that result in dramatically better clinical outcomes may be favorably received, even if they are more expensive.

CLAIMS DATABASES

The reimbursement system creates a large body of data that can be of use in understanding the size of markets for medical devices, and for their likely impact on the economics of payers and providers.

Detailed data on clinical procedures and the usage of products in them is available to qualified researchers for purchase from CMS, subject to data use agreements intended to protect the privacy of patients. Data is available for physician claims, hospital outpatient claims, ASC claims, and hospital inpatient claims on a per claim basis, as well as aggregated data, some of which is available for download from the Internet. An analysis of this claims data can be essential in supporting new technology add-on applications for inpatient and outpatient procedures, and can be used to demonstrate to CMS that a particular procedure would fit better into a higher paying APC or MS-DRG.

Medicare data is heavily biased to an older patient population. "All-payer" databases are also available from the National Center for Health Statistics and from the Agency for Healthcare Research and Quality, and from some states. There are also private companies that collect and analyze this data commercially.

CHAPTER III.2.6 CORPORATE CONSIDERATIONS ON BIOMATERIALS AND MEDICAL DEVICES: CASE STUDIES IN REGULATION AND REIMBURSEMENT

Gail D. Baura
Keck Graduate Institute of Applied Life Sciences, Claremont, CA, USA

As previous chapters have demonstrated, developing a new medical device for the US market is a complex process. Certainly, most Class II (moderate risk) and Class III (high risk) devices require US Food and Drug Administration Center for Devices and Radiologic Health (FDA CDRH, often just called "FDA") notification or premarket approval. The premarket submission requires that Good Manufacturing Processes (GMPs), including design controls, be followed. For Class III devices, significant manufacturing controls must also be applied. The manufacturing facility of the new device must be registered, and the device listed. The FDA often inspects the manufacturing facility as part of the approval process. Depending on its market, a new medical device often needs medical and private health insurance reimbursement, so that potential end users can afford to purchase the device. Finally, the US Patent Office (USPTO) requires that claims for a new invention be filed within a year of first public disclosure (often, the offer for sale), in order to protect the invention.

In this chapter we discuss these important issues, within the context of biomaterials for medical devices. Many of these issues are also covered in other chapters, so we focus here on case studies of design controls, described in more detail in Chapter III.2.3, which comprise the fundamental requirements for development of a new medical device. Case studies exemplifying the different considerations for an electrocardiogram (ECG) electrode, a tissue heart valve, and a permanent skin substitute material are highlighted.

REGULATORY STRATEGY

When a product development project is first initiated, it is prudent to determine the regulatory strategy as early as possible, in order to facilitate project planning. Class II devices require less time and resources for a 510(k) submission than do Class III devices for a premarket approval (PMA) submission. A combination product (device + drug, device + biologic) may not even be regulated as a device, but rather as a drug or biologic. Often, a Request for Designation is made to the FDA Office of Combination Products (OCP). If possible, a manufacturer tries to have a specific combination product designated as a

medical device, because regulatory requirements are less substantial compared to those for a drug or biologic.

After the determination has been made that CDRH is the appropriate regulatory center, the company's regulatory department must decide if the device is Class II or Class III. As of 2009, for a Class II device, such as an ECG electrode, one predicate device or a group of predicate devices, whose lineages can be traced to substantially equivalent devices released in the US before May 28, 1976, must be determined. These predicate devices must not currently be considered Class III devices. Most implantable devices have been designated as Class III. A truly new type of device is classified as Class III by default.

Cypher® Stent Regulatory Strategy

Johnson and Johnson's Cordis division developed the first drug-eluting stent that received FDA approval. Each Cypher® stent (Figure III.2.6.1) consists of a stainless steel mesh tube, treated with parylene C, and covered with a basecoat and topcoat. The basecoat is formulated from sirolimus and two polymers: 67% polyethylene-co-vinyl acetate (PEVA) and 33% poly n-butyl methacrylate (PBMA). A drug-free topcoat of PBMA enables controlled release of sirolimus over 90 days. Based on *in vivo* study data, sirolimus inhibits smooth muscle cell migration andproliferation, which aids in the prevention of restenosis (Cordis, 2003).
FIGURE III.2.6.1 Cypher® Coronary Stent (Cordis Corporation, Bridgewater, NJ, USA).

In its Request for Designation to the FDA OCP in 2000, Cordis stated that the primary mode of action for a drug-eluting stent is to provide: "a mechanical buttress that resists mechanical compression," while a coating on the stent serves "the ancillary purpose of retarding formation of intimal hyperplasia." The FDA agreed with this request, and designated CDRH as having primary jurisdiction (OCP, 2000). Cordis filed its Cypher® PMA submission, P020026, on June 28, 2002, and quickly responded to 24 separate requests for additional data by filing corresponding amendments. It received premarket approval for the Cypher® stent on April 24, 2003 (CDRH, 2003a), a total of 300 days.

Whenever possible, Class II status is preferable. Compared to a PMA submission, a 510(k) submission does not require clinical data or manufacturing data. Further, a 510(k) is less expensive to file, and less time is required until the FDA issues its premarket clearance decision. For the fiscal year 2009, the 510(k) and original PMA review fees were $3695 and $200,725, respectively. For fiscal year 2006, the most recent year with available statistics, 510(k) submissions required an average of 95 days between filing and notification. Similarly, original PMA submissions that were approved required an average of 335 days between filing and approval (ODE, 2008). It should be noted that the original PMA approval time for a new type of device, with which the FDA has no previous experience, may easily extend from the 335 day average by additional months, if not years. Approval may require the majority vote of an FDA Advisory Panel. For example, Gensia's GenESA device, which was the closed loop infusion device for the new drug GenESA, required 44 months until CDRH approval (CDRH, 1997a).

MEDICARE REIMBURSEMENT

Equally important to the regulatory strategy is the product's Medicare reimbursement strategy, assuming that reimbursement is critical for product success. Overwhelmingly, Medicare's national reimbursement decisions are adopted by private insurance carriers. Moreover, more clinical studies may be required for reimbursement than for FDA approval. Therefore, it is prudent to begin planning for all these studies, potentially with study overlap, as soon as possible.

The national Medicare coverage process for a new device that is not currently reimbursed generally takes one year. The manufacturer of this new device meets preliminarily with the Centers for Medicare and Medicaid (CMS), and then submits a formal request for National Coverage Determination (NCD). The formal request must include a statement of desired benefit categories, as well as supporting documentation such as the PMA summary of safety and effectiveness data, any 510(k) predicate devices, and a description of any other clinical trials in progress. Within 90 days of receipt of the formal request, CMS determines whether or not to accept the request. If the request is accepted, another 90 days passes, during which CMS accepts 30 days of public comment on the device and, if necessary, generates an internal health technology assessment. The technology assessment may extend this 90 day timeframe. At the end of this 90 day period, a proposed decision memorandum is issued.

During the first 30 days after the proposed memorandum is issued, the public may comment. Within 90 days of when the proposed decision was issued, a final decision memorandum is issued. If the decision is made to provide coverage for the device, CMS makes

this payment change effective within 180 days of the issuance of the proposed decision memorandum. A final decision may be reconsidered or appealed by the manufacturer or any other interested party, such as an insurance carrier or individual. CMS's illustration of the National Coverage Determination process is shown in Figure III.2.6.2.

It is also possible to apply for local Medicare coverage with each of 10 Medicare regions.

Cypher® Stent Medicare Reimbursement Strategy

Separate from the National Coverage Process, Cordis requested a new payment code for reimbursement of the insertion of drug-eluting coronary artery stents. Cordis argued that: "due to the absence of restenosis in patients treated with the drug-eluting stents based on the preliminary trial results, bypass surgery may no longer be the preferred treatment for many patients … Lower payments due to the decline in Medicare bypass surgeries will offset the higher payments associated with assigning all cases receiving the drug-eluting stent." The request was made in the early 2002 timeframe (CMS, 2002b), before FDA approval of the Cypher® stent. CMS solicited comments about the requested procedure code in the Federal Register on May 9, 2002, and approved a new code (effective October 1, 2002) on August 1, 2002 (CMS, 2002a).

DESIGN CONTROLS

During the course of a product development project, design controls are mandated by the FDA. As shown in the illustration of the Waterfall Design Process (Figure III.2.6.3), a product is developed in response to user needs.

The process includes design inputs, the design process, and design outputs. During the design input phase,

requirement specifications and design specifications are written. The inclusion of any FDA-recognized consensus standard in a requirement specification is not mandatory. "Conformance with recognized consensus standards is strictly voluntary" (CDRH, 2007). Regardless of requirement origin, subsequent demonstration that requirements are met must also include sufficient evidence of medical device safety and effectiveness.

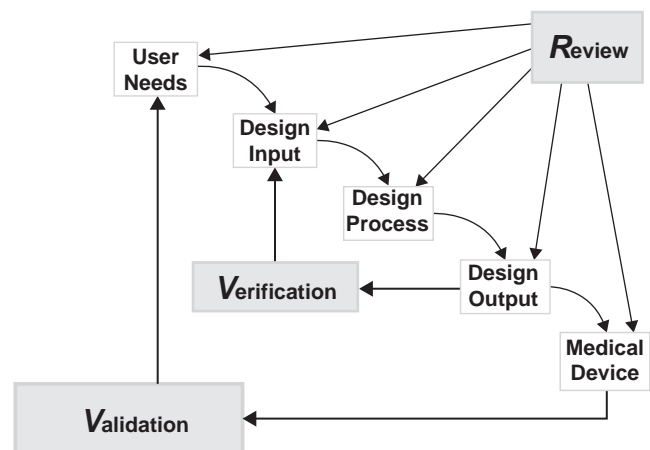
Risk analysis spans both the design input and design output phases. Initial risk analysis, during which potential device hazards are assessed, is clearly part of design input. Based on this analysis, the device design is modified to minimize the occurrence of specific hazards. However, in its guidance document, the FDA states that "the results of risk analysis" are an example of design output (CDRH, 1997b). For the purposes of design control, we consider risk analysis implementation and sign-off to be design output. These days, under ISO 14971: Medical


FIGURE III.2.6.3 Waterfall Design Process (CDRH, 1997b).
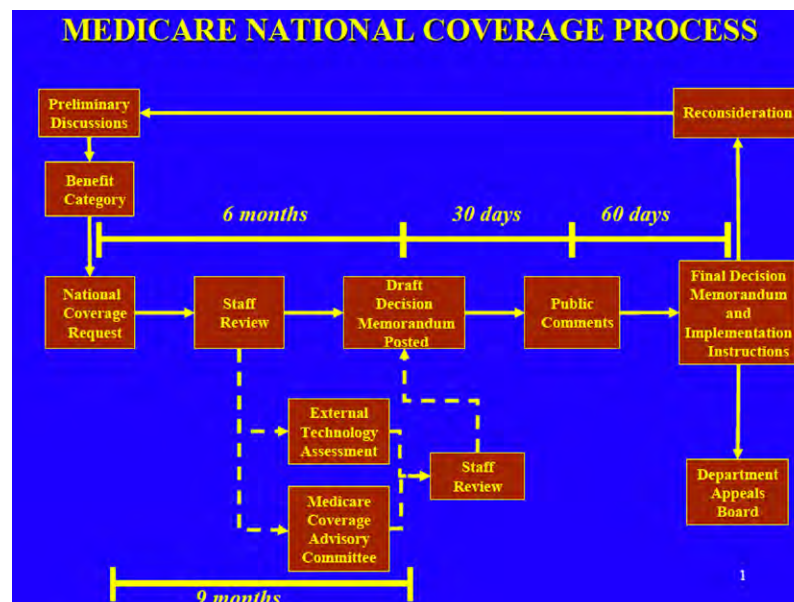

FIGURE III.2.6.2 Medicare National Coverage Process (CMS, 2009).

devices – Application of risk management to medical devices (ISO, 2007), risk management is considered a continuous process which spans well beyond design inputs and design outputs.

During the design output phase, each specific requirement from the design input phase is verified. As part of the design output phase, the new medical device is validated to ensure that user needs and clinical performance requirements are met. During each phase, a design review takes place before moving to the next phase. After validation, the design is transferred to manufacturing. Device documents are maintained in a design history file. While not mandatory for design control, it is helpful to initiate the product development process with a product requirements specification, which is not under rigid document revision control. In this way, initial marketing needs are documented.

Biomaterials Design Controls Examples

In this subsection, we describe specific examples of how biomaterials are handled by design inputs and outputs. The class of the device under development predetermines the testing complexity.

ECG Electrode. For an ECG electrode (Figure III.2.6.4), which is a Class II device, biomaterials specification and testing are relatively straightforward.

A manufacturer typically follows the national standard ANSI/AAMI EC12:2000/(R)2005 Disposable ECG electrodes. In this standard for ECG electrodes, electrical performance and biologic response requirements are defined (AAMI, 2005a). The biologic response requirements for cytotoxicity, sensitization, and irritation point to the national and international standard ANSI/AAMI/ISO 10993-1:2003 Biological evaluation of medical devices – Part 1: Evaluation and testing (AAMI, 2003). In the cytotoxicity tests, the lysis and growth inhibition of mouse fibroblast cells are determined, after exposure to an extract dilution of the electrode adhesive or gel. In the sensitization tests, erythema and edema of

human skin are assessed after two applications of electrode adhesive or gel. In the irritation tests, erythema and edema of rabbit skin are assessed after electrode adhesive or gel application. In addition to these verification tests, the manufacturer may wish to provide validation clinical data demonstrating that human heart rates determined with the ECG electrode under test are insignificantly different from heart rates determined with a predicate ECG electrode. However, clinical data are not required for a 510(k) submission. This type of simple 510(k) submission is typically cleared by the FDA within 90 days.

Tissue Heart Valve. For a porcine tissue heart valve, which is a Class III device, biomaterials specification and testing becomes more complicated. Indeed, to demonstrate safety and effectiveness of the Carpentier-Edwards S.A.V. Bioprosthesis Model 2650 aortic valve (Figure III.2.6.5), ISO 10993 testing, animal studies, and clinical trials were performed.

This valve consists of a porcine aortic valve mounted on a flexible frame. The recovered porcine valve tissue is treated with ethanol and polysorbate-80, and packaged and terminally sterilized in glutaraldehyde.

As with the ECG electrode, cytotoxicity, sensitivity, and irritation tests were performed, using samples of materials involved in the valve manufacture. Some of these materials were silk suture thread, silicone rubber, and polyethylene terephthlate cloth and film. Additionally, other ISO 10993 tests were performed to assess genotoxicity, hemocompatibility, systemic toxicity, and implantation.

As a precursor to clinical trials, *in vivo* animal studies were conducted. Since these studies were conducted in the 2001 timeframe, they followed the FDA Draft Replacement Heart Valve Guidance of 1994 (CDRH, 1994). However, the animal studies are consistent with the current national and international standard ANSI/AAMI/ISO 5840:2005 Cardiovascular implants – Cardiac valve

FIGURE III.2.6.4 Red Dot™ Foam ECG Monitoring Electrode (3M, St. Paul, MN, USA).

FIGURE III.2.6.5 Carpentier-Edwards S.A.V. Bioprosthesis Model 2650 Aortic Valve (Edwards Lifesciences, Irvine, CA, USA).

prostheses (AAMI, 2005b). Eleven juvenile sheep were implanted with the valve in the aortic or mitral position for five months. Similarly, 12 weanling rats and 12 juvenile rabbits were implanted subcutaneously with porcine aortic valve tissue for 90 days. In both studies, histopathology and calcification were assessed. In the sheep study, hemodynamic performance was also assessed.

Finally, before PMA submission in 2001, clinical trials were conducted. Again, the clinical trials followed the FDA Draft Replacement Heart Valve Guidance of 1994. These studies do not meet the current requirements of ISO 5840:2005 in terms of minimum number of enrolled patients. In one prospective study, the adverse event rates were recorded at one year for valve-related mortality, explants, reoperation, bleeding, endocarditis, hemolysis, nonstructural dysfunction, perivalvular leak, structural valve deterioration, thromboembolism, and valve thrombosis (Edwards, 2002). The time interval between premarket submission and FDA approval for this aortic tissue valve was 11 months. Eight amendments were required during the approval process (CDRH, 2002).

In the current version of ISO 5840:2005, a minimum of 150 tissue valve patients are followed for at least five years each. The complication rates for structural valve deterioration, thromboembolism, valve thrombosis, anticoagulant-related hemorrhage, endocarditis, valve dysfunction/paravalvular leak, and re-operation are recorded at one year. The complication rates for similar criteria are recorded at five years. In both cases, the observed complication rates must be within acceptable complication limits (AAMI, 2005b).

Permanent Skin Substitute. Design controls for Class III devices with which the FDA has little or no previous experience are the most difficult. As already discussed, requirements are to be determined by the manufacturer, regardless of accepted consensus standards. A device that meets these requirements must demonstrate safety and effectiveness in its FDA premarket submission. The threshold for this demonstration is made solely by the FDA.

When Advanced Tissue Sciences (ATS) submitted its request to market its Dermagraft® permanent skin substitute in December, 2000, it did not realize that 57 months would elapse before FDA approval. Dermagraft® is a cryopreserved dermal substitute composed of human fibroblasts, extracellular matrix, and a bioabsorbable scaffold (Figure III.2.6.6).

No FDA consensus standard existed in 2000, upon which permanent skin substitute submission requirements and testing could be based. In order to obtain the Indication for Use of "treatment of full-thickness diabetic foot ulcers greater than six weeks duration," ATS worked with the FDA on study protocols whose positive results would demonstrate safety and effectiveness. When ATS met with the FDA General and Plastic Surgery Devices Panel in January, 1998, its biocompatibility

FIGURE III.2.6.6 Dermagraft® Skin Substitute (Advanced BioHealing, Westport, CT, USA).

results were accepted. The cytotoxicity, irritation, systemic toxicity, genotoxcity, and stability/shipping data were deemed "adequate." It was not stated in the Panel meeting transcript if any of these tests were based on ISO 10993 specifications.

The Panel voted 7-to-2 in favor of approval with a postmarket study, in order to resolve questions about data from two clinical trials. Specifically, only a subset of patients in the pivotal randomized clinical trial met the intent-to-treat hypothesis. While this subset was treated with grafts within a retrospectively determined narrower therapeutic range of cell viability, the therapeutic range was not statistically validated (CDRH, 1998a). After the Panel meeting, the FDA continued to raise concerns with ATS about the narrower therapeutic range issue (ATS, 1998). Moreover, the premarket approval manufacturing inspection for Dermagraft® resulted in a warning letter citing issues related to contaminants, and corrective and preventive action procedures (CDRH, 1998b). On June 10, 1998, premarket approval was denied (ATS, 1998).

ATS was required to validate this therapeutic range of cell viability with a second pivotal randomized clinical trial. In its second PMA submission, ATS demonstrated in 314 patients that 91% of Dermagraft® patients had wound closure at 12 weeks, compared to 78% of the control patients ($p = 0.044$). Further, it demonstrated that the ulcers of Dermagraft® patients significantly closed faster than ulcers in the control group ($p = 0.040$) (ATS, 2001).

Because of the extended three year delay between the Panel meeting and FDA approval in September, 2001 (CDRH, 2001), ATS accumulated more debt before shipping Dermagraft® to market. ATS filed for bankruptcy in 2002, and sold its assets to its joint venture partner Smith & Nephew. After Dermagraft® failed to gain FDA approval for an additional indication for venous leg

ulcers in 2005, Smith & Nephew sold the technology to Advanced BioHealing in 2006 (Stuart, 2008).

From a general business perspective, being first-to-market is a competitive advantage for achieving the dominant market share. However, from a medical device industry perspective, being first-to-market with a Class III device means being first-to-deal with the FDA, which is an unpredictable process.

MANUFACTURING CONTROLS

Manufacturing controls partner with design controls to ensure product quality and safety. These controls oversee the manufacturing process and manufacturing facilities. At the front end of the manufacture of a specific device, purchasing controls are required for evaluating suppliers. Production and process controls are required to eliminate environmental and contaminant concerns. Inspection, measuring, and test equipment must be regularly calibrated and maintained. Manufacturing processes must be validated. Procedures must be in place for receiving acceptance activities, final acceptance activities, and nonconforming products. Corrective and preventive action, complaint file handling, installation, and servicing (where appropriate) procedures are also required (CDRH, 2003b).

For a PMA submission for a Class III device, a complete description of implemented manufacturing controls is required. While a manufacturing controls description is not required for a 510(k) submission, it is assumed that manufacturing controls are in place for the Class II device under review.

REGISTRATION, LISTING, AND INSPECTION

A manufacturer must register each of its facilities annually with the FDA, and list devices that are specified or manufactured at each facility. As of the fiscal year 2008, a fee must be paid during annual registration. For fiscal year 2009, this fee is $1851.

Registration, listing, design controls, and manufacturing controls are verified during an FDA inspection. Generally, a manufacturer is notified one week before the inspection occurs.

An initial inspection of a manufacturer's facility is conducted before its first product is market released. For Class III devices only, an inspection is generally conducted during the PMA submission process. (This is the inspection for which ATS received a warning letter.) However, if two PMAs are being reviewed during the same year period for a mature company, a second inspection may not occur. For both Class III and Class II devices, an inspector also returns to review a device recall, correction, removal or reported medical device complication. An inspector may also visit to follow up on observations from a previous inspection, which had been documented in a Form 483 warning letter.

INTELLECTUAL PROPERTY

While a few companies still patent *all* their new technologies, these days it is more cost effective to patent only technologies that create a barrier to market entry for competitors. A US patent can easily cost $25,000 to $30,000 from initial filing to issue. This cost includes attorney fees and US Patent Office (USPTO) fees. For the fiscal year 2009, the basic USPTO fees for filing a utility application, assuming at most 20 claims, total $1310. If other countries are chosen for protection, then the cost for issued patents escalates exponentially.

Three types of US patents exist: design; plant; and utility patents. A design patent protects the look or ornamentation of an article of manufacture. A plant patent protects the discovery and asexual reproduction of any distinct and new variety of plant. A utility patent protects a process, machine, article of manufacture or composition of matter.

In order for an invention to be protected as a utility patent, it must be utile, novel, and not obvious. Utility is not a high threshold to cross. An invention may be broadly interpreted to be useful, as long as it is not a law of nature or abstract idea. For an invention to be novel, it cannot be known or used by others anywhere in the world, more than one year before the inventor files his/her US patent application. Therefore, any previous public disclosure of the invention by another person, such as in an obscure foreign abstract or in an abandoned US patent, acts as prior art. If the inventor has publicly disclosed the invention, they must file for a US patent within one year of disclosure. Any similar prior art must not be obvious. In other words, a person having ordinary skill in the art of the invention must not consider the invention to be apparent. An example of obviousness would be the combination of two previous inventions.

The patent attorney representing the inventor writes broad claims for the invention, and negotiates with USPTO for allowance of these claims. For an issued patent, the invention is generally protected for 20 years from the date of US filing.

An issued patent does not guarantee that another company will not infringe on the patented invention. When this occurs, the company of the inventor is often forced to sue for infringement of specific patent claims. In anticipation of defending patent claims in the future, an inventor provides a written description, enabling disclosure, and best mode of the invention in the patent specification (the patent application text that excludes the claims) at the time of patent filing. The enabling disclosure refers to the requirement that a person having ordinary skill in the art of the invention would be taught by the patent how to make the invention. The best mode refers the best design of the invention being claimed at the time the patent application was filed. When an infringement lawsuit goes to trial in a US District Court, a jury decides the case. Either party may appeal the decision to the Court of Appeals for the Federal Circuit.

The Cypher® Stent US Patents

In 2005, in the US District Court of Delaware, Johnson and Johnson's Cordis's Cypher® stent (Figure III.2.6.1) was found to infringe on Boston Scientific's drug-eluting stent patent US 6,120,536. Claim 1 in patent '536 describes a drug-eluting stent with a coating containing a non-thrombogenic surface. Cordis appealed to the Court of Appeals for the Federal Circuit, stating that the Boston Scientific claim was obvious, in light of similar claims from Medtronic patent 5,545,208 (Figure III.2.6.7). In January, 2009, the Court of Appeals reversed the original judgment: "because the court erred as a matter of law in failing to hold the '536 patent to have been obvious" (United States Court of Appeals for the Federal Circuit, 2009).
FIGURE III.2.6.7 An illustration of the stent covered by Medtronic's US patent 5,545,208 (Wolff and Hull, 1996).

Developing a medical device with key biomaterial components for the US market is not for the faint of heart. Especially with these devices, it becomes an art to navigate the regulatory roads towards FDA approval and Medicare reimbursement. In this chapter, we have discussed issues which are important for releasing a device to the US market: regulatory strategy; Medicare reimbursement; design controls; manufacturing controls; registration, listing, and inspection; and intellectual property. We leave it to others to discuss these changes and issues for market released products, such as US postmarket surveillance, medical device reports, corrective action and preventative action, and recalls (Baura, 2012). As this chapter goes to press in 2012, the FDA is considering major changes to the regulatory process.

CHAPTER III.2.7 ETHICAL ISSUES IN BIOMATERIALS AND MEDICAL DEVICES

Taufiek Rajab[1], Andrew L. Rivard[2], Karen R. Wasiluk[2], Robert P. Gallegos[1], and Richard W. Bianco[2]

[1]Brigham and Women's Hospital, Boston, MA, USA

[2]Department of Surgery, University of Minnesota, Minneapolis, MN, USA

INTRODUCTION

Ethics is the branch of philosophy that addresses questions of morality. Biomedical ethics, therefore, narrows this focus onto the morality judgments that must be made in the field of medicine, and its allied subjects including biomaterial science. Biomaterial science has evolved at a tremendous pace, with innovations that have empowered clinicians and scientists beyond the imagination of their predecessors. This empowerment has resulted in new sets of ethical questions that were not posed previously. Questions of morality have direct relevance to the practical work of scientists and clinicians in the field as the influence of Institutional Review Boards and ethics committees continues to grow. Furthermore, there is also increasing public scrutiny of biomedical science in general. Therefore, it is important that engineers, scientists, and physicians become familiar with the relevant ethical issues, and actively participate in the debate that guides professional standards in the field of biomaterial science.

Medical device innovation often originates with an observation by a creative individual who encounters a problem in clinical practice and postulates a possible solution. To reach this solution, a linear pathway from the original idea through bench research, preclinical testing in an appropriate animal model, followed by clinical trials and eventual human use is intuitive. However, this linear pathway does not reflect the complexity of innovation. In reality, biomaterial development is recursive, with multiple iterations that may return to *in vitro* and *in vivo* testing multiple times, due to the highly regulated environment that is necessary to ensure safety for human patients. Each phase of this recursive process, including ideation, bench-work, animal research, and clinical research, has its own unique ethical requirements, which manifest in regulatory guidelines. This chapter will focus on the ethical principles that have been established and applied to the field of biomedical research and development. At the conclusion of this chapter, we will describe a pathway for the development of a new prosthetic heart valve which will be used to illustrate the application of biomedical ethics as it applies today.

PROTECTION OF PATIENTS

The paramount ethical principle in biomaterial research is the protection of patients. With this goal in mind, the US Food and Drug Administration (FDA) has established a set of regulatory guidelines to standardize studies related to medical devices. As a result, scientific investigation into the development of medical devices must be performed in accordance with defined best practice standards, which carry the weight of law. Preclinical studies must use Good Laboratory Practice (GLP), the manufacture of devices must follow Good Manufacturing Practice (GMP), and clinical trials must be in compliance with Good Clinical Practice (GCP). These Good Practice guidelines are quality systems concerned with organizational processes that are founded upon ethical principles and ensure accountability at every level from the designers, the manufacturers, and the investigators.

GOOD LABORATORY PRACTICE

Preclinical studies must be conducted according to good laboratory practice (GLP). GLP is outlined by the Organization for Economic Cooperation and Development (OECD), an international organization which countries may apply to become members. Therefore, data collected under GLP standards is accepted much more readily, as it is considered to be of exceptional quality as opposed to data obtained without adherence to GLP. Within the Code of Federal Regulations, the FDA has outlined rules for GLP. All preclinical studies in the United States that use animals must be performed using GLP prior to clinical studies in human patients. Results, either from preclinical studies in the United States that are not conducted in compliance with the FDA rules, or from studies performed in countries outside the United States that do not conform to GLP guidelines, may be inadmissible in support of an Investigational Device Exemption for use in human subjects. In a preclinical study conducted using GLP each involved entity has defined responsibilities.

The research sponsor is responsible for informing the contract laboratory that the preclinical study must be performed using GLP, and for monitoring contracted studies to make sure they are compliant. Management responsibilities include designating study directors, overseeing adequate quality assurance, ensuring that all articles are appropriately tested and that all personnel understand their roles. They also approve standard operating procedures and verify that resources are available. Management should also determine that the facility itself is GLP-compliant, document approval of the study plan, and verify that the study plan is available for inspection and quality assurance. The monitor may serve as the liaison between the sponsor and the study director, assess scientific and technical capabilities of sites to meet the requirements of the study, and be responsible for providing characterized test materials to the laboratory where the GLP study is to be performed. Study directors have overall responsibility for the performance of a study, including the interpretation, analysis, documentation, and reporting of the results. As such, the study director represents

the single point of control for a study, and ensures that a defined study plan is followed. Raw data should be fully documented, and it must be accessible for inspection by the monitor. Documentation of studies performed using GLP should be complete enough to allow experiments to be accurately reproduced by another laboratory. Study directors must also be prepared to document any deviation from the study protocol, as well as to note unforeseen circumstances affecting the integrity and quality of the data, and must take corrective action if necessary. Principal investigators may be assigned to oversee parts of a study performed at a test site, and to ensure that all phases of the study are conducted in accordance with GLP and the study plan. They are also obliged to ensure that experimental data are recorded accurately, and that deviations from the study plan or operating procedures are communicated promptly to the study director. Principal investigators should also sign a compliance statement regarding the phase of the study conducted at their test site for the study director's final report. Study personnel have the responsibility of following all protocols, reporting any deviations to the study director, keep their training updated, and informing the study director of any unusual responses or unforeseen circumstances. Finally, the quality assurance unit reports to management separately from the study director and all other study personnel and is responsible for monitoring each study to make sure that it is compliant with GLP. They are responsible for inspecting the study at intervals that ensure the integrity of the data and maintaining signed records of each periodic inspection with any problems and corrective actions taken. The quality assurance unit should also review the final report to ensure that all reported methods and results accurately reflect the raw data.

In summary, GLP is a quality system that ensures the integrity and quality of data supporting the approval and eventual manufacture of a regulated medical device. It includes compliant organization and management, a defined study plan, defined standard operating procedures, suitable facilities and material, documentation and archiving of results, as well as an independent quality assurance program. Personnel at every level of the study must understand how their role in the research is conducted within GLP regulations.

GOOD MANUFACTURING PRACTICE

Good manufacturing practice (GMP), also known as current GMP, constitutes a series of quality system requirements that govern the methods, the facilities, and the controls used by manufacturers, processors, and packagers of medical devices intended for human use. GMP ensures that all finished products are safe and in compliance with the US Federal Food, Drug, and Cosmetic Act as mandated by the FDA. GMP regulations address all facets of manufacture of medical devices, but most GMP requirements allow manufacturers the flexibility

to individually determine how they will comply with the required controls. Design controls ensure that specified design requirements are met. These controls include design validation, as well as an archived design history of all changes to the design. Document controls require manufacturers to designate an individual or individuals to review and approve all documents and subsequent changes. Identification and traceability controls mandate that each unit, lot or batch of finished devices must be identified with a control number. Production and process controls ensure that devices conform to their specifications by establishment of check-points where deviations from device specifications could occur as the result of the manufacturing process. Acceptance controls include inspections, tests, and other verifications to ensure that only accepted products are used, installed or distributed. Procedures for controlling nonconforming product must be established, including the documentation of corrective and preventative actions. Labeling and packaging controls ensure appropriate handling, storage, and distribution in order to prevent mix-ups, damage, contamination or other adverse effects on the products. All records need to be maintained in a location accessible to manufacturing officials and FDA inspectors. These include the device design, the design history records, the quality system records, and all complaint files. By mandating these controls, the GMP regulations aim to protect patients from defective medical devices, and ensure that high-quality products are manufactured.

GOOD CLINICAL PRACTICE

Once pre-clinical assessment has indicated that an investigational biomaterial or medical device is suitable for use in human patients, clinical trials must be designed according to good clinical practice (GCP) guidelines. GCP protects the rights of human subjects participating in clinical trials consistent with ethical principles, and ensures the integrity of clinical research data. Therefore, GCP defines a standard for clinical practices which encompasses the design, conduct, monitoring, termination, audit, analysis, documentation, and reporting of the studies and which ensures that the studies are scientifically and ethically sound, and that the clinical properties of the product or device under investigation are properly established (World Health Organization, 1995). All clinical trials should be conducted in accordance with the following ethical principles, based upon the Declaration of Helsinki. A clinical trial should not be initiated unless the anticipated benefits outweigh the risks. Furthermore, the rights, safety, and well-being of trial subjects take precedence over the interests of science and society. Clinical trials should be scientifically sound and described in a detailed protocol that is subject to review by an institutional review board or independent ethics committee. Informed consent must be obtained without coercion from each subject prior to participation. Each

individual providing medical care to the trial subjects should be qualified to do so. Confidentiality of records that could identify subjects should be protected in accordance with applicable regulatory requirements. Investigational products should be manufactured, handled, and stored according to GMP, and used in accordance with the approved protocol. Quality assurance systems for every aspect of the clinical trial should be implemented. By conducting clinical research in accordance with these ethical principles, GCP provides a basis for ensuring that participants in clinical trials are not exposed to undue risk, while guaranteeing that data generated from the research are valid, accurate, and fully documented.

PROTECTION OF RESEARCH SUBJECTS

In addition to their moral obligation towards patients, scientists and clinicians involved in biomaterial research have an obligation to protect their research subjects. This includes animals as well as human subjects.

Animal Use and Care

Although biomaterials undergo rigorous procedures during *in vitro* testing, this process is limited in that the assessment cannot provide definitive evidence of human safety and efficacy. Animal models are designed for anatomical, physiological, and pathological similarity to humans. *In vivo* models can provide information about the performance of a biomaterial within the context of complex interrelated living systems which can be extrapolated to human patients. Therefore, the results of animal studies have direct implications for patient safety, as well as unforeseen catastrophic events. However, animals have a moral standing even with respect to human beings, as discussed specifically in Chapter II.3.6 of this volume). Consequently, research scientists have a moral obligation not only to human patients, but also to their animal subjects. When using animals for biomaterial research, humane care and ethical treatment of the animals is essential. Guidelines with standards for treatment of animals as research subjects were first published in 1963 by the Institute of Laboratory Animal Resources. Two basic ethical principles relate to the use of animals in biomaterial research. Firstly, experimentation on living animals should be reduced to the minimum necessary to obtain the necessary scientific information. Secondly, pain, distress, and other harm to the animals used should be reduced to the minimum necessary to obtain valid scientific data. Only biomaterials and medical devices exhibiting the most promise with regard to biocompatibility, function, and efficacy through rigorous *in vitro* laboratory testing should proceed to a preclinical *in vivo* assessment using an animal model. Preclinical assessment is required for FDA approval for a device to proceed into a clinical trial. The primary purpose of *in vivo* testing is to provide a critical assessment of safety in humans, with a secondary purpose of determining efficacy in the context of comparable technology. Given the growing public sensitivity to the use of animals in research, extra care must be taken to recognize and comply with the current definitions of humane animal use and care.

Activities involving live animals should be overseen and guided by the Animal Care and Use Committee of the sponsoring institution. Investigators also need to design studies in compliance with local laws and regulations. In the United States, FDA guidelines assume compliance with the Animal Welfare Act, which governs the use of animals in research (see discussion in Chapter II.3.6 of this volume), and also related guidelines of AAALAC (Association for Assessment and Accreditation of Laboratory Animal Care), and the National Institutes of Health (NIH) (Public Health Service (PHS) Policy on Humane Care and Use of Laboratory Animals, 2002). These guidelines are enforced by the Animal and Plant Health Inspection Service (APHIS) of the US Department of Agriculture. Specific species are covered by this Act (including non-human primates, dogs, cats, rabbits, and guinea pigs), while other species are specifically exempt (mice, rats, and birds specifically bred for research use, as well as horses and other livestock species used in agricultural research). The Act also provides specifications for the procurement of animals from licensed suppliers, as well as husbandry and veterinary care. Institutions that use species covered by these regulations must be registered by APHIS and submit annual reports that contain a categorization of all animals used by the institution in the previous year with respect to the level of discomfort the animals were subject to during the course of research procedures. Regulations also require all research protocols involving animals to be reviewed and approved by an Institutional Animal Care and Use Committee prior to the initiation of the proposed study. In addition to a detailed plan of the investigation, submitted research protocols must include a discussion of alternative approaches that are less harmful to the animals, as well as a justification for the number of animals required to address the purpose of the study without being unnecessarily duplicative. In addition to the federal guidelines, some state governments have mandated additional regulations. For example, at some state-supported institutions Institutional Animal Care and Use Committee reports and deliberations must be conducted in public (e.g., Florida, Massachusetts, North Carolina, and Washington). Different regulations may apply in other countries and jurisdictions.

Human Research Subjects

Origins of human research subjects' protection are found in the Nuremberg Code, which outlined standards developed for the Nuremberg Military Tribunal against which the human experimentation conducted by Nazi Germany was judged. The Nuremberg Code outlines many of the guiding principles inherent in ethical conduct of research

involving human subjects. These include freely given informed consent without coercion, as well as the option for the human subject to withdraw at any time from the study. In 1964, the 18th World Medical Assembly in Helsinki, Finland adopted the Declaration of Helsinki, which made recommendations similar to those found in the Nuremberg Code. In the United States, the NIH issued Policies for the Protection of Human Subjects in 1966 that were based on the Declaration of Helsinki. In 1974, the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research was established and issued recommendations four years later that were titled the Belmont Report. This report identifies both basic ethical principles of research involving human subjects, as well as guidelines for conducting research in accordance with these principles. The main tenets defined by the Belmont Report are firstly respect for persons (recognition of autonomy and personal dignity of individuals, as well as special protection of those persons with diminished autonomy), secondly beneficence (the obligation to maximize anticipated benefits), thirdly non-maleficience (minimizing possible risks of harm), and finally justice (fair distribution of benefits and burdens of research). These tenets continue to form the basis of all acceptable conduct of research involving human subjects. Based on the Belmont Report, the Department of Health and Human Services (DHHS) codified regulations relating to protection of human subjects, and in 1991 the Federal Policy for the Protection of Human Subjects (or "Common Rule") was adopted. This policy was designed to unify the protection system for human subjects in all relevant federal agencies that conduct, support or otherwise regulate human subjects' research. Regulatory compliance is monitored through routine site visits and audits conducted by federal officials, as well as through the establishment of Institutional Review Boards (IRB).

Any biomaterial investigator involved in human subject research will be regulated by an IRB. The overarching purpose of an IRB is to ensure that all research is conducted with appropriate safeguards for human subjects, as mandated by the federal regulations. An IRB is a group made up of at least five individuals with diverse experience and expertise to professionally qualify the group to adequately review and monitor research activities involving human subjects that are commonly conducted by the institution. The IRB has the legal authority to approve, disprove or require modifications in the experimental design of research activities involving human subjects at the institution with which it is affiliated. Although each institution may have additional committees that review proposed research involving human subjects, no research may be initiated that has not been approved by the IRB. While the IRB overall must possess the scientific expertise to review a specific research design, the membership of the IRB must include at least one member with interests that are primarily scientific, and one member with interests that are primarily nonscientific. Members of an IRB should make every effort to avoid gender or race bias, and the member from the community at large should be a suitable representative. The number of members of an IRB can exceed the proscribed number of five, but it should not become so large that it can no longer function effectively. Investigators may be members of an IRB, but they may not participate in the review and approval of any project in which a potential conflict of interest could arise. The basic IRB review of a submitted protocol focuses on the following components: a risk/benefit analysis; adequacy of informed consent; appropriate selection of subjects; ongoing monitoring of subjects; mechanisms to ensure confidentiality; examination of additional safeguards; evaluation of incentives for participation; and plans for continuing review. The risk–benefit analysis aims to determine whether the risks to the subject are reasonable in relation to the benefits to the subject. Risk analysis is a formal procedure that includes hazard identification, evaluation of failure modes, risk estimation, risk evaluation, risk control, and continuous risk review. The risk analysis is based on the evaluated biomaterial or medical device, as well as the manufacturer's claims attributed to it. It also takes into account whether the device is novel or just an incremental modification of an existing device. The risks associated with the research are also distinguished from the risks of therapies that a subject would face, even if not participating in the research. It is important to determine that the probability and degree of harm associated with the research has been minimized as much as possible. When reviewing protocols involving medical devices, both the risks of the device and the risks associated with the procedure for using the device (e.g., the surgery to implant a heart valve) must be taken into consideration. Sponsors should make the initial risk assessment along with the study proposal. If the device study presents significant risk, the sponsor must submit an Investigational Device Exemption (IDE) to the FDA for approval. The sponsor must communicate the results of the IDE to the IRB. If the IRB finds that a device study presents non-significant risks only, the study may proceed without submission of an IDE. Adequacy of informed consent is another important consideration for the IRB. Human research subjects also need to be provided with an accurate and fair description of the anticipated risks, benefits, and possible discomforts. Federal regulations also require that the following information be provided to each subject as part of informed consent: a statement that the study involves research; explanations of the purposes; expected duration; descriptions of any planned procedures (including identification of procedures that are experimental); reasonably anticipated risks or discomforts; benefits to the subjects or to others; a disclosure of alternative treatments or procedures if they are advantageous to the subject; a statement describing confidentiality of records; contact information; and a statement that participation

is voluntary and that refusal to participate will not result in the loss of benefits to which a subject is entitled. For research involving more than minimal risk there should be explanations of compensation or medical treatments available if injury occurs as a result of the research. The IRB also needs to ensure that the informed consent document presents the information to prospective subjects in language that can be easily understood, even by those with no medical background. Sometimes it is also appropriate that subjects be re-educated and consented periodically. The criteria for selection of subjects should take into consideration the requirements of the scientific design of the study, the susceptibility to risk, the potential benefits, and whether the selection of subjects from a proposed subject population is equitable (i.e., depending on the benefit of the study to the population as a whole, rather than disproportionately favoring one segment of the population). IRBs should also evaluate whether adequate precautions are taken to safeguard the privacy of information linked to individuals that will be recorded as part of the study. Subjects should be informed that federal officials have the right to inspect research records as part of their regulatory oversight. The initial IRB review of a protocol also includes an assessment of how often a research project should be re-evaluated by the IRB. Repeated monitoring is crucial, as preliminary data may indicate that the research design or the information presented to subjects must be changed, or even that the study should be terminated before the scheduled end date. Only after research has begun can the preliminary data be used to estimate the actual risk–benefit ratio.

Although institutions are ultimately responsible for ensuring that all regulatory requirements relating to human subject research are met, IRBs and investigators also bear part of that responsibility, and can be held accountable. At the level of the investigator, the most likely sources of noncompliance include failure to submit protocols or changes in approved protocols in a timely fashion to the IRB, and problems with obtaining informed consent. Often the IRB can resolve these deficiencies without jeopardizing the safety of the research subjects. However, research involving human subjects conducted by an investigator who has avoided or ignored an IRB cannot be allowed to proceed. Once discovered, the IRB and the institution must halt the research and take measures to correct any regulatory infractions. The fitness of the investigator to engage in research involving human subjects should also be evaluated. Noncompliance with regulations can also occur at the level of the IRB. This may arise from inadequate review of research protocols, not conducting a continuous review of research with a frequency that is commensurate with the degree of risk to subjects, failing to maintain adequate records, and consistently holding meetings without the majority of members present. Failure of an IRB to perform their responsibilities in accordance with DHHS regulations can be grounds for suspension or withdrawal

of the institutional assurance. Finally, noncompliance at the institutional level is usually the result of a more systemic failure to meet their responsibilities. Institutions must provide appropriate staffing and support of an IRB so that it can function in accordance with the regulations, as well as ensure that investigators meet their obligations to the IRB as an integral part of their research using human subjects.

CONFLICTS OF INTEREST

In the process of developing a biomaterial, investigators may become involved with the business aspects of the technology. Examples include patents, company stock, royalties, a contract or other financial compensation from the medical device company, the academic institution or both. It is desirable to achieve a balance such that these rewards do not unduly influence data collection and analysis. Since research data are vulnerable to alteration by unethical participants, it is vital that principal investigators, companies, and academic institutions manage both perceived and real conflicts of interest to ensure accountability at all levels. Such potential conflicts of interest are common, and should ideally be identified and managed by the academic institution. A simple disclosure of financial interests may be enough to manage a conflict. However, in other circumstances the perceived conflict of interest may be so great that it is prudent to remove the conflicted individual from the research setting.

CONCLUSION

The emphasis of the above sections has been that compliance to ethical standards is crucial in facilitating good biomaterials and medical device research. Ethical investigators must conduct good science in the setting of GLP, GCP, and GMP standards. The rights of patients, as well as research subjects, need to be protected. Conflicts of interest should be disclosed and managed appropriately. These fundamental elements can then come together to form medical advances, which ultimately improve patient safety and healthcare outcomes. It is the full responsibility of all those contributing to the biomedical and device industry, and those advancing clinical healthcare, to abide by these widely accepted ethical standards.

A PRACTICAL EXAMPLE: THE DESIGN OF A NOVEL HEART VALVE

In this section, we will frame our discussion of the ethical principles in biomaterial research using the example of the process of designing a new heart valve. The development and ultimate production of a new heart valve begins with the incorporation of novel technology. This may either be a significant change in design or the inclusion of a new biomaterial that may improve

the performance of the valve. There are many stages of assessment through which a device must be characterized before it is approved for use in human patients. In each stage there may be test results which prompt a return to further *in vitro* or *in vivo* testing, disrupting the linear progression of development. These recursive iterations are vital to ensuring maximum patient safety and efficacy of the valve. Following the development of a prototype valve, the first *in vitro* assessments are performed. This subjects the valve to conditions that exceed physiologic limits to determine durability, wear, and hemodynamic properties. All *in vitro* experiments must follow GLP. Such experiments should be thoroughly documented, such that an independent laboratory could reproduce the experiments and obtain results suitable for a direct comparison.

Although a device undergoes rigorous procedures during its *in vitro* testing this process is limited, in that the assessment cannot provide definitive evidence of safety and efficacy in a complex interrelated living system. The primary purpose of *in vivo* animal testing is to protect patients by providing a critical assessment of predicted safety in humans. A secondary purpose of *in vivo* animal testing is determining efficacy with regard to the claims of the developer in the context of comparable technology. In this way, *in vivo* animal testing serves to protect human patients from inferior medical devices. However, only devices exhibiting the most promise with regards to biocompatibility, function, and efficacy through rigorous *in vitro* laboratory testing should proceed to preclinical animal model testing. In this way, experimentation on living animals is reduced to the minimum necessary to obtain the necessary scientific information. Animal experimentation cannot be avoided, because preclinical assessment is required for FDA approval necessary for a device to proceed into a clinical trial. The preclinical assessment of a valve incorporates multivariable analysis with respect to hemodynamic performance, *in vivo* pathological effects, ease of handling, and results in the best approximation of use of the new heart valve within a clinical setting prior to proceeding into a Phase I clinical trial. There are two organizations in the United States that dictate regulatory requirements for preclinical assessments of cardiac devices: the United States Food and Drug Administration (FDA), and the International Standards Organization (ISO), in conjunction with the American National Standards Institute, Inc. (ANSI), and the Association for the Advancement of Medical Instrumentation (AAMI). ISO 5840 has defined regulatory standards governing preclinical studies, which are specific to cardiovascular valve prostheses (ANSI/AAMI/ISO 5840:2005). Although the current FDA guidelines are in draft form, they describe nonbinding recommendations for the manufacturing, preclinical *in vitro* and *in vivo* studies, clinical investigations, and labeling for heart valves that differ, augment, and complement the regulations defined by ISO 5840:2005. The previous

FDA guidance was issued in 1994, before the FDA Good Guidance Practices were implemented in 2000, and before ISO 5840:2005 was published. The 1994 draft was withdrawn in 2005 (70 FR 824, January 5, 2005), and the FDA is in the process of drafting a new guidance. The FDA has recognized only the 2005 version of ISO 5840 (71 FR 16313, March 31, 2006). ISO standards are reviewed every five years and, if necessary, revised to reflect changes in the industry for which the standards define regulatory compliance. One major difference in the current ISO 5840:2005 guidelines from its previous version is the emphasis that is now placed on the use of risk analysis, a formal procedure by which preclinical studies are designed to mitigate to the extent possible the probability and degree of harm caused by the use of a device. Specific steps are outlined in ISO 5840:2005 to perform a risk analysis and include: hazard identification; associated failure modes; risk estimation; risk evaluation; risk control; and risk review. Risk analyses must be updated throughout the characterization of a heart valve through all phases of development. This encourages the manufacturer to strive for continued improvements in design, as well as to ensure safety and efficacy with less reliance on years of clinical assessment for verification of effectiveness. Within the regulatory framework mandated by the FDA and the ISO 5840, there are criteria that must be incorporated into the design and assessment of a new heart valve as follows:

(1) All studies must be completed using Good Laboratory Practice guidelines.

(2) Valves to be assessed must be of clinical quality.

(3) Studies must be conducted using a control valve that is of similar design and has been approved for clinical use. The only exception to this is a proof-of-concept study in which a new heart valve is so different from existing valves that have been approved for clinical use that a suitable control valve cannot be identified.

(4) *In vivo* studies must be designed to incorporate site-specific implantation of the new heart valve in both mitral and aortic positions. Of note, it is important to standardize as many of the variables as possible, including the surgeon, the device size, and the animal demographics.

(5) Ideally, the limitation of the number of implants should not be determined by the minimum regulatory requirements, but should be reflected by the study length.

(6) There should be a complete pathological examination of all animals within a particular protocol, with two independent assessments, including one performed by a veterinary pathologist, to distinguish complications caused by the model from those caused by the new heart valve.

One regulation not mandated by ISO 5840 is the choice of a definitive *in vivo* model used for preclinical assessment of heart valves, as there are a variety of

in vivo models that are relevant. These include, but are not limited to, sheep, pigs, calves, dogs, and non-human primates. Currently, there is no ideal model for preclinical assessment of heart valves, but existing models can be improved upon by incorporating additional outcomes, for example, including site-specific testing. Other potential improvements include the increased use of focused screening models, such as isolated hearts, the use of risk analysis for determining not only the end points, but also the choice of controls and power of the study, and increased communication with regards to negative findings. Compliant preclinical assessment provides not only an accurate correlation of *in vitro* and *in vivo* performance of a device, but also provides a basis for clinical trials.

Once preclinical assessment has indicated that the new valve is suitable for use in human patients, clinical trials may be designed to evaluate the safety and efficacy with regard to toxicity, efficacy, and field conditions. Complete documentation must cover therapeutic indications, contraindications, safety precautions, and safety information. Given the broad public health significance, it is critical for the clinical trial process and resultant data to conform to rigorous ethical standards. Therefore, investigators need to submit a study protocol for IRB review. This protocol will include a risk–benefit analysis, adequacy of informed consent, appropriate selection of subjects, ongoing monitoring of subjects, mechanisms to ensure confidentiality, examination of additional safeguards, evaluation of incentives for participation, and plans for continuing review. The sponsor must also submit an Investigational Device Exemption (IDE) to the FDA for approval. Subsequently, the clinical trial may be conducted according to the general principles described above. Often, during the development process, preclinical assessment, and clinical research, most cardiac valves will have undergone only short-term safety and efficacy assessment in a limited number of carefully selected human subjects before being approved for marketing.

In contrast, post-marketing safety surveillance is utilized in an effort to detect rare or long-term adverse effects not easily recognized during preclinical testing by examining a much larger patient population over a prolonged period of time. Although such events may be rare, their potentially catastrophic consequences cannot be ignored. With better documentation of such problems, future device iterations can be redesigned to attempt to eliminate failures.

CHAPTER III.2.8 LEGAL ASPECTS OF BIOMATERIALS

Jay P. Mayesh and Angela R. Vicari
Kaye Scholer, New York, USA

INTRODUCTION

Students of biomaterials engineering know that no product lasts forever, and that implantable medical devices have unwanted side-effects. In today's litigious society, these factors often transform patients and device manufacturers into warring parties in always unwelcome and sometimes financially disastrous products liability litigation over the safety of medical devices. Products liability law imposes legal responsibility on manufacturers of products (ladders, cars, and medical devices, to name a few), as well as other companies involved in the "stream of commerce," such as wholesalers, distributors, and retailers, for injuries incurred by the consumer.

Products liability falls within the area of civil law called *torts*. A tort is simply a wrongful act that may give rise to a lawsuit, for example an auto negligence lawsuit or professional malpractice claim against a doctor or lawyer. If the plaintiff is successful, a tort lawsuit results in an award of money to the plaintiff called *damages*.

Products liability plaintiffs typically rely on four theories of liability. First, they claim that the manufacturer was *negligent*, meaning that the manufacturer failed to use reasonable care in designing and manufacturing the product. Second, plaintiffs claim that the manufacturer breached legally enforceable promises, called *warranties*, because the product did not meet recognized performance expectations or have the qualities expected of products of its type. Third, plaintiffs sue under *strict liability*, where a manufacturer is held responsible for a

product that was unreasonably dangerous to the consumer or carried inadequate warnings, regardless of the degree of care exercised or any promises made by the manufacturer. Strict liability rests on two assumptions about law and economics – first, that imposing liability on a manufacturer, even without a showing of carelessness on the manufacturer's part, is fair because the manufacturer is best able to discover and correct defects in products before they cause harm, and second, that in the event of personal injury attributable to a product, the manufacturer can afford to compensate the injured party, add the cost of injury to the product and, if necessary, raise the price of the product to recover the cost. Finally, plaintiffs sue device manufacturers for *consumer fraud*, which involves a wide range of improper practices with respect to the advertising, marketing, and sale of medical devices. Many consumer fraud claims allege that a device is not performing in the way it was represented or advertised to perform (because of false advertising, product defects or other reasons). To avoid liability under each of these legal theories, device manufacturers must design, manufacture, and sell products that are reasonably safe, they must disclose written warnings to physicians (and sometimes to patients) about risks associated with the products, and they must advertise, market, and sell products in a truthful manner.

This chapter describes "mass tort" products liability litigation involving implantable medical devices – that is, personal injury litigation implicating thousands of individuals making a claim for an injury as a result of an alleged failure of a medical device. Although the individual injuries vary, most if not all claims arise out of the same mode of failure, insufficient warning or a false claim. Faced with numbers of cases involving hundreds of millions of dollars, the parties often attempt to consolidate mass tort claims in order to streamline pretrial procedures, either by class action or by consolidated litigation, in which all cases are assigned to one judge. In the federal courts, such consolidated litigation is termed "multidistrict litigation" or "MDL." Many states have their own analogs to MDL.

Although medical device mass torts raise complicated scientific and medical issues, in the United States legal system lay jurors, untrained in medical science, are the arbiters of reasonable safety, adequate disclosure, and causation. The vagaries of the jury system always create a degree of risk and uncertainty for litigants. That risk is compounded in medical device litigation when jurors are asked to discern which of many competing medical and scientific theories is more credible. Outcomes become even more unpredictable in cases involving unsettled or evolving areas of science.

To help illustrate the subtle and complex world of mass tort litigation, the six largest subjects of medical device litigation are described below, followed by a discussion of some of the obstacles faced by litigants in prosecuting and defending these claims, including the problems posed by science in the courtroom.

INTRAUTERINE DEVICES

The first mass tort litigation involving a medical device arose out of injuries to women who received intrauterine devices ("IUDs"). In the early 1970s, the IUD was presented to the public as a safe, effective alternative to oral contraceptives. In the following decades, serious reproductive health risks associated with IUDs ensued, prompting women to sue the manufacturers.

A. H. Robins, the manufacturer of the Dalkon Shield, bore the brunt of IUD litigation. Because the Dalkon Shield predated the Medical Device Amendments of 1976 (see later discussion), no requirements for pre-market testing were in place. As described in the case *Tetuan v. A. H. Robins Co.* (241 Kan. 441 [1987]), A. H. Robins was anxious to make inroads in the market and stave off competitors, and thus began marketing the device in 1971 having performed few safety and efficacy studies. While internal corporate documents reflected the company's concern with the paucity of information on the product, A. H. Robins nevertheless publicly touted the benefits of the Dalkon Shield, distributing product cards that claimed the Dalkon Shield was superior to other forms of contraception, and placing advertisements in popular magazines. These efforts earned the Dalkon Shield a dominant position in the IUD market.

As further detailed in *Tetuan v. A. H. Robins Co*, shortly after the device came onto the market the manufacturer began to receive adverse incident reports from doctors about health problems believed to have been induced by the Dalkon Shield, including septic abortions and an increased incidence of pelvic inflammatory disease ("PID"). The Dalkon Shield, like other IUDs, has a string that descends through the cervix from the uterus to allow the user to ensure the device is in place. Before marketing the Dalkon Shield, the manufacturer had knowledge that the string had a "wicking" tendency, meaning it could transport fluid by capillary action into the uterus and introduce bacteria into an otherwise sterile environment. The string was surrounded by a nylon-6 sheath, but the sheath biodegraded in the moist body environment, permitting wicking. The wicking was alleged to be the cause of the comparatively high rate of infections and injuries in women who used the Dalkon Shield.

Between 1970 and 1974, approximately 2.2 million women in the United States used the Dalkon Shield (*In re Northern Dist. of Cal.*, *Dalkon Shield IUD Prods. Liability Litigation*, 693 F.2d 847, 848 [9th Cir. 1982]). The device had been linked to 16 deaths and 25 miscarriages by the middle of 1975 (H.R. Rep. No. 94-853, p. 8 [1976]). By the end of 1975, the lawsuits against A. H. Robins were sufficiently numerous that they were consolidated before a district court in Kansas for pretrial purposes (*In re A. H. Robins Co., Inc.*, "*Dalkon Shield Products Liability Litigation*," 406 F. Supp. 540 [J.P.M.L. 1975]), and the number of lawsuits continued

to multiply. By early 1976, more than 500 lawsuits seeking compensatory and punitive damages totaling more than $400 million had been filed (H.R. Rep. No. 94-853, p. 8 [1976]). Although A. H. Robins was successful in early suits, once certain damaging corporate documents became public the tide turned, and plaintiffs began to win large verdicts. In May of 1985, in the pivotal *Tetuan* case, a Kansas jury awarded $9.25 million in damages. Shortly after the *Tetuan* verdict, A. H. Robins filed for bankruptcy reorganization (Vairo, 1992). Under the reorganization plan a trust fund of $2.475 billion was established to pay outstanding claims against the manufacturer. The bulk of the fund came from another healthcare company that agreed to make the contribution in order to acquire A. H. Robins (Vairo, 1992).

IUD plaintiffs have claimed injuries such as uterine perforations, infections, ectopic pregnancies, spontaneous abortions, fetal injuries and birth defects, sterility, and hysterectomies (*In re Northern Dist. of Cal.*, *Dalkon Shield IUD Prods. Liability Litigation*, 693 F.2d 847 [9th Cir. 1982]). The theories asserted included failure to warn, unsafe design, breach of warranty, and fraud. Plaintiffs prevailed at trial and were able to negotiate large settlements because the defenses that manufacturers typically rely on in medical device litigation were less likely to avail the IUD defendants. Sometimes medical device manufacturers argue that their device cannot be linked with the type of injuries suffered by the plaintiffs. In IUD cases, causation had been a less defensible issue as compared to other medical device litigation because medical experts generally agree on the type of injuries IUDs can produce (Vairo, 1992). Although an IUD manufacturer may successfully argue that the plaintiff's injury had another cause, such as a sexually transmitted disease, the general causative correlation between IUDs and certain injuries is not in question.

In light of evidence that they were not sufficiently candid about health problems associated with their devices, IUD manufacturers also had difficulty proving they satisfied their duty to warn physicians of the risks of IUD use. For instance, in *Nelson v. Dalkon Shield Claimants Trust* (1994 WL 255392 [D.N.H. June 8, 1994]) the court refused to dismiss the plaintiff's claims because the evidence showed that A. H. Robins failed to issue public warnings about the risks associated with the Dalkon Shield's string. Statutes of limitation, which provide an injured party with a fixed amount of time to file suit after an injury occurs, frequently have provided IUD manufacturers with their strongest defense. Injuries caused by IUDs may not manifest themselves for many years, and an even greater amount of time may pass before the user becomes aware that the IUD may have caused the injury.

The Dalkon Shield was ultimately linked to "thousands of serious injuries to otherwise healthy women" (Vladeck, 2005). By October 1984, the manufacturer had settled or litigated approximately 7,700 Dalkon Shield cases (Sobol, 1991).

PEDICLE SCREWS

Pedicle screws are bone screws that are implanted in the pedicles of the spine and are used to anchor a variety of stabilizing hardware. Litigation involving pedicle screws was sparked by a December 1993 exposé on the ABC news program, 20/20. The story publicized allegations that orthopedic screws, which had received FDA approval only for use in the long bones of the arms and legs, were being implanted in the pedicles, a procedure associated with a high rate of complications (Hoyle and Madeira, 2001). The story spawned a multitude of lawsuits, which were consolidated before a Pennsylvania district court for all pretrial procedures (*In re Orthopedic Bone Screw Products Liability Litigation*, 1998 WL 118060 [E.D. Pa. Jan. 12, 1988]).

Plaintiffs alleged several variants of device failure. They complained that bone screws implanted in their spines broke, loosened, corroded or were malpositioned, causing, among other injuries, pseudarthrosis, neurogenic bladder, and arachnoiditis. In addition to device failure, plaintiffs also alleged that manufacturers committed fraud-on-the-FDA by seeking FDA approval for orthopedic screw use only in the long bones of the arms and legs, but then promoting their use in spinal surgery. Ultimately, the United States Supreme Court rejected this theory of liability in a case called *Buckman v. Plaintiffs' Legal Committee* (531 U.S. 341 [2001]), in which it held that such fraud-on-the-FDA claims are not actionable by plaintiffs in product liability cases. The Supreme Court reasoned that if courts were permitted to find insufficient disclosures made by a manufacturer to the FDA, even though those same disclosures were deemed appropriate by the FDA, the FDAs ability to protect the public would be frustrated. Plaintiffs also attempted, unsuccessfully, to impose liability on doctors and medical associations, alleging they conspired with manufacturers to commit fraud by conducting medical seminars that promoted bone screws for unapproved uses.

In addition, plaintiffs argued that manufacturers should be liable for failing to warn of the risks inherent in pedicle screws. Many failure-to-warn claims involving pedicle screws were dismissed by courts under the "learned intermediary" doctrine, which provides that, in the case of most medical devices, a manufacturer has discharged its duty to warn once it has informed the medical community (not the patient) of the risks associated with the device. Dismissals under this doctrine occur when the implanting surgeon testifies that he was aware of the risks through sources entirely independent of the manufacturer's product literature.

In addition, plaintiffs claimed, usually without success, that the pedicle screws were defective. In *Toll v. Smith & Nephew Richards, Inc.*, 1998 WL 398062 [E.D. La. July 14, 1998]), for instance, the court dismissed the case because the plaintiff could not make the required

showing that an alternative design capable of preventing the alleged injury existed. Courts have found that lack of FDA approval for use of orthopedic screws in the spine does not strengthen plaintiffs' claims of defect, and that "off-label" use of a medical device (that is, use for a purpose other than which it is FDA-approved) is not prohibited. Finally, since spinal surgery can have complications regardless of the instrumentation used, plaintiffs' claims have frequently failed because they could not show their injuries were not complications of surgery unrelated to the use of the screws.

As the discussion indicates, many claims against pedicle screw manufacturers were dismissed by courts prior to trial. However, a handful of cases reached juries, with mixed results. A Louisiana jury rendered a verdict against one manufacturer in the amount of $318,000 after finding the pedicle screw was unreasonably dangerous (Anonymous, 1995a), and a Texas jury awarded the plaintiff $451,000 against one manufacturer for misrepresenting the safe and effective use of its pedicle screws (Anonymous, 1998b). On the other hand, a Pennsylvania jury rendered a verdict for the defendant manufacturer (Anonymous, 1995b), and a Tennessee trial ended with a hung jury (Anonymous, 1998c).

The financial strain of the massive litigation prompted one manufacturer, AcroMed, to settle and agree to contribute $100 million and the proceeds of its insurance policies to a settlement fund. In exchange, the manufacturer, as well as its distributors and physicians and hospitals that used its products, were released from suit under any products liability theory (*In re Orthopedic Bone Screw Products Liability Litigation*, 176 F.R.D. 158 [E.D. Pa. 1997]). Approval of this $100 million settlement was based, in part, on an expert economist's opinion that AcroMed had an estimated value of about $104 million, and that based on AcroMed's financial condition, limited insurance coverage, defense costs, and adverse verdict potential, the $100 million settlement was "at the outer boundary of what AcroMed can afford to pay" (*In re Orthopedic Bone Screw Products Liability Litigation*, 176 F.R.D. at 170). Interestingly, within a few weeks after the settlement was declared final, AcroMed was sold for $325 million, more than three times the expert's estimated value of $104 million.

The death knell of the pedicle screw litigation came in July 1998 when the FDA approved bone screws as safe and effective for spinal surgery.

SILICONE BREAST IMPLANTS

Since the early 1960s, an estimated two million silicone breast implants have been implanted in women, for both breast augmentation and reconstruction. Silicone breast implants are made out of a poly(dimethyl siloxane) ("PDMS") elastomer shell, to which fumed amorphous silica is added, encasing PDMS gel or saline (see Chapters I.2.2.B and II.5.18). Some implants have been manufactured with a thin layer of polyurethane foam covering the elastomer shell; this was thought to decrease the formation of capsular contracture (hardening of the scar capsule surrounding the implant with resultant disfigurement), one of the common local complications of breast implants.

Physicians have long recognized that silicone breast implants (including those filled with saline) occasionally cause local complications such as capsular contracture, and that implants can rupture, often necessitating surgery to remove and replace the implants. However, it was not until the early 1990s, spurred on by a television exposé and the publication of several case reports of women with implants who developed autoimmune diseases, that breast implants exploded into mass tort litigation. The FDA, having classified silicone breast implants as Class III devices that "present a potential unreasonable risk of illness or injury" in 1988, enforced the requirement that manufacturers collect and provide safety data on the devices. At this point there were no controlled epidemiological studies exploring the relationship between breast implants and systemic disease. Citing the lack of safety data, the FDA imposed a moratorium on the use of silicone breast implants, except in clinical studies.

Meanwhile, tens of thousands of implant recipients sued the implant and raw material manufacturers, claiming that they had developed autoimmune diseases, such as lupus, scleroderma, and fibromyalgia. To establish that the implants caused illness, plaintiffs' lawyers relied on uncontrolled case reports of autoimmune disease in women with implants, and on anecdotal testimony by treating physicians to persuade juries that the implants caused illness. They also relied on early case reports of autoimmune disease following direct injections of silicone liquid and paraffin into the breasts of Japanese women. Although none of these sources of evidence scientifically established that breast implants cause autoimmune disease, several early plaintiffs won large verdicts.

After publication of the first well-controlled epidemiological studies refuting an association between implants and recognized autoimmune diseases, many plaintiffs modified their injury claims. They alleged that they had developed "atypical" autoimmune diseases with signs and symptoms that would not have been looked for in the studies that tracked the classic autoimmune diseases.

Plaintiffs premised liability on assertions that manufacturers defectively designed the implants and failed to warn physicians and patients of health risks. A central allegation in plaintiffs' lawsuits was that silicone has myriad ill effects on the immune system. Plaintiffs claimed that, as a result of rupture of the implants and "gel bleed" of low molecular weight PDMS through the elastomer shell, silicone microdroplets migrate to remote organs where the silicone causes a chronic inflammatory response and the development of silicone granulomas (Plaintiffs' Submission and Proposed Findings, 1997).

Moreover, they claimed that silicone is an antigen capable of eliciting an immunologic response in the body, and that silicone acts as an adjuvant, heightening the body's immunologic response to other substances. Plaintiffs claimed that silicone, through these mechanisms, exacerbates existing autoimmune diseases, and causes classic and atypical autoimmune diseases in exposed women.

In addition to citing gel bleed as a factor in causation, plaintiffs offered several theories that implicate biodegradation of silicone. They alleged that silicone, migrating throughout the body, is picked up by phagocytes and transformed into crystalline silica which, they claimed, was immunogenic and caused connective-tissue disorders. Moreover, they alleged that the silicone biodegrades into silanols, relying on *in vivo* NMR spectroscopy studies that purported to identify silicone and its metabolic byproducts in the blood and livers of exposed women. Other scientists were unable to replicate these NMR findings (Macdonald et al., 1995; Mayesh and O'Hea, 1997).

In a medical science atmosphere of anecdotal case reports and uncertain elaborate scientific theories, even though no epidemiological studies supported causation, the industry was prepared to spend approximately $4 billion to settle claims globally. The plaintiffs demanded more money, and settlement fell apart. Faced with potential liability and enormous defense costs, Dow Corning, the largest manufacturer of breast implants, was forced into bankruptcy.

Over time, scientific evidence began to mount against causation. Each epidemiology study from leading institutions such as the Mayo Clinic, Harvard Medical School, Johns Hopkins University, the University of Michigan, and the University of California failed to show any association between silicone breast implants and any classic or atypical autoimmune disease. Nonetheless, occasionally manufacturers were still subjected to substantial jury verdicts.

In 1996, the coordinating MDL judge, before whom all lawsuits filed in federal court were consolidated for pretrial proceeding, appointed a National Science Panel of four impartial scientific experts. An immunologist, epidemiologist, toxicologist, and rheumatologist were charged to evaluate the scientific data in relation to connective tissue diseases and immunologic dysfunction (National Science Panel, 1998). These experts were instructed to "review and critique the scientific literature pertaining to the possibility of a causal association between silicone breast implants and connective tissue diseases, related signs and symptoms, and immune system dysfunction."

On three occasions in 1996 and 1997, the panel of four court-appointed scientists heard testimony from expert witnesses chosen by the lawyers for plaintiffs and for the manufacturers. The panel received more than 2000 documents from counsel, and the panel members performed their own literature searches. The panel

concluded in November 1998 that available data did not support a connection between silicone breast implants and any defined connective tissue disease or other autoimmune or rheumatic condition (National Science Panel, 1998).

IMPLANTABLE CARDIAC DEFIBRILLATORS

Implantable cardiac defibrillators ("ICD") are small, battery-powered devices used to treat a variety of potentially fatal cardiac arrhythmias by delivering electrical therapy to the heart. They do so through small wires called "leads" that on one end are attached to the ICD, and on the other end are attached directly to the patient's heart muscle through a coronary vein. If electrodes on the leads detect that the patient's heart is out of rhythm, the ICD sends an electric shock to the heart muscle through the leads in order to correct the problem (see Chapter II.5.3.C).

Since the first human use of an ICD was reported in 1980, use of these devices has expanded dramatically, and their design has undergone remarkable change. Modern ICDs are implanted transvenously, provide physiologic pacing in up to three cardiac chambers, perform a number of automated functions and self-checks, and can deliver pacing or high voltage therapies to treat life-threatening arrhythmias. A pacemaker-dependent ICD patient will receive more than 100 million paced beats over the device's lifetime.

As with many evolving technologies, advances brought with them new safety risks. The risks spawned two major products liability litigations involving ICDs, both of which centered on the manufacturer's failure to warn of known problems with the product.

In February 2002, Guidant Corporation identified certain electrical flaws with one of its ICD products. As a result, the company made manufacturing changes to reduce the short circuit risk. However, the company did not notify physicians or patients of these failures or of the manufacturing changes. It continued to sell ICDs manufactured using the older process while it phased in the newer version. The company justified its decision to continue selling older devices and not notifying physicians of the new modifications on the grounds that the overall failure rate of the device, even including these events, was extremely low and because the device was performing better than its design specifications. It also concluded that the risk of explanting the device was greater than the risk of device malfunction.

The company eventually announced that there were problems with its ICD after the death of a 21-year-old college student with a genetic heart disease. Guidant acknowledged that the student's ICD short-circuited, and subsequently told his doctors that it was aware of 25 other cases in which the ICD had been affected by the same flaw. Following this disclosure to the student's

physicians, Guidant was contacted about a *New York Times* article that was set to run entitled "Maker of Heart Devices Kept Flaws from Doctors" (Meier, 2005). The company's first public announcement came hours before the *New York Times* published its article – more than three years after it had allegedly become aware of the problem. By June 2005, there had been two deaths reported to the FDA suspected to be associated with this malfunction. By October 2005, there were 21 clinical failures, including three patient deaths, worldwide.

Over the next several months, Guidant announced several additional physician notifications covering a significant number of similar products. The company also began issuing a series of recalls for what amounted to over 100,000 devices in the United States. The company had different problems with different devices, some more serious than others, involving electrical shorts, as well as other defects, including memory errors and premature battery depletion.

A spate of personal injury lawsuits followed, and a multidistrict litigation commenced in November 2005. Unlike many of the other large mass torts discussed in this chapter, the parties settled the litigation soon after. In July 2007, the parties entered into an initial $195 million proposed settlement. After more individual settlement claims than anticipated were submitted, the parties commenced renegotiation, resulting in an increase in the settlement fund to $240 million. The agreement covered 8550 patient claims, including all of those that had been consolidated in the multidistrict litigation, as well as other filed and unfiled claims throughout the United States.

Guidant was not the only ICD manufacturer to face lawsuits. In 2006, patients with ICDs utilizing Medtronic's Sprint Fidelis leads as a component began to suffer painful shocks. An investigation by a physician at the Minneapolis Heart Institute concluded that the shocks were caused by fractures in the leads, and that the leads were failing at a significantly higher rate than other leads, a sentiment echoed by another physician at Cornell University Medical Center in New York (*In re Medtronic, Inc. Sprint Fidelis Leads Products Liability Litigation*, 592 F. Supp. 2d 1147 [D. Minn. 2009]). Plaintiffs claim that upon being confronted with this information, Medtronic undertook a campaign to defend its leads, even though it knew that they were unsafe. As part of that campaign, Medtronic purportedly delayed filing "adverse event reports" with the FDA concerning failures of the leads.

In May 2007, Medtronic filed a supplemental application to the FDA containing design and manufacturing changes to the Sprint Fidelis leads. According to plaintiffs, Medtronic filed this supplement in order to correct defects endemic to the leads. Yet, Medtronic did not advise the FDA that it was filing the premarket approval ("PMA") supplement because of the lead failures, instead merely informing it that the proposed

changes were intended to make the leads more "robust." The FDA approved Medtronic's PMA supplement in July 2007, but previously manufactured (and allegedly defective) Sprint Fidelis leads continued to be shipped to hospitals and implanted into patients.

On September 10, 2007, Medtronic filed more than 120 adverse event reports concerning Sprint Fidelis leads. On October 7, 2007, Medtronic suspended sales of the leads but did not inform the FDA, doctors or the public of its decision, and they continued to be implanted into patients. On October 15, 2007, Medtronic recalled the Sprint Fidelis leads, and the FDA issued a "Class I" recall shortly thereafter, the most serious type of medical device recall. At the time of the recall, approximately 257,000 Sprint Fidelis leads remained implanted in patients.

Following the recall, plaintiffs across the country began to file actions against Medtronic alleging (among other things) claims for negligence, strict products liability, fraud, and breach of express and implied warranties. According to the plaintiffs, the leads were not adequately tested prior to seeking FDA approval, the method of manufacturing, which involved direct resistance spot welding of two different metals, was prone to damaging them, and Medtronic knew (but failed to disclose to the FDA) that this welding technique was likely to result in the leads failing. Finally, plaintiffs claimed that Medtronic failed to take adequate steps to ensure that the Sprint Fidelis leads were not damaged during production, including failing to perform adequate testing on the leads' components, and failing to take corrective action to prevent lead failures.

Although a multidistrict litigation was commenced on February 21, 2008, in the United States District Court for the District of Minnesota, many of the claims were dismissed on the ground of preemption (*In re Medtronic, Inc. Sprint Fidelis Leads Products Liability Litigation*, 592 F. Supp. 2d 1147 [D. Minn. 2009]). As discussed further below, preemption is a powerful defense available to manufacturers in cases involving devices that were approved through the FDAs premarket approval process.

ARTIFICIAL HEART VALVES

Artificial heart valves are composed primarily of metal or carbon alloys, and are classified according to their structure as caged-ball, single tilting-disk or bileaflet tilting-disk valves (Vongpatanasin et al., 1996) (see Chapter II.5.3.A). All three types have been the subject of product liability litigation.

In the late 1970s, 15 suits were brought against a manufacturer of a caged-ball valve. Plaintiffs claimed that defects in the valve caused it to wear out prematurely, resulting in major embolic complications, premature open heart surgery to replace the valve, and catastrophic popet-ball escape from the valve cage. The theories of liability included negligence in the design, manufacture, and testing of the valve, breach of express

or implied warranties, and strict liability (*In re Cutter Labs, Inc. "Braunwald-Cutter" Aortic Valve Products Liability Litigation*, 465 F. Supp. 1295 [J.P.M.L. 1979]). The manufacturer incurred significant legal expenses, yet was only partially successful in defending the lawsuits (*Lindsay v. Cutter Laboratories, Inc.*, 536 F. Supp. 799 [W.D. Wis. 1982]).

Beginning in the mid-1980s, a manufacturer of a tilting-disk valve, implanted in 50,000 to 100,000 patients between 1979 and 1986 (*Bowling v. Pfizer*, 143 F.R.D. 141 [S.D. Ohio 1992]), became the object of numerous lawsuits due to the valve's potential to fracture. Plaintiffs alleged that even before the valve was marketed, the first instance of valve failure due to "strut fracture" occurred in clinical trials. The valve consists of a disk located inside a metal ring covered by a Teflon sewing ring, which is sutured to the heart. The disk opens and closes rhythmically, allowing blood to pass through the heart. The disk is held in place by two wire holders, the inflow and outflow struts. When the overflow strut fractures, the disk escapes from the ring, causing uncontrolled blood flow through the heart, usually resulting in death. According to a Congressional report on the valve, based in part on examination of the manufacturer's internal documents, strut fracture was most likely caused or exacerbated by deficiencies in quality control procedures.

The number of lawsuits mounted, and eventually the manufacturer entered into a settlement with a class of plaintiffs implanted with its valve who had not yet experienced fracture. Under the terms of the settlement, the manufacturer agreed to establish a $75 million Patient Benefit Fund for research and heart valve replacement surgery, and a Medical Compensation Fund of between $80 million and $130 million to provide cash payments to valve recipients. The settlement also guaranteed immediate cash payments in the event of a fracture, and provided for contribution of another $10 million for spouses of class members (*Bowling v. Pfizer*, 143 F.R.D. 141 [S.D. Ohio 1992]).

The issue of whether a plaintiff whose heart valve has not failed can make a legally valid claim against a manufacturer has been addressed repeatedly. Generally, courts have demonstrated little willingness to entertain lawsuits based on a valve recipient's fear of failure because either physical injury or an actual device failure is a prerequisite to imposing liability on a manufacturer. However, exceptions to the general trend can be found. For instance, in a California case, *Kahn v. Shiley*, 217 Cal. App. 3d 848 [1990], the court allowed a plaintiff to proceed with her fraud claim because the court reasoned fraud does not challenge the safety or efficacy of the medical device. Because fraud allegations focus exclusively on the defendant's conduct, the fact that the plaintiff's valve had not failed was immaterial. In another case, *Michael v. Shiley, Inc.* (46 F.3d 1316 [2d Cir. 1995]), a court allowed a plaintiff to proceed to trial because, unlike most plaintiffs asserting fear of future valve failure, she suffered a tangible injury because she underwent surgery to replace her heart valve.

The most recent round of litigation concerning artificial heart valves involves the Silzone heart valve, which has a patented silver elemental coating on the sewing cuff, the part of the valve that is sewn to the patient's body. The purpose of the coating is to use silver's antimicrobial properties to help combat endocarditis, an infection of heart tissues and a common cause of prosthetic valve failure. Although the silver-coated Silzone valve was approved for commercial distribution in 1998, the FDA prohibited the company from claiming that the silver coating would reduce the risk of endocarditis.

Following FDA approval, the device manufacturer enrolled 792 patients in a multi-national clinical trial designed to study whether the silver-coated heart valve reduced the incidence of endocarditis in humans. The study was never completed, however, because the monitoring board found that recipients of the Silzone valve were more likely than controls to experience a complication called "paravalvular leak," requiring the valve to be removed and replaced.

With these results, the manufacturer voluntarily recalled all of its unimplanted Silzone products. As part of the recall, the manufacturer immediately notified hospitals and physicians, instructing them not to use the valves. The company also sent letters regarding the care and management of patients with its implanted valves, and established a reimbursement program to pay for uninsured medical costs associated with the detection, diagnosis, and treatment of paravalvular leak.

These remedial measures, however, did not stop a tide of tort litigation by the patients who received the silver-coated Silzone valves. Some of these claimants alleged bodily injuries as a result of an explant or other complications, which they attributed to the Silzone product. Others, who had not had their valve explanted, and who were asymptomatic with no apparent clinical injury to date, sought compensation for past and future costs of medical monitoring.

A number of individual lawsuits were filed and consolidated in a multidistrict litigation in a Minnesota federal court, which then consolidated various class action complaints consolidated into one class action. A class action is a form of lawsuit where a large group of people collectively bring their claims. The proposed class must consist of a group of individuals that have suffered a common injury, and in many cases, the party seeking certification must show that common issues between the class and the defendants will predominate the proceedings, as opposed to individual fact-specific conflicts between class members and the defendants.

Class actions alleging physical injury from defective medical devices often fail to meet these requirements, because such cases inevitably involve individual issues. In addition, nationwide classes are often not certified because there is no national body of product liability

law. Plaintiffs must sue under the law of a particular state, and differences in state law make class resolution of personal injury claims impracticable.

The Silzone consolidated class action was brought by five named plaintiffs on behalf of themselves and over 11,000 other Silzone valve recipients. The litigation presents a sort of class action rollercoaster ride, as the case bounced between the district court and the Eighth Circuit Court of Appeals for five years. In 2004, the district court certified a nationwide class of plaintiffs who had been implanted with the Silzone valve seeking injunctive relief in the form of medical monitoring, as well as a consumer protection class under Minnesota's consumer protection law. This decision was reversed by the Eighth Circuit Court of Appeals in 2005. The appellate court rejected the medical monitoring class because the class presented "a myriad of individual issues making class certification improper" (*In re St. Jude Med., Inc.*, 425 F.3d 1116, 1122 [8th Cir. 2005]). However, it remanded the case to the district court for it to reconsider the consumer class decision, because the lower court did not properly analyze whether the law of Minnesota should apply to the claims of all of the potential members of the proposed nationwide class.

On remand, the district court determined that Minnesota law should apply to all claims in the nationwide class, and recertified the consumer protection class (*In re St. Jude Medical, Inc.*, 2006 WL 2943154 [D. Minn. 2006]). The manufacturer appealed again and won. In 2008, the Eighth Circuit held that the district court erred in certifying the consumer protection class, because there were material variations in the representations made by the manufacturer concerning the valve, as well as material differences in the kind and degree of reliance on those representations by the potential class members. The Eighth Circuit recognized that trial would require physician-by-physician inquiry into each doctor's sources of information about the valve, and held that the case was not suited for trial as a class action (*In re St. Jude Medical, Inc.*, 522 F.3d 836 [8th Cir. 2008]).

Following the Eighth Circuit's rejection of the consumer protection class action the plaintiffs continued to pursue their claims by trying to substitute "omissions" for affirmative misrepresentations in their allegations, but in light of the appellate court's prior rulings, the district court refused to certify the class (*In re St. Jude Medical, Inc.*, MDL No. 01-1396 (JRT/FLN), 2009 WL 1789376 [D. Minn. June 23, 2009]).

As of April 24, 2009, there were only three individual Silzone cases pending in federal court, and seven individual state court suits concerning Silzone. The plaintiffs in these cases were requesting damages between $10,000 to $100,000 and, in some cases, an unspecified amount (St. Jude Medical Form 10-Q [May 12, 2009]).

HIP/KNEE PROSTHESIS IMPLANTS

Prosthetic hip implants used in total hip replacements are made up of two components – a socket-like shell that is surgically inserted into the acetabulum of the pelvis, and a ball-like device to replace the femoral head (see Chapter II.5.6). The Inter-Op Shell manufactured by Sulzer Orthopedics was one such implant. It was constructed of an outer, porous titanium covered cup and an inner polyethylene cup, and was designed to bond with the natural bone.

In September 2000, Sulzer began to receive adverse reports from surgeons complaining that patients were experiencing symptoms post-operatively that suggested a defect in the hip implant. There were reports of severe pain, loose implants, second surgeries, inability to bear weight or walk, and other health complications. Sulzer initiated an investigation, and after eight weeks, they identified the cause of the problem. During the manufacturing process, a small amount of a mineral-based oil lubricant leaked into the machine coolant. Residual amounts of the lubricant remained on the surfaces of the shell, interfering with the bonding process between bone and shell. On December 8, 2000, Sulzer recalled many of its Inter-Op acetabular shells. According to the company, residue remained on the surface of the shells following the machining process which could prevent the implant from properly bonding with the bone.

Initially, Sulzer offered to pay for revision surgery, which cost between $20,000 and $70,000 per patient. Many patients, however, were frustrated with the fact that Sulzer did not offer to pay for pain and suffering associated with revision surgery and rehabilitation. Also, many of the patients' revision surgeries would be covered by Medicare, and so patients felt the offer was not genuine compensation for their surgery or for their pain. In 2001, patients began filing lawsuits against Sulzer, basing their claims on theories of strict liability for manufacturing a defective product, breach of warranty, negligence, and strict liability for failure to warn. Damages sought against Sulzer included: all pain and suffering associated with the recall implant; all past and potential future medical expenses associated with the defective hip implant; and all loss of earnings and/or earning capacity associated with the surgery. Many patients also sought punitive damages.

Around the same time, in early 2001, Sulzer began receiving adverse incident reports regarding its Natural Knee II Tibial Baseplate, an orthopedic knee implant. The Tibial Baseplate is one component of a system used for complete knee replacements. The Baseplate is inserted into the tibia or shin bone. While some implants are cemented into the bone, the Natural Knee II, like the Inter-Op Shell, was designed to allow the bone to grow into and around the implant. Again, surgeons reported that patients were experiencing poor recovery progress and ambulatory pain. X-rays showed radiolucencies under the baseplate, suggesting that the implant had separated from the bone. Sulzer discovered that the same

manufacturing problem that caused the hip implants to fail was causing the knee implants to fail to bond. In May 2001 Sulzer announced a recall of its knee implants, and informed surgeons who had implanted its Tibial Baseplates of the unanticipated adverse clinical outcomes.

As knee implant patients began to file suits, and hip implant patients continued to file suits, Sulzer realized that it would have a difficult time trying a case in which it had voluntarily discovered and already admitted responsibility for the cause of the defect. In attempts to settle the matter without going bankrupt, Sulzer opened its books up to plaintiffs' attorneys and financial advisors who engaged in extensive discovery regarding the company's liability insurance and financial condition. A $1 billion settlement was approved on May 8, 2002.

PREEMPTION

Prior to 1976, medical device manufacturers were not required to seek FDA approval for a new medical device. In that year, a new regulatory scheme was implemented under the Medical Device Amendments of 1976 ("MDA"). The new regulatory regime established various levels of oversight for medical devices, depending on the risks that they presented. Class I, which includes such devices as elastic bandages and examination gloves, is subject to the lowest level of oversight. Class II, which includes, for example, powered wheelchairs and surgical drapes, is subject to certain performance standards and postmarket surveillance measures. Most medical devices are considered Class II devices. The devices receiving the most federal oversight are those in Class III. These devices usually sustain or support life, are implanted or present potential serious risk of illness or injury.

The MDA also includes a "preemption" provision, Section 360k(a), which states that: "no State … may establish … any requirement (1) which is different from, or in addition to, any requirement applicable under this chapter, and (2) which relates to the safety and effectiveness of the device …" Device manufacturers frequently argue that the MDAs preemption provision precludes plaintiffs from bringing lawsuits under state tort law. The preemption defense succeeds if a court finds that Congress intended that the federal regulatory scheme govern the question of device safety to the exclusion of state tort law.

The extent to which state tort law claims are preempted is determined by the manner in which a medical device is approved by the FDA. In 2008, in a case called *Riegel v. Medtronic Inc.* (128 S. Ct. 1999), the Supreme Court addressed preemption in the context of Class III medical devices. New Class III medical devices, such as the balloon catheter at issue in the *Riegel* case, must receive premarket approval ("PMA") before they can be legally marketed. The PMA process is the "rigorous" process through which the FDA weighs any probable benefit to health from the use of the device against any probable risk of injury or illness. A manufacturer must submit what is typically a multivolume application including, among other things, full reports of all studies and investigations of the device's safety and effectiveness, a full statement of the device's components, ingredients, and properties, and of the principle or principles of operation, a full description of the methods used in, and the facilities and controls used for, the manufacture, processing, and a specimen of the proposed labeling. The FDA then spends an average of 1200 hours reviewing each application, and grants premarket approval only if it finds there is a reasonable assurance of the device's safety and effectiveness. In *Riegel*, the Supreme Court held that PMA approval imposes "specific federal requirements" applicable to a particular device, and that state law tort claims impose requirements that "are different from, or in addition to" the requirements imposed by federal law. Thus, the Court found that the plaintiff's claims against Medtronic under New York law based on strict liability, breach of implied warranty, and negligence in the design, inspection, distribution, labeling, marketing, and sale of the catheter were preempted by the MDA.

However, most medical devices are not approved through the PMA process; rather, they are marketed after receiving FDA approval through the less rigorous "premarket notification" process. Premarket notification facilitates the marketing of medical devices that are new to a company, but "substantially equivalent" to a device already on the market (known as a "predicate" device). Substantial equivalence means that the new device has the same intended use as the predicate, and is at least as safe and effective as the predicate device. In 2005, the FDA authorized the marketing of 3148 devices through the premarket notification process, and granted PMA approval to just 32 devices.

Unlike PMA-approved Class III medical devices, there is only a limited preemption defense available in litigation involving devices that were approved through the premarket notification process. Whether state law tort claims are preempted depends on whether FDA regulation of these devices constitutes a specific "requirement" applicable to the particular device. Courts have held that certain non-PMA-approved medical devices, such as tampons (*Papike v. Tambrands Inc.*, 107 F.3d 737 [9th Cir. 1997]), and contact lens solutions (*Tuttle v. CIBA Vision Corp.*, 2007 WL 677134 [D. Utah March 1, 2007]), meet this threshold, because specific FDA regulations govern the labeling of such products.

Interestingly, Congress has chosen to subject medical devices and prescription drugs to different regulatory schemes. Despite its enactment of an express preemption provision for medical devices in the MDA, Congress has not enacted such a provision for prescription drugs. Thus, in 2009, in a case called *Wyeth v. Levine* (129 S. Ct. 1187 [2009]), the Court held that the FDAs approval of prescription *drug* labeling does not preempt a plaintiff's state law tort suit, alleging deficiencies in the approved label.

The disparity between the medical device and prescription drug regulatory schemes creates possible tension regarding the scope of a preemption defense in a case involving a "combination" product that combines drugs, devices, and/or biological products, such as the Silzone artificial heart valve discussed above, a drug-eluting stent or a tapered metallic spinal fusion cage. At least one court has held that where the FDA regulates a combination product as a medical device, express preemption under the MDA applies (*Riley v. Cordis Corp.*, 2009 WL 1606650 [D. Minn. June 5, 2009]). However, in the Silzone heart valve MDL, the court questioned, although it did not decide, whether a combination product would be subject to the MDAs express preemption provision (*In re St. Jude Medical, Inc. Silzone Heart Valves Prods. Liab. Litig.*, 2004 WL 45503 [D. Minn. 2004]).

SCIENCE IN THE COURTROOM

When medical device lawsuits reach the trial phase, the expert witness assumes a critical role. Whether an allegedly defective medical device caused the plaintiff's injury is an issue deemed beyond the ken of the average juror, and courts therefore require the litigants to present scientific evidence in the form of expert opinions. The courtroom, however, is a forum ill-suited to discussion of scientific principles, and the scientific evidence communicated to jurors often fails to meet the standards of reliability our judicial system envisions.

Laypersons who lack schooling in the fundamentals of scientific inquiry are prone to biases. For instance, a layperson would be more inclined to accept coincidence as proof. As Marcia Angell, the former editor of the *New England Journal of Medicine*, noted, many people might find a reasonable proposition that mere temporal relationship, i.e., that health complications followed breast implantation, is sufficient proof that implants caused the injuries (Angell, 1996). A scientist, on the other hand, is trained to understand that association is not causation, and anecdotal reports are no substitute for scientific data. Studies also show that laypersons are likely to ignore epidemiological evidence, and that they have a so-called "hindsight bias," i.e., they tend to favor facts that are more consistent with the ultimate outcome (Haskel, 2007).

The gap between a layperson's and a scientist's understanding of cause and effect yawns even wider in the courtroom, because both the goals and the methods of science and litigation are at odds (Mayesh and Ried, 1986). Litigation and science employ disparate standards of proof, as well as disparate measures of causation. Science examines causative correlations in the population at large, whereas litigation asks whether a particular device caused a particular plaintiff's injury. Moreover, litigation and scientific inquiry demand quantitatively different standards of proof. Scientific inquiry seeks to establish causal relationships to a 95% degree of certainty, whereas

judicial inquiry requires only a 51% probability of correctness. Under these circumstances, it is easily imaginable that a jury could determine that a systemic disease was caused by exposure to an implanted device, while a scientist would find the same evidence merely sufficient to suggest an interesting hypothesis (Mayesh and Ried, 1986b).

As a practical matter, the judicial system's goal of timely conflict resolution would not be well-served by imposing the standards of the scientific community on the courtroom. Lawsuits must be resolved in a few years. Questions of science typically take decades of testing and data accumulation before repeatability can be achieved and the question thereby answered. To resolve the tension, the judicial system has fashioned a compromise by allowing juries to hear only that scientific evidence deemed by the judge to be reliable and generally accepted within the scientific community. In modern federal practice, this is called the *Daubert* standard after the US Supreme Court decision, *Daubert v. Merrell Dow* (509 U.S. 579 [1993]). Federal trial judges are given wide discretion to admit or preclude evidence under this standard (Mayesh and Ramallo, 2007).

The saga of DNA identification is an example of how judges serve as the gatekeepers of whether scientific evidence is allowed before the jury. Until DNA typing became generally accepted as reliable, it was not allowed into the courtroom. Now that it has been established as accepted methodology, DNA proof may be put before the jury although, of course, subject to rigorous dispute over correct methodology. This model, however, does not always prove satisfactory.

Because litigants face admissibility hurdles over scientific evidence, litigation-driven science has become a growing phenomenon. Fortunately, the few courts that have confronted litigation science to date have generally been skeptical of the value of these studies. For example, in *In re Breast Implant Litigation* (11 F. Supp. 2d 1217 [D. Colo. 1998]), the court excluded the testimony and opinions of a plaintiff's rheumatology expert, in part, because his patients were litigants who had been referred to him. The court also excluded the testimony of the plaintiff's biomaterials expert, in part, because the vast majority of his business came from plaintiffs involved in breast implant litigation.

Because scientific inquiry is typically characterized by a degree of uncertainty, deft litigants may succeed in casting doubt upon strong scientific proof. On the other side, experts for hire are sometimes allowed to spin unproven theories in order to strengthen the inclination of jurors to assume that anecdotes are the equal of data, and association the correlate of cause. At the conclusion of the evidence, 12 laypersons, who have listened to experts express conflicting opinions, vote on which is more persuasive. The opinions themselves need not be held with more than a "reasonable degree" of scientific certainty, which the giver of the opinion may define as "more probable than not." Although the jurors usually need to be unanimous, their measure of confidence need only reach

"a fair preponderance of the credible evidence," meaning 51%. Little wonder, then, that there is a disconnect between real science and courtroom science. As the great jurist, Learned Hand, observed in the beginning of the last century: "But how can the jury judge between two statements each founded upon an experience confessedly foreign in kind to their own? It is just because they are incompetent for such a task that the expert is necessary at all" (Hand, 1902).

BIOMATERIALS ACCESS INSURANCE ACT

Plaintiffs suing the manufacturer of an allegedly defective device sometimes also join as defendants the suppliers of its raw materials and component parts. The incentive to sue a raw material supplier is particularly strong if the supplier has significant financial resources and the medical device manufacturer has limited assets. For instance, DuPont, a supplier of Teflon used in TMJ implants, spent $26 million litigating more than 650 lawsuits over implants used to treat TMJ after the small manufacturer of the implants went bankrupt (Murphy, 2000). Although bulk suppliers have consistently succeeded in having suits against them dismissed, the cost of litigation can nonetheless be substantial. After weighing the risk of becoming embroiled in expensive litigation against tiny profits derived from the medical device market, bulk suppliers began to deny manufacturers access to their products, and the United States faced a serious biomaterials shortage in the 1990s.

To address the dwindling supply of biomaterials essential for the manufacture of implantable devices in 1998 Congress passed the Biomaterials Access Assurance Act ("BAAA"). The act shields suppliers of raw materials and component parts from liability, unless the supplier is also the manufacturer or seller of the device or furnished materials or components that did not comply with contractual requirements or certain other specifications. Under the act, a supplier named in a lawsuit is entitled to move for dismissal immediately. Once a motion to dismiss is filed, the supplier is excused from participation in any "discovery," the expensive and time-consuming process by which litigants seek information from each other before trial. Limited discovery is allowed only to determine whether a supplier failed to comply with contractual requirements or specifications.

After dismissal from the lawsuit, the supplier may still face liability in certain, limited circumstances. After a verdict against the device manufacturer, the plaintiff or manufacturer can require the supplier to pay part of the judgment if the court determines that the supplier's negligent or intentional conduct was a cause of the plaintiff's injury. The plaintiff may utilize this procedure if the full amount of damages cannot be recovered from the manufacturer.

Although the BAAA was enacted in 1998, there appears to be only one reported decision concerning the act or its interpretation. In 2008, the United States District Court for the District of Colorado dismissed claims brought against a company that manufactured the femoral hip head component of a hip replacement system, because the company was not the manufacturer of the implant, was not the seller of the implant, and did not furnish raw materials or component parts that failed to meet applicable contractual requirements or specifications (*Whaley v. Morgan Advanced Ceramics, Ltd.*, 2008 WL 901523 [D. Colo. March 31, 2008]).

LIABILITY OF THE DESIGN ENGINEER

For several reasons, an individual design engineer is an unlikely defendant in medical device cases. First, plaintiffs know that manufacturers are more likely to have the financial resources to compensate them for their injuries. Second, a plaintiff gains a "David and Goliath" tactical advantage by suing only the manufacturer, and not the design engineer. A jury will be more inclined to sympathize with a plaintiff if the case is viewed as a confrontation between a single individual and a corporate giant.

If sued, a design engineer is theoretically not immune from liability. However, the theories available to plaintiffs are less expansive when suing a design engineer as opposed to a manufacturer. For example, courts have recognized that the policy objectives underlying strict liability would not be furthered by applying the theory of strict liability to design engineers. Courts have reasoned that design engineers provide a professional service, and do not occupy the same superior position that allows manufacturers to discover defects and spread economic losses. Although the law of strict liability is subject to some flux and uncertainty, the great weight of judicial precedent provides a good deal of assurance that a design engineer who develops a medical device will not be held liable.

That being said, design engineers may be liable under a theory of professional malpractice, which asks whether the design engineer has exercised the degree of care reasonably expected in the profession. Liability will only be imposed if the design engineer is found to be at fault for failing to live up to that standard.

In addition, a design engineer can be held criminally liable if he or she is also a corporate or compliance officer. For example, in *U.S. v. Caputo* (517 F.3d 935 [7th Cir. 2008]), an appeals court upheld the criminal convictions of a device designer and his assistant. They were alleged to have marketed an unapproved medical device, known as an autoclave, which left a harmful blue-green residue on brass instruments employed for procedures in the eye. Their convictions were upheld because they wore multiple hats: the device designer was also the President and CEO of the manufacturer, and his assistant was also the Vice President of Regulatory Affairs and Chief Compliance Officer. As a practical matter, however, a design engineer is very rarely named as a defendant.

TABLE III.2.8.1	Department of Justice Settlements 2003–2007		
Company	**Product**	**Date**	**Settlement Amount**
Serono, S.A.	Serostim	October 2005	$704 million
The Purdue Frederick Company	OxyContin	May 2007	$634 million
Bristol-Myers Squibb	Abilify	September 2007	$500 million
Schering-Plough Corporation	Temodar and Intron A	August 2006	$435 million
Pfizer	Neurontin	May 2004	$430 million
InterMune, Inc.	Actimmune	October 2006	$36.9 million
Eli Lilly and Company	Evista	December 2005	$36 million
Pfizer, Inc.	Genotropin	April 2007	$35 million
Jazz Pharmaceuticals, Inc.	Xyrem	September 2007	$20 million
Cell Therapeutics, Inc.	Trisenox	April 2007	$10.5 million
Medicis	Loprox	May 2007	$9.8 million

DEVICE MARKETING AND PROMOTION

With increasing frequency, plaintiffs suing medical device manufacturers allege that the manufacturer promoted the product in an improper manner. One type of improper promotion is known as "off-label" promotion, whereby a manufacturer promotes a medical device for some other indication than that for which it has been approved by the FDA. Once the FDA has approved a medical device for marketing, a physician may prescribe it for any use, even uses not approved by the FDA. Often, such off-label use of a medical device becomes the standard of care. Nonetheless, although off-label *use* of medical devices by physicians is accepted and occurs frequently, device manufacturers are prohibited from engaging in off-label *promotion*. A medical device that is labeled or promoted for a use that has not been approved or cleared by the FDA is considered to be misbranded by the FDA.

Government scrutiny of off-label promotion is on the rise. During calendar years 2003 through 2007, the FDA issued 42 regulatory letters in response to off-label promotions requesting companies to stop dissemination of violative promotions. During that same time, the Department of Justice settled 11 civil and criminal cases that involved, at least partially, off-label promotion. The settlements in these cases were for staggering amounts (Table III.2.8.1). And, although they involved pharmaceutical companies, medical device manufacturers are certainly not immune to such investigation.

DEFENSIVE MANUFACTURING AND MARKETING

Although little can be done to prevent a plaintiff from initiating a lawsuit, the best defense to a products liability suit is having manufactured a safe, well-designed product with adequate warnings. In virtually every lawsuit alleging injury caused by a medical device, the plaintiff – and eventually jurors – will have access to the manufacturer's internal corporate documents. These include lot histories, manufacturing specifications, results of toxicology and safety tests, quality assurance documents,

FDA submissions and compliance reviews, adverse event incident reports, and intracorporate memos discussing all of these, whether paper or email. The majority of these documents will have been prepared many years prior to the lawsuit, often by personnel who are no longer employed by the manufacturer at the time of trial.

If the manufacturer makes the proper investment up front in designing, manufacturing, and selling the product, these documents can be the best proof that the manufacturer performed all necessary safety testing, that the product conformed with all government and industry standards, that no manufacturing defects occurred, that warnings and instructions for use were legally appropriate, and that the manufacturer complied with all regulatory requirements for device approval. Moreover, the documents should establish that the manufacturer took appropriate post-market safety surveillance, and had adequate quality assurance systems. This includes documentation that it was responsive to complaints from doctors and patients, had a method of tracking such complaints as well as resolving them, and when appropriate, took post-market action, such as product recall and issuing revised warnings.

CONCLUSION

Very few things are certain in either law or science. However, when it comes to products liability, scientists and lawyers alike can safely bet that scientists will always test and expand the limits of current technology, creative plaintiffs' counsel will constantly be developing novel theories of liability, and defendants will be equally creative in trying to rebut those claims.

CHAPTER III.2.9 CLINICAL TRIALS FOR MEDICAL DEVICES

Gary L. Grunkemeier,[1] Ruyun Jin,[1] Lian Wang,[1] and Albert Starr[2]
[1]Medical Data Research Center, Providence Health & Services, Portland, Oregon, USA
[2]Oregon Health & Science University, Portland, Oregon, USA

INTRODUCTION

The designation "Clinical Trial" is usually interpreted to mean "Randomized Clinical Trial" (RCT), and an RCT is usually considered to be the gold standard for biomedical studies. We take the position that randomized controls are not necessary or even the best option for many medical device studies, and that the maligned historical controls, if used in carefully designed prospective observational studies, will yield as good or better information regarding the safety and efficacy of a new medical device, with advantages in the areas of generalizability (external validity), speed, cost, and ethical considerations.

Our experience with clinical trials for valve replacement, the first life-supporting device in heart surgery, runs the gamut from first-in-man, to the rapid development and implantation with significant refinements, starting in small numbers of patients hoping for improved performance, and finally to large-scale distribution and long-term follow-up of all patients receiving the device – all before the US Food and Drug Administration (FDA) became involved in 1974, when the Bureau of Medical Devices and Diagnostic Products was created. The FDA had the benefit of looking back at this heart valve development experience for developing guidelines for future medical devices. Also, early on before the FDA or major medical societies provided guidelines, our group had experience with randomized clinical trials of coronary artery bypass surgery (CABG). This has given us insights into the process that provides a clear perspective for the evaluation of various clinical trial methodologies. From the very beginning, surgeons and cardiologists of our team at the Oregon Health and Sciences University were allied with in-house mathematicians and statisticians, providing a powerful tool in pushing forward the frontiers of cardiac surgery.

Since our experience is primarily with heart valve replacement devices, we will begin by giving a brief history of heart valve development. Then we will critically assess the pinnacle position customarily assigned to *randomized* studies in the so-called "hierarchy of evidence," discuss the pragmatic view being adopted by the FDA, and the consequent alternatives to RCTs that have been advocated and used successfully for medical devices (especially heart valves). Then we mention some methods that have been proposed to improve observational studies, and to make comparative studies more adaptive, and conclude the heart valve story with the latest technological breakthrough – transcatheter implantation.

THE FIRST SUCCESSFUL HEART VALVE PROSTHESIS

Our perspective on clinical trials for medical devices was shaped by our work in the clinical investigation of heart valve prostheses. Creating them and deploying them in patients required original thinking in many areas of science, medicine, and ethics. A comprehensive review of heart valve function and dysfunction, and of the various devices available for repairing and replacing them, is given elsewhere in this volume (Schoen and Padera, 2010). Here, we give a brief discussion of some of the considerations involving the first human valve implants.

The first Starr-Edwards caged-ball heart valves were produced in a cabin workshop (Figure III.2.9.1) by retired engineer M. Lowell Edwards (Figure III.2.9.2), and implanted into black Labrador dogs. In 1960, after many dogs had been implanted, the decision was made to begin a clinical series. Although many dogs were dying, because the valves were being occluded by blood clots, humans have a less intense clotting mechanism, plus they would be given anticoagulant medicine which the dogs, for practical reasons, were not given. Interestingly, the cardiologists pushed the surgeon into acting sooner than

FIGURE III.2.9.1 The cabin in which Lowell Edwards produced the first Starr-Edwards heart valves.
FIGURE III.2.9.2 Lowell Edwards inside his workshop cabin.

he had intended, because their patients were dying of end-stage heart failure. The technique of randomization was certainly known by this time, it had been developed for agricultural experiments in the 1920s (Fisher, 1926) and extended to clinical applications by 1951 (Hill, 1951). But the laboratory dogs had not been randomized, and no thought was given to doing so with the patients. Instead, a dying patient was presented with a possibility of living.

The first successful implant was in 1960 (Starr and Edwards, 1961). Continual bench testing was being performed on the valve configuration and, as might be expected with any mechanical solution to a mechanical problem, incremental improvements in design were introduced. Between 1960 and 1966 there were nine mitral and five aortic valve "sub-models" (Figure III.2.9.3), each with slight improvements to certain mechanical parameters. (Such development would have been impossible if an RCT were required at each incremental step.) By 1964–1966 the development cycle had resulted in a stable design that was then unchanged until the valves were finally discontinued in 2007. Now (2010) in its 52nd year, the company that Lowell Edwards founded is still the leading manufacturer of heart valves (Figure III.2.9.4), and has distributed more than 1.5 million devices to date – none of which relied on RCTs to gain regulatory approval.

CRITIQUE OF MEDICAL DEVICE RCTs

Some studies must be observational, since it is not always possible to perform an RCT. An RCT may not be optimal or possible in public health research (Victora et al., 2004) or, for example, to study myocardial preservation techniques in open heart surgery (Liu et al., 1998). In situations where an RCT is possible, it may not be necessary to perform one. Obvious mechanical solutions to mechanical problems, such as seat belts or airbags in automobiles, parachutes in airplanes (Smith and Pell, 2003), and many other situations (Glasziou et al., 2007) do not require randomization. In fact, the frequency of surgical RCTs was only 9% in 1993 and 8% in 2006 (Barkun et al., 2009). Drugs, as opposed to medical devices, usually require an RCT, but the beneficial effects of aspirin and penicillin were discovered without one. It has been estimated that fewer than 20% of all clinical policies are based on randomized studies (Hornberger and Wrone, 1997).

We will discuss how heart valve prostheses have been evaluated clinically, including their regulatory requirements. But first, we present a general critique of randomized studies which have problems that are often not appreciated. Then we discuss why they are particularly ill-suited for the evaluation of many medical devices.

Hierarchy of Evidence: Fact or Myth?

It is widely, though not universally (Concato, 2004), assumed that there is a spectrum of evidential value for

medical studies. At the lowest end is the anecdotal evidence of a case report, at the highest end is the "unassailable" evidence of the RCT. But, we (Grunkemeier and Starr, 1992; Grunkemeier et al., 2006), and others (Black, 1996; Concato et al., 2000; Padkin et al., 2001; McCulloch et al., 2002; Victora et al., 2004; Grapow et al., 2006; Hordijk-Trion et al., 2006; Steg et al., 2007; Vandenbroucke, 2008) believe that there is a valid and important role in the advancement of medical knowledge for the large, well-conducted, real-world prospective observational study, using historical controls. In fact, a recent review article (Treasure, 2009) suggested that the usual hierarchy of evidence for medicines should be

inverted for the purpose of evaluating interventions, and an associated editorial (Moghissi, 2009) concluded that: "Logically, therefore, the benchmark which applies to the evaluation of drugs needs to be modified for the interventional procedures." This inversion of the hierarchy of evidence had been proposed earlier (Vandenbroucke, 2008).

A classic 1988 study demonstrated that analysis of an existing cardiac database could reproduce the results of randomized studies comparing surgery to medical management of coronary artery disease (Hlatky et al., 1988). A 1999 paper comparing surgery to coronary angioplasty showed no differences between the findings of an RCT and database analyses (Lewsey et al., 1999). Many subsequent studies have agreed that the value of observational (non-randomized) studies is not less than that of RCTs. A paper in the *British Medical Journal* on the relative merits of observational and randomized studies summarized an exhaustive review of the topic from a previous Health Technology Assessment study (Britton et al., 1998), and concluded that: "Treatment effects obtained from randomized and non-randomized studies may differ, but one method does not give a consistently greater effect than the other" (McKee et al., 1999).

Two reviews in the 2000 *New England Journal of Medicine* showed that the results of RCTs and large observational studies in many areas of research reached the same conclusions with regard to treatment effects. One paper reviewed 136 reports concerning 19 diverse treatments (Benson and Hartz, 2000), and the other evaluated 99 reports dealing with five clinical topics (Concato et al., 2000). A critical, but balanced, editorial accompanying these two papers expressed fear that these publications might result in fewer RCTs being done, and cited three situations where RCTs disagreed with observational

studies, but added that: "Detection of serious but rare side-effects requires very large numbers of patients, and can be achieved only through analysis of records from routine clinical practice" (Pocock and Elbourne, 2000). A balanced editorial discussion of these two papers in the *British Medical Journal* presented an analysis using the combined data sets from both studies, and noted the "striking concordance between the estimates obtained with the two research designs" (Ioannidis et al., 2001). A 2006 editorial in the *Journal of Thoracic and Cardiovascular Surgery* (Grapow et al., 2006) discussing studies of the relative benefits of CABG and percutaneous coronary intervention (PCI) concludes that: "only by considering both results from RCTs and large cohort studies can real-life clinical situations be reflected to a degree capable of providing applicable treatment guidelines useful in a daily clinical setting." A 2004 paper discussed the conflicting conclusions regarding the effect of hormone replacement therapy on acute coronary outcomes from a large RCT that found evidence contrary to all known observational studies (Garbe and Suissa, 2004); this should not be too surprising, considering a published indictment of "most published research findings" (Ioannidis, 2005).

Carefully planned, prospective observational studies have several advantages over randomized studies, especially with regard to the evaluation of a medical device. Results in "real-world" patients are obtained faster and cheaper. Randomized studies are expensive, ponderous, and slow. Once a study question arises, it may take a few years before the RCT is planned and implemented with patient recruitment, and a few more years after that before the results are available. Often, especially when the study involves a medical device, the results of the trial are obsolete by the time the trial results are available, because the device has been superseded. In the meantime, an ongoing observational study following the same patients, and observing the same outcomes and trends can provide an immediate answer to the same study question.

Internal Validity at the Expense of External Validity

Participants in RCTs are highly selected, and do not represent the patients to whom the winning therapy will eventually be applied. The providers (hospitals and physicians) that administer the RCT are highly selected, as are the patients who consent to this rather unnatural method of treatment selection. The patients must satisfy strict inclusion/exclusion criteria, resulting in less risky patients without common comorbidities. But, once the device is approved, it is used in the "real-world" on a much wider range of patients, and at a much wider range of centers (Britton et al., 1999; Hordijk-Trion et al., 2006; Steg et al., 2007; D'agostino and D'agostino, 2007). The result of these selection criteria severely limits the generalizability of the results to patients outside of the RCT (McKee et al., 1999). Moreover, RCTs

have their own "internal" problems. The randomization itself is not always done or done correctly (Altman and Bland, 1999). Blinding is not always done effectively (Ney, 1989; Berger and Exner, 1999), and can lead to masking an effect or even reversing the direction of an effect (Kunz and Oxman, 1998). Intention-to-treat analysis is not always done correctly (Hollis and Campbell, 1999), and such problems are accentuated for RCTs that evaluate surgical techniques (McCulloch et al., 2002; Anyanwu and Treasure, 2004). And: "the very act of random allocation may reduce the effectiveness of the intervention" (Black, 1996). Practical clinical trials have been advocated as a means to restore the goal of external validity (Tunis et al., 2003; Glasgow et al., 2005).

MEDICAL DEVICE REGULATORY TRIALS

The US Food and Drug Administration (FDA) has been responsible for granting marketing approval of medical devices in the US since the passage of the Medical Device Amendments (MDA) in 1976 (Holden, 1976). The MDA lists three device categories: Class 1 are common, low-risk devices, subject to "general controls" only; Class 2 devices are higher risk, and subject to "special controls;" Class 3 devices are the highest risk, and require a pre-market approval (PMA) application, involving a comprehensive clinical study. In approving such devices, the FDA is mandated to "rely upon valid scientific evidence to determine whether there is reasonable assurance that the device is safe and effective." Valid scientific evidence is broadly defined to include "evidence from well-controlled investigations, partially controlled studies, studies and objective trials without matched controls, well-documented case histories conducted by qualified experts, and reports of significant human experience with a marketed device, from which it can fairly and responsibly be concluded by qualified experts that there is reasonable assurance of the safety and effectiveness of a device under its conditions of use" (Office of the Federal Register, 2009). The FDA insists on RCTs for drugs, but is more equivocal on the preferred testing paradigm for devices (Chen et al., 2006), partly because of the fundamental differences between drugs and devices.

Medical Devices Differ from Drugs

The RCT methodology was developed for agricultural experiments (Fisher, 1926), and has been successfully adapted to the clinical testing of drugs. But medical devices are not drugs. Drugs solve a biochemical problem, their action is systemic, cannot be seen directly, and is often not well-understood. In contrast, medical devices solve a mechanical problem, their action is local, and the mechanism can be directly or indirectly observed. A heart valve can be seen to open, allow forward blood flow, and then close, preventing appreciable retrograde blood flow (Figure III.2.9.5), and it can do this repeatedly
FIGURE III.2.9.5 Schematic of the mechanical function of the caged-ball mitral valve.
FIGURE III.2.9.6 Effectiveness of the valve prosthesis in reducing cardiac enlargement: before (left); and after (right) mitral valve replacement.

for many years. Several Starr-Edwards heart valves have been implanted for more than 45 years, and hence have cycled approximately 1.8 billion times (Gao et al., 2004). The clinical efficacy can be measured objectively, for instance as reduced heart size and pulmonary congestion on a chest X-ray (Figure III.2.9.6). Also, drugs are basically temporary; they can be re-dosed or discontinued with ease, whereas implanted devices are more difficult to change. And, unlike a drug regimen, noncompliance

with an implanted medical device is not an option. Incremental improvements in the original Starr-Edwards heart valves each modified a small aspect of the design (Figure III.2.9.3), with a resultant small change in function. With a drug, a slightly different formulation might have a greatly different, and unpredictable, effect (Neaton et al., 2007; Pennello and Thompson, 2008).

An almost universal aspect of medical devices is their ongoing evolutionary improvement, so that by the time

a large, long-term RCT is completed, the device manu-facturer may have introduced another, improved model. This happened with the two large heart valve RCTs of the 1980s (Hammermeister et al., 2000; Oxenham et al., 2003); by the time these trials were completed, the valves used were no longer being manufactured. Also, by the time they were completed, the results that they obtained had already been reported by numerous observational studies (Grunkemeier et al., 2006).

The effect of a drug is independent of the prescribing physician, but the effect of an implanted medical device depends on the skill of the implanting physician and surgical team (Ergina et al., 2009). Finally, for drugs, multi-center trials can recruit thousands of patients over a relatively short time, but for devices, the number of patients available is much smaller. Recent FDA-written publications have acknowledged these differences: "However, use of an RCT study design is especially challenging in certain circumstances, including cardio-vascular device development" (Zuckerman and Muni, 2005), and: "Consequently, nonrandomized clinical studies play a substantial role in the evaluation of medical devices" (Li and Yue, 2008).

FDA Heart Valve Guidance

The original FDA requirement for approval of a new heart valve specified the collection of certain data; completeness and accuracy of the collected data were important, but the decision for marketing approval was based on the subjective opinion of the reviewers (Sapirstein, 2001). In 1993 the FDA, in consultation with a committee of experts from industry and academia, pro-duced a Guidance Document for heart valve prostheses (Division of Cardiovascular, Respiratory, and Neuro-logical Devices; Center for Devices and Radiological Health; US Food and Drug Administration, 1994). This document requires a well-designed, adequately pow-ered, prospective, single-arm study. The results of this study are measured against target values called Objective Performance Criteria (OPC), which is really a euphemism for historical controls. The OPC values were gleaned from a large literature on FDA-approved heart valves (Grunkemeier et al., 1992; Wheatley, 2004), and a sample size of 800 valve-years was shown to be adequate to evaluate the performance of a heart valve candidate for FDA approval (Grunkemeier et al., 1994).

Why would the FDA permit historical controls for pre-market approval of new heart valves? First, the existing valves worked very well, and had solved the big initial problems of insecure attachment, rejection, infec-tion, etc. The OPC concept was based on the fact that heart valves have well-defined performance profiles, and that the expected complications are well-known (Table III.2.9.1) and well-defined (Aitkin et al., 1983; Akins et al., 2008b,c). Also, the complication rates for approved valves tend to cluster around certain norms (Figure

III.2.9.7), based on a review of 37,000 mechanicalvalves with 187,000 valve-years of follow-up from 95 pub-lished series, and 24,000 biological valves with 132,000 valve-years from 70 published series (Grunkemeier et al., 2000). The FDA felt justified for making this deci-sion since: "… the use of a prospective concurrent con-trolled clinical trial, the gold standard of study design, presented insurmountable problems for the testing of a cardiac valve prosthesis – problems such as the size of study samples necessary for the statistical analysis of extremely low adverse event rates. A compromise was adopted, whereby rates for the most frequently occurring complications for approved valve prostheses, as reported in peer-reviewed literature, were to be applied as com-parators to those complications experienced with any new valve design" (Sapirstein, 2001).

TABLE III.2.9.1	**Complications for Evaluating Clinical Performance of Mechanical and Biological Heart Valves, and Objective Performance Criteria (OPC) Values for Complication Rates (Percent/Year)***	
Definitions from the Guide-lines for Reporting Mortality and Morbidity after Cardiac Valve Interventions	**OPC Values**	
	Mechanical Valves	**Biological Valves**
Embolism: any embolic event that occurs in the absence of infection after the immediate perioperative period. May be manifested by a neurologic event or a noncerebral embolic event.	3.0	2.5
Valve thrombosis: any thrombus not caused by infection attached to or near an operated valve that occludes part of the blood flow path, interferes with valve function or is sufficiently large to warrant treatment.	0.8	0.2
Bleeding: any episode of major internal or external bleeding that causes death, hospitalization or permanent injury, or necessitates transfusion.	3.5 (1.5)	1.4 (0.9)
Parivalvular leak: resulting in dysfunction of an operated valve, as diagnosed by reoperation, autopsy or clinical investigation.	1.2 (0.6)	1.2 (0.6)
Endocarditis: any infection involv-ing an operated valve.	1.2	1.2

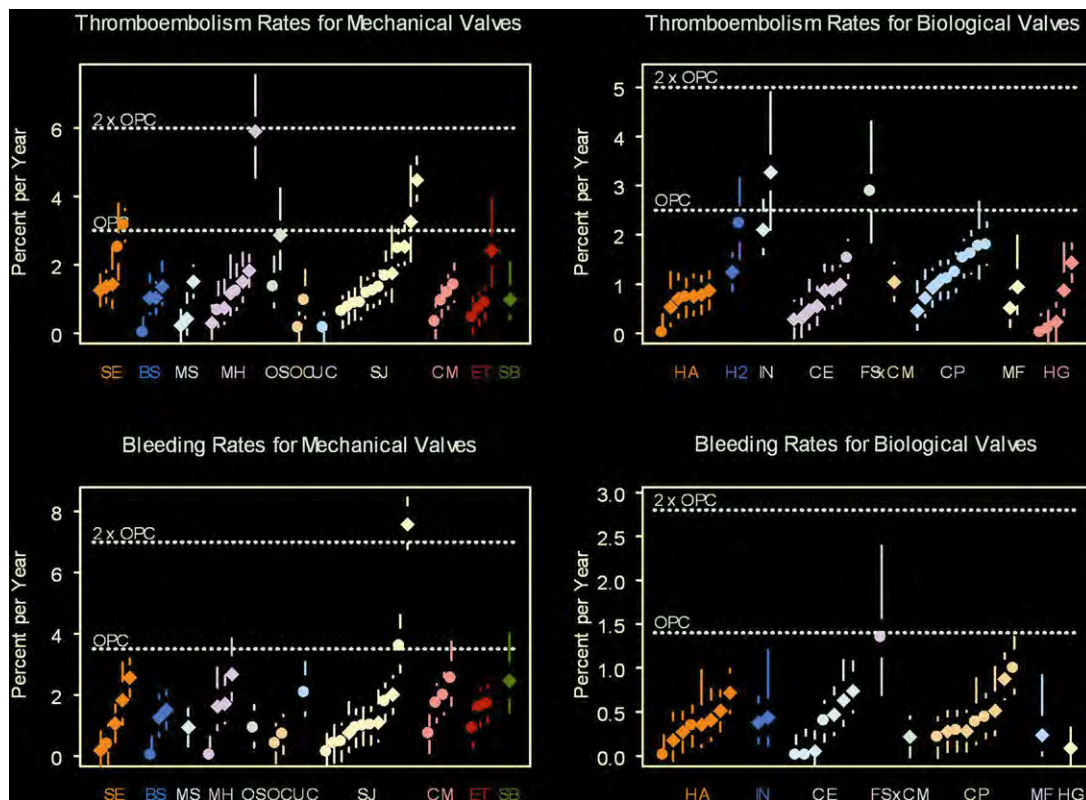
*The complications and definitions are from the Guidelines for Reporting Mortality and Morbidity after Cardiac Valve Interventions (Akins et al., 2008a,b,c). The OPC values are taken from Appendix K of the Draft Replacement Heart Valve Guidance (Division of Cardiovascular, Respira-tory, and Neurological Devices; Center for Devices and Radiological Health; US Food and Drug Administration, 1994). Numbers in parentheses are the OPC for major events.


FIGURE III.2.9.7 Figures demonstrating the well-established rates and ranges of thromboembolism and bleeding for mechanical and biological valves. The height of each symbol represents the rate from one published series, with 90% confidence intervals shown by the vertical bars. The OPC (Objective Performance Criteria) are shown by horizontal lines. The FDA requirement, that the upper confidence limit be less than twice the OPC, is achieved by all but two of these valve series.

Support for the FDA Position

An endorsement of the FDA-mandated 800 valve-year criterion was recently reported. A huge randomized four-year study, designed to include 4400 patients from 17 centers, was undertaken to evaluate a new valve sewing ring designed to reduce endocarditis (Schaff et al., 1999). Since endocarditis is so rare, the study required over 10,000 valve-years of follow-up, but was prematurely terminated by the DSMB (Data Safety Monitoring Board) because of an unanticipated, statistically significant increase in re-operation for paravalvular leak (Schaff et al., 2002). However, a single-arm study of only 800 valve-years would have shown that the new sewing ring had a significantly greater incidence of major paravalvular leak than the OPC allowed (Grunkemeier et al., 2006).

Further endorsement of this FDA decision can be inferred from a randomized comparison of the earliest, caged-ball Starr-Edwards valve, and the most widely-used, modern, bileaflet St. Jude Medical valve. After five years of follow-up, the study found no difference in rates of complication or of symptomatic improvement between the two valves in either the aortic or mitral position (Murday et al., 1998). Note that even though these two valve models look nothing alike (Figure III.2.9.8), they perform the same basic mechanical functions (opening and closing) equally well.

The OPC approach is outlined in a recent paper written by members of the CDRH (Center for Devices and Radiological Health) (Chen et al., 2006), which states the FDA position: "The FDA is willing to accept alternative designs and controls, such as OPC, when based on sound arguments that they will provide sufficiently robust data … Since their introduction in 1994, the FDA has approved 15 cardiac valve prostheses with data derived from single-arm studies … a study design with OPC that has served well for open surgical cardiac valve replacement with established technology." At a Circulatory System Device Panel meeting, the FDA suggested using an OPC for survival to transplant for left ventricular assist devices used as a bridge to transplant (Neaton et al., 2007). An enhanced version of the OPC concept has also been recommended for evaluation of coronary artery stents (O'Malley et al., 2003).

Current FDA Draft Heart Valve Guidance

In January 2010, the FDA issued a Draft Guidance for heart valve IDE (Investigational Device Exemption) and PMA (US Department of Health and Human Services, 2010a). The section on *Clinical Investigations* follows the theme of the previous guidance document for conducting a clinical trial for heart valves. The FDA continues to endorse the use of
FIGURE III.2.9.8 Starr-Edwards (left); and St. Jude Medical (right) mechanical heart valves. (Reproduced with permission from St. Jude Medical)

historical controls (OPC): "Based on our long history in the evaluation of heart valves and the extensive reporting in the literature, FDA believes that a single-arm study with literature-based controls is the least burdensome approach to clinical evaluation of a replacement heart valve. Your clinical study should include appropriate controls including literature-based objective performance criteria (OPCs) for safety data, and literature articles and reports for both safety and effectiveness data."

IMPROVING OBSERVATIONAL STUDIES

Two 2004 papers in *The Lancet* (Lawlor et al., 2004; Vandenbroucke, 2004), and an accompanying commentary (Concato and Horwitz, 2004), describe the strengths of observational studies, and suggest ways of improving them. A recent series of three articles in the *British Medical Journal* provides a "critical appraisal" of observational (cohort) studies (Mamdani et al., 2005; Normand et al., 2005; Rochon et al., 2005). Their premise is that there is a place for observational studies, since RCTs: "face important ethical and logistical constraints, and have been criticized for focusing on highly selected populations and outcomes." They offer ways to improve cohort studies, but go on to say: "However, the promise of cohort studies as a useful source of evidence needs to be balanced against concerns about the validity of that evidence." And the series concerns itself with best methods for producing valid evidence, in the design (Rochon et al., 2005), assessment (Mamdani et al., 2005), and analysis (Normand et al., 2005) of such studies.

A 2007 article in the *Journal of the American Medical Association* (*JAMA*) compared three methods for removing the effects of selection bias in observational studies: multivariable model risk adjustment; propensity

score analyses; and instrumental variable analysis (Stukel et al., 2007). An accompanying editorial (D'agostino and D'agostino, 2007) concluded: "RCTs should not always be considered as the only source of valid scientific information. The data collected from such studies are strong only if it can be shown that in fact a truly random sample of eligible patients participate and complete the protocol as designed." A 2007 letter in *JAMA* (Vandenbroucke, 2007) makes an interesting point about safety rather than efficacy: "When restricted to negative unexpected effects, observational research is equally reliable as randomized trials, which was recently shown by a comparison of randomized versus observational studies of adverse effects of treatment" (Papanikolaou et al., 2006; Vandenbroucke, 2006).

Propensity Score Analysis

The propensity score (PS) method was introduced in 1983 (Rosenbaum and Rubin, 1983), but has only become popular in recent years. A PubMed search (March 2010) for papers with "propensity score" in the title produced the following numbers of citations for the years 2001 to 2009, respectively (of course many studies used the PS method without including it in the title of the paper): 4, 5, 12, 16, 23, 25, 34, 43, and 43. One of the co-introducers of the PS method published a very readable description, including an intuitive appreciation for the validity of this method (Rubin, 1997). The FDA has suggested that: "For nonrandomized controlled trials, the use of propensity score analysis may allow a more appropriate comparison of control to treatment data" (Chen et al., 2006). An informative FDA perspective on the use of propensity score (PS) methods in medical device trials was recently published (Yue, 2007), along with seven discussion papers and a rejoinder.

Guidelines for Reporting (STROBE)

The well-known CONSORT (CONsolidated Standards Of Reporting Trials) statement was developed to improve the reporting of RCTs (Begg et al., 1996). Similarly, the recently developed STROBE (STrengthening the Reporting of OBservational studies in Epidemiology) statement contains recommendations on what should be included in an accurate and complete report of an observational study. The STROBE recommendations were simultaneously published in many journals (Von Elm et al., 2007a,b,c,d,e,f), and a supplementary elaboration was also simultaneously published in several journals (Vandenbroucke et al., 2007a,b,c). The STROBE checklist for cohort studies (Table III.2.9.2), and similar lists for case-control and cross-sectional studies are available at the STROBE website (Strobe, 2007). This website currently (2012) lists 110 journals that refer to the STROBE statement in their Instructions to Authors.

ADAPTIVE AND BAYESIAN TRIALS

In a traditional trial, patients are assigned equally to two treatments, and only at the end of the trial when the predetermined number of patients have been treated are we allowed to look at the data and decide which treatment is more effective. We begin by assuming that the therapies are equivalent (clinical equipoise), but if we were permitted to look at the accumulating data, we might discover that one of the treatments has already shown itself to be superior, and we could stop the trial and offer the superior treatment to the remaining patients. Another possibility is that the treatments are so similar that the trial should be stopped for futility or more patients than originally planned should be recruited. In an *adaptive*, also called *response-adaptive* trial (Rosenberger and Lachin, 1993), patient outcomes can be used as soon as they become available. This confers an ethical advantage, since fewer patients will be subjected to the inferior treatment during the trial.

Adaptive designs have been around for a long time. So-called *multi-armed bandit* designs originated in 1952 (Robbins, 1952), named after the *one-armed bandit* nickname for a slot machine gambling device. When used in a clinical trial, a bandit design aims to minimize the number of patients who get the inferior treatment. (In fact, the term *treatment arm* comes from the analogy to the bandit problem, where the "arms" represent different slot machines.)

An interesting form of adaptive trial is called *play the winner* (Zelen, 1969). The assignment of the current patient is decided by the result of the previous patient. If the previous patient's treatment was successful, it is used again on the next patient; if not, the other treatment is used. This requires that the treatment outcome is known quickly (e.g., procedural success). As an extreme example, in a trial of parachute versus no parachute, there

would be only two possible outcomes: if the first patient is assigned "parachute," and the outcome is survival, then all future patients would be assigned parachute, and no patients would die. The worst case would be that the first patient is assigned "no parachute," and then there would be only one death in the trial.

Bayesian Analysis

Bayesian statistical methods are better for many applications, including clinical trials, than the more commonly used "frequentist" methods (reminds one of the putative superiority of Apple Macintosh computers in a world dominated by Windows-based computers). Bayesian designs allow prior knowledge to formally influence the results derived from the current study data, to apply knowledge about similar devices to formally augment the data generated by the present study device, just as one tends to do in everyday life. For example if 0 out of 5 new devices fail, the point estimate for failure is 0%, with an extremely wide *confidence interval*. But if this result comes from a device that is very similar to a previous device, about whose failure rate a substantial amount of (historical) information is already available, that information can be used to augment the results from a small sample of new devices (Connor and Berry, 2005). Moreover, the Bayesian summarization of the results is in terms of the probability of an effect being in a certain interval (*credible interval*). This is a natural, understandable summary statistic – the answer that most clinicians want, and that many erroneously think they are getting from a *confidence interval*, the frequentist counterpart. Medical inference is naturally deductive, as is the Bayesian approach, whereas traditional statistical methods are inductive (Goodman, 1999). Thus, most clinicians are Bayesians at heart. The Bayesian approach lends itself rather ideally to medical device trials (Hobbs and Carlin, 2008), especially when there is an incremental change to a new model, and information is available for previous models that are very similar to the new device (Figure III.2.9.3). Bayesian trials can often be shorter, with fewer patients involved, than a frequentist trial, because of the contribution of the prior information to the study.

The FDA is actively supporting the use of Bayesian methods for new device applications. An FDA workshop in April 2008 emphasized Bayesian analysis and adaptive designs in the evaluation of medical devices.

- In February 2010 the FDA published a *Guidance for the Use of Bayesian Statistics in Medical Device Clinical Trials* (US Department of Health and Human Services, 2010b).
- A recent talk on Bayesian Statistics, "Bayesian Statistics at the FDA: The Pioneering Experience with Medical Devices," was given by Greg Campbell, Director, Division of Biostatistics, of the CDRH (Center for Devices and Radiological Health) (Campbell, 2009).

TABLE III.2.9.2		STROBE Checklist of Items That Should be Included in Reports of Cohort Studies
	Item No	**Recommendation**
Title and abstract	1	(a) Indicate the study's design with a commonly used term in the title or the abstract (b) Provide in the abstract an informative and balanced summary of what was done and what was found
Introduction		
Background/ rationale	2	Explain the scientific background and rationale for the investigation being reported
Objectives	3	State specific objectives, including any prespecified hypotheses
Methods		
Study design	4	Present key elements of study design early in the paper
Setting	5	Describe the setting, locations, and relevant dates, including periods of recruitment, exposure, follow-up, and data collection
Participants	6	(a) Give the eligibility criteria, and the sources and methods of selection of participants. Describe methods of follow-up (b) For matched studies, give matching criteria and number of exposed and unexposed
Variables	7	Clearly define all outcomes, exposures, predictors, potential confounders, and effect modifiers. Give diagnostic criteria, if applicable
Data sources/ measurement	8*	For each variable of interest, give sources of data and details of methods of assessment (measurement). Describe comparability of assessment methods if there is more than one group
Bias	9	Describe any efforts to address potential sources of bias
Study size	10	Explain how the study size was arrived at
Quantitative variables	11	Explain how quantitative variables were handled in the analyses. If applicable, describe which groupings were chosen and why
Statistical methods	12	(a) Describe all statistical methods, including those used to control for confounding (b) Describe any methods used to examine subgroups and interactions (c) Explain how missing data were addressed (d) If applicable, explain how loss to follow-up was addressed (e) Describe any sensitivity analyses
Results		
Participants	13*	(a) Report numbers of individuals at each stage of study, e.g., numbers potentially eligible, examined for eligibility, confirmed eligible, included in the study, completing follow-up, and analyzed (b) Give reasons for non-participation at each stage (c) Consider use of a flow diagram
Descriptive data	14*	(a) Give characteristics of study participants (e.g., demographic, clinical, social) and information on exposures and potential confounders (b) Indicate number of participants with missing data for each variable of interest (c) Summarize follow-up time (e.g., average and total amount)
Outcome data	15*	Report numbers of outcome events or summary measures over time
Main results	16	(a) Give unadjusted estimates and, if applicable, confounder-adjusted estimates and their precision (e.g., 95% confidence interval). Make clear which confounders were adjusted for and why they were included (b) Report category boundaries when continuous variables were categorized (c) If relevant, consider translating estimates of relative risk into absolute risk for a meaningful time period
Other analyses	17	Report other analyses done, e.g., analyses of subgroups and interactions, and sensitivity analyses
Discussion		
Key results	18	Summarize key results with reference to study objectives
Limitations	19	Discuss limitations of the study, taking into account sources of potential bias or imprecision. Discuss both direction and magnitude of any potential bias
Interpretation	20	Give a cautious overall interpretation of results considering objectives, limitations, multiplicity of analyses, results from similar studies, and other relevant evidence
Generalizability	21	Discuss the generalizability (external validity) of the study results
Other Information		
Funding	22	Give the source of funding and the role of the funders for the present study and, if applicable, for the original study on which the present article is based

*Give information separately for exposed and unexposed groups.

- A Special Issue on Medical Device Clinical Studies appeared in the *Journal of Biopharmaceutical Statistics* (Vol. **18**(1), 2008), with Guest Editor Lilly Yue of CDRH/FDA. Many of the papers are written by FDA staff, and Bayesian statistics are prominently featured.
- The FDA and Johns Hopkins University co-sponsored a workshop, "Can Bayesian Approaches to Studying New Treatments Improve Regulatory Decision-Making?" The proceedings were published in the August 2005 issue of *Clinical Trials* (Alderson, 2005).

Bayesian Adaptive Trials

Bayesian methods are particularly well-suited to adaptive clinical trials, as was pointed out in a recent FDA guidance document that lists the advantages of a Bayesian adaptive trial, including modifying the sample size (to stop or to continue patient recruitment), and possibly stopping the trial early either for success, futility or harm (US Department of Health and Human Services, 2010b). A primary advantage of adaptive trials, and particularly Bayesian adaptive trials, stems from ethical considerations. These designs are most ethical, because they minimize the number of patients who ultimately get the inferior treatment, within the clinical trial itself, as opposed to the usual fixed sample size trial (Berry, 2004, 2006). This chapter is not intended to be a cookbook on how to design a Bayesian adaptive trial, but excellent cookbooks do exist (Spiegelhalter et al., 2004).

CLINICAL TRIALS FOR TRANSCATHETER VALVES

We began this chapter with the story of the first successful heart valve. The latest technology and current clinical study challenge for this type of medical device is the percutaneous or transcatheter replacement heart valve. In the US, the first FDA-approved (2010) transcatheter valve is for the pulmonary position (Medtronic Melody® Transcatheter Pulmonary Valve), intended to treat desperate congenital situations under the Humanitarian Device Exemption, in a relatively small percentage of patients. The overwhelming clinical impact will be from devices developed to treat the growing population of adult patients with severe aortic stenosis.

Note on terminology: Both *percutaneous* and *transcatheter* have been used to describe this type of heart valve intervention. Since these valves can sometimes be implanted via an incision in the left ventricular apex, as well as by the more common femoral artery, using catheterization techniques, *transcatheter* is the more-encompassing adjective. Also, since the native (or failed bioprosthetic) valve is not explanted, but compressed against the aortic root, the term "implantation" is preferable to "replacement." Thus, although PAVR (Percutaneous Aortic Valve Replacement) is still being used (Chiam and Ruiz, 2009),

TAV (Transcatheter Aortic Valve) and TAVI (TAV Implantation) are the preferred acronyms.

Historical Perspective

The first CABG surgery was performed in 1967 (Favaloro et al., 1967). Then, just 10 years later, cardiologists discovered a way to repair clogged coronary arteries using catheters, at first just dilating them with a catheter-placed balloon (Gruentzig, 1982), then inserting a (bare metal) stent as well to keep the artery expanded (the Palmaz-Schatz stent was FDA-approved in 1994), and more recently using drug-eluting stents (the Cypher® stent was FDA-approved in 2003; the Taxus® stent was FDA-approved in 2004) to attenuate restenosis of the stent. Contrast that 10-year lag time with how long it took to discover a way to perform heart valve insertion via catheter; the first transcatheter aortic valve implantation was performed more than 40 years (Cribier et al., 2002) after Starr's surgical replacement (Starr and Edwards, 1961). However late arriving, this new cardiologic/surgical partnership paradigm will be transformational in the treatment of heart valve disease in the future.

In the early 1990s, there was another pending paradigm shift in heart valve prostheses, marked by the introduction of *stentless* bioprosthetic valves. The original tissue or bioprosthetic heart valves, developed by Carpentier and first marketed by Hancock, a company later bought by Medtronic, were porcine valves with a frame-like structure called a *stent* that supported the leaflets and attached to the sewing ring. Then, to obtain anticipated improvements in hemodynamics and durability, motivated by the perceived advantages of human homograft transplant valves, several valve manufacturers started producing porcine valves *without* a stent. At that time, we argued for the use of single-arm studies for evaluation of these valves: "Moreover, for evaluating a new heart valve, the primary purpose should be estimation rather than comparison with a current device. This can be accomplished faster, in a more generalizable way, and with more concern for patient care by using non-randomized comparison groups" (Grunkemeier and Starr, 1992). In fact, several stentless valves were FDA-approved by the late 1990s, based on prospective, single-arm, historically-controlled (using OPC) observational studies. As we have seen, implantable devices, especially innovative devices such as TAVs, and their implantation are adaptive in nature, and thus eminently well-suited to adaptive study designs and the use of historical controls.

Clinical Trials: The Societies Weigh In

In 2005, the "Clinical Development of Percutaneous Heart Valve Technology," a joint position statement from the Society of Thoracic Surgeons, the American Association for Thoracic Surgery, the American College

of Cardiology, the Society for Cardiovascular Angiography and Interventions, the US Food and Drug Administration, the Centers for Medicare and Medicaid Services, and numerous representatives from industry, recommended that RCTs should be used to evaluate TAVI (Vassiliades et al., 2005a,b,c,d).

However, a more recent (2008) position paper gives another perspective from the Europeans, who are already quite experienced with TAVI. Both the Edwards Lifesciences SAPIEN and Medtronic CoreValve® devices have already received their CE (Conformité Européenne) Mark approvals in 2007, and are being marketed in Europe, with about 50,000 implants to date (2012). This position paper is jointly from the European Association of Cardio-Thoracic Surgery and the European Society of Cardiology, in collaboration with the European Association of Percutaneous Cardiovascular Interventions (Vahanian et al., 2008a,b,c), and states that: "The Committee believes that randomized trials are highly desirable once greater experience has been acquired, and only small modifications in the technology used are to be expected." This statement agrees with our previous arguments: "Although randomization is not practicable for establishing the adequacy of a new heart valve, it is an optimal strategy for comparing subtle differences in an established valve" (Grunkemeier et al., 2000). "Marketing approval can be based on an absolute comparison with qualifying standards through the use of historical controls. However, short-term studies (randomized or not) cannot detect increased rates of rare or late events. Long-term post-market studies, including RCTs where appropriate, can be used to detect rare complications and differences with regard to late-occurring complications among otherwise comparable valves" (Grunkemeier, 1998).

This revolutionary TAV therapy was mentioned as the motivation for the FDA rethinking the design of device trials (Chen et al., 2006). A recent overview points out the benefits of the Bayesian approach and of propensity score analysis in clinical trials, and discusses how best to assess results and outcomes: "which may require a paradigm shift in mindset. Apart from the randomized controlled trial, some of the more novel concepts in trial design which may be more suitable in this area are also explored" (Chiam and Ruiz, 2008).

The Devices and Their Clinical Trials

To date there are at least 17 TAV contenders, seven of which have already been used clinically (Chiam and Ruiz, 2009). Two of these are currently the most well-developed: the Edwards Lifesciences SAPIEN valve (Figure III.2.9.9, left); and the Medtronic CoreValve® (Figure III.2.9.9, right). Technical details of these valves are given elsewhere in this volume (Chapter II.5.3); below we focus on their clinical studies.

Edwards Lifesciences SAPIEN Valve. Edwards Lifesciences, the company started by Lowell Edwards as chronicled at the beginning of this chapter, is producing a balloon-expandable bovine pericardial TAV. The valve is based on the first-ever-in-man TAV implanted in 2002 (Cribier et al., 2002). Edwards has designed an RCT, called the PARTNER (Placement of AoRTic traNscathetER valves) Trial to seek FDA approval (US National Institutes of Health, 2007). This is two studies in one: in one study (PARTNER A), the SAPIEN valve is randomized against a conventional, surgically implanted valve; in the other study (PARTNER B), SAPIEN is randomized against medical management in patients who were not considered suitable for surgery. In November 2011 Edwards received FDA approval to use the SPAIEN valve in these latter, "unoperable", patients. The PARTNER Trial design specifies 22 exclusion criteria, so deployment will not be to the "real-world" of aortic valve patients, and the problem of internal versus external validity in this study must be addressed. The SAPIEN leaflet material has already changed from untreated equine to treated bovine pericardium, the
FIGURE III.2.9.9 Transcatheter heart valve implantation devices: Edwards Lifesciences SAPIEN (left); and Medtronic CoreValve® (right). Reproduced with permission from Edwards LifeSciences and CoreValve.

catheter sizes have changed, a next-generation Edwards SAPIEN XT valve has already received the CE Mark. Not only are the devices continually evolving, but the operator skills and patient selection (Chiam and Ruiz, 2009) are also improving with time, and consequently the mortality and major complications are continuing to decrease. "In the initial 15 patients there were five deaths for an early mortality of 33%. After this initial learning curve, seven of the remaining 56 patients died, for an early mortality of 12.5%" (Ye et al., 2010). These changes are almost entirely on the SAPIEN arms of the study, not the control arms. In this setting, a fixed, randomized study seems to violate what was said in a short, but important, FDA publication (Sapirstein, 2001) which mentions that the OPC method was chosen for heart valves because an RCT: "presented insurmountable problems for the testing of a cardiac valve prosthesis …" And, although this: "approval process … has the limitations characteristic of any nonrandomized or non-concurrent controlled study. It was accepted as necessary in part to accommodate timely availability of technologic advances for the fabrication of prosthetic cardiac valves" (Sapirstein, 2001).

In September 2010, the PARTNER Trial reported promising early results for the study in 358 patients with severe, symptomatic aortic stenosis, who were deemed inoperable. They concluded that the SAPIEN valve: "… as compared with standard therapy, significantly reduced the rates of death from any cause, the composite end point of death from any cause or repeat hospitalization, and cardiac symptoms, despite the higher incidence of major strokes and major vascular events" (Leon et al., 2010).

Medtronic CoreValve®. CoreValve, Inc. was founded in 2001, and performed its first-in-man transcatheter valve procedure in 2004. Its ReValving System is comprised of a porcine (originally bovine) pericardial tissue valve, mounted on a self-expanding frame. As of November 2010 it had been implanted in more than 20,000 patients worldwide. Medtronic acquired CoreValve in 2009, and in 2010 began the CoreValve Advance International Post Market Study. This is an observational study in the "real-world" patient population of an estimated 1000 patients in 70 cardiac centers in 13 countries outside the US (US National Institutes of Health, 2010). Yet, to get approval for marketing in the US, an RCT of about 1200 patients will soon be launched (Medtronic, Inc., 2010).

SUMMARY

We discuss clinical trials for medical devices using heart valves as an example. During the past 50 years, many excellent heart valve prostheses have been developed and successfully introduced into clinical use. Since 1976, the FDA has overseen the market approval process in the US. Perhaps surprisingly, the FDA requirement for the definitive clinical trial is based on historical controls, called Objective Performance Criteria (OPC), rather than on

randomized clinical trials (RCT). This method was introduced in a 1993 guidance document, and again upheld in a 2010 draft guidance document. Although RCT is the preferred method of clinical evaluation for drugs, for heart valves in particular, and for most medical devices in general, a well-designed and carefully monitored single-armed prospective study using historical controls is sufficient, and more efficient in terms of cost and duration of the study. For comparative trials, the FDA has also advocated adaptive designs, and in particular Bayesian adaptive designs. These result in more humane trials, because the fewest number of patients in the trial are subjected to what turns out to be the inferior therapy. The most recent development in this arena is heart valves intended to be implanted using a catheter. Although not yet approved for marketing in the US, these revolutionary valves promise to transform the treatment of aortic stenosis, especially in the elderly. Two different companies are mounting clinical trials of these devices, both using RCTs. It will be interesting to see whether any new clinical information about the performance of these valves comes from the RCTs that is not already known, or will become known, from the nonrandomized observational studies.

CHAPTER III.2.10 ENTREPRENEURSHIP IN BIOMATERIALS

Robert Langer,[1] Jason Fuller[2] and Mark Levin[2]
[1]Department of Chemical Engineering, Massachusetts Institute of Technology Cambridge, MA, USA
[2]Third Rock Ventures, Boston, MA, USA

INTRODUCTION

Start-up companies are an integral part of the biomedical product development landscape. Although most medical devices are manufactured, marketed, and sold by large companies, their fundamental technologies are often born in the university setting, and incubated in small start-up companies (Kahn, 1991).

Starting a company can be a great opportunity to raise the awareness of academic work, and also to have a significant impact on the industry and on patients' lives. It is a complex process of bringing together people, ideas, money, and business. The start-up environment is a fast-paced, dynamic, and collaborative home for a project, and with the right vision, team, technology, and plan, a start-up company can be highly efficient at creating significant development progress and creating considerable value.

However, we want the reader to understand the risks inherent in starting a company: a relatively small percentage of start-up companies get a product to market (Gompers, 2008), and the effort required can be substantial. Therefore, the decision to spin out one's research into a company should not be taken lightly.

Many paths can bring a technology or product to market, and many of the functional challenges of patent protection, product design, regulatory approval, reimbursement, and ethical issues are described earlier in this book. These challenges are faced both in established companies and start-ups. However, the culture, pace, politics, risk profile, and potential reward differ between start-up and large company. It is recommended that the biomaterials specialist consider entrepreneurship as one of many potential avenues for developing a successful product.

This chapter will step into the shoes of an entrepreneur planning to start a company. First, we will survey the entrepreneurial ecosystem with a focus on the interconnections between its members and the transfer of resources into the company. After an overview of the start-up process, we will cover the criteria entrepreneurs use to decide which company ideas are worth spinning out, and which ones are better suited to academic exercises or large company projects. We will finish with several tips on entrepreneurial decision making, and how venture capital firms decide which companies to fund.

The fundamental message of this chapter is that academics, entrepreneurs, and investors should carefully choose which companies to start, join or fund. In this chapter, we will develop five criteria for starting a new company. As you read the various sections, keep these criteria in mind, and we will revisit them at the end of the chapter.

Suggested criteria for choosing research projects to spin into a company include the following (Kent Bowen et al., 2004):

1. Is this a high impact area?
   a. Clinically high impact (will it help patients?)
   b. High impact to potential commercial partners (will it create shareholder value?)
   c. Scientifically high impact (is the technology new and important?)
2. Have you published a seminal paper?
3. Have you obtained a protecting patent?
4. Have you demonstrated efficacy data in animals?
5. Can you build a great team?

THE ENTREPRENEURIAL ECOSYSTEM AND THE START-UP PROCESS

The creation of a start-up company assumes that a small, focused, and highly motivated team can efficiently develop a new product and that the company can be the appropriate investment vehicle for those involved. In a start-up, inventors of intellectual property, shareholders, employees, and other key players acknowledge that the start-up is the best vehicle for commercializing the technology, as opposed to licensing to a company, for example. This advantage may exist for a number of reasons: for example, universities may lack the facilities or infrastructure to take a project to the next step or large companies may be constrained by their organizational bureaucracy. In other cases, the choice of spinning out a project into a new company is purely financial (Chatterji, 2009).

Although start-up companies lack some of the structural challenges common in universities and large companies, they have their own risks. Start-up companies have a narrow focus, sometimes on a single product or narrow platform, they cannot diversify risks in the ways large companies can. Therefore, if a start-up encounters an enormous setback, with no way to compensate, it may trigger the company's demise. Start-up companies do fail for reasons beyond anyone's control, and all parties should understand that although the risks are high, the rewards are great if the company succeeds. The challenge for the start-up company is then to share these risks and rewards in an equitable way between all of its members. Bringing together all of these partners is the first challenge of building a company.

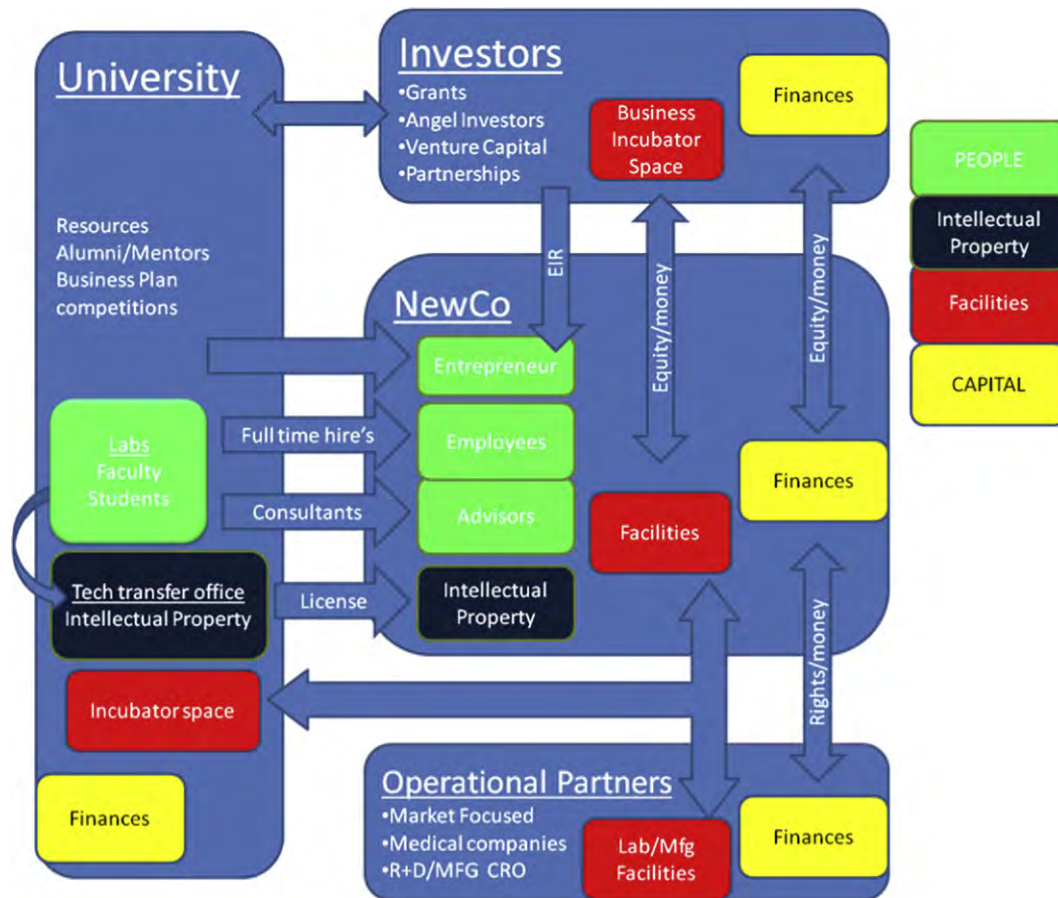
Figure III.2.10.1 summarizes the process of transferring these people and resources into the start-up company, NewCo. In the figure, the four main components of a start-up are color-coded as described below.


FIGURE III.2.10.1 The entrepreneurial ecosystem. A representation of the complex interplay between investors, universities and existing companies in the industry.

The essential components of a biomedical start-up include:

1. People (green);
2. Technology (intellectual property) (blue);
3. Facilities (red);
4. Capital (yellow).

It is the combination of these components that leads to successful companies. When brought together, these raw materials lead to the creation of high value products, as shown in Figure III.2.10.2. The process of bringing them together is a complex and high-risk exercise.

Each of the pieces is typically legally "transferred" from other organizations to the start-up. The typical organizations in the entrepreneurial ecosystem include:

1. The university (or hospital);
2. The start-up;
3. Funding agencies;
4. Corporate partners.

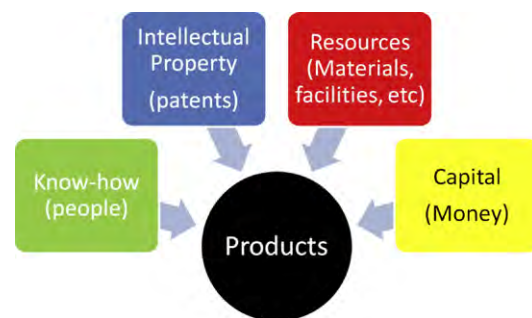
Figure III.2.10.1 shows the connections between these organizations. At the center of the ecosystem, the start-up must build relationships with the university, the funding agencies, and its corporate partners. As the start-up builds these relationships and negotiates to bring in


FIGURE III.2.10.2 Inputs to generating innovative life science products.

people, IP, facilities, and capital, a number of decisions are required.

These decisions are made by the shareholders in the company. When a company is incorporated, it becomes a discrete legal entity. Shares of the company, each of which represents ownership of a fraction of the company, are distributed between its owners. The shares have value because the shareholders are entitled to their fraction of the start-up's future profit. Capital investment (cash), intellectual property rights, and services can all be exchanged for shares. Since the start-up company is private and there is no market where shareholders can sell their shares,

it typically sells chunks of shares to equity investors in exchange for a cash investment. This equity investment sets the price of the shares, and gives the company money to begin operating. As the pieces come together, the relationship with each partner is formalized with a contract outlining the specific terms of the relationship. The company exchanges money or shares in exchange for people (labor), technology (IP rights), and facilities.

The following subsections review each of these relationships within the start-up ecosystem. We will first discuss the university (or research hospital), a common source of technologies and scientists. Our discussion of the university will consider the research lab environment, the technology transfer office, and other university resources. Next, we will cover the start-up company itself and its components. Funding agencies will be covered next, as there are many options for funding a start-up company. Finally, we will cover corporate partners and their role in helping build new, innovative companies.

The University (or Hospital)

Universities and/or research hospitals are a site of innovation. New technology, new biomaterials, new devices, and new biological concepts can all provide the motivation and genesis for a new company. As Figure III.2.10.1 shows, several connections exist between the university and the start-up company. Universities play a central role in connecting the other organizations in the ecosystem, and in disseminating knowledge (Rothaermel and Ku, 2007). The primary interface for the start-up and the university is between academic experts who may become founders or advisers to the company and through the licensing of intellectual property. The university's fundamental strengths are innovation, cutting-edge expertise, and IP generation. Its research labs are often staffed by the brightest innovators in the world who invent intellectual property ("IP"), which the university owns and then transfers to the start-up company. As Figure III.2.10.1 shows, thought leaders interface directly with the start-up company, as well as technology transfer officers.

Innovation Engine: The Research Lab. The research lab is the university's innovation engine. Many aspects of the university research lab make it the ideal site for fundamental discovery. The university's research goal is to push the frontiers of scientific and technological discovery. Therefore, researchers are not directly focused on inventing a specific product, but instead can think very creatively about new technologies or the application of technologies to new problems. They can take high risks as part of the learning process. This culture contrasts with the culture inside an early-stage start-up, where specific milestones (set at the beginning) determine the company's success. The academic lab must create publications, whereas the start-up company must meet very specific stated goals on time.

Culture The academic culture tends to reward people who enjoy and excel at being the first to communicate a new idea or discovery (Stalcup, 2006). Although the multidisciplinary nature of modern technology and its application to medicine require teams of researchers from diverse backgrounds to work together, ultimately, all academics are required to be the contributing author of numerous top publications. This creates a healthy competition between academics, which speeds academic progress, since multiple labs want to be the first to publish.

Another feature of the academic culture is the unlimited pursuit of intellectual inquiry. There is no limit to how risky a research project could be, in terms of leading to a tangible outcome, as long as it has a high likelihood of leading to academic publications. Because academic research is understood to be a learning process, and fundamental research is high-risk in nature, it is very difficult to put definitive timelines on results in academic research. This is in contrast with development work done in a company setting, which typically has very specific timelines and milestones for completion, but creativity is also very important in small companies.

The culture inside a start-up company is focused on working together to meet milestones. If the whole company does not succeed from one milestone to the next, the company could be shut down. Most key employees in the start-up company are shareholders, and therefore their compensation is tied to the company's success. The competitor of a start-up is not the person across the lab bench; instead, it's the clock. In a start-up company, creativity is important, but reaching the next phase of development, and with it the next value milestone, is required. Figure III.2.10.3 illustrates some of the factors that induce the change in culture as a company progress through the development process.

What Makes a Lab Conducive to Entrepreneurship? Specific cultural and practical aspects tend to appear in entrepreneurial academic labs. If you are a faculty member running a research lab, you have significant control over the culture in your lab. If you are a student interested in joining an entrepreneurial lab, you might evaluate the lab on its history of the aspects listed below.

1. Hiring researchers with an interest in starting companies, and encouraging them to act on those interests.
2. Solving problems that have impact and could potentially be translated into products, especially in areas where you are willing go against the conventional wisdom.
3. Being willing to work on high-risk problems. The solutions to the problems may take a long time or have a low probability of success; however, if the solution to the problem is very important, it's worth trying to solve. This can lead to the fundamental discovery and patent, which can be taken to the next step (product development) in a start-up.

Fundamental Research

- Creativity
- Freedom of thought
- Novel invention and discovery
- Few discoveries generate products

Translational Research

- Feasibility testing for generating products
- Additional IP generation
- Technology integration

Product Development

- Economic focus
- Timelines
- Accountability
- Process
- Organization
- Planning/milestones

Academic Lab

- Feasibility testing for generating products
- Additional IP generation
- Technology integration

Small Company

- Feasibility testing for generating products
- Additional IP generation
- Technology integration

Larger Company

- Manufacturing standards
- Clinical trial milestones
- Organization structure
- Corporate policy

FIGURE III.2.10.3 Activities and cultures through company growth.

4. Encouraging a collaborative environment. The academic process can induce competition. There are other ways to promote a culture of collaboration that will help people think like entrepreneurs. For example, broad projects that require technologies from multiple backgrounds induce people to work together. Focusing diverse teams on important problems is a critical focus.

5. Paying attention to IP early and focusing work in areas where there is room for significant IP filings. Finding areas were a new discovery can lead to a seminal patent will help lead to fundable spin-off companies.

6. Building a good relationship with the technology licensing office at your university (see Figure III.2.10.1).

7. Building relationships with venture capital firms and corporate partners. It is important to understand what problems they are facing, so that when you have an idea that is relevant to those problems, you will know where to turn (see Figure III.2.10.1).

8. Helping to promote entrepreneurship at your university. Many schools encourage faculty and students to participate in entrepreneurship programs, and some offer grants and other support for small translational research projects.

How to Decide when it Makes Sense to Move a Company Out of the Academic Lab   Many factors contribute to the decision of when to move a research project from the academic research lab into a company. As mentioned above, it is typically after fundamental IP has been filed and significant proof of concept has been completed that development work starts in a new company. Before the development work begins, the researcher should ask a number of questions, including the following:

Do you have enough data and confidence?

You will take the plunge into the company either as a full-time employee or as a significant adviser to the company. You will have to be involved in getting funding,

recruiting employees and senior management, and making the company move forward. It is your time and energy, your career, and your reputation that you will invest in building this company. It is in no-one's interest for you to prematurely try to start a company. Therefore, you should wait until you feel confident in taking the leap into the start-up world. This may require extensive interaction with advisers in IP, commercial and/or clinical development, and entrepreneurs, but you should have a strong positive feeling about your venture. To succeed, a company concept takes more than great lab work and great data: it takes a diverse team of great people to build a successful company. It also takes a diverse team of great people to know which companies to build.

Have you created enough value to generate interest from investors?

Equity investors exchange cash for equity in the company. Pre-money valuation is the company's value immediately before the transaction, and post-money valuation is its value after the transaction. Pre- and post-money valuations are related through the following equation:

$$\text{Pre-money valuation} + \text{venture investment} = \text{post-money valuation}$$

The relationship between share price, valuation, and number of shares is:

$$\text{Share price} = \text{pre-money valuation} / \text{number of pre-money shares}$$

Sometimes (but not always) share price is set to $1/ share at the first venture funding, and therefore pre-money valuation is equal to the number of pre-money shares. Share price can change after each round of venture funding, and at each round of funding the following relationship is valid:

$$\text{Share price} \times \text{Number of new shares issued} = \text{Venture investment}$$

The company's value increases as the company makes more progress and generates more data. Therefore, it can be to the founders' advantage to generate as much data as possible using grants before taking an equity investment. There are several benefits to having more data: you will be more confident, possibly making it easier or quicker to raise money, and you will retain more ownership in the company after funding.

What is your IP protection?

NewCo will license IP from the university. Usually, the company must be formed before the license agreement is executed. Sometimes the university technology licensing office will pressure founders to execute a license agreement in an attempt to quickly recoup the cost of the patent application. This is just one of the considerations in the decision of when to incorporate the venture. This is not necessarily the right time to start a company, but it is possible that the technology transfer office may license the IP to another company (having a great relationship with them helps).

What are the funding opportunities for the company?

Without significant funding, it may be pointless to create a virtual company (described in the sidebar), especially if there is significant funding to continue the research in the lab.

Definition of Terms

Founders are generally the thought leaders involved in assembling the vision the company is founded around. Founding a company is a process by which the company becomes legally incorporated. Corporations have limited liability, which protects their shareholders and employees' assets from legal liability related to the company's operations.

A **virtual company** is a company that has no physical assets, facilities, lab space or offices. All of the company's employees work from home or from their own remote or virtual locations.

Pre-money valuation is a company's value before it has taken any cash investment. Post-money valuation is a company's value after a dilutive equity investment. Post-money = pre-money + amount invested. In a dilutive equity investment, investors exchange money in exchange for shares in the company. As the company issues more shares (at a given valuation), the current owners are diluted or own less of the company. Non-dilutive funding comes from sources that do not exchange equity for money, but rather give money for free.

Licensing terms are agreed upon reimbursement for the rights to operate a business in an area covered by the patents a university holds. The terms of an agreement typically include cash payment, equity, and/or royalties.

Due diligence is the investigation of an opportunity as a potential investment. Due diligence is done by investors, entrepreneurs, large companies, and others to determine an investment's merit. The process usually involves learning about the expected challenges and timeframe for generating a valuable enterprise, the costs associated with the venture, and the expected future value of the investment.

What is your academic grant funding situation?

Because pre-money valuations increase, and the probability of getting venture funding increases with every positive experimental result, it can make sense to continue making progress in the academic lab so long as funding allows and so long as there is no significant pressure to license the IP from the university. There are clear examples of start-up companies that have been started in a virtual mode. This is one potential way to start a company early with a very small investment, and avoid much of the challenge of being diluted by a large investment at a low early-stage valuation. It allows the research scientist to leverage the research dollars raised from grants. One potential drawback to this approach is that universities often issue policies restricting research sponsorship from flowing into labs where the principal investor is a founder or shareholder of the sponsoring company.

Technology Transfer Office. In the previous section, we discussed that the purpose of the university lab is to innovate and to publish and patent its innovation. The technology transfer office is the central clearinghouse for licensing IP from the university.

Chapter III.2.4 in this book reviews the patent process itself. The transfer of IP rights to a new company is an important step, and is outlined in Figure III.2.10.4. University employees and faculty are usually required to assign the IP rights to the university for any invention where they used university resources. They are required to document an invention through a standard disclosure (Jensen et al., 2003), which is a legal document that describes the invention and becomes the basis of a provisional patent. The submission of a disclosure triggers an internal process by which the technology transfer office evaluates the invention to determine whether it merits investing in patent protection. There is a fairly extensive literature on evaluating patents (Allison et al., 2004). Case agents are usually assigned to a particular project and/or faculty member, and when a decision is made to move forward with an application, they will help manage the process of hiring the appropriate legal counsel to draft the application.

The same patent agent will typically be heavily involved in the process of licensing the IP to a start-up company that will be commercializing the technology, as shown in Figure III.2.10.4. Sometimes there is a licensing agent (a different person form the patent agent) who manages the licensing process. In some cases, technology transfer offices also have other resources for entrepreneurs. These can include investing venture or seed funds, business plan competitions, translational research grants for researchers, and so forth.

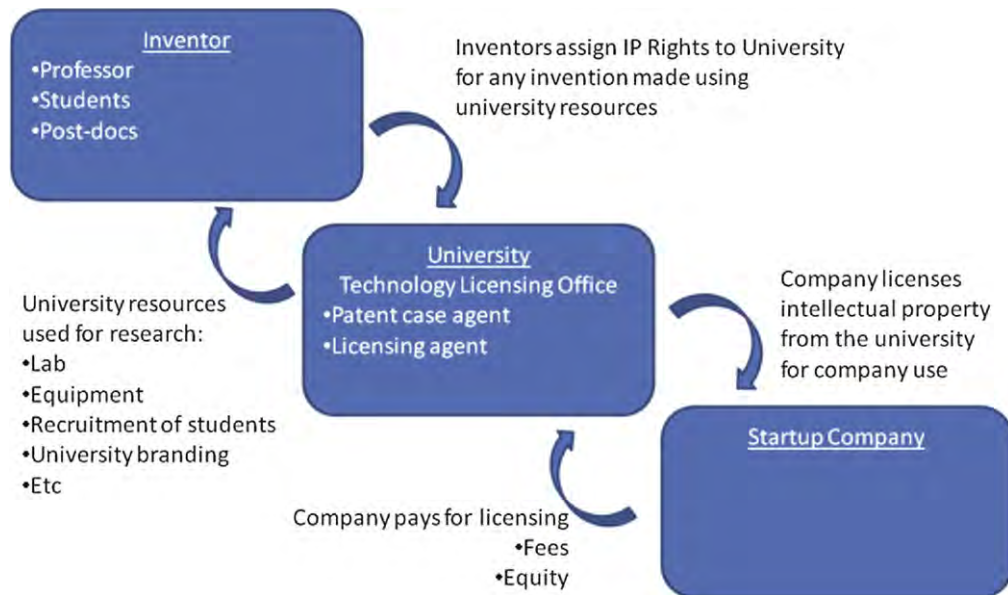
Patents As described earlier in this book, the Bayh-Dole Act of 1980 gave universities the opportunity to retain IP for government grant funded research. As owners of the IP, universities decide to whom they will license this IP, and under what terms (Lin and Kulatilaka, 2006; Macho-Stadler et al., 2007). When a university licenses a patent to a company, the company and the university then enter a partnership where the university typically retains the ownership of the patent, but grants the company permission to develop and


FIGURE III.2.10.4 The flow of resources and intellectual property between inventors, universities and startup companies.

sell product(s) covered by the particular patents being licensed. The company and or the university can usually enforce the IP protection rights against another organization if that organization is infringing on its patent's rights by developing or selling a product covered under the patent.

Sometimes competitive situations arise where more than one group is interested in licensing a particular patent. Large and small companies can both have an interest in the same IP, so entrepreneurs can find themselves competing with large, established companies for IP rights. Some universities consider the opinions of the inventors, and rely on them to help determine which organization would be the best partner for the university. Often, the small company interested in licensing the technology is being founded by faculty or students involved in inventing the technology, which adds an additional layer to the university's decision-making. One factor that favors the academic founder is that many universities have identified the process of entrepreneurship as an important part of their mission, as well as being very lucrative (Nelson, 2001; Owen-Smith and Powell, 2003). Sometimes universities believe that some technologies are better suited to licensing to large companies, and although generating revenue is not the university's mission, licensing agreements with large companies can bring in large amounts of cash quickly.

Licensing terms for a given industry or a given university are not standardized (Thursby et al., 2001). When dealing with a new start-up company, the university will typically propose being compensated with equity in the company (in addition to cash). This introduces a component of risk on the university's part, since the equity will only have any real value if the company succeeds. However, if the company is very successful, the university will share in the rewards.

The university is not interested in owning a controlling stake in the company; rather, it wants to recoup the financial cost of pursuing patent applications for a number of technologies. Successful IP licenses pay for a large number of patents that are not lucrative; therefore, the university needs to generate enough revenue to cover the costs of ongoing IP submissions. The university may also seek royalties as a percentage of revenue (or profit) from selling the product. This ensures that the university will also share in the proceeds if the company succeeds from a revenue standpoint.

In addition to IP, many university faculty and students are involved with start-up companies either as employees, entrepreneurs or advisers. These individuals can benefit significantly from their activities with the start-up company. Although entrepreneurial and industrial experience is rarely seen as supporting an associate professor's case for tenure, many universities look favorably on faculty who are actively involved in building great companies. These faculties are often limited by a conflict-of-interest agreement that they must sign when they initiate their employment at the university. The inherent conflict-of-interest results from academic investigators potentially becoming biased in their scientific work, because they have a financial interest in the results. This is particularly relevant in the case of human clinical trials, where a single researcher could directly influence (even if subconsciously) the selection of individuals. For this reason, academics who are company shareholders (and therefore have a financial interest in the company) are sometimes not allowed to have active operational collaborations between their academic labs and the company (Bagley and Dauchy, 2002).

Venture Groups/Arms Many universities facilitate company creation and technology transfer by operating an entrepreneurship center, venture group or a special

center as part of the technology transfer. In any case, this office advises faculty and the technology transfer officers on the array of options for licensing the technology and many start-up issues, like hiring a team, finding lab space, raising money, and the like. In some cases, this group has the ability to invest a small amount of money in the new company on behalf of the university. This process has the effect of financially aligning the university with both IP ownership and equity ownership.

Alumni Networks Most universities keep records of their alumni for fundraising purposes. Often, the most successful alumni are the most likely to give large gifts, as well as the most likely to be interested in providing mentorship to new companies spinning out of the university. Your alumni office may be willing to share that information with budding entrepreneurs. This can be a great way to find experts with complementary backgrounds to your own, especially those with experience building companies.

Some universities have official mentorship programs designed to provide specialized advice to entrepreneurs at the university. These groups try to retain successful entrepreneurs who typically have good intentions. Within the context of the university system, mentors typically have noble intentions; however, there can be an occasional experience with a "mentor" who is completely self-interested and trying to hijack a new company concept. This should not deter you from working with the alumni from your institution; however, you should use good judgment when interacting with potential mentors, regardless of when or how you meet them.

Business Plan Competitions Business plan competitions have enormously increased the awareness and interest in student entrepreneurship at many universities. These competitions help motivate and mobilize student teams around exciting new company concepts. These business plan competitions provide prize money and support for moving a company concept forward. Perhaps most importantly, they provide a forum for company builders to meet with other entrepreneurs and to bounce their ideas off other teams in a very non-threatening and supportive environment. Often, the prize money these organizations award is not significant enough to build a company; however, there are many other benefits to competing in a business plan competition, such as great publicity, visibility to potential investors, and free mentorship. If your venture would benefit from publicity, business plan competitions typically have great relationships with the media, and often set up interviews for print, radio or video news with their finalists' teams. Additionally, the finalists and winners of a business plan competition are often local celebrities on campus, which can help significantly in the recruiting process, and also in raising visibility within the university system and the technology transfer office.

Classes Many schools of engineering, science, and management offer classes in entrepreneurship, business plan writing, entrepreneurial finance, and venture

capital. All of these classes can be extremely useful in helping students understand and set expectations for working with investors and entrepreneurs.

The Start-Up Company

The company is the central entity in the start-up process. Referring back to Figure III.2.10.1, there are many components to a successful start-up company. All of these pieces are necessary, and they must all work together. The founders must not underestimate the challenges of building the company: they must overcome significant hurdles in the process of putting the company together. Again, from Figure III.2.10.1, the main components of a start-up company are people, IP, capital, and physical assets.

People. People are the most important component of the start-up company. Many investors and academics will jokingly say, "I'd rather back an A team with a B idea than a B team with an A idea." A great entrepreneurial team will unselfishly work hard, work together, and be completely honest with itself about where the company is going. A great team will adjust the strategy and vision of the company as needed. Every start-up will encounter unexpected hurdles, and it will be up to the team to creatively overcome them.

Entrepreneurs Entrepreneurs are the people who pull together the company concept in the beginning. As depicted in Figure III.2.10.1, entrepreneurs can come from universities, from venture capital firms or be unaffiliated. The entrepreneur is a project manager, cheerleader, and generally the company's leader. As you can imagine, the goal of the entrepreneur is to create value and to sell that value to investors, employees, and collaborators. Being a good salesperson is a crucial skill for the entrepreneur.

Although entrepreneurs can come from anywhere, typically they are not the inventors of a technology; rather, they meet the inventors through their networks and work closely with them to generate companies. Some academics have friends who are entrepreneurs who they work with over and over again, and other serial entrepreneurs work with different scientific founders. Serial entrepreneurs are professionals who start company after company. They generally have a better track record than first-time entrepreneurs (Gompers, 2008). Many research studies have analyzed factors that make entrepreneurs successful. Some of the most important characteristics include social skills (Baron and Markman, 2000), personal networking (Witt, 2004), and motivation (Buttner and Moore, 1997).

To evaluate a new company idea, an entrepreneur will undertake a "due diligence" process of analyzing the opportunity. The entrepreneur is trying to convince himself or herself that the opportunity is worth taking, and that it is worth investing time into building the company. This process typically involves asking experts to help evaluate the technology, market opportunity, appetite

for funding, and general excitement about the company. This process is somewhat similar to the due diligence process a venture capitalist would use to evaluate an opportunity for funding. The entrepreneur evaluates the opportunity for its ability to raise funding and succeed.

If you are an academic or a student who is interested in playing the role of the entrepreneur, you should certainly take an objective view of the project and ask yourself whether you would be passionate about the idea if it were not your own. When you have invested so much in an idea already, it can be difficult to objectively analyze the opportunity.

Building a successful company takes hard work on the part of a number of people. The team is very important, and typically includes experts from business, technology, and medicine. One of the key aspects to a successful start-up is the seamless collaboration between business and technical leaders. The general culture in the company has a great effect on the organization's efficiency. Generating great cultures is a non-trivial task, and many entrepreneurs fail because they do not have the appropriate temperament. Many books have been written about how managers can and should interact with each other to form great cultures (Kotter and Heskett, 1992; Collins, 2001; Flamholtz, 2001; Johnson and Phillips, 2003).

Founders Founders are individuals who are involved in the company at its inception. They can be academic experts who lend technical credibility, help recruit talented individuals to the company or invent the technology, or who are entrepreneurs. Ultimately, these experts typically will join the company's scientific advisory board, and in some cases the board of directors. Sometimes, they can be full-time company employees, but they typically maintain an academic or clinical appointment to maintain their professional credibility.

Management Team The management team is the group that makes strategic operational decisions. The typical management team is comprised of a Chief Executive Officer ("CEO"), a Chief Medical Officer ("CMO"), a Chief Scientific Officer ("CSO"), a Chief Operating Officer ("COO"), and others. In the early days of a start-up company, all of these positions may not be filled. Management teams are flexible, and are designed to cover all the needed skill-sets. Collectively, this team should be an expert in every relevant area. Often the recruitment of the full-time management team will be coordinated with the venture group backing the company, and will not be the responsibility of the founding academics. The entrepreneur may or may not become a part of the management team as the company moves forward.

Board of Directors The board of directors ("BOD") typically is responsible for choosing the company's strategic direction. This group of people has specific legal responsibilities, and is required to provide governance to the company (Bagley and Dauchy, 2002). In addition to their official legal requirements, the BOD usually represents the company's investors and advises the management team on how to move forward in the investors' best interest. The board usually includes the CEO and/or president of the company, as well as representatives of the investors, and often a representative of the founders and an independent representative who is typically an expert in the industry and well-connected with other groups, especially with established companies that may become interested in acquiring the new start-up.

Employees Employees are perhaps the most important component of the start-up. They perform the company's operations and support the executive management team in executing the plan developed with the board. Typically, employees can come from labs that invented the key technology or collaborating labs. Having world-renowned founders and a top management team immensely helps in recruiting great employees. There are several resources on recruiting great employees and building effective cultures (Kotter and Heskett, 1992; Collins, 2001).

Advisers Start-up companies typically will hire any number of industry experts to help them operate. One of the challenges with an early-stage company is that there are limitations to the number of full-time employees the company can afford; however, a large number of job functions need to be completed. Many of the job functions required for operating an early-stage company only require a fraction of the resources of a full-time employee. In particular, some of the technology-agnostic functions like accounting or financial governance do not require a full-time employee. In this case, it is common to have a part-time employee serve in a flexible capacity on an hourly basis.

Ideas and Intellectual Property. Intellectual property is very important for the new company. It is often the only "property" the NewCo owns. Most start-ups don't employ in-house IP attorneys at a very early stage. Typically, their IP advice comes from an external counsel, who may be compensated with options or shares of equity in the company instead of with cash. This is especially common for early-stage companies before they have raised capital. Detailed analysis of IP is covered in an earlier chapter in this book, as well as in the section on technology transfer.

Although the IP licensed from the university is typically the basis for the company, additional IP is generated inside the company. Developing a strategy for IP development is an important activity of the management team. IP is especially important in medical device companies because there are many theoretical ways to solve most medical problems. Having a strong IP portfolio can be key to protecting the start-up's market. The selection of IP experts is key to understanding the competitive landscape, as well as pushing the company's own patent applications.

Physical Resources. Physical resources are required for the company to operate. These can be in the form of offices, lab space, assets, equipment, and the like. As

mentioned earlier in this section, early-stage companies can often operate in a virtual fashion and collaborate with the inventor's labs within the university. Although this process can be a delicate balancing act of avoiding and managing potential conflicts of interest, it is often more appropriate to minimize the requirements for physical resources by operating the company out of a home office, for example. However, most universities have strict policies on IP ownership, and if a member of the university generates an invention, idea or another form of IP using any university resources, then the university has a claim to (at least partial) ownership of that IP.

Capital. There are many sources of capital, and raising capital is a very complex process. The main considerations are how much capital to raise, where to raise it from, and at what valuation. Multiple sources of capital are described in detail in the next section, but in this section we will cover the strategic decisions a company must make to meet its fundraising needs.

Early-stage capital investment is very important for the company, and the management team must constantly operate the company in the most capital-efficient way. The company must raise enough money to operate and grow comfortably, but it must not raise or spend more money than required, since this leads to unneeded dilution.

There is a clear trade-off between raising a large and a small amount of money. If the company intends to grow rapidly, it needs to raise a significant amount of money. Many finance textbooks and courses cover the basics of corporate/entrepreneurial finance (Smith and Smith, 2000; Denis, 2004; Brealey et al., 2006). Ultimately, there is no specific answer to how fast a company should grow, and it is a strategic decision for the management team and the BOD. From the perspective of the founders, dilution is a major trade-off.

The next strategic question is determining the source from which the start-up should raise money. The main sources of funding are grants, venture capital, and corporate partnerships.

Grants Grants are a great source of capital for the company, and a number of government and non-government grant agencies are described in the "Sources of Capital" section. Because grant funding is not exchanged for equity, it is non-dilutive and is therefore very attractive.

Grant writing can be a very time-consuming process. The time and effort put into grant writing can pay off if the grant is awarded. However, grants are not awarded to the majority of grant applicants. Therefore, when a small company is thinking strategically about raising money, it must also consider that the time, energy, and resources spent preparing applications for the grant process may not pay off in the long run. The company must find the right balance between risk-taking and stability.

An additional feature of grant funding is that the oversight is largely only financial in nature. Grant money is typically not managed by a person representing the interests of the grant who sits on the BOD. This is completely unique when compared to capital raised through the sale of equity to investors. This stems from the fact that private investors have purchased equity for the main purpose of generating return on capital during a given duration.

Venture Capital Venture capital is the most common source of funding for start-ups. When choosing whether to work with a venture capital firm, you should consider a number of things. The potential pros of building a company with a venture capital firm include:

1. The probability of the company's success increases (experienced company builders get involved and bring extensive networks to the company).
2. Things will move faster in the direction of financial return.
3. It is typically easier to recruit senior management to the company after the validation of significant venture funding, especially from a firm with a good track record.

But the potential cons of building a company with a venture capital firm include:

1. There will be substantial dilution for the founder(s) and entrepreneur(s).
2. Founders will give up substantial control in corporate decision-making.
3. Investors are likely to identify new senior management.

Ultimately, the entrepreneur(s) must see the venture capitalists as true partners in the business, and this is easiest when they have a strong relationship. Venture capital firms and angels almost always contribute to building the company. This can be through their position on the company's board or, in some cases, by contributing entrepreneurial or operational capabilities. More experienced investors with better track records have a higher probability of taking a start-up company to a successful exit (Gompers, 2008).

Talking to Venture Capital Firms Venture capital firms have a significant preference for companies founded or recommended by someone in their network. Therefore, networking is very important. If you are interested in potentially starting a company and raising venture money in the future, it makes sense to build relationships with several venture capital firms in your area (both of expertise and geography). Firms are always in need of expertise for evaluating new investment opportunities, and often hire experts in various fields to help them understand opportunities. If you are actively looking for venture funding but do not have an existing network in the venture industry, it likely makes sense to find an entrepreneur (either an academic or a business professional) who has a successful track record of building companies and raising venture capital. Ideally, you'll find

an entrepreneur with expertise in building and selling successful companies.

Important Differentiating Factors between Venture Firms Many factors define the venture firms you may consider working with.

SIZE Large firms tend to want to do bigger deals, and may be interested in investing larger amounts over a longer period of the company's lifetime. Their downside is that their partners may be very busy or focused on other later-stage companies in their portfolio and have less time to work with early-stage investment.

VALUATION Valuation is the often the largest point of contention or negotiation between start-up and venture capitalists. The entrepreneur should remember that valuation is important, and stock ownership is only relevant if the company is ultimately successful. Building a good working relationship with your investors and board of advisers is more important from this standpoint than the actual valuation.

The structure of the deal and terms on the term sheet are just as important as the actual valuation (Wilmerding, 2003; Gold et al., 2005). Many venture capital firms attempt to add terms that give them preferential status over the entrepreneurs and employees of the company.

EXPERIENCE Experienced investors bring more to a deal than money. They have years of experience building companies, and they will likely have a better context for setting the direction of the company than inexperienced investors. Many successful entrepreneurs start venture capital firms, and individuals as well as firms have great reputations. Venture capital funding offers are three times more likely to be accepted when they come from a firm with a strong reputation. In one study these respected firms often get a 10 to 14% discount on equity (Hsu, 2004).

WILLINGNESS TO HELP BUILD THE COMPANY Some venture capital firms will help identify business leaders and entrepreneurs to join the company or join the company themselves.

When you begin speaking with venture capital investors, don't be alarmed if things move slowly. If and when you have developed a relationship with venture capitalists and you would like to discuss funding opportunities, your first challenge will be to piqué their interest to convince them to initiate the due diligence process (Dooley and Dooley, 2003). This process will take place over a timeframe that is mutually agreed upon by you and the venture capitalist. The venture capitalist will ask you a number of questions over the course of weeks or months in a process somewhat analogous to an extended job interview. At the end of the process, you may get an "offer" in the form of a term sheet that outlines the valuation and terms for potential investment or the venture capitalist may decide to pass on the investment. In either case, you will have learned a lot about what it takes to build a company, and you can apply this experience to the next venture capitalist interaction you have.

Sources of Capital

The previous section reviewed the funding scenario from the perspective of the start-up's strategic decision-making process. This section will review more specific information about each of the sources of capital: grants; venture capital; and corporate partnerships. Figure III.2.10.1 shows the various types of funding that can flow into a start-up company. Each of these sources has its own unique challenges and opportunities. Below is a review of each of these sources.

Grants. Grants, by definition, are money that is given to an organization for a specific project related to an interest of the grant agency. Often grant money comes from government sources, and in addition to academic funding, many government agencies have grant programs available for early start-up research efforts inside companies. The purpose of these grants is to improve the competitiveness of the local or national economy, to support the generation of new and better medical technologies, and to develop new companies.

Perhaps the most common entrepreneurial grants issued by the government are the US Small Business Administration's Small Business Innovation Research (SBIR) grant and the Small Business Technology Transfer Program (STTR). These grants are typically awarded to small businesses developing technology in an area that is important for national health, national security or the like. These grants are awarded in escalating phases. Phase one feasibility grants are typically intended for the initial phases of projects, and are awarded for a 12-month period in an amount up to $100,000. These grants are intended to allow the company to demonstrate a proof of principle,and generate initial data on their concept. Phase two grants allow the company to expand on the data generated in the phase one grant, and they are awarded for up to 24 months and in an amount ranging from $500,000 to $750,000. The final phase three grants are typically funded outside the SBIR, and involve the commercialization of the technology. Solicitations for these SBIR grants are posted on several government and other websites available through http://www.sbir.gov. These grants are offered by the Department of Defense, Department of Energy, National Institutes of Health, National Science Foundation, and National Cancer Institute, among other government organizations.

Several firms offer consulting services to help write and/or advise start-ups in the strategic process of applying for SBIR grants. If the entrepreneur has limited experience writing grant applications, it may be advantageous to hire an experienced leader to supervise the grant writing process. Studies of SBIR recipients have concluded that SBIR awardees are more successful when

the academic principal investors are involved in the company (Toole and Czarnitzki, 2007).

In some cases, non-government organizations offer grants. Examples of philanthropic organizations include the Bill & Melinda Gates Foundation, the Carnegie Foundation for the Advancement of Teaching, the Kauffman Foundation, the Ford Foundation, and others. Many larger corporations have extensive corporate foundations that donate money to causes in society's best interests. **Venture Capital Firms and Business Angels.** In 2008, there were 382 venture capital investments in medical devices and equipment companies, which totaled $3.4 billion. Therefore, the average venture investment in 2008 was $9 million (Money Tree, 2009). The collective investment of business angels is harder to track, but a recent report predicts that angel investing in US medical devices and equipment was $3.1 billion in 2007 (Sohl, 2008).

Venture capital firms are usually partnerships that raise an investment fund from a variety of investors called limited partners. Sources of funding for venture firms are wealthy individuals, institutional investors, endowments, and the general partners (individuals) in the fund themselves. Venture capital firms raise money with the intent of returning the investment plus a substantial return to their investors. Financial incentives are used to ensure motivation, and usually there are incentives to build companies that have a high probability of "exit." A successful exit is the sale of the company for a significant multiple of the amount invested, and this usually means the company must be put together quickly and meet a number of milestones that increase its value moving toward acquisition or going public. This approach may (or may not) be in the entrepreneur's best interest. Often, when start-up companies take a significant equity investment, the company's founders lose financial control of the company through dilution. This may be the best option for the entrepreneur, but some early-stage company builders do not like to relinquish control, since they have some personal connection to the company they have built.

Corporate Partners

Many large companies are involved in start-ups, and this is becoming a more popular, particularly for medical device and pharmaceutical companies who are struggling to gain access to new drugs or devices as their pipelines are not full. Public markets follow economic trends, and at the time of press were mostly out of the picture, acquisitions are currently the primary exit possibility for start-up companies. Therefore, building a relationship with large companies is of utmost importance for the successful start-up company, which should focus on making itself an attractive acquisition target.

Medical device, pharmaceutical, and biotech companies have developed sponsored research programs with universities to help academics fund translational research (Business Wire, 2009). This approach usually involves research money flowing into the university similar to a grant, but it is usually accompanied with a blanket license agreement that grants a license in any resulting IP to the sponsoring company. Therefore, in some ways, this approach is not compatible with starting a new company.

Another model that has also become interesting to venture investors is early-stage collaborations with large companies. This model theoretically allows the technology to spin into a start-up company, yet creates a relationship with a potential acquirer early to maximize the probability of acquisition by signing an option agreement on the company. Admittedly, this strategy can limit upside for the start-up company if it is wildly successful, but it can also help keep management focused on the company's operation, since it will not have to focus on finding an acquisition partner. In addition, it helps diversify the financial risk, as well as leverage the large company's scientific resources.

The start-up company benefits from working with a large company because publically announced collaborations can bring money, credibility, and expertise into the company. These aspects of doing a collaboration deal lead to value creation and ultimately liquidity.

As a start-up company is courting potential buyout partners, there is a trade-off in timing analogous to the beginning of the company. As the start-up operates further it generates higher value, which should be reflected in the buyout price. However, as more capital is used, current shareholders take on significantly more dilution.

Even in the absence of an official collaboration with a large company, close interactions and discussion about technologies can help early-stage companies. At a minimum, close interactions with large companies can help any start-up management team build the company with the maximum probability of acquisition.

BUILDING A SUCCESSFUL START-UP

As mentioned throughout the text, many things need to fall in place for a start-up company to move forward. Ultimately, only you can define what success means for your start-up venture. However, the authors have assembled some general guidelines based on past experience of building companies that have received funding.

This section reviews some of our thinking on the key questions of why, how, when, and which company to start. Many potential entrepreneurs blindly fall in love with an idea or stick to an idea just because it was their idea, pushing it forward passionately. But in the end, the company's projects do not reach the market. In the pharmaceutical world, there is always the risk of not clearing clinical trials, which will typically signal the end is near for the company. On the other hand, many company

concepts fail for other reasons. Some common stumbling blocks for early-stage companies include:

1. Wrong management (CEO, CSO or others make poor operational decisions).
2. Running out of funding.
3. Missing technical milestones.
4. Participating in the wrong clinical trial.
5. Burning too much money.

Many of these mistakes could have been avoided, or at the very least, red flags should have alerted the start-up team that there were substantial problems with the concept that should have come up during the due diligence process.

The following sections provide a guideline for the potential academic entrepreneur to do his own due diligence, and to be honest about the opportunity before he or she jumps in blindly. Indeed, great company concepts are not that common, and the process for self-evaluation should be just as rigorous as the process the venture capitalist carries out.

The potential entrepreneur should spend significant time reflecting on himself or herself, as well as the questions posed here. Often, many entrepreneurs gloss over this part of the process. They suffer from being biased toward their own idea, sometimes so much that they are blinded to the rest of the landscape. In fact, sometimes other opportunities are there but go unnoticed, because the entrepreneur is too focused on his or her own work.

Why Start a Company?

Starting a new company is not something that should be taken lightly. It is a lot of hard work. It takes a lot from the people involved, and there is significant risk involved with pushing forward in a given entrepreneurial area. As an entrepreneur or an employee of an early-stage company, you will need to roll up your sleeves and get your hands dirty. You will most likely do everything from sweep the floor to cashing the big checks from time to time. The start-up mentality is very different from that in the corporate or academic world. You should ask yourself whether you are truly passionate about the idea you are considering building a company around, and then ask yourself why you are passionate about it.

Choosing the Right Company Concept

Many academic scientists are interested in building companies. The reader might ask, what will make the difference between a successful start-up and one that fails? No formula can guarantee success in a start-up company. However, the authors have developed a list of criteria that can form a general guideline for research

projects that have high potential to raise money and ultimately become successful companies (Kent Bowen et al., 2004).

1. Choose a high impact area?
   a. Clinically high impact (will it help patients?)
   b. High impact to potential commercial partners (will it create shareholder value?)
   c. Scientifically high impact (is the technology new and important?)
2. Publish a seminal paper?
3. Obtain a protecting patent?
4. Demonstrate efficacy in animals?
5. Build a great team?

Doing Your Own Due Diligence to Prepare for the Venture Capitalist Pitch

The due diligence process has been defined over and over again by the venture capital industry. Generally speaking, this is the process of getting comfortable contributing a significant investment. In the case of the entrepreneur, the investment is his or her own blood, sweat, and tears. In determining whether and what to invest, venture capital firms use several criteria, and there are several books, websites, and publications on venture capital due diligence (Camp, 2002; Gladstone and Gladstone, 2002). Here, we will focus on the issues of specific relevance to the technical evaluation of an early-stage biomedical company concept.

This list of potential due diligence questions will sum up most of the content of this chapter in a simple table that the reader can easily refer back to in the future. The answers to these questions are typically summarized in a presentation that is delivered to the venture capital group to spark its interest in doing its own due diligence.

1. Team: Is the academic founding team outstanding? When thinking about all the potential top academic founders in the world, are a substantial number of very top people involved as founders of this company? This is important because it gives the company confidence that this will be the leading company in the field. Has the entrepreneur or have the founders done a good job of assembling the top scientific team in the area? Have you done background checks on the other founders?

   Is there an extraordinary management team in place or can one be recruited? One of the largest stumbling blocks for an early-stage company is an inexperienced management team that demands retention of control of the company. If the company's intention is to obtain significant funding, it will need to have seasoned management with a serious track record of success.
2. Technology: This includes the existing technology and the technology plan that could be laid out for the company. Is there a high probability of success? Has

the company thought through a research and development path for the next several years? What are the milestones along the way? How much will it cost to reach each of those milestones? How long will it take, and how much will it cost to get to clinical validation of the product? Are there any simple, cheap experiments that could significantly improve the probability of success? Is the technology in an area that is of critical importance to large companies that may acquire the company in the future?

3. Financial: How will this project appear to a potential investor? What is a reasonable pre-money valuation? Given the pre-money valuation, funding requirements, and expected exit options, is it possible to generate appropriate venture capital returns?

4. Market: What is the overall market for the product or concept? What are the commercial issues with respect to this market? Who are the competitors, and how will the new product be positioned relative to the existing products? Who are likely acquirers, and have they done similar deals in the past? What has the value of these deals been?

5. IP: Is the IP strong enough to build a company? Have you asked an independent IP attorney to review the IP? Is there freedom to operate given the other IP in the space?

CONCLUSIONS

We hope to have made a positive impact on our readers by giving them a better sense of the basic mechanics of starting a company and what some of the challenges would be. We started the chapter by giving a basic overview of the company-building process, and explained where the pieces of a start-up company come from and how they are transferred into the new company. Next, we analyzed how to distinguish between an opportunity that may represent a successful company and one that may be less attractive.

Together with the other information in this book, and perhaps some personal interaction with business and legal advisers, readers can better evaluate the start-up process as something that makes sense to pursue for their technology.

| Case Study | **The Drug Eluting Stent Industry** |

Innovation in the stent industry exemplifies many of the concepts explored in this chapter. The market forces around the stent market combined with innovation in many start-ups led to an explosion in the market and a revolution in the way patients were treated.

The Clinical Need
Coronary artery disease occurs when atherosclerotic plaques clog the arteries that supply the heart. It affects about 13 million Americans, and this number has grown significantly due to an aging population, obesity, lack of exercise, and other factors. In the 1980s the surgical option for severe coronary artery disease was bypass surgery, with the non-surgical option of balloon angioplasty. Balloon angioplasty has grown in popularity, since it is much cheaper and less invasive. However, balloon angioplasty is often accompanied by restenosis and reclosing of the artery in 30–40% of cases within six months of the procedure.

Bare Metal Stents
To address the high recurrence of arterial narrowing and blockage, bare metal stents were introduced. Deployed with balloon angioplasty, stents physically limit an artery's ability to reclose after the procedure. However, even with a stent in place many arteries developed scar tissue and reconstrict. With the market demanding solutions offering better quality of life, local delivery, and more cost efficiency, the first use of the coronary stent (Palmaz) started in the early 1990s. Others joined the market, and by the early 2000s the number of stent procedures had reached one million. This was a revolution in the way coronary artery disease was treated. However, there were still over 150,000 patients in the US requiring reprocedure due to restenosis.

Drug Eluting Stents
The first commercially available drug eluting stent was the Cypher stent from Johnson and Johnson. These stents combined the mechanical support of keeping the artery open plus the ability to locally deliver restenosis-preventing drugs released directly from the stent. The use of drug eluting stents decreased restenosis significantly to below 10%. Because outcomes were increased significantly, drug eluting stents were quickly adopted and used in hospitals.

Development of Technology in Small Companies
Cordis, which was founded in 1957 in a garage in Miami, had retained the culture of a small and innovative company. Several technologies came out of this company including angioplasty catheters, pacemakers, and ultimately stents. It was the combination of several product/technologies developed in Cordis, Biosense, and other start-ups that enabled the image guided drug eluting stent market to grow so quickly. This is a common practice in the medical device world; many new technologies are developed at small innovative companies, and then acquired by large companies to fill their product pipelines.

Reimbursement and Adoption
With any new medical device, reimbursement is very important. Medical procedures are reimbursed by Medicare and/or private healthcare providers (insurance companies). In the case of drug eluting stents, cost was very high. Cypher drug eluting stents sold for $3195 at their introduction. Medicare, for the first time in history, announced its reimbursement level for drug eluting stents before FDA approval was complete. The cost increase for using a drug eluting stent instead of a bare metal stent is approximately $2800. This cost is associated with the increased cost of the stent, and the cost of additional blood thinning drugs (Plavix for six months). Medicare decided to increase the reimbursement for the procedure by only $1800; therefore, hospitals were forced to absorb the extra cost of the procedure. Several studies have found the stents to be useful in terms of outcome, but their cost effectiveness is still debated.

Additional reading on the development of the drug eluting stent market, as well as statistics from this case study can be found in Currie and Arundine, 2005; Denend and Zenios, 2006; Ofek and Wickersham, 2008.

CHAPTER III.2.11 POSTMARKET CONSIDERATIONS IN BIOMATERIALS AND MEDICAL DEVICES

David W. Feigal, Jr
Adjunct Faculty, Sandra Day O'Connor School of Law, Arizona State University, Santa Rosa Valley, CA, USA

The postmarket period is defined as the time when a product is in the marketplace, that is, it is no longer investigational and is available for commercial use. Consumer protection laws, such as the US Food Drug and Cosmetic Act (FDCA), create regulations, with the force of law, that determine both the manufacturers' requirements after placing products into commerce, and the authorities of regulatory agencies, such as the US Food and Drug Administration (FDA) to enforce these laws. From its inception over 100 years ago, the FDA has been concerned with products in the marketplace, and was given authorities for postmarketing regulation long before it had the premarket authority to grant marketing authorization.

The first consumer protection laws for medical products date back to 1902 and 1906, when Congress enacted the first Federal laws regulating biologics and drugs. While biologics were required to meet standards of safety, purity, and potency, the drug consumer protections focused on "truth in advertising" (misbranding) and adulterated products, and provided the US Food and Drug Administration (FDA) with the authority to remove such products from interstate commerce (Hutt, 1989). Devices would not be regulated by the FDA until laws were passed in 1933 and 1935 defining devices and extending some of the FDA's drug authority to these products. Emphasis remained on fraudulent claims and unsafe products. The FDA did not have authority to report adverse effects in the postmarket period for drugs until 1973, and it was not mandatory for medical devices until 1984 (Gross, 2007), eight years after the more comprehensive medical device regulation in the United States.

Many forces lead to the Medical Device amendments of 1976 which expanded the FDA's authority to premarket and postmarket regulation of medical devices. Arguably, one of the most salient factors was public concern about device safety problems which had been identified in the postmarketing period. Problems with the Shiley heart valve, the Dalcon Shield, orthopedic and cosmetic implants were not caused by misbranding or adulteration. Design and manufacturing problems were unknown until products were on the market. The need for postmarket safety shaped the authorities given to the FDA in the 1976 and 1984 device amendments to the FDCA and Safe Medical Device Act that followed in 1990. The FDA was given the power to recall medical devices, and require tracking, postmarketing studies, and postmarketing surveillance reporting – not only of manufacturers, but also of health facilities 30 years before all the same authorities were granted to the FDA for drugs.

How, then, do these authorities apply to biomaterials? When the biomaterial for all intents and purposes *is* the device, such as latex gloves, silicone implants, and ceramic orthopedic implants, the reporting of problems for the biomaterial will be intrinsically tied in with reports of problems with the devices, even though not all problems will be caused by the biomaterial (Bright, 2007). When the biomaterial is a small component, coating or is only part of a drug delivery container, biomaterial problems may be more difficult to identify, and may not come to the attention of the biomaterial supplier. The Quality Systems (or "device good manufacturing practices") require device manufacturers to have Corrective and Preventive Action (CAPA) systems in place to identify problems. Reporting medical device problems to the FDA or other regulatory authorities is the first line of defense to find and prevent unsafe medical devices, and to ensure that new or unanticipated problems are quickly identified and promptly remedied.

THE FDA's POSTMARKETING PROGRAMS

Postmarketing programs can be broadly grouped by whether they study exposure or adverse events, and whether the data collection is active or passive. A clinical trial is an example of an active exposure study; a registry of all recipients of a specific device using healthcare billing records is a passive exposure study; a spontaneous adverse event reporting program is a passive event driven program, while programs that actively train participating hospitals to report "near misses" and adverse events is an example of an active event driven program.

The FDA has the authority to require manufacturers, user facilities, and importers to participate in some of these programs, and can require clinical trials, registries, and tracking as part of the conditions for approval. Some postmarketing programs, such as clinical trials and active registries, require informed consent, Institutional Review Board (IRB) approval, and must comply in the US and other countries with health record privacy laws. Other programs, like MedWatch or tracking programs, are not considered clinical studies, *per se*, and although they must protect the confidentiality of the patients and reporters, do not require the patient's consent to provide medical information to the device manufacturer or regulatory authority.

PASSIVE EVENT SURVEILLANCE: SPONTANEOUS REPORTS

MedWatch

In 1993 the FDA reorganized its postmarketing adverse experience reporting systems into the MedWatch program (Kessler, 1993) to provide a single reporting system for drugs, biologics, and medical devices. Millions of reports have been collected, including over 200,000 medical device reports (MDRs) each year. Adverse event reporting is not limited to events where the casual relationship between the medical product and the adverse event is known.

Definitions

The FDA's postmarketing system relies on several important definitions, quoted below from the regulations (US Government Printing Office, 2009):

Medical Device Report (*MDR*) reportable event (or reportable event) means: (1) an event that user facilities become aware of that reasonably suggests that a device has or may have caused or contributed to a death or serious injury; or (2) an event that manufacturers or importers become aware of that reasonably suggests that one of their marketed devices: (1) may have caused or contributed to a death or serious injury, or (2) has malfunctioned and that the device or a similar device marketed by the manufacturer or importer would be likely to cause or contribute to a death or serious injury if the malfunction were to recur. (*The regulations presume that the malfunction will recur.*)

Caused or *contributed* means that a death or serious injury was or may have been attributed to a medical device, or that a medical device was or may have been a factor in a death or serious injury, including events occurring as a result of: (1) failure; (2) malfunction; (3) improper or inadequate design; (4) manufacture; (5) labeling or (6) user error.

Malfunction means the failure of a device to meet its performance specifications or otherwise perform as intended. Performance specifications include all claims made in the labeling for the device. The intended performance of a device refers to the intended use for which the device is labeled or marketed.

Serious injury means an injury or illness that: (1) is life-threatening; (2) results in permanent impairment of a body function or permanent damage to a body structure or (3) necessitates medical or surgical intervention to preclude permanent impairment of a body function or permanent damage to a body structure. *Permanent* means irreversible impairment or damage to a body structure or function, excluding trivial impairment or damage.

All manufacturers selling finished medical devices or ready for use components are required to monitor and identify significant adverse events involving medical devices in order to detect and correct problems in a timely manner. Events which must be reported include device-related deaths, serious injuries, and reportable malfunctions. The FDA requires a report within 30 calendar days from manufacturers, except when the event requires remedial action to prevent an unreasonable risk of substantial harm to public health, in which case the report must be made within five days. User facilities are required to report deaths and serious injuries to the manufacturer or the FDA within 10 calendar days.

Serious adverse events (SAEs) are of particular importance, and even single reports or small clusters of reports have allowed identification of important problems that have allowed prompt actions to mitigate risk. An important objective of medical device reports is to identify signals of potential new problems that can be evaluated further with appropriate methods. Manufacturers' quality systems have corrective and preventive action (CAPA) systems which usually include training and reporting programs, so that anyone within the company who learns of an SAE can initiate the reporting process. In the US, criminal convictions and substantial fines have resulted from failure to report MDRs (Justice Department, 2003).

While the FDA uses a single form for all medical products, there are specific information fields and types of problems that are unique to medical devices. Medical devices reports indicate whether the device malfunctioned or whether there was a "user error," i.e., if the device functioned properly but an adverse event was caused by an error in how the product was used. For example, if there was an injury from a device from an unskilled operator a MedWatch report should be filed.

MDR Limitations

It is recognized that although manufacturers are required to report all known reportable adverse reactions, only a fraction of adverse events associated with medical devices are reported in the MDR system. Some events are more likely to be reported than others: unusual events; problems with a newly implanted device; clusters of events (which often occur by chance); and publicized device problems. Unfortunately, although it is known that the degree of under-reporting varies widely, it is not known what the degree of reporting is, even for a single device, making it difficult to interpret trends.

MDR information is often incomplete, and may not even include enough data to identify the model of the medical device or even with certainty the manufacturer, and reports may be missing key details that would help assess the relationship between a device malfunction and injury. MDR reports themselves have a disclaimer that they are not intended to establish a causal relationship, but by casting a broad net, they hope not to miss signals of new problems, even if initially they are not recognized as caused by the device.

BIOMATERIALS AND MEDWATCH

For some devices most adverse experiences associated with medical devices have nothing directly to do with the biomaterial. However, when the biomaterial provides essential properties that determine the use of the device it may be hard to separate biomaterial failure from device failure. For example, the biomaterial may be the problem in the case of adverse experiences associated with rupture of the silicone shell of breast implants or with metal fatigue of a dental implant, or the wear debris from the coating of an orthopedic implant. If the final device manufacturer has also developed the biomaterial then it is straightforward for the manufacturer to consider the role of the biomaterial to the other features of the finished device. It is more difficult when the biomaterial is supplied by a separate developer who may have incomplete knowledge about the final product, but may get a complaint about an SAE that requires reporting. In general, the FDA will hold the final manufacturers responsible, but there are examples when they have used their enforcement tools to deal with a problem that was caused by a common source supplier of a component or biomaterial.

ACTIVE EVENT SURVEILLANCE

Active event surveillance systems typically train a group of hospitals and clinicians in reporting methods, and provide more accurate estimates of trends for relatively common adverse events. Cooperative efforts to capture adverse events have also been organized to assess specific technologies by specialty healthcare professional groups.

In countries with national health systems, the Ministry of Health may be able to create active surveillance at a national level. In the US, with larger passive surveillance systems most reporting comes from manufacturers, while in the UK most reporting comes from the hospitals and facilities of the National Health Service.

Active surveillance has several advantages over passive surveillance. First, the data collection is more standardized. Any monitoring system for events must be based on a precise common vocabulary for both events and outcomes. For example, device failure modes for implantable devices can be organized into predefined categories, rather than the somewhat idiosyncratic clinical descriptions found in MedWatch reports.

Second, much more relevant detail is available to characterize patients. Clinical descriptions are usually often more consistent and completely documented in an active surveillance system. The real-world use active surveillance programs can better identify whether there are subpopulations particularly vulnerable to specific device failures. Third, the medical devices can be better characterized. Not only can the make and model number be more accurately captured in active surveillance, but there is also an opportunity to evaluate other device characteristics, such as the age of the device.

The FDA's MedSun Program

In 1998 the FDA began to recruit acute care hospitals and long-term care facilities to participate in the MedSun active surveillance network (Rich, 2002). Healthcare facilities, as part of their own Quality Assurance programs, usually have internal incident reporting systems to identify potential risks and injuries to patients from problems relating to patient falls, medication errors, equipment malfunctions, and other misadventures. The FDA has obtained ongoing funding to establish a network of several hundred institutions that would anonymously share not only adverse events, but also "near misses." The analysis of "near misses" in the aviation industry had been adapted to improve anesthesia equipment decades earlier (Barach and Small, 2000), which produced anesthesia safety changes that resulted in improvements, largely from better human factor engineering. The hope was that an active surveillance program in hospitals could provide an early warning about device design and manufacturing, and use problems for a broader group of medical devices.

While the strength of spontaneous reporting was identifying low frequency, and events of unusual severity or in unusual situations, the MedSun program is designed to provide a better insight into some of the more common problems, and to train participating facilities to take corrective actions to decrease risk. The program has organized subnetworks with special interests in medical devices for cardiovascular, pediatric, ophthalmologic, diagnostic, and home use.

FDA TRACKING AND CLINICAL TRIAL REQUIREMENTS

Mandated Clinical Trials

At the time of approval of a Class III device, premarket approval (PMA) application companies must agree to "conditions of approval" requirements which can include commitments to conduct clinical trials or registries to assess safety issues. These active studies are more likely to represent "real world" use and a much larger experience than the studies conducted prior to approval, starting with the use or exposure to the device, and prospectively collecting adverse experience and other outcomes.

The FDA also has an infrequently used authority from the Food and Drug Modernization Act in section 522 of the Act (Food Drug and Cosmetic Act, Sec. 522 Postmarket Surveillance). (Hence, these are referred to as 522 studies.) When the device is an implant to be in place for more than a year or is a life-sustaining device, or when failure of the device could lead to a serious adverse event, the FDA can mandate a 522 clinical study. Since the FDA already has mechanisms under conditions of approval to require Class III studies, the 522 studies have been applied to Class II products cleared under 510(k), where there are no authorities to impose conditions for approval. In practice, perhaps in part because most high risk products are Class III products, the FDA has required few 522 studies.

Tracking. Products meeting the same criteria as a 522 study can also be required to have a tracking system for product traceabililty. The purpose of the tracking is not to collect safety data or data of any kind, beyond information on how to locate a patient with a tracked device. The tracking is required for devices where there is some likelihood that patients with those devices might need to be contacted if there was a product recall or other safety program, such as reprogramming a pacemaker or early replacement of a battery. Active implants are the most common products to have tracking requirements.

NEW FDA DEVICE SAFETY INITIATIVES

The Center for Devices has recently announced efforts to improve the MDR system. The five main areas they highlighted are:

- Working toward an electronic reporting system for adverse medical device events;
- Unique ways to identify medical devices, including standardized and globally accepted names;
- Ways to improve device information in patient records;
- Improved internal collaboration on postmarket safety issues; and
- Identifying opportunities to improve the safety of medical devices through collaborative efforts with professional organizations and the medical device industry.

The first is designed to improve both the timely acquisition of reports at the FDA, and to allow better cross-manufacturer evaluation of emerging signals. As companies automate they may improve their internal capacity to evaluate new problems. The FDA is not only interested in an improved MDR system, but is also interested in making company annual reports more useful. The fourth initiative is an internal FDA effort, although it may change the way that the premarket staff evaluate applications for new products. Manufacturers may need to systematically describe their postmarketing experience with older approved products that use some of the same technology. Finally, the last bullet point emphasizes the need to solve many problems across a whole group of manufacturers, even though the tendency historically has been to focus on the company where a problem is first identified.

Postmarket Surveillance Outside the United States

The medical device regulatory framework is much more varied from country to country than pharmaceutical regulation, in part reflecting the shorter history of device regulation compared to drugs. While the premarket approval and risk classification in Europe and some other countries is an activity delegated to non-government third parties, Notified Bodies, as described in the previous chapter, and results in market authorization across the entire European Union (EU), postmarket safety systems are a country-by-country responsibility, and are not delegated to third parties.

Passive spontaneous reporting systems, like the US FDA's MedWatch program, have their parallels in most countries. The medical device quality systems which include many of the elements that collect and respond to reports of adverse events and complaints are also nearly universal. The EU, US, Canada, Australia, and Japan participate in the Global Harmonization Task Force (GHTF) which, like the International Conference on Harmonization (ICH) for drugs and biologics, develops harmonized guidance documents. The GHTF Study Group 2 develops postmarket surveillance/vigilance guidances which can be found at www.ghtf.org/sg2.

SUMMARY: WHAT DOES POSTMARKETING SURVEILLANCE TEACH US?

First, postmarketing surveillance is one of the best ways to identify low frequency events which are usually not detected in premarket evaluation, even when clinical trials are required to market a new medical device. The type of event may be unsuspected or it may be an "event of interest" based on known problems with similar devices, or suspected from failure mode assessments from the design of the device. Postmarket surveillance has an unusual breadth, since the FDA and other competent authorities will receive reports from all products in their countries and, in this increasingly harmonized world, reports from other countries. Early detection provides manufacturers with opportunities for early mitigation, with redesign or better training in the use of their products.

Second, changes in the frequency of reports over time can detect problems or suggest mitigation of problems when a design change is made that would be difficult to assess in clinical testing. Assessing the temporal trends in the rate of lead failure of pacemakers, for example, has been useful to ensure safe use or identify problems that may be the result of design or biomaterial changes.

Third, problems that develop only after prolonged use or exposure to a biomaterial may only be available from postmarket surveillance. Late failures of implants, pacemaker leads or orthopedic implants are all difficult to determine from premarket testing or clinical studies.

Fourth, postmarket surveillance is a "real world" test of medical devices and biomaterials in patient subgroups, with off-label uses, with concomitant use of other products that are not all possible to test before marketing.

In summary, while postmarket surveillance is necessarily more observational than the controlled experiments more typical of premarket evaluation, it provides an important safety net and is the only practical method to detect medical device problems that occur at too low a frequency or only after prolonged use, or are unlikely to be observed until a product has real-world use.

APPENDIX A: PROPERTIES OF BIOLOGICAL FLUIDS

Steven M. Slack[*]

This appendix represents a compilation of information relevant to biomaterials scientists regarding the properties and composition of several body fluids, i.e., blood, plasma (serum), cerebrospinal fluid, synovial fluid, saliva, tear fluid, and lymph. Where possible, ranges of values are provided, but the reader should recognize that significant variations are possible, particularly in states of disease. Further, the data reported here reflect adult measurements and may be substantially different in a pediatric population. Values for cerebrospinal fluid refer to the lumbar region, those for synovial fluid refer to the

knee joint, and those for lymph refer to the thoracic duct, unless otherwise specified. Table A1 lists the physico-chemical properties of these fluids. Table A2 provides the typical cellular composition of human blood. Table A3 shows the normal volumes of these fluids in males and females, and presents equations whereby such volumes can be estimated from the mass of the individual. Next, Table A4 lists the approximate concentrations of the major proteins present in various biological fluids. Tables A5 and A6 present the concentrations of inorganic and organic species, respectively, in these fluids. Table A7 provides data on the major plasma proteins, i.e., concentration, molecular weight, isoelectric point (pI), sedimentation coefficient (S), diffusion coefficient (D), extinction coefficient (E_{280}), partial specific volume (V_{20}), carbohydrate content (C), and half-life. Finally, Tables A8 and A9 present information on the proteins involved in the complement pathway and blood coagulation pathway, respectively. Some of the information contained in this appendix have been previously published in Black, J., & Hastings, G. (eds.) (1998). *Handbook of Biomaterial Properties*. Chapman & Hall: New York, NY, pp. 114–124.

---

[*]**Dr. Steven M. Slack** died on April 29, 2010. He was Professor in the Department of Biomedical Engineering and Associate Dean of Graduate Studies in the Herff College of Engineering, at the University of Memphis in Tennessee. He will be sorely missed by the four editors of this textbook, by his colleagues around the world, and especially by his many students at the University of Memphis.

TABLE A1	Physico-chemical Properties of Several Biological Fluids					
Property	Whole Blood	Plasma (Serum)	Cerebrospinal Fluid	Synovial Fluid	Saliva	Tear Fluid
Freezing-point depression[a]	0.557–0.577	0.512–0.568	0.540–0.603	—	0.07–0.34	0.572–0.642

[a]Units are °C.
[b]Units are mosm/kg H_2O. Calculated from freezing-point depression.
[c]pH measured from arterial blood and plasma, and from cisternal portion of CSF.
[d]Measured at 20°C.
[e]Measured *in vitro* at 37°C for whole blood, plasma, and synovial fluid, and at 38°C for cerebrospinal fluid. The viscosity of serum is slightly less than plasma due to the absence of fibrinogen.
[f]Units are S/cm. Measured at 25°C for plasma, 18°C for CSF.
[g]Relative to water at 20°C.
[h]Units are cal/g °C.
[i]Units are dyn/cm. Measured at 20°C.

TABLE A2	Cellular Composition of Blood	
Cell Type	Cells/µl	Half-Life in Circulation
Erythrocytes	$4.6–6.2 \times 10^6$ (M)	25 ± 2 days
	$4.2–5.2 \times 10^6$ (F)	
Leukocytes		
Neutrophils	3000–5800	6–8 hours
Eosinophils	50–250	8–12 hours
Basophils	15–50	?
Monocytes	300–500	1–3 days
Lymphocytes	1500–3000	Variable
Platelets	$1.5–3.5 \times 10^5$	3.2–5.2 days
Reticulocytes	$2.3–9.3 \times 10^4$	—

TABLE A3	Volumes of Various Biological Fluids[a]				
Parameter	Whole Blood	Erythrocytes	Plasma	CS Fluid	Tear Fluid
Volume (ml)	4490 (M)	2030 (M)	2460 (M)	100–160	4.0–13
	3600 (F)	1470 (F)	2130 (F)		

[a]The following equations can be used to estimate blood volume (BV), erythrocyte volume (EV), and plasma volume (PV) from the known body mass (b, kg) with a coefficient of variation of approximately 10%:

Males (M)

$BV = 41.0 \times b + 1530$
$PV = 19.6 \times b + 1050$
$EV = 21.4 \times b + 490$

Females (F)

$BV = 47.16 \times b + 864$
$PV = 28.89 \times b + 455$
$EV = 18.26 \times b + 409$

Factor IX	5.0	57,000	24
Factor X	12	58,800	24–40
Factor XI	2.0–7.0	160,000	48–84
Factor XII	15–47	80,000	50–60
Factor XIII	10	320,000	216–240
Protein C	4.0	62,000	10
Protein S	22	77,000	—
Protein Z	3.0	62,000	60
Prekallikrein	35–50	85,000	—
High molecular weight kininogen	70–90	120,000	—
Antithrombin III	210–250	58,000	67

APPENDIX B: PROPERTIES OF SOFT MATERIALS

M. Cristina L. Martins
Universidade do Porto, Portugal

TABLE B1	Mechanical and Physical Properties of Common Polymers Used as Biomaterials and the Respective Applications							
Polymer	Tensile Strength (MPa)	Tensile Modulus (GPa)	Elongation (%)	Tg (°C)	Tm (°C)	Water Absorption (%)	Water Contact Angle (°)	Biomedical Applications
Polyethylene: Low density polyethylene – LDPE[1]	4–16	0.1–0.3	90–800	−20	95–115	<0.01	93–95	Tubing[1,4,5]; shunts[1]; catheters[3–5]
High density polyethylene –HDPE[1]	21–38	0.4–1.2	20–1000	−125	135–138	<0.01	91	Plastic surgery implants
Ultra high molecular weight polyethylene – UHMWPE[2]	39–48	0.8–1.6	350–525	−160	125–138	–	–	Acetabulum in total hip prostheses[4]; artificial knee prostheses[4]
Polypropylene[1]	30–38	1.1–1.6	200–700	0	165	<0.01	104	Heart valve structures[1]; oxygenator[3,4] and plasmapheresis[1] membranes; unabsorbable sutures[1,3,4]; disposable syringes[1,3,4]
Polyvinylchloride – PVC (rigid)[1] (plasticized)[1]	35–62 10–24	2.4–4.1 –	2–40 200–450	87–90	212	0.1–0.4	80	Catheters[3]; maxillofacial prostheses[6]; blood bags[1,3,5,7]; tubings[1,5,7]; plasmapheresis membrane[1]
Poly(tetrafluoroethylene) – PTFE[1]	14–35	0.4	200–400	−10	327	0	110	Oxygenator membrane[1]; vascular graft[1,5]; catheter coatings[1,5]; facial prosthesis[1]; heart valve structures[4]; stapes prosthesis (in tympanoplasty)[4,5]
Poly (dimethylsiloxane)[1]	2–10	–	100–600	(−)120–(−)123	–	0.02	101–109	Oxygenator membrane[1,4]; tubing[1,5,7]; shunts[1,4]; breast, joint, tracheal, bladder, and maxillofacial prostheses[4]; heart pacemaker leads[4]; heart valve structures[4]; burn dressings[4,5]
Poly (ethylene terephthalate) – PET or Dacron[1]	59–72	2.8–4.1	50–300	69–82	265–270	0.1–0.2	73–78	Vascular grafts[1,4]; heart valve structures[3]; shunts[1]; laryngeal, esophageal, and bladder prostheses[5,4]; nonabsorbable sutures[3,4,6]; tendon reconstruction[6]
Polyamides (nylons)[1]	62–68	1.2–2.9	60–300	45–75	200–270	1.5	–	Hemodialysis membrane[1]; nonabsorbable sutures[1–3]
Poly (ether urethane) (e.g., Pellethane)[8]	35–48	<0.01	350–600	(−)43– (−)60	188–204	–	62–107	Percutaneous leads[1]; catheters[1,7]; tubings[1,3]; intra-aortic balloons[1]; wound dressings[1]
Poly (ether urethane urea) (e.g., Biomer)[8]	31–41	<0.01	600–800	(−)53–(−)67	120–150	0.02	63–69	Artificial heart components[1]; heart valves[1]; tubing[4]; vascular graft prostheses[4]
Polystyrene[1]	35–83	2.8–4.1	1–3	116	137	0.10	45[b]	Tissue culture dish[1,3]
Polycarbonate[1]	55–66	2.4	100–130	150	267	0.2	62[b]	Connectors[4]; oxygenator, hemodialysis, and plasmapheresis membranes[4]
Polysulfones[1]	70.3	2.5	50–100	190–285	–	0.22	–	Artificial heart components[1,7]; heart valve structures[1,7]; oxygenator, hemodialysis, and plasmapheresis membrane[4]

(Continued)

TABLE B1	Mechanical and Physical Properties of Common Polymers Used as Biomaterials and the Respective Applications *(Continued)*							
Polymer	Tensile Strength (MPa)	Tensile Modulus (GPa)	Elongation (%)	Tg (°C)	Tm (°C)	Water Absorption (%)	Water Contact Angle (°)	Biomedical Applications
Poly(aryl-ether-ether-ketone): PEEK[9] (OPTIMA LT1)	93	4[c]	30–40	~143	~343	–	–	Orthopedic and spinal implants
Poly (methyl methacrylate) – PMMA[1]	48–76	3.1	2–10	110	160	0.3–0.4	62	Dentures[1,4,6]; plasmapheresis[1] and hemodialysis membranes[3,4]; bone cement[1,3–6]; intraocular lens[1,3–5]; middle ear prosthesis[1,3]
Poly (2-hydroxyethylmethacrylate) – PHEMA[1]	0.3	0.8	50	115 (dry)	–	>1	–	Catheter coating[1,7]; drug delivery devices[1]; soft contact lenses[1,6]; vascular prosthesis coatings[1]; burn dressings[1,6]
Poly(vinyl alcohol)[4] (98–99% hydrolyzed) (87–89% hydrolyzed)	67–110 24–79		0–300	85 58	230 180	–	–	Drug delivery devices[4,6]
Poly (ε-caprolactone) (MW: 44,000)[10]	16	0.4	80	−62	57	<0.2	–	Drug delivery devices[7]
Poly (glycolic acid)-PGA[11] (fibers)	57 750	6.5 13.4	–	35 –	225 233	–	–	Drug delivery devices; absorbable sutures[6,7]
Poly (lactic acid) – PLA[10] L-PLA (Mw: 50,000–300,000) D,L-PLA (Mw: 107,000–550,000)	28–48 29–35	1.2–3.0 1.9–2.4	6–2 6–5	54–59 51–53	170–178 –	–	–	Drug delivery devices[6]
Poly(ortho ester)[d] (Mw: 99,700)	20	0.82	220	55	–	0.2–1	–	Drug delivery devices[1,7]
Poly(β-hydroxybutyrate) – PHB[10] (Mw: 370,000) P(HB-co-22 mol% hydroxyvaleric acid)[10] (Mw: 227,000)	36 16	2.5 0.62	2.5 36	1 −5	171 137	– –	– –	Drug release devices; sutures; artificial skin[10]; cardiovascular patches; orthopedic pins; nerve guides; wound dressings; bone marrow scaffolds[12]
Cellulose acetate[4]	13.1–58.6	0.6–1.8	6–50	–	306	2.0–6.5	–	Hemodialysis membrane[6,7]
Collagen[13,e] (uncross-linked fibers) (cross-linked fibers)	0.70–1.12 29.7–63.9	(1.5–2.2) × 10⁻³ 0.271–0.495	61.1–74.8 12.9–18.3	–	–	–	–	Hemostatic agent; vascular prosthesis; heart valves; tendons and ligaments; wound and burn dressings; absorbable sutures[6,14]
Silk[15,16,f] (with sericin) (without sericin)	500 610–690	5–12 15–17	19 4–16	–	–	–	–	Nonabsorbable sutures[6,7]; wound healing dressings; scaffolds for regeneration of bone, cartilage, tendon, and ligament tissues[12,16]
Chitosan[17,g] (Mv: 8.73 (±0.55) × 10⁵) (Deacetylation (%) = 98.17 ± 0.35)	56.2–67.6	2.93–3.30	26.9–33.3	50.8–53.2	–	–	–	Surgical sutures; dental implants; artificial skin; rebuilding of bone; corneal contact lenses; drug release devices[18]

[a]Applications are dependent of the polymer morphologic form.
[b]values are averages of advancing and receding contact angles.
[c]Flexural modulus.
[d]Transcyclohexane dimethanol (t-CDM): 1,6-hexanediol (1,6-HD) = 35:65.
[e]Acid-soluble collagen obtained from rat tail tendons. Collagen fibers coextruded using NaCl (coagent).
[f]*Bombyx mori* single-brin silkworm silk.
[g]Chitosan films.

APPENDIX C: CHEMICAL COMPOSITION OF METALS USED FOR IMPLANTS

Jack E. Lemons
University Professor, Schools of Dentistry, Medicine and Engineering, University of Alabama at Birmingham, Birmingham, AL, USA

Biomaterial	Nominal Composition (Elements)	Tensile Strength (MPa), (Min)	Elongation (%), (Min)	Comments
Iron (Fe) Alloys	Fe-18Cr-2.5Mo	480	30	Cast and Wrought Forms
	Fe-18Cr-14Ni-2.5Mo	150–1350	10–40	
	Fe-Zr-10Ni-3 Mn	74–1100	10–35	
	Fe-15Ni-2.5Mo	490–860	4–40	
	Fe-22Cr-13Ni-5 Mn-2.5Mo	690–1035	12–35	
	Fe-23 Mn-21Cr-1Mo	827–1379	12–30	
Cobalt (Co) Alloys	35Co-35Ni-20Cr-10Mo	241–1580	3–60	Cast and Wrought Forms
	Co-28Cr-6Mo	655–1192	8–20	
	40Co-20Cr-16Fe-15Ni-7Mo	1240–2275	1–65	
	Co-20Cr-15 W-IONi	190–896	20–45	
Titanium (Ti) and Alloys	99Ti (Grade I-IV)	240–550	4–30	Cast and Wrought Forms
	Ti-6Al-4 V	860	8	
	Ti-6Al-4 V (ELI)	825–860	8–10	
	Ti-6AL-7Nb	800	10	
	Ti-13Nb-13Zr	560–860	8–15	
	Ti-12Mo-6Zr-2Fe	931	12	
	Ti-15Mo	690–724	12–20	
	Ti-3Al-2.5 V	621–862	10–15	
Tantalum (Ta)	99Ta	172–517	12–30	Deposit and Wrought Forms
Zirconium (Zi) Alloy	Zr-2.5Nb	450	15	Wrought Forms
Nickel (Ni) Titanium (Ti) Alloy	45-57Ni-Ti	551	10-May	Wrought Forms

*Data from ASTMF04, Volume 13.01, Medical and Surgical Materials and Devices, 2011.

APPENDIX D: THE BIOMATERIALS LITERATURE

Buddy D. Ratner
Professor, Bioengineering and Chemical Engineering, Director of University of Washington Engineered Biomaterials (UWEB), Seattle, WA, USA

In the last ten years, we have seen the launch of many new biomaterials journals, and the publication of new books, paralleling the growth of the field and the increasing globalization of biomaterials and medical devices. Though this list of journals and books cannot be complete, it does illustrate the breadth of the field and may provide some guidance in working with this complex, multi-disciplinary literature.

As of the 2010 listing of impact factors by the Institute for Scientific Information, the following are some of the lead journals in the field classified as "biomaterials:"

European Cells & Materials (eCM) (9.650)
Biomaterials (7.882)
Lab on a Chip (6.26)
Nanomedicine (6.202)
Biomacromolecules (5.325)
Acta Biomaterialia (4.822)
Tissue Engineering (4.636)
Soft Matter (4.457)
Journal of Biomedical Materials Research Part A (3.044)

This list is particularly interesting because many of the most influential journals impacting biomaterials are not "classical" biomaterials journals.

Biomaterials Journals (or Journals with Significant Biomaterials Content)

Acta Biomaterialia (Elsevier)
Advanced Drug Delivery Reviews (Elsevier)
Advanced Healthcare Materials (WILEY-VCH Verlag GmbH & Co.)
American Journal of Drug Delivery (Wolters Kluwer)
American Society of Artificial Internal Organs Transactions
Annals of Biomedical Engineering (Springer – Official Publication of the Biomedical Engineering Society)
Annual Reviews of Biomedical Engineering
Artificial Cells, Blood Substitutes, and Biotechnology (Informa Healthcare) (T. M. S. Chang, editor)
Artificial Organs (Raven Press)
Artificial Organs Today (T. Agishi, editor; VSP Publishers)
Bio-Medical Materials and Engineering (T. Yokobori, editor; Pergamon Press)
Biofabrication (Institute of Physics)
Biofouling (Harwood Academic Publishers)
Bioinspiration and Biomimetics (Institute of Physics)
Biointerphases (American Institute of Physics)
Biomacromolecules (American Chemical Society)
Biomaterial–Living System Interactions (BioMir; V. I. Sevastianov, editor)

Biomaterials (including Clinical Materials) (Elsevier)
Biomaterials Forum (Society For Biomaterials)
Biomaterials: Processing, Testing and Manufacturing Technology (Butterworth)
Biomatter (Landes Bioscience)
Biomedical Engineering OnLine (Electronic – http://www.biomedical-engineering-online.com/start.asp)
Biomedical Materials: Materials for Tissue Engineering and Regenerative Medicine (Institute of Physics)
Biomedical Microdevices (Kluwer)
Biosensors and Bioelectronics (Elsevier)
Cell Stem Cell (Cell Press – Official Journal of the International Society for Stem Cell Research (ISSCR)) (Elsevier)
Cell Transplantation – The Regenerative Medicine Journal (Cognizant Communication Corporation)
Cells Tissues Organs (Karger)
Clinical Biomechanics (Elsevier)
Colloids and Surfaces B: Biointerfaces (Elsevier)
Dental Materials (Elsevier, Official Publication of the Academy of Dental Materials)
Drug Delivery Systems & Sciences (Euromed Scientific)
Drug Delivery Technology (Montville, NJ)
Drug Targeting and Delivery (Academic Press)
e-biomed: *The Journal of Regenerative Medicine* (Mary Ann Liebert, Inc.) *discontinued*
European Cells and Materials (eCM) (Electronic – http://www.eurocellmat.org.uk)
Expert Review of Medical Devices (Expert Reviews Ltd, London)
Frontiers of Medical and Biological Engineering (Y. Sakurai, editor; VSP Publishers)
IEEE Transactions on Biomedical Engineering
International Journal of Artificial Organs (Wichtig Editore)
International Journal of Biomaterials (Hindawi Publishing Corp.). Open access: http://www.hindawi.com/journals/ijbm/contents.html
International Journal of Nanoscience (World Scientific Journals, Imperial College Press, London)
Journal of Applied Biomaterials and Biomechanics (Wichtig Editore)
Journal of Bioactive and Compatible Polymers (Sage Publications)
Journal of Biochips & Tissue Chips (OMICS Publishing Group)
Journal of Biomaterials Applications (Sage Publications)
Journal of Biomaterials Science: Polymer Edition (VSP Publishers)
Journal of Biomedical Materials Research A (Wiley-VCH – Official Publication of the Society for Biomaterials)
Journal of Biomedical Materials Research B: Applied Biomaterials (Wiley-VCH – Official Publication of the Society for Biomaterials)
Journal of Biomimetics, Biomaterials, and Tissue Engineering (Transtech Publications, Inc)
Journal of Controlled Release (Elsevier)
Journal of Developmental Biology and Tissue Engineering (academicjournals.org)

Journal of Drug Targeting (Harwood Academic Publishers)

Journal of Engineering in Medicine (Institution of Mechanical Engineers)

Journal of Long Term Effects of Medical Implants (CRC Press)

Journal of Materials Science: *Materials in Medicine* (Kluwer Academic Publishers – Official Journal of the European Society for Biomaterials)

Journal of Medical Devices (ASME)

Journal of Mechanical Behavior of Biomedical Materials (Elsevier)

Journal of Nanobiotechnology (BioMed Central, Springer)

Journal of Neural Engineering (Institute of Physics)

Journal of Oral Tissue Engineering (Japanese Association of Regenerative Dentistry)

Journal of Tissue Engineering (Wiley Interscience)

Lab on a Chip (RSC Publishing)

Langmuir (American Chemical Society)

Macromolecular Bioscience (Wiley-VCH)

Materials in Medicine (Springer – Official Publication of the European Society for Biomaterials)

Medical Device and Diagnostics Industry (Canon Publications)

Medical Device Research Report (AAMI)

Medical Device Technology (Astor Publishing Corporation)

Medical Plastics and Biomaterials (Canon Communications, Inc.; not publishing)

Nano (American Chemical Society)

Nano LIFE (World Scientific Journals, Imperial College Press, London)

Nanobiology (Carfax Publishing Co.)

Nanobiotechnology (Springer Publishers)

Nanomedicine (Future Medicine)

Nanotechnology (Institute of Physics Publishing Co.)

Nature Biotechnology (Nature Publishing Group)

Nature Materials (Nature Publishing Group)

Small (Wiley-VCH)

Soft Materials (Taylor & Francis Group, London)

Soft Matter (RSC Publishing, London)

Stem Cells (AlphaMed Press)

The Open Biomaterials Journal (Bentham Publishers – http://www.bentham.org/open/tobiomtj/EBM.htm)

Tissue Engineering (Mary Ann Liebert, Inc.)

Trends in Biomaterials & Artificial Organs (Society For Biomaterials And Artificial Organs – India)

Wound Repair and Regeneration (Blackwell Publishing)

APPENDIX E: CHAPTER II.5.2 — NONTHROMBOGENIC TREATMENTS AND STRATEGIES

Michael V. Sefton[1], Cynthia H. Gemmell[1], and Maud B. Gorbet[2]

[1]Department of Chemical Engineering and Applied Chemistry, Institute of Biomaterials and Biomedical Engineering, University of Toronto, Canada

[2]Department of Systems Design Engineering, University of Waterloo, Canada

INTRODUCTION

This chapter addresses the methods to improve the blood compatibility of biomaterials, the subject of a large body of literature in the biomaterials field and a topic of great importance clinically. To appreciate the contents of this chapter, a familiarity with material in Chapters I.2.12, I.2.17, II.2.6, II.3.5, and II.5.16D is expected.

HISTORICAL

In 1963, Dr. Vincent Gott at the Johns Hopkins University changed the field of biomaterials by failing to reproduce an earlier experiment. He was trying to show that an applied electric field could minimize thrombus formation on a metal surface. He obtained this result, but was somewhat mystified when he discovered that the wire leading to his negative graphite electrode was broken. He soon realized the importance of rinsing his electrode with a common disinfectant (benzalkonium chloride) and heparin prior to implantation. Thus, the first heparinized material was born. Robert Lehninger (Leininger et al., 1966) at Battelle Memorial Institute in Columbus, Ohio followed up with better quaternary ammonium compounds, and soon afterwards a host of chemical derivatization methods were devised to adapt the original GBH (graphite benzalkonium heparin) method to plastics and other materials. The principles underlying these strategies and others for lowering the thrombogenicity of materials are detailed here with examples.

CRITERIA FOR NONTHROMBOGENICITY

Thrombogenicity is defined (Williams, 1987) as the ability of a material to induce or promote the formation of thromboemboli. Here we are concerned with strategies to lower thrombogenicity, if not actually reduce it to zero, "nonthrombogenicity." Thrombogenicity should be thought of as a rate parameter, since low rates of thrombus or emboli formation are probably tolerable because the fibrinolytic or other clearance systems exist to remove "background" levels of thromboemboli. We are principally concerned with rates of thrombi formation that are sufficient to occlude flowpaths in medical devices (e.g., block the lumen of catheters) or rates of emboli formation that cause downstream problems such as myocardial infarction or transient ischemic attacks. The mechanisms of thrombogenicity are described in Chapter II.2.6, the methods to measure thrombogenicity are described in Chapter II.3.5, while the effects of fluid flow on thrombus development and embolization are described in Chapters II.3.5 and II.1.6.

Thrombi are produced through aggregation of activated platelets and/or the thrombin dependent polymerization of fibrinogen into fibrin. Thrombin is directly responsible for fibrin formation but it is also an important agonist of platelet activation. A simple model of thrombin generation is illustrated in Figure II.5.2.1a. The variety of mechanisms that lead to thrombin generation are lumped into a single parameter, k_p (cm/s), a rate constant that relates the rate of production of thrombin (per unit area), R_p (g/cm^{2}s), to the thrombin concentration at the surface of a material C_w (g/mL):

$$R_p = k_p C_w \tag{1}$$

(a)

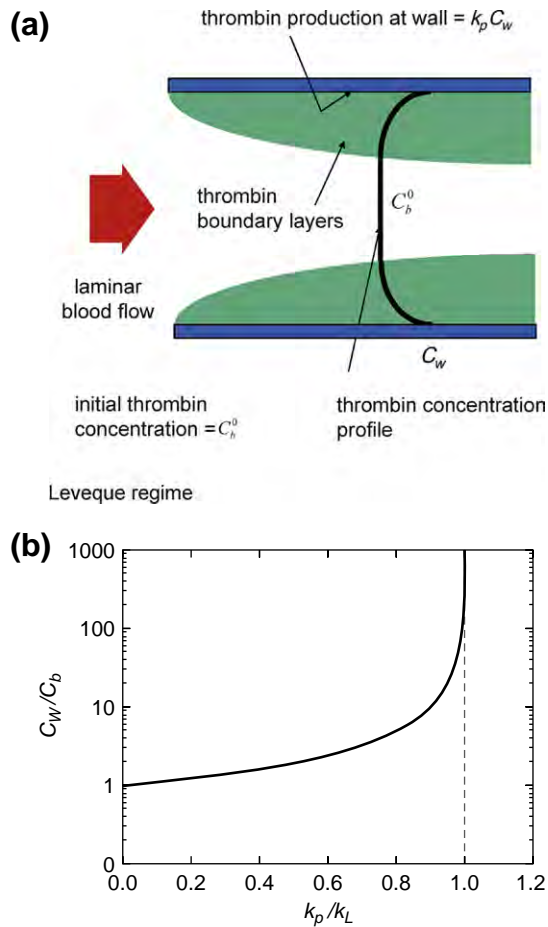
(b)


FIGURE II.5.2.1 (a) Model illustrating thrombin production at the surface of a tube as a balance between autoaccelerative production at the surface and mass transfer away from the wall. (b) Schematic illustration of Equation (2) showing the dramatic increase in wall to bulk concentration ratio as the mass transfer coefficient k_L becomes equal to the first-order autocatalytic production constant (k_p). Since k_L decreases with increasing axial position down a tube, increasing k_p/k_L corresponds to increasing x. (Adapted from *Rollason and Sefton, 1992*.)

k_p includes both the procoagulant effect of the material (via clotting factors and platelets) less any coagulation inhibition processes. A material balance (Basmadjian, 1990; Rollason and Sefton, 1992) equating the rate of production at the surface to the rate of transport away from the surface $k_L(C_w - C_b)$ for tubes greater than about 0.1 mm in diameter (Leveque region) gives:

$$\frac{C_w}{C_b^0} = \frac{1}{1 - k_p / k_L(x)} \tag{2}$$

where C_b^0 is the concentration of thrombin at the inlet to a tube. $k_L(x)$ is the local mass transfer coefficient which is infinite at the tube inlet and decreases as one proceeds down the tube. Hence, C_w/C_b^0 increases progressively down the tube (Figure II.5.2.1b). When $k_L = k_p$, C_w becomes infinite, and a thrombus is expected. For a simple tube in laminar flow, k_L is in the order of 10^{-3} cm/s, and so k_p must be less than this to avoid a thrombus. Experimental results suggest that k_p is in the order of 10^{-3} for simple materials like polyethylene, but $<10^{-4}$ for heparinized materials (Rollason and

Sefton, 1992). According to this model, only such low k_p materials can be expected to minimize thrombin production. This is one of the reasons heparinization and other active methods of inhibiting thrombin formation are so popular as strategies for imparting low thrombogenicity. There are, however, other criteria that must also be met.

It is also a requirement that platelet interactions with the surface do not lead to thrombosis. To some extent, platelet adhesion is inevitable. Once adherent, platelets change shape and release their granule contents which can activate bulk platelets. While it is intuitive to suggest that a nonthrombogenic surface should not support platelet adhesion it has not, unfortunately, been that simple. While most studies focus on evaluating the platelet compatibility of surfaces by measuring *in vitro* platelet adhesion, some *ex vivo* studies (Hanson et al., 1980; Cholakis et al., 1989) have demonstrated that even in the absence of adhesion, platelets can be "consumed." That is, the platelets are activated by the material leading to their premature removal from the circulation (Chapter II.3.5). This becomes apparent as a significant shortening of platelet lifespan, if not also a decrease in systemic platelet count. Whether this process is initiated by nonadhesive direct contact with the material or is the result of adherent platelet release, or even the effect of complement activation is currently unknown. Nevertheless, such an observation suggests that low platelet adhesion is not a sufficient criterion of *in vivo* platelet compatibility. Rather, low thrombogenicity is characterized by both low platelet adhesion and low platelet activation (see Chapter II.2.6 for a definition of activation); the latter may even be more important than the former. Leukocyte activation (expression of procoagulant activities such as tissue factor or CD11b upregulation; Gorbet and Sefton, 2004) and complement activation may also be key components in thrombogenicity (see Chapters II.2.4 and II.2.6), and in the future these too may become critical parameters defining the thrombogenicity of the surface. In an attempt to evaluate more than just platelet adhesion on biomaterials, flow cytometric techniques have been developed to measure bulk (or circulating) activated platelets, platelet microparticles, platelet–leukocyte aggregates and activated leukocytes (such as C11b upregulation) (Gemmell et al., 1995; Baker et al., 1998; Snyder et al., 2007). It is expected that such assays will result in better correlation between *in vitro* and *ex vivo/in vivo* performances.

While blood cells play an important role in material-induced thrombosis, concerns over in-stent thrombosis have renewed the interest in developing biomaterials to support and promote endothelialization. The potential thrombogenicity of these cells on a biomaterial add another dimension to this topic (McGuigan and Sefton, 2007).

INERT MATERIALS

Much of the effort in biomaterials research over the past 35 years has been directed towards the development of

Make surfaces hydrophilic

Hydrogel coating or surface graft, e.g.,

N-vinyl pyrrolidone

PEG immobilization [-CH$_2$CH$_2$-O-]$_n$

SO$_3^-$ SO$_3^-$ SO$_3^-$

Heparin-like surfaces

Make surfaces hydrophobic

Albumin affinity e.g., C$_{18}$ alkylation

N$^+$ PO$_4^-$

Phosphorylcholine copolymers (membrane mimicry)

Microstructure control

Hydrophobic/hydrophilic domains

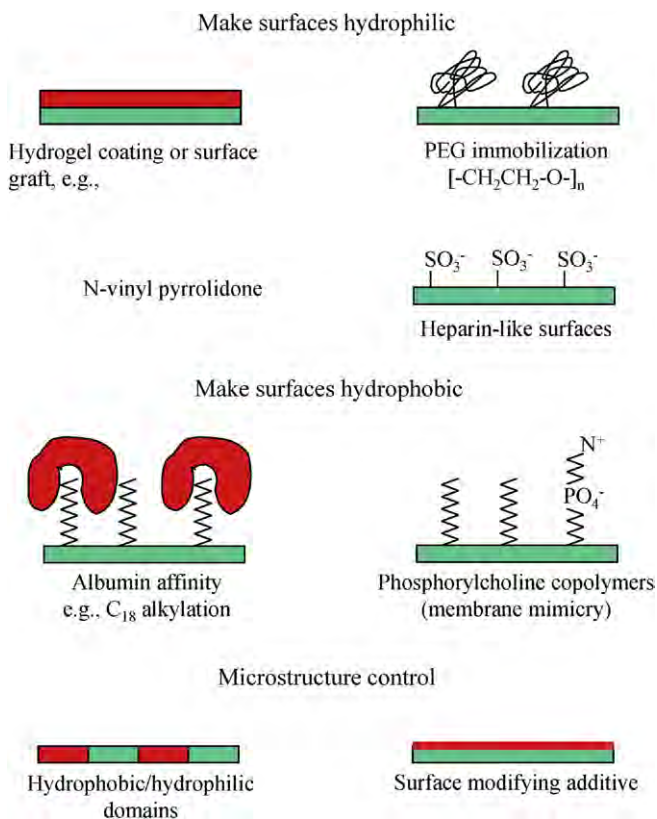
Surface modifying additive


FIGURE II.5.2.2 Potential strategies for preparing inert surfaces with low thrombogenicity.

inert materials that do not react with platelets and coagulation factors. As outlined in Figure II.5.2.2, a number of approaches, often conflicting, have been developed. For example, there is still no consensus as to whether a surface should be hydrophilic or hydrophobic. The lack of agreement is largely due to our incomplete understanding of the biological pathways to materials failure and our inability to fully evaluate blood–material responses. In developing materials with lower thrombogenicity, researchers have primarily focused their efforts on modifying the surfaces of existing polymeric materials, like polyurethanes, silicone rubber, and polyethylene. This approach is reasonable, since it is only the surface chemistry of a material that should dictate its biological responses. As illustrated by the following discussion, the full range of surface modification strategies outlined in Chapter I.2.12 has been used, albeit with limited success. On the other hand, in comparing many plasma modified surfaces, Sefton et al. (2001) did not identify a modification chemistry that was superior to the base material in terms of platelet or leukocyte activation. Despite the successes in reducing protein and cellular deposits on some materials, a truly nonthrombogenic surface does not yet exist.

Hydrogels

A popular method to improve the blood compatibility of biomaterials is to increase surface hydrophilicity by incorporating a hydrogel at the surface. All commonly used hydrogels (see Chapter I.2.5) that can be cast, chemically cross-linked, or surface grafted have been used. By definition, hydrogels permit the retention of large amounts of water without dissolution of the polymer itself. This makes them similar to biological tissues, in that they are permeable to small molecules and possess low interfacial tension. It was Andrade who first postulated that since the interfacial free energy between blood and vascular endothelium was near zero, material surfaces which tend to have an interfacial energy of zero should have minimal thrombogenicity (Andrade et al., 1973). Today, considerable experimental evidence supports the claim that materials with minimal interfacial energy, like hydrogels, do not strongly support cell and/or thrombus adhesion. Unfortunately, such generalizations are always flawed by exceptions. A hydrogel (cellulose) used as a dialysis membrane material (Cellophane™) is well recognized as being thrombogenic, possibly because it is also a strong activator of the complement system (Chapter II.2.4). Furthermore, low adhesion (or low protein adsorption) is not the same as low thrombogenicity.

In the early 1980s, a number of polymers were grafted with hydrogel surfaces in an effort to decrease their thrombogenicity. For example, in a large *ex vivo* study (Hanson et al., 1980), a variety of surface grafted copolymers were prepared and evaluated for platelet consumption in a baboon shunt model of arterial thrombogenesis. Although few platelets were found adherent to the graft surface, the higher the water content, the greater the rate at which the graft tubing caused the destruction of the circulating platelets (Figure II.5.2.3). Even though this study concluded that hydrogels did not possess low thrombogenicity, utilization of hydrogels remains a popular approach to lower thrombogenicity. It is likely that platelet consumption will be of concern only in applications with large surface areas. On the other hand, platelet consumption is evidence of platelet
FIGURE II.5.2.3 Rate of cannula platelet consumption per unit area (in baboons) is directly related to the graft water content of shunts grafted with eight acrylic and methacrylic polymers and copolymers. HEMA: hydroxyethyl methacrylate; EMA: ethyl methacrylate; AAm: acrylamide; MAAC: methacrylic acid. Mean values 1 S.E. *(From Hanson et al., 1980, with permission.)*

activation, and the local (as opposed to systemic) consequences of such activation have yet to be defined.

Rather than radiation grafting of hydrogels onto materials, surfaces can also be simply coated with hydrophilic polymers, such as poly(vinyl pyrrolidone), PVP. While coating with PVP is intended to increase lubricity and ease catheter insertion, benefits on thrombogenicity (and bacterial adhesion) have been noted (Francois et al., 1996).

Polyethylene Glycol (PEG) Immobilization

Immobilization of the water-soluble synthetic polymer, polyethylene glycol (PEG, $-CH_2CH_2O-$), is a widely used approach to making a biomaterial surface more protein and cell resistant. It also makes the surface hydrogel-like. This approach was promoted by Edward Merrill, who recognized the lack of hydrogen bond donor sites on the PEG molecule and postulated that such sites might be involved with protein binding (Merrill and Salzman, 1983). A widely recognized theory that helps to explain the nonthrombogenicity of PEG-containing surfaces was presented by Nagaoka et al. (1984). They reasoned that the presence of diffuse hydrophilic polymers, covering a significant portion of a biomaterial surface, would exert a steric repulsion effect towards blood proteins and cells (Figure II.5.2.4). The dominance of steric repulsion over the van der Waals attractive forces was hypothesized to be dependent on the extension and flexibility of the polymer chain in the bulk solution. The resulting excluded volume effect results from a loss in configurational entropy of the PEG that in turn results from the rise in the local osmotic pressure occurring when PEG chains are compressed when blood elements approach the surface. This effect is dependent on both the chain length (N, monomers/chain), and the surface density
FIGURE II.5.2.4 Structure of polyethylene glycol (PEG) modified surfaces. (a) At low surface coverage ($D >> R_F$), molecules assume conformation and size similar to random coil. (b) At high surface coverage ($D << R_F$), molecules are more extended, chain-like and form a dense brush. *(Adapted from de Gennes, 1980.)*

of chains (σ, number of chains per unit area). A simple scaling relationship relates these parameters (and a, the monomer size) to the thickness, L, of the polymer layer at the surface, for the case of a good solvent (specifically an athermal solvent), and when the chain density is high (distance between chains, D) is less than the Flory radius, R_F (de Gennes, 1980):

$$L \cong Na\sigma^{1/3} \qquad (3)$$

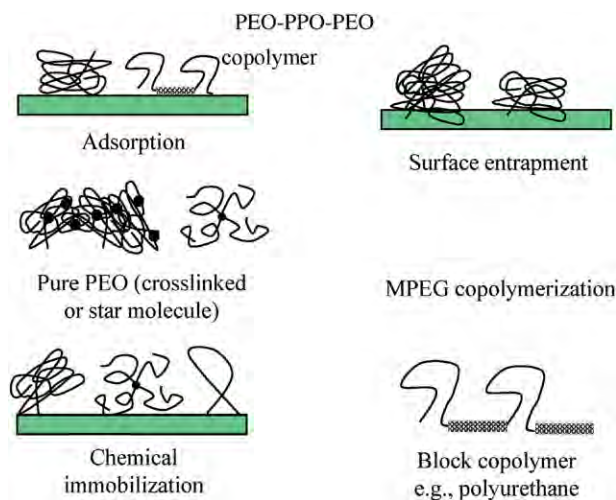
Jeon and Andrade (1991), and among others, have theoretically modeled protein–surface interactions in the presence of PEG and concluded that steric repulsion by surface-bound PEG chains was largely responsible for the prevention of protein adsorption on PEG-rich surfaces. An extended discussion of PEG surface–protein interactions is presented in Chapter I.2.10, particularly


FIGURE II.5.2.5 Methods for incorporating polyethylene glycol (PEG) onto the surfaces of materials. PEO: poly(ethylene oxide); PPO: poly(propylene oxide); MPEG: methoxypolyethylene glycol methacrylate.

addressing the limited protein resistance of very short PEG chains where steric considerations are not relevant.

As shown in Figure II.5.2.5, a number of approaches have been used to enrich surfaces with PEG. For example, it has been grafted to surfaces via a backbone hydrogel polymer, such as in the preparation of methoxypolyethylene glycol monomethacrylate copolymers (Nagaoka et al., 1984). It has also been covalently bonded directly to substrates via derivatization of its hydroxyl end groups with an active coupling agent or, alternatively, the hydroxyl end groups have been reacted with active coupling agents introduced onto the surface (Desai and Hubbell, 1991a; Chaikof et al., 1992; Tseng and Park, 1992). The commercial availability of a large number of reactive PEG molecules (e.g., amino-PEG, tresyl-PEG, N-hydroxysuccinimidyl-PEG) has greatly facilitated the use of covalent immobilization strategies. Unfortunately, it is difficult to achieve the required high surface coverages by immobilization, since the first molecules immobilized sterically repel later molecules that are attached, unless thermodynamically poor solvents are used. The surface fraction may then be too low to completely "mask" the other functional groups that may be present. Pure monolayers of star PEG have been grafted to surfaces in an attempt to increase surface coverage (Sofia and Merrill, 1998), and radio frequency plasma polymerization of tetraglyme has been used to the same end (Shen et al., 2001). Other investigators have used block copolymers (e.g., Pluronic™) of PEG and PPO [poly(propylene oxide)] by adsorption, gamma irradiation, or as an additive (McPherson et al., 1997); some have combined PEG with other strategies such as phosphorylcholine (Kim et al., 2000), cyclodextrin (Zhao and Courtney, 2007) and negatively-charged side groups (from vinyl sulfonic acid sodium salt) (Lee et al., 2004).

PEG has also been incorporated, by both ends, into polyetherpolyurethanes (Merrill et al., 1982; Okkema

et al., 1989). Unfortunately, the results in this case depend on a combined effect of surface microphase separation and the hydrogel (hydrated chain steric exclusion) effect of the PEG side chains. While some have noted lower thrombogenicity, others have not. For example, Okkema et al. (1989) synthesized a series of poly(ether-urethanes) based on PEG and poly(tetramethylene oxide) (PTMO) soft segments, and noted that the higher PEG-containing polymers were more thrombogenic in a canine *ex vivo* shunt model. Since PEG-containing polyurethanes have a considerable non-PEG phase, Chaikof et al. (1989) prepared a cross-linked network of PEG chains using only small polysiloxane units.

A number of investigators have noted that the beneficial effect of PEG is molecular weight dependent. Nagaoka et al. (1984) were one of the first to demonstrate that increasing the PEG chain length of hydrogels containing methoxy poly(ethylene glycol) monomethacrylates led to reductions in protein and platelet adhesion (Figure II.5.2.6). To some extent, however, the benefit of high molecular weight PEO[1] is compromised by the crystallizability of long chain PEO. In some cases, the benefit of longer chains may reflect particular process advantages (such as surface entrapment). Chaikof et al. (1992), with end-linked PEO, and Desai and Hubbell (1991b), with physically entrapped PEO, found lowest protein and platelet or cell deposition with high molecular weight PEO (>18,000 Da). However, when studying PEG-modified polyurethanes, Tan and Brash (2008) noted the importance of PEG surface density over length: the shortest PEG chain (MW: 550) allowed for a higher surface density and provided the highest reduction in protein reduction compared to modification with longer chains of PEG (MW 2,000 and 5,000).

It is clear that incorporation of PEG results in reduced levels of cell (including platelet) adhesion and protein adsorption when compared to unmodified and typically hydrophobic substrates. It is far less clear whether the reduced adhesion or adsorption translates to lower material thrombogenicity (Llanos and Sefton, 1993a,b). Further, it is not clear whether reduced adhesion/adsorption is due specifically to the thermodynamic effects of PEG or PEO, or to the increase in surface hydrophilicity after its immobilization. While the *in vitro* results have looked promising, the lack of correlation between the few *in vitro* and *ex vivo* studies is of concern. More recent efforts with plasma deposited tetraglyme (Shen et al., 2001) have led to surfaces with ultra-low adsorbed fibrinogen, suggesting that previous attempts at using PEG modification have not been successful because of the inability to achieve the desired ultra-low (<5 ng/cm²) levels of adsorbed protein. On the other hand, more recent studies from the same group (Zhang, et al., 2008; Zhang and Horbett, 2009) show that such surfaces are

---

[1]PEG >10 kD is called PEO [poly(ethylene oxide)], reflecting the different monomer and polymerization process used.
FIGURE II.5.2.6 Effect of PEG (or "POE") chain length (*n*) on the adhesion of platelets (from activated platelet rich plasma) and adsorption of plasma proteins (from plasma) onto poly(methyl methacrylate co-methoxypolyethylene glycol methacrylate) gels. Mean values and standard deviation are shown. Both protein adsorption and platelet adhesion were measured by total protein anaylsis. A relative platelet adhesion value of 0.3 corresponded to an Scanning Electron Microscopy (SEM) platelet adhesion density of ~80 platelets/1,000 μm². *(From Nagaoka et al., 1984, with permission.)*

not as resistant to protein adsorption as expected when exposed to physiological conditions (undiluted plasma). Low amounts of adsorbed von Willebrand Factor (vWF) (and not fibrinogen only) also played a significant role in platelet adhesion under high shear rates. There is also new evidence that properties of PEO and PEG surfaces may also be affected by the sterilization process (see Box 2). This highlights the importance of testing modified surfaces under physiological conditions before drawing conclusions from *in vitro* studies using (surrogate) markers such as platelet adhesion or fibrinogen adsorption.

Albumin Coating and Alkylation

The early observation that surfaces coated with albumin did not support protein adsorption and platelet adhesion (reviewed by Andrade and Hlady, 1986) led many investigators to lower material thrombogenicity by either albumin coating or enhancing the affinity of albumin for surfaces via alkylation. It is thought that albumin adsorption lowers thrombogenicity, since it does not possess the peptide sequences to enable interaction with cells (platelets and leukocytes) or the enzymes of the coagulation cascade. It adsorbs relatively tightly onto hydrophobic surfaces, while having a poor affinity for hydrophilic surfaces. Consequently, utilization of this strategy entails increasing the hydrophobicity of the surface, which is the opposite of the above discussed strategies whereby the hydrophilicity of the surface was increased. Albumin coating is consistent with another hypothesis, developed early in the 1970s, which

suggested that hydrophobic surfaces with critical surface tensions (conceptually related to surface free energy) around 20–30 dynes/cm would have a lower thrombogenicity (Baier et al., 1970).

A limitation of relying on albumin coating is that other proteins will adsorb to the surface displacing the albumin, limiting the long-term effectiveness of this strategy (see Chapter II.1.2). To prevent displacement, glutaraldehyde cross-linking (Kottke-Marchant et al., 1989) or covalent immobilization has been used (Hoffman et al., 1972; Matsuda and Inoue, 1990). Reduced platelet adhesion was observed *in vitro* with a multilayer of albumin on polyethersulfone deposited using a layer-by-layer technique (Sperling et al., 2006). Since albumin has binding pockets for long alkyl chains, Munro et al. (1981) demonstrated that surfaces with long carbon chains (C-16 or C-18) have a high affinity for albumin, and provided for a dynamically renewable natural albumin layer. Albumin adsorption (from diluted plasma) was enhanced on alkylated cellulose membranes (Frautschi et al., 1995). Butylation (but not longer alkyl chains) of polyvinyl alcohol hydrogel also dramatically reduced platelet reactivity in a dog shunt (Strzinar and Sefton, 1992) suggesting that some of the observed benefit was due to the creation of a hydrophobic surface (Duncan et al., 1997).

Zwitterionic Group/Phospholipid Mimicking Surfaces

A number of investigators have hypothesized that a surface similar to the external zwitterionic outer phospholipid membrane of cells should be nonthrombogenic.[2] Since phosphorylcholine (PC) is the major lipid head group

---

[2]Upon cell activation, the negatively-charged phospholipids that are preferentially located on the cytoplasmic face of the cell membrane flip to the outer membrane, which accelerates blood clotting by enabling assembly of the prothrombinase and tenase complexes.

on the external surface of blood cells and red blood cells are inert in coagulation assays, PC has been the choice of many investigators for incorporation into surfaces.

Durrani et al. (1986) prepared a series of reactive derivatives of phosphorylcholine that were designed to react with surface hydroxyl groups and surface acid chlorides on various materials. Another approach involved coating materials (Campbell et al., 1994; Lewis et al., 2000; Iwasaki et al., 2002), or blending a polyurethane (Ishihara et al., 1995, 1999) with a methacryloylphosphorylcholine (MPC; Figure II.5.2.7)/polyacrylate copolymer. Platelet adhesion was significantly reduced on phosphorylcholine coated expanded polytetrafluoroethylene (ePTFE) grafts at 90 minutes in dogs, and anastomotic neointimal hyperplasia and neointimal cell proliferation were also reduced (Chen et al., 1998). Ishihara et al. (1998) have attributed the low protein adsorption of their phospholipid polymers to the high free water fraction, a mechanism that has been confirmed by other investigations (Chen et al., 2005). A further modification has involved grafting only the polar part of phosphorylcholine onto ammonia plasma treated ePTFE to promote more of the red blood cell-like properties while preventing lipid uptake (Chevallier et al., 2005). This led to significant reduction in both platelet and leukocyte adhesion.

A recent approach has also been to modify materials (for example polyurethane) using zwitterionic polymers/monomers such as carboxybetaine or sulfobetaine (Figure II.5.2.8a,b) to mimic the cell membrane (Yuan et al., 2003; Jiang et al., 2004; Kitano et al., 2005). Zhang et al. (2008)
FIGURE II.5.2.7 Chemical structure of poly(2-methacryloyloxy-ethyl phosphorylcholine).

prepared polymeric brushes containing zwitterionic groups by surface initiated atom transfer radical polymerization using sulfobetaine methacrylate (polySBMA) and carboxybetaine methacrylate (polyCBMA) on gold surfaces. Not only did such zwitterionic polymeric brushes exhibit superlow protein adsorption, with the polyCBMA brushes adsorbing less than 0.4 ng total protein/cm^2 (experiments performed in 100% plasma), but significantly reduced platelet adhesion was also observed. The polyCBMA also demonstrated unique anticoagulant properties, suggesting that such a material may offer excellent blood compatibility, although the mechanism by which polyCBMA is superior to polySBMA is currently unclear.

Surface Modifying Additives (SMAs)

The blending of a copolymer, composed of polar and nonpolar blocks, to a base polymer appears to be a successful means to lower material thrombogenicity. The strategy, originally developed by Thoratec Laboratories Inc., is a means to alter the surface properties of materials without affecting bulk properties (Ward et al., 1984). The copolymers, added in low concentration, migrate to the base polymer surface during and after fabrication, and dramatically change the outermost surface molecular layers that comprise the region that determines biocompatibility (Tsai et al., 1994). The copolymers have a structure which is amphipathic, that is, certain groups or segments will have an attraction for the continuous phase (major polymer component of the blend), while other portions of the molecule will have little attraction for the base polymer and will be of lower polarity (Ward et al., 1984) (see Chapter I.2.12). They have been used to lower the thrombogenicity of cardiopulmonary bypass and hemodialysis components by using SMA blended polymers or SMA coated surfaces. A clinical evaluation of the effects of SMA on cardiopulmonary bypass circuits demonstrated a reduction in platelet interactions with no effect on complement activation (Gu et al., 1998).
FIGURE II.5.2.8 Generic structures of zwitterionic molecules (a: carboxybetaine and b: sulfobetaine) and two common NO donors: (c) zwitterionic (I) and cation-stabilized (II) diazeniumdiolates, and (d) an S-nitrosothiol. *(From Frost et al., 2005.)*

Fluorination

The incorporation of fluorine into materials is also a strategy to lower thrombogenicity. Polymers with fluorinated chains are highly hydrophobic, and it is believed that the fluorine group's low surface energy modulates protein adsorption and platelet adhesion/activation. Preparing fluorine-rich surfaces is often facilitated by the tendency of fluorine-containing functional groups to concentrate on the surface of the polymer during preparation. Kiaei et al. (1988) found a strong effect of a fluoropolymer plasma on thrombus formation and plasma-induced graft polymerization of a fluorocarbon on polyethylene also reduced platelet adhesion (Lin et al., 2000). Fluoroalkyl groups as chain extenders have also been used to prepare nonthrombogenic polyurethanes (Kashiwagi et al., 1993). Using a similar approach, Wang and Wei (2005) showed that increasing fluorine content in polyurethanes by decreasing soft segment length resulted in a decrease in platelet adhesion and activation (of adherent platelets). Fluorinated surface-modifying macromolecules (SMMs) used to increase polyetherurethane biostability also improved blood compatibility (Jahangir et al., 2002), although the effect does not appear to be directly correlated with a decrease in fibrinogen adsorption (Massa et al., 2005).

Heparin-Like Materials

A number of synthetic polymers have been synthesized or modified in order to prepare polymers with chemical similarity to heparin, and thus possess heparin-like activities. For example, Fougnot et al., (1983) synthesized sulfonate/amino acid sulfamide polystyrene derivatives in order to create insoluble heparin-like materials. Some investigators (e.g., Grasel and Cooper, 1989) only incorporated sulfonate groups in an effort to lower thrombogenicity by surface thrombin inhibition. Enhanced binding and inactivation of thrombin was found, suggesting that these weak heparin-like molecules are sufficiently dense to lower thrombogenicity. A newer approach combined sulfonation and PEG-like materials in the use of sulfonated cyclodextrin polymers (Park et al., 2002); and improved blood compatibility was recently seen in a canine shunt model (Han et al., 2006).

Self-Assembled Surface Layers

Self-assembled surface layers (Whitesides et al., 1991) have been envisioned as useful templates to nucleate or organize ordered, designed biomaterials (Ratner, 1995; see Chapter I.2.12). Self-assembled monolayers (SAMs) of alkylsilanes supported on oxidized polydimethyl siloxane (PDMS) rubber have been used as a model system (Silver et al., 1999). The authors reported that surfaces grafted with hydrophobic head groups (CH_3 and CF_3) had significantly lower platelet and fibrinogen deposition than the surfaces composed of hydrophilic head groups

in a canine *ex vivo* arteriovenous series shunt model. In a later *in vitro* study (Sperling et al., 2005), contradictory results were obtained whereby SAMs with –CH_3 exhibited the most platelet adhesion compared to –COOH and –OH. Reduced TAT formation was observed for –CH_3 and –COOH. These studies highlight the difficulty of generalizing the effect of surface modification on blood compatibility. In addition to producing zwitterionic polymeric brushes (see Section "Zwitterionic Group/Phospholipid Mimicking Surfaces"), Zhang et al. (2008) produced a series of SAM surfaces using oligoethyleneglycol, phosphorylcholine, oligophosphorlycholine, mixed SO_3^-/$N^+(CH_3)_3$ and mixed COO^-/$N^+(CH_3)_3$; there was no significant difference in platelet adhesion or fibrinogen adsorption among these SAMs.

ACTIVE MATERIALS

The limited success of the various surface treatments for lowering thrombogenicity has encouraged researchers to pursue other strategies. The most popular strategy, and the one that started the field, is the heparinization of surfaces, although the incorporation of other antithrombotic and antiplatelet agents into materials is gaining popularity (Figure II.5.2.9). Currently, the antithrombotic agents utilized have mainly been against thrombin (hirudin, curcumin, thrombomodulin).

The incorporation of antiplatelet agents into materials has been limited by the instability and complex mechanism of action of these agents. Platelet GPIIb/IIIa antagonists (e.g., ReoPro, Centocor) and agents against factor Xa (low molecular weight heparins, LMWH) or inhibitors of tissue factor expression (extrinsic pathway) are currently being used systemically during cardiovascular surgery. There is potential for such drugs to be included in novel strategies to modify materials.

Heparinization

Heparinization of surfaces continues to be the most popular technique for lowering the thrombogenicity of materials. As illustrated in Figure II.5.2.10, heparin is a linear, acidic carbohydrate composed of repeating disaccharide units that are O- and N-sulfated. The molecular weights of heparin chains range from 1,200 to 40,000 Daltons, with a mean molecular weight of approximately 10,000. Depending on its molecular weight and structure, it can inhibit, in association with its cofactor (antithrombin III), the serine proteases: thrombin and factor X. Since thrombin is also a potent platelet activator, binding it into an inactive complex should help minimize platelet activation. Investigators have been able to covalently, ionically, and physically attach heparin to various substrates utilizing a number of chemistries. The main concern has been that once immobilized, the heparin should be able to assume its native conformation, and be able to interact with antithrombin III.

Prostacyclin
Thrombomodulin

FIGURE II.5.2.9 Agents, other than heparin, that have been incorporated into biomaterials to actively control thrombogenicity. Hirudin and curcumin are thrombin inhibitors. Prostacyclin (PGI2) is a natural inhibitor of platelet function while DMP728 is a small molecule GPIIb/IIIa antagonist. Thrombomodulin inhibits thrombin by activating protein C.

The effectiveness of heparin as an agent capable of increasing synthetic venous graft patency and reducing downstream anastomotic neointimal hyperplasia and cell proliferation was demonstrated using a novel polytetrafluoroethylene-based local drug delivery device. Heparin was infused adjacent to the graft wall and at downstream anastomotic sites for 14 days and demonstrated effectiveness (Chen et al., 1995).

Ionically Bound Heparin and Controlled Release Systems. If negatively-charged heparin is bound ionically to the surface, then heparin will be slowly released over time due to exchange with the blood. A similar effect is obtained if heparin is dispersed within a hydrophobic polymer. Selected techniques to produce materials which release heparin at biologically significant rates have been discussed in depth by a number of investigators (Sefton et al., 1987; Amiji and Park, 1993). Ionic approaches involve binding the highly negatively charged heparin onto a cationic surface through ionic binding. The limitation is that the leaching of heparin will eventually leave the surface unprotected. Certain non-ionic approaches are also characterized by high release rates (due to relatively unstable bonds), so that determining heparin release rate (in addition to amount bound) is a primary means of characterizing these surfaces. Limitations to the use of dispersed systems include the loading capacity of heparin, which prevents long-term usage and the heterogeneity of heparin leading to the early release of lower molecular weight chains.
FIGURE II.5.2.10 (a) Antithrombin III-binding pentasaccharide of heparin. The pentasaccharide sequence is composed of three glucosamine (units 1, 3, and 5), one glucuronic acid (unit 2) and one iduronic acid (unit 4) units. Structural variants are indicated by –R′ (–H or –SO$_3$–) or –R″ (–COCH$_3$ or –SO$_3$–). The 2-O-sulfate groups (asterisk), a marker component for the antithrombin-binding region, and sulfate groups indicated by (•) are essential for high-affinity binding to antithrombin. (b) The mechanism of action of heparin and antithrombin III. (c) The reducing end of heparin formed by treatment with nitrous acid. *((a) from Fiore and Deykin, 1995; (b) from Bauer and Rosenberg, 1995, with permission.)*

The thromboresistance of heparinized materials based on controlled release appears to be due to a microenvironment of heparin in solution at the blood–material interface. The relationship between release rate (N, g/cm^{2}s) and surface concentration (C_s, g/cm^3), for heparin or any other agent released from the inside wall of a tube of radius r_0 is given by (Basmadjian and Sefton, 1983):

$$\frac{C_s}{Nr_0/D} = 1.22\left[\frac{x/r_0}{ReSc}\right]^{1/3} \tag{4}$$

where D = diffusivity (cm^2/s); r_0 = tube radius; x = axial position; Re = Reynold's number = $2r_0 v \varrho/\mu$; Sc = Schmidt number = $\mu/\varrho D$; v = average velocity; ϱ = density; μ = viscosity. The diffusivity of heparin is ~7.5 × 10^{-7} cm^2/s and the critical C_s (minimum therapeutic level) for heparin is ~0.5 μg/mL.

Use of tridodecyl methylammonium chloride (TDMAC; Lehninger, 1966), a lipophilic, cationic surfactant, eliminated the need for the graphite coating that was part of the original graphite–benzalkonium–heparin (GBH) method (Gott et al., 1963). TDMAC and the many other quaternary ammonium compounds enabled heparin to be ionically bound to a wide range of biomaterials. Unfortunately, such compounds are surfactants with potentially toxic consequences, and are known to be eluted from the surfaces within a week.

Quaternizable amino groups have also been incorporated directly into polymers to improve the stability of the ionically bound heparin. Tanzawa et al. (1973) synthesized a graft copolymer with a dimethylaminoethyl group by UV initiated copolymerization of N,N-dimethylaminoethyl methacrylate (DMAEM) and methoxypolyethylene glycol methacrylate (MPEG). Use of this technique (Angiocath™, Toray Industries) to coat poly(urethane) catheters indicated that a minimal heparin elution rate of 0.04 μg/cm^2/min was needed to render the catheter thrombus free *in vivo* (Idezuki et al., 1975). This value is consistent with Equation (4).

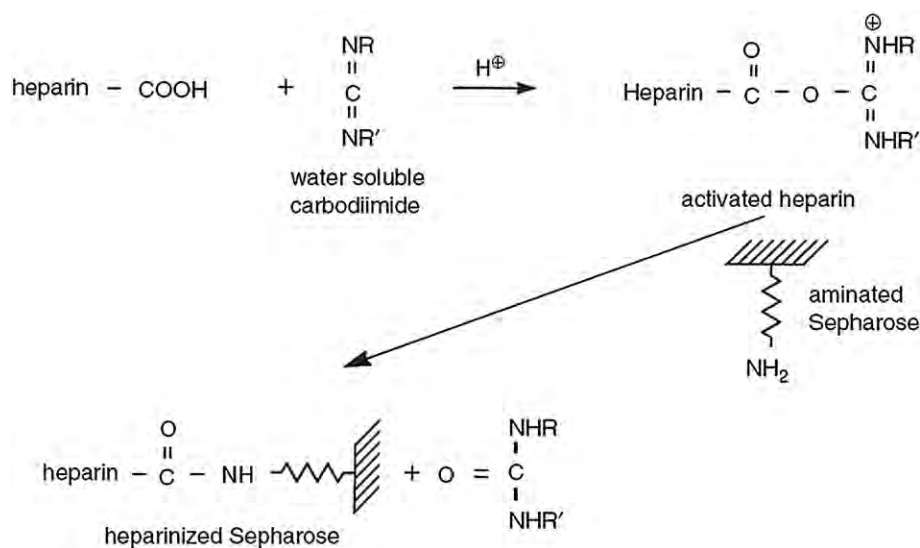
A commercial procedure (Baxter Bentley Healthcare Systems, Irvine, CA) to ionically bind heparin (Duraflo


FIGURE II.5.2.11 One-step carbodiimide activation of carboxyl groups of heparin for binding to aminated Sepharose. For EDC, R = $(CH_2)3N(CH_3)_2$. For a carboxylated substrate (e.g., hydrolyzed polymethyl acrylate) its carboxyl groups may be activated by carbodiimide in a separate step for subsequent reaction with the free amine groups of heparin.

II™) has been used to coat cardiopulmonary bypass circuits and other devices. While heparin coating of extracorporeal circuits is designed to reduce surface thrombus formation, its effect on complement, contact activation, and inflammation is unclear and often contradictory (see below).

Covalently Bound Heparin. To impart a degree of activity longer than that possible with ionic linkages, heparin has been covalently immobilized to material surfaces. It is now recognized that the conformation of the attached heparin and the point of attachment (end point versus multipoint) are critical factors determining the catalytic efficiency of the immobilized heparin. Lindhout et al. (1995) studied the antithrombin activity of surface-bound heparin under flow conditions. They demonstrated that the rate of thrombin inactivation of the antithrombin–heparin surface equals the maximal rate of transport of thrombin toward the surface when the surface coverage of antithrombin exceeds 10 pmol/cm^2; thus indicating that a higher intrinsic catalytic efficiency of a surface does not necessarily result in a higher antithrombin activity.

Many of the coupling methods listed in Chapter I.2.17 have been used for heparin. For example, Heyman et al. (1985) attached 1-ethyl-3-(3-dimethylaminopropyl) carbodimide (EDC) activated heparin covalently onto chemically modified polyetherurethane catheters through a diamino alkane spacer. The immobilized heparin retained its ability to bind and inactivate thrombin and factor Xa. Unfortunately, carbodiimides (Figure II.5.2.11) are recognized as less than ideal activating agents for immobilizing heparin, since the acidic conditions used can result in a loss of anticoagulant activity.

Larm et al. (1983) developed a technique by which heparin can be covalently end point-attached (commercialized as the Carmeda® BioActive Surface, CBAS®) to the surface of plastics, as well as glass and steel. Heparin is first partially depolymerized by deaminative cleavage using nitrous acid to produce heparin fragments terminating in an aldehyde group (Figure II.5.2.10c). The heparin is then covalently linked to the primary amino groups of polyethylene imine (PEI) (Figure II.5.2.12a). This technique results in a highly stable, low thrombogenicity coating that has been demonstrated to retain its efficacy *in vivo* for four months in dogs (Arnander et al., 1987), and during patient treatment with an artificial lung (Bindslev et al., 1987). There was also a beneficial effect on *in vivo* bacterial colonization of treated polyurethane central venous catheters (Appelgren et al., 1996).

The commercial Trillium® coating (developed by Bio-Interactions Ltd and marketed by Medtronic) combines covalently binding heparin with polyethelene oxide and sulfonate groups (Figure II.5.2.12b). Clinical studies with Duraflo, Carmeda, and Trillium have shown that while they enable the use of reduced systemic anticoagulation (Ovrum et al., 2001), they do not reduce the post-operative acute phase response (van den Goor et al., 2004; Hoel et al., 2004). Complement and leukocyte activation play an important role in the biocompatibility of extracorporeal circulation devices, and it appears that the benefit of heparin coatings is limited to anticoagulation.

Heparin has also been covalently immobilized via its terminal serine at the end of the protein–carbohydrate linkage region to polyvinyl alcohol hydrogel. The heparin is bound during the Lewis acid catalyzed cross-linking of polyvinyl alcohol chains with glutaraldehyde. The heparinized polyvinyl alcohol hydrogel possessed significant anticoagulant activity, although the platelet incompatibility of the hydrogel substrate led to significant platelet consumption in an *ex vivo* canine shunt model (Cholakis et al., 1989).

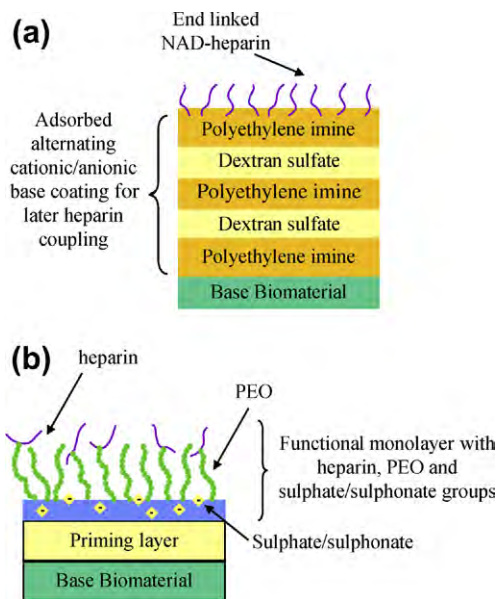
Park et al. (1988) have covalently bound heparin to a polyurethane using PEG spacer groups. The increasingly mobile nature of the longer hydrophilic spacer chains were considered to have increased the observed bioactivity of


FIGURE II.5.2.12 Commercial surface treatments used for cardio-pulmonary bypass (CPB) and potentially also for vascular grafts. (b) Trillium™ coating: The priming layer is hydrophilic and strongly binds to the base material, PEO chains and sulphate and sulphonate groups are covalently attached to the priming layer, while heparin is covalently bound to PEO. (*Adapted from Shivpal and Luthra, 2002.*)

immobilized heparin by providing a more bulk-like environment for the heparin. An intravascular oxygenator and carbon dioxide removal device (IVOX®; CardioPulmonics, Salt Lake City, UT) also uses covalent heparin bound to a PEG spacer. The PEG is grafted onto a plasma polymerized polysiloxane on a base material after plasma amination of the surface. Heparin has also been immobilized on silicone via an N-succinimidyl carbonate PEG and the grafted heterobifunctional PEG allowed for high heparin density resulting in both low fibrinogen adsorption and high specificity for ATIII (Chen et al., 2005).

Du et al. (2007) covalently grafted an antithrombin/heparin complex onto a PEO modified polyurethane in the presence of a free radical initiator. This increased anti-FXa activity compared to grafted heparin alone, and was shown to significantly reduce material thrombogenicity in a chronic rabbit model (Klement et al., 2006).

Thrombin Inhibition without Heparin

Recognizing the importance of inhibiting material-induced thrombin generation, agents other than heparin have been used to inhibit thrombin and thereby lower the thrombogenicity of the material. For example, hirudin, a potent thrombin inhibitor, has been covalently bound to biomaterials. Compared with heparin, hirudin is advantageous because it has no influence on platelet function, no immune-mediated platelet activating activity and most importantly, it does not require the presence of endogenous cofactors like antithrombin III. Thus, the

polypeptide hirudin is thought to be able to block clot-bound thrombin that is inaccessible to inhibition by a heparin/antithrombin III complex. On the other hand, heparin functions as a catalyst. That is immobilized heparin, if not blocked by adsorbed protein, can continually accelerate the inactivation of thrombin by antithrombin III. It is unclear how long a covalently immobilized hirudin surface would remain effective, and even whether an immobilized hirudin could gain access to the clot-bound thrombin. Nevertheless, Ito et al. (1991) used heterobifunctional cross-linking reagents to derivatize hirudin to form covalent cross-links between hirudin and albumin, producing active conjugates for immobilization to surfaces. Others have immobilized hirudin to a polylactide–glycolide copolymer (Seifert et al., 1997). Another group has exploited controlled release of hirudin for this purpose (Kim et al., 1998). Small molecule thrombin inhibitors, like D-Phe-Pro-Arg chloromethyl ketone (PPACK) and others under development may prove useful as alternatives.

Because of the affinity of benzamidine toward thrombin and its potential to reduce complement activation (which may participate in platelet activation), amidine derivatives are currently being considered to enhance blood compatibility. Gouzy et al. (2004) immobilized a benzamidine derivative (with a hydrocarbon side chain) onto a maleic anhydide copolymer via a PEG spacer; platelet adhesion and activation was reduced on the modified surface, as well as thrombin–antithrombin complex formation. They subsequently correlated thrombin binding to the amount of immobilized benzamidine derivative, with the amount immobilized being dependent on spacer length and immobilization chemistry (Salchert et al., 2005). Yim and Sefton (2008) converted the surface nitrile groups of poly-acrylonitrile-co-vinyl chloride films into amidine groups by first reacting nitrile with diethyl ether and hydrogen chloride followed by reaction with ammonia in ethanol (Pinner's synthesis). While the amidine surface modification was limited, reduced platelet adhesion and activation was observed, as well as a reduction (although not significant) in platelet microparticle formation.

Another approach involves immobilizing thrombomodulin, an endothelial cell associated protein that inhibits thrombin by activating protein C. Using a small scale dialyzer it was demonstrated that immobilized human thrombomodulin (on cellulose) still had co-enzyme activity for activation of protein C and anticoagulant activity (Kishida et al., 1995). An amino terminated silane was used to couple thrombomodulin to glass, and the authors reported both anticoagulant activity and reduced platelet adhesion (Han et al., 2001). Thrombomodulin has also been immobilized (using an azido group via PEG) onto pancreatic islets, with a view to minimizing the thrombogenicity of the islet and enhancing islet engraftment after portal vein infusion (Stabler et al., 2007). Further work is needed to appreciate the potential of such surfaces.

Immobilization of Anti-Platelet Agents

There has been considerable interest in incorporating anti-platelet agents into materials to lower material thrombogenicity, especially given the commonly observed adhesion of platelets on biomaterials. Endothelial cells lining the natural vessel wall help prevent thrombus formation by secreting anti-platelet agents such as nitric oxide (NO) and prostacyclin (PGI2). Thus, a biomaterial containing anti-platelet agents is consistent with our understanding of endothelial cell function. Prostacyclin is potent yet unstable, and efforts to maintain its biological activity during immobilization, coupled with concern for the ability of platelets in the bloodstream to be affected by the immobilized prostacyclin, has limited the enthusiasm for such a strategy. On the other hand, a simpler approach, which also more closely mimics the biological environment, is to incorporate PGI2 or NO into materials for release. Unfortunately, the inability to load sufficient drug into materials for release limits the materials' lifespan, and this approach may be limited to be used in short-term cardiovascular devices such as oxygenators, sensors, and catheters. A novel approach to overcome such limitations is to use endogenous NO donors to generate NO at the blood–material interface. NO is an anti-platelet agent and a potent inhibitor of smooth muscle proliferation. This approach is described in more detail below.

Despite these challenges, many investigators have incorporated anti-platelet agents into surfaces. For example, Ebert et al. (1982) immobilized prostaglandin F2α using a diaminododecane spacer arm. The F2α was subsequently converted to the unstable prostacyclin. The benefits of spacer arms are described elsewhere (Chapter I.2.17). A related approach is to add an anti-platelet agent, such as prostaglandin E1 (PGE1), in addition to heparin into a polymer. A PGE1-heparin compound was synthesized and incorporated into a polyurethane (Jacobs et al., 1985). Also, prostacylin has been incorporated into polymer matrices for controlled release (McRea and Kim, 1978). Aspirin, capable of inhibiting the generation of the platelet activator thromboxane A2, has also been incorporated into polyvinyl alcohol membranes used in hemodialysis (Paul and Sharma, 1997), while a dipyrimadole (Persantin) derivative was photo-immobilized on a polyurethane (Aldenhoff et al., 1997).

Two basic approaches exist to create NO releasing polymers: N-diazeniumdiolates or S-nitrosothiols (Figure II.5.2.8c,d). These can either be blended into polymers or covalently bonded to a side chain or to the polymer backbone (Frost et al., 2005). While S-nitrosothiol-based NO releasing materials have been synthesized (e.g., with polyvinyl alcohol (PVA) and PVP (Seabra and de Oliveira, 2004)), there is currently only limited biocompatibility data on such an approach (Bohl and West, 2000). On the other hand, NO-releasing materials using diazeniumiolates have demonstrated great efficiency in reducing thrombus formation in various animal models (Frost et al., 2005; Skrzypchak et al., 2007). Another approach is to use endogenous NO donors to produce NO locally. Duan and Lewis (2002) used endogenous S-nitrosoproteins in plasma to produce NO from immobilized cysteine to minimize platelet adhesion on a polyurethane and a poly(ethylene terephthalate). A lipophilic copper complex has also been incorporated into polyvinyl chloride (PVC) and polyurethane (PU) films that was able to generate NO from nitrite under physiological conditions (Oh and Meyerhoff, 2004).

A new generation of anti-platelet agents based on inhibiting fibrinogen binding to activated platelet GPIIb/IIIa receptors offers a fresh approach to lowering the thrombogenicity of surfaces via drug release. These agents, from blocking monoclonal antibodies to small peptides and compounds (e.g., DMP728, Figure II.5.2.9), not only block platelet aggregation, but will also likely block platelet adhesion to artificial surfaces. Some have already been incorporated into stents for release (see Section "Strategies to Lower the Thrombogenicity of Metals," below, and Chapter II.5.3.B).

Immobilization of Fibrinolytic Agents

Some investigators have sought to promote fibrinolysis on artificial surfaces by the surface generation of plasmin. Clot lysis is achieved by the action of plasmin (formed from plasminogen) on fibrin. However, the action of such surfaces may be "too little too late." Sugitachi and Takagi (1978) immobilized urokinase, a fibrinolytic enzyme that acts on plasminogen, on various materials. A slightly different approach is to immobilize plasminogen and then convert it to plasmin, so as to impart fibrinolytic activity to a surface (Marconi et al., 1996). A disadvantage of utilizing streptokinase and urokinase to cleave plasminogen to plasmin is that these agents activate both circulating and fibrin-bound plasminogen. This contrasts with the action of tissue plasminogen activator (tPA), an endogenous serine protease that converts only fibrin-bound plasminogen to plasmin. A nonpharmacological approach to developing fibrinolytic surfaces for blood-contacting applications was the preparation of lysine-derivatized polyurethane surfaces (Woodhouse and Brash, 1992). The expectation was that these surfaces exhibit fibrinolytic activity because the lysine residues promote the selective adsorption of plasminogen from plasma through the lysine-binding sites in the plasminogen molecule.

USE OF ENDOTHELIAL CELLS AND RGD PEPTIDES

It is intuitive to believe that the ideal nonthrombogenic surface for vascular grafts and other devices will consist of an intact luminal endothelial cell layer. Herring et al. (1984) seeded Dacron™ and ePTFE grafts with endothelial cells in a preliminary clotting step with blood and endothelial cells. Autologous endothelial cells were seeded onto ePTFE grafts (6–7 mm inner diameter) for 153 patients, and a significant improvement in the

patency rate in the infrainguinal position at seven years was reported (Meinhart et al., 2001).

To promote endothelialization of vascular grafts either *in situ* or *in vitro*, the role of surface chemistry, pore size, and protein coatings have been investigated (McGuigan and Sefton, 2007). Using a rat model, Wang et al. (2004) found increased endothelialization in porous polyurethane grafts. To increase endothelial cell attachment and proliferation, surface modification using an anhydrous ammonia gaseous plasma technique (Sipehia, 1990; Pu et al., 2002) or UV irradiation (Olbrich et al., 2007) has proven successful *in vitro*. Some approaches are focused on modifying the surface with proteins or peptides that will promote adhesion and proliferation of endothelial cells. Coating or covalent binding of materials with extracellular matrix (ECM) proteins such as fibronectin (Van Wachem and Hubbell, 1987), collagen, laminin, and elastin have shown some success *in vitro*. A more elegant approach (Massia and Hubbell, 1990) has been to immobilize RGD ECM peptide sequences, (see Chapter I.2.17) to encourage endothelial cell attachment. This approach has been adopted by many others, but most results remained at the proof-of-concept stage with *in vitro* studies (for a thorough review of the potential use of peptides to enhance vascular graft endothelialization, refer to de Mel et al., 2008).

Immobilizing growth factors such as VEGF, ECGF, or a metalloproteinase inhibitor have also been shown to promote endothelial cell proliferation on graft materials *in vitro*. It is important to note that while graft endothelialization might occur from cell migration from the anastomosis or from infiltration, it is thought that endothelial progenitor cells (EPC)[3] may also play a role in graft endothelialization, and thus increasing the mobilization of EPC through surface modification (e.g., CD34 immobilization; Aoki et al., 2005) is another approach.

Since considerable differences exist in the potential for endothelialization between humans (low) and animals (higher, e.g., canines), translation of results from animal studies can be problematic. A detailed discussion of this issue is presented by Zilla et al. (2007). With immobilizing adhesion peptide sequences, there is a concern that regions not covered by endothelial cells would lead to enhanced platelet and thrombus deposition, or that the attached endothelial cells might indeed be activated (see Box 3).

STRATEGIES TO LOWER THE THROMBOGENICITY OF METALS

While polymers represent the principal class of materials used in cardiovascular setting, metallic surfaces are also used in mechanical heart valves and stents. Most metals are highly thrombogenic and life-long anticoagulant and anti-platelet therapies are required with the use of mechanical heart valves while the optimum therapy for

---

[3]EPC are circulating bone-derived progenitor cells. They circulate in blood at low concentration and share some similarities with monocytes.

BOX 3 | Associated Facts: Endothelial Cell Activation on Vascular Grafts

When endothelial cells (EC) are expected to adhere onto vascular grafts (or any cardiovascular material) to provide a nonthrombogenic surface, it is required that the cells express a non-activated, nonthrombogenic phenotype, such that leukocytes and platelets do not bind to them and the endothelial cells are able to inhibit coagulation and platelet activation. While many investigators measure endothelial cell adhesion to a substrate, few characterize the actual phenotype of the adherent cells (McGuigan and Sefton, 2007). It is not a simple matter to determine adherent EC thrombogenicity *in vitro*, since cell seeding density, the cell origin (e.g., adipose tissue versus umbilical vein), shear rate, and culture conditions (serum versus no serum, human versus bovine serum) seem to affect the expression of ICAM-1, VCAM-1 (leukocyte adhesion receptors), PECAM-1 and E-selectin (platelet adhesion receptors), and the effects are material dependent. Difference in the *in vivo* endothelialization process between humans and animals (e.g., canines) further complicates matters (Zilla et al., 2007).

BOX 4 | Area of Further Interest: A Benefit of "Poor" Material Blood Compatibility

While metallic stents are being modified to reduce their potential thrombogenicity, thrombogenicity may be beneficial to the promotion of osteogenesis with orthopedic implants. Upon implantation, osteogenic cells interact first with the blood clot that occupies the wound site, and platelet activation releases growth factors, such as PDGF, and cytokines, such as TGFβ (both contained in platelet's α granules), that are recognized to stimulate bone growth. As such, platelet concentrates are currently being used during surgery to improve bone regeneration. More generally, thrombogenicity is a special case of inflammation (Gorbet and Sefton, 2005b), and enhancing thrombogenicity may be a strategy for creating materials with improved healing characteristics in situations such as in orthopedics.

---

stented patients is a much discussed topic, especially with drug eluting stents (see Box 4).

To reduce the thrombogenicity of the materials used in prosthetic heart valves, three approaches for surface modification have been explored: coating whereby a layer of metal oxide is deposited on the metal (plasma deposition); oxidation of the metal; and ceramic or polymer coating. Deposition of tantalum-doped titanium oxide films significantly reduced platelet activation and fibrin deposition in an *in vivo* dog model (Huang et al., 2003). Coating with oxynitrites on stainless steel also improved overall *in vitro* and *in vivo* biocompatibility (Chen et al., 2003). A layer of oxide on titanium has also been prepared by oxidation in a solution of H_2O_2, and this reduced platelet adhesion *in vitro* (Takemoto et al., 2004). Diamond-like carbon (DLC) (Mikhalovska et al., 2004) and apatite composite (Muramatsu et al., 2003) have also been coated on various metals, and both a reduction in fibrinogen adsorption and platelet adhesion have been observed *in vitro*. More recent approaches focus on coatings with multilayers of collagen and sulfated chitosan (Li et al., 2008), or covalently
FIGURE II.5.2.13 Immobilization of a phospholipid polymer (PMA: poly(2–methalcryloyloxyethylphosphorylcholine-co-methacrylic acid)) on Ti-6Al-4V. *(From Ye et al., 2008.)*

attaching a phosphorylcholine containing polymer (see Figure II.5.2.13; Ye et al., 2008). Despite these efforts, low temperature isotropic pyrolytic carbon remains the choice for heart valves (see Chapter II.5.3.A).

Developing stent coatings for the metals currently used (stainless steel, cobalt chromium, tantalum, and Nitinol) in bare metal stents were sought as a means of reducing the thrombosis rates of such stents (Van Belle et al., 2007), and to at least indirectly influence restenosis. Due to its inertness, gold was deposited on stents, but increased re-stenosis rates were observed (Hara et al., 2006). Randomized clinical trials of heparin-coated tantalum stents (Blezer et al., 1998) showed that there was no significant improvement in re-stenosis or clinical outcomes compared to uncoated stents (Wohrle et al., 2001). Other efforts to reduce thrombogenicity included coating tantalum stents with polymers such as polyetherurethane and parylene to reduce platelet adhesion density (Fontaine et al., 1996) and radiation grafting N-vinyl-pyrrolidone (NVP) onto plasma-treated stainless steel stents (Seeger et al., 1995). Hyaluronic acid coating also reduced platelet thrombus formation on stainless steel stents and tubes in a primate thrombosis model (Verheye et al., 2000). In another study, metal/polymer composite stents loaded (40% by weight) with a potent anti-platelet agent (GPIIb/IIIa antagonist; >90% elution in 89 hours) reduced, by almost a factor of 2, platelet adhesion in dogs two hours after stent deployment (Santos et al., 1998). r-hirudin has also been immobilized on Nitinol stents coated with functionalized paracyclophanes (Lahann et al., 2001). As with vascular grafts, a phosphorylcholine coating has also been explored to improve stent endothelialization with BiodivYsio™ (Biocompatibles,

Surrey, UK), a PC-coated stainless coated stent. However, it did not show significant improvement compared to bare metal stents in clinical trials (Abizaid et al., 2007). The relationship between thrombogenicity and clinical outcomes such as re-stenosis remains a hypothesis.

The early work on reducing stent thrombosis has been supplanted by drug-eluting stents (DES) to reduce re-stenosis rates. Rapamycin or sirolimus eluting stents in which the therapeutic agent is blended in a nonerodible polymer and coated onto the surface of the stent have the dramatic effect of eliminating in-stent re-stenosis for at least six months after deployment (Morice et al., 2002). Paclitaxel is an antineoplastic agent used in chemotherapies. However, the concern that DES appear to have higher risk of late thrombosis (Box 5) has renewed interest in developing surface strategies to lower stent thrombogenicity. Also, because of late thrombosis, there has been an interest in biodegradable stent materials. A drug delivery stent based on phosphorylcholine coating releasing zotarolamus (Endeavor ZES, Medtronic) performed well in clinical trials and received US Food and Drug Administration (FDA) approval recently (Slottow et al., 2007). Full and early endothelial coverage of the stent would also potentially address both the issues of re-stenosis and thrombosis. For example, a covalently coupled polysaccharide coating with an antibody (anti-CD34) to bind circulating endothelial progenitor cells has been deposited on stainless steel stents with positive initial clinical reports (Aoki et al., 2005). Other means of promoting endothelialization (see Section "Use of Endothelial Cells and RGD Peptides") are also under active investigation for stents.

BOX 5	Clinical Correlations: Drug Eluting Stent Induced Thrombosis

Drug eluting stents (DES) have significantly reduced the rates of re-stenosis. However, clinical data, albeit not without dispute, suggests that DES increase the risk of late thrombosis (>30 days after implantation). While changes to the antithrombotic and anticoagulant regimen have resolved some of the concerns, ongoing animal and *in vitro* research (Lüscher et al., 2007) has suggested that in addition to preventing neointima formation (the intended use of the therapeutic agent being delivered), paclitaxel and sirolimus inhibit re-endothelialization and induce tissue factor, thus creating a pro-thrombotic environment at the local site of stent implantation. The proprietary nondegradable polymers used in these stents have also been reported to be linked to inflammatory reactions at the site of implantation, although it is not clear whether these are different from what is seen with metals. A chronic inflammatory reaction would further contribute to a prothrombotic state around the stent. The clinical concerns have driven a resurgence in stent endothelial-ization strategies.

SUMMARY

It is an axiom that the interactions between materials and blood are complex. Hence, it is no surprise that developing low thrombogenicity materials (let alone ones with zero thrombogenicity) are challenging. Medical device manufacturers relying on elegant device designs and systemic pharmacological agents have significantly improved existing materials. Adverse effects are minimized and existing devices, if not risk-free, provide sufficient benefit to outweigh the risks. The focus of research in biomaterials is to make better materials that have fewer risks and greater benefits. Stents that "actively" prevent re-stenosis are a great example of how modifying a material can have a dramatic clinical effect. Inert materials, such as those with immobilized PEG, can resist protein and platelet deposition, but these may only be at best surrogate markers for thromboembolic phenomena. On the other hand, incorporating anticoagulants such as heparin can be an effective means of reducing thrombin production rates below critical values (e.g., $k_p < 10^{-4}$ cm/s), but this may not be sufficient to prevent platelet activation and consumption. Many strategies for lowering thrombogenicity have been identified, and they all show a beneficial effect in at least one assay of thrombogenicity. However, few if any have made the transition from a one-parameter benefit to multiple benefits, or from *in vitro* to *in vivo*. These issues are discussed more fully in Chapters II.2.6 and II.3.5.

Which approach will ultimately be successful is impossible to predict. Certainly there is much activity in biomembrane mimicry and PEG immobilization. There are many new anticoagulants and antithrombotics under development, but few have yet to be incorporated into material surfaces. In recent years, combining strategies such as reducing both protein adsorption and thrombin production have become prevalent. The commercial Trillium® coating is an example of the benefit of combining various approaches. Finally, as new hypotheses are developed to understand cardiovascular material failure, new approaches will be identified for inhibiting undesired pathways. The failure to produce the ideal nonthrombogenic material, despite over 30 years of research, merely reflects our limited understanding of blood–material interactions (Zilla et al., 2007; Ratner, 2007). Perhaps the right strategy for producing a nonthrombogenic material will have little to do with controlling platelets or thrombin, but will be directed towards leukocytes, endothelial cells, or complement (Gemmell, 1998; Wetterö et al., 2003). Ongoing research is expected to improve the blood interactions of materials used in medicine to address important clinical needs.

CASE STUDY	Nonthrombogenic Materials and Strategies

Michael V. Sefton and Maud B. Gorbet

ISO10993-4, Biological Evaluation of Medical Devices Part 4: The Effects on Blood (AAMI, 1995), which manufacturers of medical devices need to use as guidance to register their products, includes thrombosis and coagulation among the tests that need to be done. However, specific test methods are not detailed. With a view to clarifying this question, a series of plasma-modified tubes (along with an unmodified control and other commercially available tubing) were prepared, surface characterized, and exposed to heparinized whole blood (1 U/mL heparin) for one hour at 37°C (Sefton et al., 2001). The surface modifications included several different plasma vapors (H$_2$O, CF$_4$, and fluorine). The 1.5 mm ID tubing was incubated with whole blood on a rocking platform to gently agitate the blood and keep the cells from overtly settling. This system does not probe the effect of shear on cell activation; rather the agitation and long incubation time are thought sufficient to create "well-mixed" conditions.

Some of the results from this study are shown in Figure II.5.2.14 and Table II.5.2.1. One of the conclusions from this study is that the materials with the lowest levels of platelet and leukocyte activation (microparticle formation, CD11b upregulation) were the unmodified materials (polyethylene, Pellethane™, a polyurethane), and that the surface modifications tested here had either no effect or only made things worse from the perspective of platelet and leukocyte activation. The scanning electron micrographs showing little cellular deposit on the polyethylene or Pellethane™ were consistent with the flow cytometry findings. Except for those materials that were worse, the other materials expressed similar levels of activation for platelets, leukocytes, and the other markers tested; i.e., the majority of the "inert" materials (in the absence of bioactive components like heparin) appear to have a similar non-specific effect on blood.

The results from this study contrast sharply with other studies (many of them cited in this chapter) showing large differences in blood interactions between different biomaterials. This highlights the lack of consensus about blood–materials interactions. Reasons for this lack of consensus are discussed in Chapter II.3.5.

Continued

FIGURE II.5.2.14 Cell activation and SEM (scanning electron microscope) results after 60 min contact with whole blood (1 U/mL heparin) at 37°C in rocking platform. Flow cytometry results are mean ±SD. (a) Microparticle levels (percentage of platelet events); (b) Leukocyte CD11b upregulation (expressed relative to the maximum upregulation obtained with a phorbol ester). (c) SEM. Scale bar is 10 μm in all. Modified materials are designated with name of base materials and gas introduced into plasma (H_2O, NH_4, CF_4, or F). Presented data is a subset of those studied and figures are adapted from those published (Sefton et al., 2001). PE: polyethylene, PEU: Pellethane.

Continued

CASE STUDY | **Nonthrombogenic Materials and Strategies (continued)**

TABLE II.5.2.1 | **Most Biomaterials are the Same**

Parameter	EDTA Control (or Equivalent)	Value for Most Materials
Platelet count loss (%)	0 (by definition)	25–35
P-selectin (% positive)	6.4	~8–9
Platelet–leukocyte aggregates (fluorescent intensity)	46	~200–250
CD11b upregulation (% of maximum)	15	~50–60
L-selectin shedding	11	~70–90

Most materials, despite very different non-specific chemical modifications, resulted in similar levels of platelet and leukocyte activation. These were higher than the corresponding negative control values. The similarity of CD11b upregulation values is seen in Figure II.5.2.1b, while the presence of exceptions that were more activating is seen in the microparticle results in Figure II.5.2.1a.

APPENDIX F: CHAPTER II.5.16 — DRUG DELIVERY SYSTEMS: H, MUCOSAL DRUG DELIVERY

Ying Lu and Kinam Park
Departments of Biomedical Engineering and Pharmaceutics, Purdue University, Lafayette, IN, USA

INTRODUCTION

Mucous membranes line various body cavities and structures that are connected or exposed to the external environment, such as the respiratory, gastrointestinal (GI) and reproductive tracts as well as structures such as the eyes, nose and mouth. A mucosal drug delivery system delivers drugs across the mucosa for both local and systemic therapeutic effects. Mucosal drug delivery is used to increase bioavailability and therapeutic efficacy of drugs both locally and systemically. One of the most fundamental problems is how to overcome the protective barrier functions of the mucosa. Clearly, this requires understanding of the characteristics of the mucosa, the principles and mechanisms of the mucosal drug delivery process, as well as the properties of the dosage form itself that will overcome these barriers while allowing the drug to achieve optimum performance in its target environment. This chapter is designed to

1. Provide an overview of the structure and permeability properties of the mucous membranes.
2. Examine the main principles and mechanisms of mucosal drug delivery, including strategies to enhance mucosal drug delivery mechanisms.
3. Discuss examples of mucosal drug delivery systems.

MUCOUS LAYER

The main functions of the mucous membrane include absorption, secretion, lubrication, entrapment of foreign substances and antibacterial action (Ross, Romrell, and Kaye, 1995). Some mucous membranes are highly specialized for their function, as in the case of the membranes lining the GI tract, especially in the region of the small intestine, which have characteristics that adapt them for efficient absorption. Some mucous membranes are secretory, with secretions that are either watery in consistency or more viscous. Watery mucus is secreted by serous cells and contains numerous active enzymes. These enzymes aid in the metabolic activities of the body, such as digestion. A more highly viscous mucus is secreted by mucous cells with lubrication as their primary function. In the respiratory tract, for example, the viscid mucus helps to trap foreign particles and remove them from the body. Particles here include drug and drug-containing nanoparticles. Depending on its physiological location, the mucous membrane may vary in structure, but all mucous membranes can be considered to comprise several layers: a mucous layer, an epithelial layer covered by the mucous layer, a basement membrane that anchors the epithelium to underlying tissue layers, and a connective tissue layer (lamina propria) (Smart, 2005).

Mucus is continuously secreted by cells located in the epithelial layer or specialized glands adjacent to tissues. The resulting mucous layer either forms a gel layer that adheres to the epithelial layer or is present as a suspended form adjacent to the epithelial layer. The thickness of the mucous layer varies on different mucosal surfaces. For example, in the human GI tract, the mucous layer is thickest in the stomach (50–450 µm) (Kerss, Allen, et al., 1982) and colon (110–160 µm); in contrast, in the oral cavity, the thickness of the mucous layer is less than 1 µm (Sonju, Christen, et al., 1974). The thickness of the mucous layer is dependent upon the balance between the rate of secretion and the rate of degradation and shedding. On some mucosal surfaces, the mucous secretion is so rapid that it is very difficult for particles to diffuse through the mucous layer against the "upstream" motion of mucous secretion (Cone, 2009). On the other hand, the barrier motion of thinner mucous layers are predominately due to degradation and shedding, where the particles bound to the mucus are cleared before transport across the mucous layer.

The major components of mucus are mucin glycoproteins, lipids, inorganic salts and water, which comprise more than 95% of the total mucus weight (Marriott and Gregory, 1990). Mucin fibers are the structural units of mucus. In general, there are two distinct families of mucin molecules: cell-associated mucins and gel-forming mucins (Cone, 2005). Cell-associated mucins are anchored to the cell surface through a transmembrane domain and range from 100 to 500 nm in length. Gel-forming mucins (or secreted mucins) are formed from mucin monomers linked end-to-end by disulfide bonds, and therefore are much longer and can be up to several microns in length (Carlstedt and Sheehan, 1984). Regardless of the type of mucin molecule, there are several common characteristics of mucin fibers. Each mucin fiber is similar to a flexible string with a densely coated layer of short glycans on the surface (Cone, 2009). These short glycans interact with mucin by forming O-linkages to the threonine and serine residues in the proline, threonine, serine domains of the mucin protein. Many of the glycans terminate in a negatively charged carboxyl group, which makes the glycosylated region highly hydrophilic. In addition, many negatively charged sulfate-bearing glycans are N-linked to the ends of the mucin monomers, further adding to the hydrophilic nature of the mucin. These glycosylated and highly hydrophilic regions are interspersed by "naked" relatively hydrophobic protein regions that fold into globular beads and stabilize themselves by forming numerous disulfide bonds. In mucous gels, each mucin overlaps and entangles with on the order of 10–100 other mucins (Figure II.5.16.1).
FIGURE II.5.16.1 A basic unit of the mucin structure. Multiple basic units are linked to form a monomer mucin molecule, and the monomers are in turn linked by disulfide bonds to make polymeric structure of mucin.

PRINCIPLES OF MUCOSAL DRUG DELIVERY

Mechanisms of Mucosal Drug Delivery

In mucosal drug delivery, the ability of the drug particles to cross the mucosal membrane barriers is critical to achieving the desired therapeutic effect in the body. Although mucous membranes vary in structure and function, the basic modes of drug transport mechanisms are common to all mucosal drug delivery throughout the body (Chien, 1995). In order for a drug particle to reach the capillaries present in the lamina propria, it must successfully traverse several mucosal barriers.

The basic mechanism of transport in the mucous layer is diffusion. Early views of mucous layer diffusion held that small molecules diffuse readily through the mucous layer, but macromolecules such as globular proteins were assumed to be unable to penetrate this layer (Cone, 2009). However, more recent investigations demonstrated that a number of macromolecules also rapidly diffuse through the mucous layer. Important experiments by the Saltzman and Cone research groups showed that soluble globular proteins diffuse freely through human cervicovaginal mucus, while secreted antibodies such as IgM are only slightly slowed by the same mucus (Saltzman, Radomsky, et al., 1994). Studies conducted by Olmsted et al. (Olmsted, Padgett, et al., 2001) substantiated the claim that viruses with a diameter of 30 nm should be able to diffuse through the cervicovaginal mucus unhindered. Furthermore, they showed that Norwalk virus (38 nm) and human papilloma virus (55 nm) penetrated the mucous layer at diffusion rates approximately equal to that in water. These results demonstrate that particles with a range of sizes are capable of diffusing through the low viscosity pores within the viscoelastic mucous layer matrix (also see Lai et al., 2007; Lai, Wang, and Hanes, 2009). However, due to the restriction set by the size of the mucous pores, not all particles are capable of diffusing through the matrix. Olmsted et al. also established that the herpes simplex virus with a diameter of approximately 180 nm was almost completely unable to cross the mucous layer. This is in accordance with the obstruction scaling model (Amsden, 1999), which estimated the average mucous pore size to be around 100 nm.

The diffusion of particles through the mucous matrix is not merely determined by their particle size comparative to the mucous matrix pore size. There are also other factors that may facilitate or inhibit the diffusion of these particles. Recent works show that antibodies may have a secretory component that makes them slightly muco-phillic (Corthesy and Kraehenbuhl, 1999, pp. 93–111). This characteristic facilitates the transport of antibodies across the mucous layer by forming weak bonds between the antibodies and the mucin fibers. Furthermore, scientists have observed that capsid viruslike particles diffuse freely through the mucous matrix, but polystyrene spheres of similar sizes are trapped by the mucus. This phenomenon is explained by the fact that, although the polystyrene spheres have a diameter smaller than the mucous pores, they form hydrophobic interactions with the hydrophobic regions on the mucin fibers. In addition, charge–charge interactions between the particles and the mucin fibers also play an important role in determining the diffusivity of substances across the mucous layer. As we can see, diffusion of particles through the mucous matrix is by no means a simple process that only involves an unequal distribution (concentration gradient) of particles across a barrier, which we traditionally tend to associate diffusion with. Transport across the epithelium has been described elsewhere as transport across cell layers, and will not be dealt with in this section.

Barriers to Mucosal Drug Delivery

One of the most fundamental problems encountered in mucosal drug delivery is poor bioavailability due to the numerous barriers the drug must overcome to reach the blood stream. In summary, a barrier can be classified as a physicochemical barrier or a metabolic barrier (Rathbone and Tucker, 1993). Physicochemical barriers stem from the structure and properties of the various mucosal membrane layers, while metabolic barriers arise due to the presence of active enzymes in the mucosal membrane environment.

The mucous layer is a critical barrier in mucosal drug delivery (Cone, 2009; Hanes and Demeester, 2009). In order to penetrate across the mucous layer, a particle must avoid the rapid mucus clearance and adhesion to mucin fibers. This is no easy feat. Mucus is continuously secreted, then shed and discarded, or digested and recycled. The continuous secretion of mucus means that a particle must migrate "upstream" against the mucus flow in order to reach the epithelium. In addition, in some places the mucus is shed and cleared at such a rapid rate that particles are engulfed and removed before having sufficient time to diffuse through the mucous layer. This is especially the case in the eyes, where the shedding of the tear film occurs within a matter of seconds. Besides the dynamic properties of the mucus, the chemical properties

of the mucin fibers also contribute toward the barrier functions of the mucous layer. Mucin fibers contain negatively charged and therefore highly hydrophilic regions interspersed with hydrophobic domains. By conforming to the surface of an incoming particle, a mucin fiber can form multiple, low-affinity hydrophobic and/or hydrophilic ionic or H-bonds with this particle. Although these bonds are easily broken, their number is such that, at any given time, one or more of these types of bonds will "link" the particle to the fiber. The effect is especially important for relatively large hydrophobic molecules, which can simultaneously form many such low-affinity bonds with mucus. Relatively small hydrophobic molecules are less prone to be trapped by the mucous matrix, because they can only bind to mucin fibers monovalently. Furthermore, positively charged molecules bind tightly to mucin fibers via ionic interactions with the large number of negatively charged glycans. When the concentration of such positively charged particles is high, the mucous gel can collapse, causing the formation of large channels within the mucous layer. This phenomenon can actually be utilized to enhance mucosal layer permeability.

The metabolic barriers to mucosal drug delivery mainly refer to the degradation of particles by active enzymes in the mucosal membrane environment. In part, these metabolic barriers evolved out of the body's defense mechanism, which permits the body to degrade foreign substances that may be potentially harmful. However, this defense mechanism may also function against the successful delivery of useful drug particles. During the mucosal permeation process, there are several main locations that the drug particles may be subjected to premature metabolism: (1) the lumen of the route of delivery, prior to making contact with the mucous layer; (2) on the surface of the mucosal layer; or (3) within the mucosal membrane environment. The effect of metabolism is especially detrimental to the delivery of peptide and protein drugs, which are susceptible to various peptidases present in the mucosal membrane. These peptidases inactivate the peptide and protein drugs by cleaving the peptide bonds, acting as a form of presystemic first-pass effect. The types of molecules subject to degradation and the extent of degradation are dependent upon the specific mucosa. For example, a study conducted by Yamamoto et al. indicated that proteolytic degradation of insulin and proinsulin in the rabbit mucous membrane is consistently high in the rectum and consistently low in the vagina, but in the nose and mouth the degree of proteolytic activity differs with the peptides (Yamamoto, Hayakawa, et al., 1990).

General Strategies to Enhance Mucosal Drug Delivery

In order to enhance delivery of drugs and drug particles across the mucosal membrane, drug transport, absorption and eventual bioavailability all need to be improved.

In order to realize this goal, the drug molecules and nanoparticles must overcome the physicochemical and metabolic barriers described in the previous section. In order to facilitate this, it is often necessary to utilize additional compounds in combination with the drug molecules to enhance mucosal membrane penetration. Currently, there are two main approaches, one involves the usage of permeation enhancers and the other employs compounds that act as mucoadhesives.

> In order to enhance delivery of drugs and drug particles across the mucosal membrane, drug transport, absorption and eventual bioavailability all need to be improved. Currently, there are two main approaches, one involves the usage of permeation enhancers and the other employs compounds that act as mucoadhesives.

Permeation Enhancers. Permeation enhancers are compounds that can increase the permeability of the mucosal membrane and/or ability of the drug compound to cross the membrane, thereby increasing the absorption and bioavailability of the drug molecule (Shen and Lin, 1994). Depending on the mechanisms of action, permeation enhancers can be further divided into the following groups: (1) compounds that enhance permeation by altering the permeability of the membrane; (2) compounds that enhance permeation by altering the properties of the drug itself; and (3) compounds that can inhibit the enzymatic degradation of drug molecules in the mucosal environment (Robinson and Yang, 1999; Shen and Lin, 1994). Examples of each class of enhancers are listed in Table II.5.16.1. In general, permeation enhancers are designed to alter the tight junctions and cell membranes, and thus their effects are nonspecific. Not only the drug molecules but also any molecules present adjacent to the permeation enhancer will be absorbed, making this approach rather undesirable.

Mucoadhesives. Another strategy that has been the subject of greater interest than permeation enhancers is the use of mucoadhesive compounds. Mucoadhesives are compounds that prolong the contact between drug and mucosal membrane at the site of action (localized delivery) or at the site of absorption (systemic delivery). One of the primary advantages associated with mucoadhesives is the lengthening of the contact time, which provides drug particles with a longer time to diffuse across the mucous layer. Another major advantage is the strong interaction between drug and mucous layer forms a local barrier that prevents the metabolic activities of the nearby enzymes from degrading the drug particles (Makhlof, Werle, et al., 2008).

Currently, there are six general theories that have been adapted to explain the mechanism of mucoadhesion (Smart, 2005). They are the electronic theory, the wetting theory, the adsorption theory, the diffusion theory, the mechanical theory and the fracture theory. However, due to the relative complexity of this process, no single theory can completely and satisfactorily

TABLE II.5.16.1	Summary of Common Permeation Enhancers Used in Mucosal Drug Delivery
Permeation Enhancers	**Mechanism of Action**

Ionic Surfactants
  Sodium deoxycholate
 	
  Sodium taurodeoxycholate
  Sodium glycocholate
 	
  Sodium lauryl sulfate
  Sodium laurate
	Decrease viscosity of membrane by
	• Extracting membrane proteins and lipids
	• Fluidizing the membrane
	• Disrupting associated glyco-proteins in mucous layer

Chelating and complexing agents EDTA, cytochalasin, citric acid	Alter tight junctions, increasing paracellular transport

Fatty acids and derivatives
  Oleic acid, lauric acid, sodium caprate, acylcarnitines
  Mono(di)glycerides
	• Change epithelial cell mem-brane molecular arrangement
	
	• Alter tight junctions, increas-ing paracellular transport

Salicylate and analogs
  Sodium salicylate
 	
  3-Methoxysalicylate
  5-Methoxysalicylate
	• Increase solubility and dissolution of drug
	• Calcium chelating
	• Interact with membrane proteins

Others
  Cationic polymers
 	
  Poly-L-arginine, chitosan
  Aminated gelatins
  Poly(acrylates), polycarbophil, carbomers
  Glycyrrhetinic acid
  Azone
	Ion–ion interaction with mucous membrane, inducing opening of tight junctions
	
	Mucoadhesive, inhibit enzymatic activity
	Inhibit leucine aminopeptidase
	Increase membrane fluidization

EDTA, ethylenediaminetetraacetic acid.

TABLE II.5.16.2	Common Mucoadhesive Polymers Used in Mucosal Drug Delivery
Mucoadhesive Polymers	**Mechanism of Action**
Poly(acrylates)	Interact with the mucus via physical chain entanglement accompanied by hydrogen bonding
Chitosan and derivatives	• Form hydrogen bonds • Cationic nature allows interaction with negatively charged mucus

Thiolated polymers
  Chitosan conjugates with TGA, TBA, TEA, or glutathione
 	
  PAA conjugates with glutathione or cysteine
	• Form disulfide bonds with thiol groups on the cysteine-rich domains of mucin fibers
	• Ionic interactions with mucous substrate
	• Hydrophobic interactions with mucous substrate

Other polymers Hyaluronic acid, CMC, HPMC and PEG	Physical entanglement, ionic interactions

TGA, thioglycolic acid; TBA, thiobutylamidine; TEA, thioethylamidine; PAA, poly(acrylic acid); CMC, carboxymethyl cellulose; HPMC, hydroxypropyl-methyl cellulose.

thiolated polymers, polyethylene glycol (PEG), polox-amer gels, dihydroxyphenylalanine and lectins.

MUCOSAL DRUG DELIVERY SYSTEMS

While the concepts presented thus far can be applied to all mucosal drug delivery systems, it is important to real-ize that each route of mucosal drug delivery system has unique physiological characteristics that may change the specific formulation strategy used to deliver drugs via that particular route. In the following section, we will examine the major mucosal drug delivery systems in more detail, with particular emphasis on the appropriate strategies and materials used for each route of the muco-sal delivery system.

Nasal

The principle location for nasal drug penetration is in the respiratory region of the nasal passage. The respiratory region is highly vascularized, with a dense network of fenes-trated capillaries in the lamina propria. The nasal mucosa is generally considered to be penetrable for small molecules, while larger molecules may need the help of permeation enhancers to cross (Worakul and Robinson, 2002). Enzy-matic activity in the nasal mucosa is low compared to other mucosal membranes in the body (Sarkar, 1992). However, the rapid rate of mucociliary clearance presents a major barrier to mucosal delivery in the nasal passage.

One approach to prolong absorption is to increase the viscosity of the dosage form. However, highly viscous

explain this phenomenon, and we have to conclude that the mechanism of mucoadhesion is probably due to some combination of the six theories. Regardless of the specific basis for each theory, the general consensus is that there are two major stages in the mucoadhesion process (Wu, 1982): the contact stage and the consolidation stage. In the contact stage, wetting occurs between the mucoadhe-sive material and the mucus. In the consolidation stage, various interactions occur to consolidate and strengthen the adhesive interaction, leading to a prolonged contact time.

A number of polymeric materials have been shown to display mucoadhesive properties (Table II.5.16.2). The most widely investigated groups of mucoadhesive mate-rials are poly(acrylates) and chitosan (Makhlof, Werle, et al., 2008). Recently, new materials that allow speci-ficity or prolonged and strengthened contact have also been investigated. Examples of these new materials are

formulations are difficult to administer. Thermogelling systems were introduced as a way to circumvent this problem. These systems have low viscosity at room temperature, but can form a viscous gel at body temperature. Some examples are Poloxamer 407 solution (Juhasz, Lenaerts, and Ong, 1990), ethyl (hydroxyethyl) cellulose combined with small amounts of sodium dodecyl sulfate in water (Pereswetoff-Morath, Bjurstrom, et al., 1996) and gellan gum (Gelrite).

Another approach to sustain drug release at the site of administration and avoid rapid mucociliary clearance is the use of bioadhesives and bioadhesive microspheres. An early study by Nagai et al. (Nagai, Nishimoto, Nambu, Sozuki, and Sekine, 1984) demonstrated that the bioavailability of freeze-dried powder form of insulin combined with Carbopol 943 (Carbopol® is a lightly cross-linked polyacrylic acid) was equivalent to the parenteral administration of insulin solutions of three times the dose. In another study, Morimoto et al. (Morimoto, Tabata, et al., 1987) developed a nasal delivery system for nifedipine using a mixture of the drug, PEG 400 and Carbopol 941 as mucoadhesives. The results showed that a relatively high plasma drug concentration was achieved and maintained. Nakamura et al. (Nakamura, Ohta, et al., 1996) experimented on several different mucoadhesives in the nose. Their study demonstrated that xanthan gum had the longest residence time, followed by tamarind gum, hydroxypropyl cellulose (HPC) and polyvinyl alcohol. Microspheres not only have increased residence times through strong adhesive interactions with the mucous layer, but also can widen the tight junctions temporarily (Pereswetoff-Morath, 1998). Illum et al. (Davis, Illum, et al., 1987) showed that the half-life clearance of the starch microspheres was approximately 240 min compared to 15 min for control formulations of liquids and powders. A study conducted by Witschi and Mrsny (Witschi and Mrsny, 1999) found that protein transport across Calu-3 cells (a type of cell line derived from human respiratory tract epithelial cells) was increased by using Carbopol and chitosan microparticles.

Buccal

Buccal drug delivery is the administration of drugs through the mucosa lining the insides of the cheeks. The buccal mucosa is relatively thick and dense, with multiple layers of cells in the epithelium, which decrease the permeability of the mucosa considerably. It is also difficult to keep the formulation in place due to both the huge amount of saliva that is secreted and the reflex action of swallowing. What's more, we have to also take into consideration the abundance of enzymes present in the oral cavity, which can enzymatically degrade the drug particles.

Strategies to enhance the absorption of buccal-delivered drugs have been studied extensively in the past. In a promising study for buccal drug administration, Nagai

was able to formulate a small, double-layered tablet, with an upper layer of lactose and a lower layer of mucoadhesives containing HPC and Carbopol 934P (CP). There have been numerous other studies that explore the use of other mucoadhesives besides just HPC and CP. Robinson et al. (Robinson, Longer, et al., 1987) were able to design a buccal patch using polycarbophil (polycarbophil is a synthetic polymer of polyacrylic acid crosslinked with divinyl glycol). This patch was tested in dogs and found to remain in place while eating and drinking. More recently, buccal adhesive tablets of metronidazole were formulated using CP, hydroxypropylmethyl cellulose and sodium carboxymethyl cellulose as mucoadhesives (Ahuja, Khar, et al., 1998). These tablets were held in place in the buccal cavity for 6 h and released metronidazole continuously. Other materials that have also been experimented on for enhancing buccal delivery include hydroxyethyl cellulose (Anders and Merkle, 1989), polyvinylpyrrolidone, sodium alginate (Remunan-Lopez, Portero, et al., 1998) and gellan gum.

Ophthalmic

Any ocular administration of drugs is countered by the reflex tear and blinking action, which will quickly remove the drugs from the site of contact, resulting in poor bioavailability of the drugs and inadequate therapeutic effect. Therefore, the main challenge in ophthalmic drug delivery is to retain the drug for a sufficiently long period of time on the ocular mucosa. The appropriate strategy is to choose a vehicle for the drug that will retard ocular drug elimination and increase the amount of contact time. Examples of such vehicles are gels, nano- and microparticles and polymer matrices (Sintzel, Bernatchez, et al., 1996).

Gels or viscous solutions have been extensively investigated for their use in ophthalmic drug delivery. Most of these gels are prepared from hydrophilic polymers, which prolong the corneal residence time; consequently, drug bioavailability is improved. The most widely used hydrophilic polymers for gels or viscous solutions are semisynthetic derivatives of cellulose and poly(vinyl alcohol). Other viscosifiers include many natural or semisynthetic polysaccharides such as dextran, xanthan and gellan gum, as well as synthetic polymers such as polyacrylates, especially poly(acrylic acid). Another mucoadhesive that is often used to increase vehicle contact time with the corneal surface is hyaluronic acid.

Since the administration of highly viscous drug formulations is an important issue that needs to be considered, in situ gelling systems have been developed that allow a solution with a relatively low viscosity at room temperature to become more viscous at temperatures approaching that of the eye. The polymers that have been successfully used in such systems are Pluronics® and Tetronics® (Vadnere, Amidon, et al., 1984). Other types of in situ gelling systems that depend on the change in chemical environment

when contacting the eye utilize polymers such as cellulose acetophthalate latex (Gurny, Boye, and Ibrahim, 1985) and the gellan derivative Gelrite.

Micro- and nanoparticles have demonstrated the ability to improve corneal contact time. The commonly used materials for microspheres are poly(lactic acid), poly(glycolic acid), their copolymers as well as natural polymers such as albumin or gelatin (Sintzel, Bernatchez, et al., 1996). The materials most often used for the formulation of nanospheres are polyalkylcyanoacrylates, polycaprolactones and copolymers of lactic and glycolic acids (Sintzel, Bernatchez, et al., 1996).

Pulmonary

The primary site of pulmonary drug absorption is within the alveoli. The delivery of drugs via the pulmonary mucosal route is often met with a variety of difficulties. The major barriers are represented by the geometry of the pulmonary tract, mucociliary clearance, pulmonary enzymes as well as macrophage activities (Worakul and Robinson, 2002). The geometry of the pulmonary tract presents a problem for the targeting of drug molecules to site of absorption and could cause particles to impact or deposit prematurely on the upper respiratory tract, where they are likely to be engulfed by mucus and removed. Within the lung, there is a diverse population of enzymes such as amine oxidase, reductases and esterases, which can metabolize the drugs (Cohen, 1990). Although cilia and mucus are absent in the alveoli, there are numerous macrophages that are capable of engulfing insoluble foreign substances and transporting them to the ciliated epithelium for clearance (Florence and Attwood, 1998).

One general approach to solve these problems is to design particles with low mass density (porous) and large diameters (10–15 μm), using biodegradable polymers or lipophilic carriers to prevent enzymatic metabolism of the drug or carrier system (Edwards, Hanes, et al., 1997). Grenha et al. produced a new pulmonary drug delivery system through the complexation of chitosan-tripolyphosphate nanoparticles with phospholipids and microencapsulating these complexes by spray-drying with mannitol (Grenha, Remunan-Lopez, et al., 2008). The resulting microspheres had adequate characteristics for delivery to the deep lung. Kawashima modified the surface of powders by using (hydroxypropyl-methylcellulose)phthalate, which dramatically improved the inhalation properties of the powders compared with the original unaltered formulation (Kawashima, Serigano, et al., 1998). Ben-Jebria et al. (Ben-Jebria, Chen, et al., 1999) utilized dipalmitoylphosphatidylcholine as lipophilic carrier to sustain bronchodilation in the lungs. They found that the inhalation of large porous particles inhibited bronchoconstriction more than three times longer than small porous particles.

Another approach is to enhance the retention time within the lungs. One method that has been extensively studied is the entrapment of drug particles in liposomes. Taylor et al. (Taylor, Taylor, et al., 1989) studied the effect of sodium cromoglycate inhaled as a solution or encapsulated in dipalmitoylphosphatidylcholine-cholesterol liposomes and found that the encapsulated drug displayed longer retention times within the lung. In another experiment, cytosine arabinoside in free or liposome-encapsulated form was given to rats via intratracheal instillation (Juliano and McCullough, 1980). The encapsulated form prolonged the effect of the drug in the lung. Mucoadhesives have also been used. Tahara et al. successfully prepared poly(lactide-co-glycolide) nanospheres and modified the nanosurface with chitosan to improve mucosal peptide administration (Tahara, Yamamoto, et al., 2007).

Gastrointestinal

> The oral route of drug administration is still by far the most popular delivery route due to its relative ease of administration and high patient compliance. However, oral dosage forms commonly encounter several problems that can influence their absorption from the GI tract. These problems include (1) the variations in pH as drug particles travel through the GI tract; (2) the profusion and huge variety of enzymes that are present in the GI tract; and (3) the complex and diverse absorptive surfaces throughout the GI tract.

Due to the limited absorption surface area and blood supply in surrounding tissues of the stomach, most of the drugs delivered via the gastric route have been for local effects within the stomach. The acidic environment in the stomach and the presence of enzymes such as pepsin can be detrimental to the stability of the drug particles delivered to the stomach. In addition, peristaltic contractions within the stomach greatly affect the ability of the drug to adhere to the mucosa lining for efficient drug delivery. However, despite these difficulties, progress has been made toward stabilizing the formulation at acidic pH values and prolonging the gastric residence time using a variety of methods.

There are typically three types of methods to prolong gastric retention (Conway, 2005). The first is through the design of a floating system, which utilizes the floating behavior of substances in the gastric fluid. Multiple-unit divided systems such as microspheres have been extensively studied. Polymers often used in this type of formulation include casein-gelatin (Bulgarelli, Forni, et al., 2000), acrylic polymers such as Eudragits (Lee, Park, et al., 1999) and alginates (Murata, Sasaki, et al., 2000). A second approach is the use of mucoadhesive systems. Akiyama et al. (Akiyama, Nagahara, et al., 1995) prepared microspheres of CP dispersion in polyglycerol esters of fatty acid (PGEF) that prolonged GI transit time by adhering to the gastric or upper intestinal mucosa. Nagahara et al. (Nagahara, Akiyama, et al., 1998) tested this system for the anti-*Helicobacter pylori* effect of amoxicillin and found that the amount of the drug left in the

stomach of Mongolian gerbils was approximately three times higher than that of the drug in 0.5% methylcellulose suspension. This effect was attributed to the increase in adhesion due to the CP-PGEF system. Chitosan, one of the most widely investigated mucoadhesives for gastric delivery, has produced results that show improved adhesion and sustained release of drugs in the stomach (Sugimoto, Yoshida, et al., 1998) and so have studies involving microencapsulation with combinations of polycarbophil and Carbopol. Finally, the third approach to prolong gastric mucosal retention time is the employment of swelling systems, which mainly include the family of polymeric hydrogels. Some examples of these hydrogels are chitosan-poly(acrylic acid) hydrogel, chitosan-poly(*N*-isopropylacrylamide) stimuli-responsive hydrogel and (acrylamide-co-acrylic acid) hydrogel (Chen, Blevins, et al., 1998; de la Torre, Enobakhare, et al., 2003).

It is important to point out that these bioadhesive systems for intestinal mucosal delivery are nonspecific. Targeting a particular area on a mucosal surface is very difficult, but recent advances have been made using lectin. Lectins are proteins capable of interacting specifically with epithelial cells by binding with sugar residues on the surface of the cells (Pusztai, Bardocz, and Ewen, 1999). In two separate studies, Lehr, Bouwstra, et al. (1992) and Naisbett and Woodley (1994) found that tomato lectin binds specifically to the small intestine in vitro. Thus, bioadhesive systems are sometimes formulated by grafting lectins onto the surface of microspheres, nanospheres and liposomes.

Vaginal

One of the key features of the vaginal mucosa is that its thickness varies with the menstrual cycle, which is regulated by fluctuations in hormonal levels. Estrogen increases the mucosal thickness and the amount of endocervical fluid while decreasing the viscosity of the fluid. Progesterone increases the amount of glycogen and fluid secretion from the epithelium as well as the viscosity of the fluid. These cyclic changes affect the absorption of drug particles in different ways. For example, Okada et al. investigated the effect of the estrus cycle on vaginal absorption of insulin, phenolsulfonaphthalein and salicylic acid in rats (Okada, Yashiki, et al., 1983). They concluded that the estrus cycle has more effect on hydrophilic compounds than on hydrophobic compounds. This must be taken into consideration when formulating drugs for vaginal mucosal delivery. Another factor is the presence of enzymes such as β-glucuronidase, acid phophatase, phosphoamidase and various proteases in the vaginal mucosa. These enzymes could potentially degrade the drugs designed for vaginal mucosal delivery.

Vaginal delivery systems typically suffer from short residence times. Robinson and Bologna presented a possible solution to this problem by using a vaginal delivery system consisting of Polycarbophil® (Robinson and Bologna, 1993). This system was able to remain on the vaginal tissue for 3–4 days. Lee and Chien (Lee and Chien, 1996) used CP as a gel base and combined nonoxynol 9 with a chelating agent (ethylenediaminetetraacetic acid). This vaginal drug delivery platform demonstrated a longer contact time with the vaginal mucosa. Another formula made from Nonoxynol 9 coprecipitated with polyvinylpyrrolidone with or without iodine was incorporated into bilayer tablets or hard gelatin capsules. These systems were able to release their contents rapidly and sustained drug levels for at least 4 h (Digenis, Nosek, et al., 1999). The longer residence time on the vaginal mucus is especially important for delivery of microbicides. Kiser et al. used hydroxyethylcellulose gel to deliver tenofovir and to block HIV from penetrating the vaginal mucus (Kiser et al. 2012). In a recent research by Albertini et al., the lipid–hydrophilic matrix Gelucire 53/10 was used as a carrier for the antifungal drug econazole nitrate along with several other mucoadhesive polymers such as chitosan, sodium carboxymethyl cellulose and poloxamers (Lutrol F68 and F127) (Albertini, Passerini, et al., 2009). It was found that the poloxamers–matrix combination best improved the bioavailability of the low-bioavailable drug and its mucoadhesive strength. Other formulations that were found capable of enhancing vaginal mucosal delivery include microspheres of hyaluronic acid esters (Richardson, Whetstone, et al., 1996) and liposomes incorporated into polyacrylamide gel (Jain, Singh, et al., 1997).

CONCLUSIONS

This chapter presents an overview of mucosal drug delivery and includes descriptions of the structure and composition of the mucosal membrane, the mechanisms of transport, the barriers drug particles may face, strategies to overcome these barriers, and some specific mucosal drug delivery systems. However, our current knowledge of this field is still far from being sufficient and many areas are yet to be understood. Although mucosal drug delivery offers a number of advantages over traditional routes of delivery (such as parenteral delivery), there are still many challenges facing us in designing an effective mucosal drug delivery system.

APPENDIX G: CHAPTER II.5.16 — DRUG DELIVERY SYSTEMS: I, SMART HYDROGELS AS *IN VIVO* DRUG DELIVERY SYSTEMS

Sungwon Kim and Kinam Park
Departments of Biomedical Engineering and Pharmaceutics,
Purdue University, Lafayette, IN, USA

INTRODUCTION

Hydrogels have been studied for more than a 100 years, initially as colloidal systems; however, systematic studies on the biological use of hydrogels began in 1960 with the introduction of poly(hydroxyethyl methacrylate) gels by Wichterle and Lim (Wichterle and Lim, 1960). Since then, the number of publications on hydrogels per year increased gradually until 1990, when the number began to grow exponentially. Currently, the number of publications on hydrogels per year is close to 4000. This is partly due to the introduction of smart hydrogels (also called intelligent hydrogels) that have been an essential tool in the development of advanced biomaterials and drug delivery systems (DDS).

Ordinary hydrogels are those that swell by absorbing a large amount of water and shrink (or deswell) as the water is removed. "Smart" hydrogels are those that have the ability to undergo sharp structural changes in response to small changes in environmental stimuli, such as temperature and pH. The structural changes include not only swelling/deswelling, but also sol–gel phase transition, degradation, and shape transformation. The environmental stimuli can be divided into three categories: physical, chemical, and biological. Individual stimuli and polymers that react to the stimuli are listed in Table II.5.16.1. The four major areas of applications of smart hydrogels are controlled drug delivery, tissue engineering, bioseparations, and biosensor/bioimaging (Bayer and Peppas, 2008; Qiu and Park, 2001;

TABLE II.5.16.1	Environment-Sensitive Polymers to Make Smart Hydrogels for Drug Delivery	
Stimulus	**Polymer**	**References**
Physical Stimuli		
Temperature	Polyphosphazene	(Al-Abd, Hong, Song, and Kuh, 2010)
	Chitosan neutralized with dibasic salts (e.g. β-glycerophosphate, DHO)	(Ruel-Gariepy et al., 2004; Ta, Han, Larson, Dass, and Dunstan, 2009)
	PEG-modified chitosan/α-CD complex	(Huh et al., 2004)
	Poly(γ-CD-NMA-*co*-HMAAm)	(Siemoneit et al., 2006)
	Genetically engineered silk-elastin-like protein (SELP)	(Banta, Wheeldon, and Blenner, 2010; Dinerman, Cappello, El-Sayed, Hoag, and Ghandehari, 2010; Dinerman, Cappello, Ghandehari, and Hoag, 2002)
	NIPAAM copolymers	(Park and Hoffman, 1994; Jeong, Kim, and Bae, 2002)
	PEO-*b*-PPO-*b*-PEO	(Jeong et al., 2002)
	Block copolymers of PEG and polyesters	(Jeong et al., 2002; Nguyen and Lee, 2010)
Electric fields	Poly(AMPS-*co*-BMA)	(Kwon, Bae, Okano, et al., 1991)
	Complex of PEOx/PMAA or PEOx/PAA	(Kwon, Bae, and Kim, 1991)
	Acetylated chitosan	(Ramanathan and Block, 2001)
	Cross-linked chondroitin 4-sulfate	(Jensen, Hansen, Murdan, Frokjaer, and Florence, 2002; Murdan, 2003)
Magnetic fields	Nanocomposite of iron oxide in poly(PEGMMA-*co*-PEGDMA), PVA, κ-carrageenan hydrogels*	(Daniel-da-Silva et al., 2009; Meenach, Hilt, and Anderson, 2010; Lao and Ramanujan, 2004; Liu, Hu, Liu, Liu, and Chen, 2008)
	Nanocomposite of poly(3-morpholinopropylamine-*co*-DEGDA)/iron oxide nanoparticle	(Hawkins, Satarkar, and Hilt, 2009; Liu, Hu, Liu, and Chen, 2006)
Ultrasound	Microcomposite of Dex-CHO/CMC-ADH containing liposome and microbubble	(Epstein-Barash et al., 2010)
Pressure	PMMA/PVP or PMMA/CE complex	(Minghetti, Cilurzo, Tosi, Casiraghi, and Montanari, 2003)
Chemical Stimuli		
pH	PHEA	(Casadei, Pitarresi, Calabrese, Paolicelli, and Giammona, 2008)
	β-CD hydrogel cross-linked by EPI	(Rodriguez-Tenreiro, Diez-Bueno, Concheiro, Torres-Labandeira, and Alvarez-Lorenzo, 2007)
	HP-β-CD/Carbopol ms-IPN	(Yang and Kim, 2010)
Ion species	PAAm with CaM and phenothiazine peptide—Ca^{2+} sensitivity	(Banta et al., 2010; Ehrick et al., 2005)
	PEG tetraacrylate hydrogel with CaM—Ca^{2+}-sensitivity	(Banta et al., 2010; Murphy, Dillmore, Modica, and Mrksich, 2007)
	Poly(NIPAAm-*co*-BCAm)—Ba^{2+} and Cs^+ sensitivity	(Ju, Chu, Liu, Mi, and Lee, 2008; Pi, Ju, Wu, Xie, and Chu, 2010)
	Melamine hydrogel—oxoanion (e.g. NO_3^{3-}, PO_4^{3-}, ATP, SO_4^{2-}) sensitivity	(Shen, Cai, Jiang, and Zhang, 2010)
Ionic strength	Genetically engineered SELP	(Banta et al., 2010)
	Pullulan acetate nanogel	(Park et al., 2007)
Drug	PAAm/genetically engineered GyrB conjugate responding to coumermycin and novobiocin	(Ehrbar, Schoenmakers, Christen, Fussenegger, and Weber, 2008)
Biological Stimuli		
Glucose	Copolymer of acrylated GBP and AAm	(Ehrick et al., 2009)
	Poly(NIPAAm)/poly(NIPAAm-*co*-MPBA) core/shell microgel	(Zhang, Guan, and Zhou, 2007)
	Poly(AAm-co-MPBA) microdevices	(Siegel et al., 2010)
	Poly(AG-*co*-SPAK), poly(AG-*co*-VP), and poly(AG-*co*-AAm) loading PEGylated Con A	(Kim and Park, 2001)
	Copolymer of SMD, DMAAm, MBAAm, methacryloyl enzymes (GOD and/or catalase)	(Kang and Bae, 2003)
Antigen	Copolymer of acrylated GAR IgG and acrylated rabbit IgG	(Miyata, Asami, and Uragami, 1999)
Enzyme	IPN structure of gelatin and dextran degraded in the presence of α-chymotrypsin and dextranase	(Kurisawa and Yui, 1998)
	Ionic complex of NAH-Dex and CMD degraded by dextranase	(Kamimura, Ooya, and Yui, 2001)
	Cross-linking PEG with enzyme-degradable peptide (e.g. HNE, MMP)	(Aimetti, Machen, and Anseth, 2009; Lei and Segura, 2009)
	Methacrylated gelatin degraded by MMP-1	(Sutter, Siepmann, Hennink, and Jiskoot, 2007)

*The nanogel converts magnetic energy to heat energy, rather than inducing a structural change.

Siegel et al., 2010). Most of the smart hydrogels that have been used for developing stimuli-responsive DDS are summarized in a book published recently (Bajpai, Shukla, Saini, and Tiwari, 2010). Of the various smart hydrogels, the temperature- and pH-responsive hydrogels have been most widely studied for the development of DDS (Ganta, Iyer, and Amiji, 2010, pp. 555–585; Kim, Kim, Min, Park, and Lee, 2010, pp. 293–308). Successful utilization of smart hydrogels for controlled drug delivery requires understanding of both the properties of smart hydrogels and the biological requirements that are necessary for drug delivery.

SMART HYDROGELS FOR DRUG DELIVERY

Smart hydrogels have been used to deliver various drugs for time periods ranging from hours to weeks. For oral delivery formulations, the drug delivery to the body is supposed to be completed within 24 h. Transdermal formulations are usually used to deliver a drug on the time-scale of a day to a week. On the other hand, other drug delivery routes, such as implanted depot systems, or localized DDS such as pumps, take from days to months to deliver drugs. Thus, when smart hydrogels are used for delivering drugs, the delivery routes as well as the drug release duration both need to be considered.

When smart hydrogels are used for delivering drugs, the delivery routes as well as the drug release duration need to be considered. For oral delivery formulations, the delivery is supposed to be completed within 24 h. Transdermal formulations usually deliver the drug from between a day to a week, while implanted depot systems and pumps deliver the drug in months.

The composition of the smart hydrogel and the design of the system are both very important. For example, oral formulations of smart hydrogels should be designed to control the drug release rate (1) as pH changes from stomach (gastric) to intestine (enteric) or (2) as the location along the gastrointestinal tract changes, e.g. upper small intestine vs. the colon (Hejazi and Amiji, 2003). If a smart hydrogel system is to deliver a drug with a release duration of weeks or longer, they will usually need to be implanted into the body. Such implantable systems must satisfy the important issues of safety and efficacy. Unless these considerations are considered, smart hydrogels cannot be used clinically no matter how smart they are.

It is important to examine the particular requirements of each application of a smart hydrogel system. Quite often, smart hydrogel DDS are proposed without a clear understanding of the clinical necessities that each drug delivery route will demand. Temperature-responsive hydrogels have been the most widely studied among

the smart hydrogels for development of DDS (Yoshida et al., 1995), especially poly(*N*-isopropylacrylamide) or PNIPAAm. In this case, a PNIPAAm/drug solution at ambient temperature will become a gel when it is injected into the body at 37°C due to the "smart polymer" temperature-dependent sol–gel phase transition. Because most thermosensitive polymers are based on acrylic monomers, they are not biodegradable, and thus the PNIPAAm gel residue may require surgical removal after the drug release is completed. This problem is often overlooked in publications proposing such thermally sensitive polymers and hydrogels as clinically useful DDS.

Recent research efforts have been focused on the development of smart hydrogels for *in vivo* use. These have special properties due to the use of new monomers and/or new combinations of existing systems. Such new smart hydrogels, or "smarter hydrogels", are discussed in the next section.

NEW SMART HYDROGELS FOR *IN VIVO* APPLICATIONS

Despite advances in drug delivery technologies over the last three decades, controlled delivery of protein drugs is still a major challenge (Jorgensen and Nielsen, 2009, p. 442). Due to its hydrophilic nature, a hydrogel DDS should be an excellent carrier for delivering hydrophilic drugs such as peptide or protein drugs. Many different environmentally sensitive polymeric compositions have been synthesized over the past 30 years. Some good examples of the newer smart hydrogels include (1) enzyme-responsive hydrogels that deliver proteins, such as albumin; (2) drug molecule-sensitive hydrogels for delivery of a protein; (3) hydrogels designed to deliver two proteins; and (4) magnetically controlled hydrogels (Ehrbar et al., 2008; Satarkar and Hilt, 2008). It is also important to remember that depot-type hydrogel systems should be biodegradable and biocompatible after the drug has been delivered (He, Kim, and Lee, 2008). Sometimes smart hydrogel DDS exhibit drug release duration of no more than a day or two, limiting their useful delivery route to oral administration.

Among the polymers incorporated in recent smart hydrogel DDS, natural biomacromolecules, such as nucleic acids (e.g. DNA), peptides and proteins (e.g. collagen, spider silk and albumin) and polysaccharides (e.g. hyaluronic acid and pullulan), have been utilized for their potential biocompatibility and degradability. It should be noted that the body's immunological response to such natural biomolecules is a major consideration for any *in vivo* application of such materials. Some may also have significant bioactivity, such as DNA and hyaluronic acid. One noteworthy development in smart natural hydrogels is the use of DNA as the backbone of a hydrogel network (Um et al., 2006). Branched DNA was used to construct three-dimensional hydrogels that were biocompatible and biodegradable. These two properties are ideally suited for making implantable long-term DDS.

Insulin was used as a model protein to demonstrate the long-term release from the DNA hydrogels, which subsequently degrade into harmless materials in the body.

> Among the molecules incorporated in recent smart hydrogel DDS, natural biomolecules, such as nucleic acids (e.g. DNA), peptides and proteins (e.g. spider silk and collagen), and polysaccharides (e.g. hyaluronic acid), have been utilized for their biocompatibility and degradability. It should be noted that the body's immunological response to such natural biomolecules is a major consideration for any in vivo application of such materials.

A recently developed DNA hydrogel for cell-free synthesis of functional proteins is an excellent example of a biomimetic hydrogel (Bayer and Peppas, 2008; Park, Um, Funabashi, Xu, and Luo, 2009). These hydrogels produce proteins with compositions derived from the genes incorporated as a part of the gel scaffolding. The improved gene stability, higher local concentration and faster enzyme turnover resulted in high efficiency and the yield of more than a dozen proteins. These protein-producing gels can be expected to deliver therapeutic proteins continuously over a long period of time.

In addition to the versatility of materials and the innovative function of smart hydrogel systems, the definition of the hydrogel has also broadened. Recent advances in nanotechnology have resulted in a new form of hydrogels, i.e. a colloidal solution of hydrogel nanoparticles called "nanogels". In the conventional definition, a hydrogel is a physically or chemically cross-linked polymer network, which absorbs a large quantity of water without dissolution (Lin and Metters, 2006). Nanogels are also stabilized by chemical bonds or physical cross-linking including hydrophobic interactions, affinity interactions, H-bonding and ionic bonding. Their hydrodynamic volume is larger than that of the dried nanogel due to the absorption of water (hydration) by the nanogel particles. The drug release mechanisms of nanogels are similar to those of microscopic and macroscopic smart hydrogels, such as sol–gel phase transition, degradation, and swelling/deswelling. An example of a biologically inspired design is a virus-mimetic nanogel vehicle (Lee, Kim, Youn, Oh, and Bae, 2008). This nanogel was made of a hydrophobic core of poly(L-histidine-*co*-phenylalanine) poly(His-*co*-Phe) covered by a poly(ethylene glycol) inner shell and an albumin outer shell. Poly(His-*co*-Phe) is pH sensitive and undergoes reversible swelling and deswelling as the pH changes between 7.4 (normal physiological pH) and 6.4 (endosomal pH), thus stimulating the endosomal release of the loaded doxorubicin.

IDEAL SMART HYDROGELS FOR SELF-REGULATED INSULIN DELIVERY

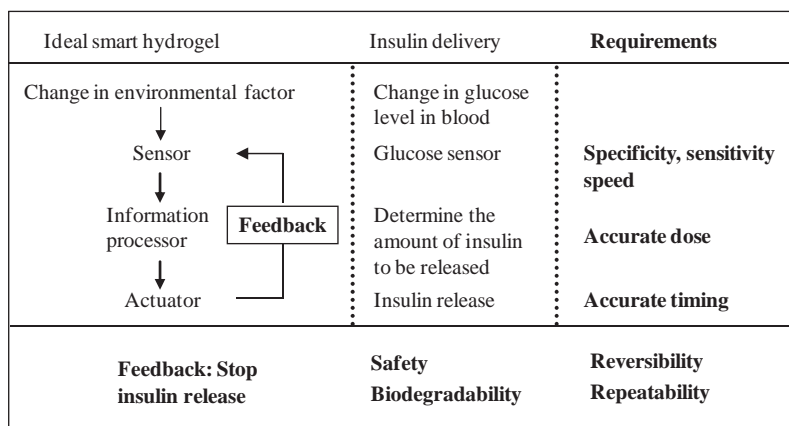
In demonstrating protein release from smart hydrogels, insulin has been frequently used as a model protein. But delivery of insulin, as a representative of peptide


Figure II.5.16.1 This figure shows many of the design considerations for an ideal, implantable smart hydrogel system that will deliver just the right amount of insulin in response to a specific change in the blood glucose level. The system needs to have high specificity to glucose only, and high sensitivity to small changes in glucose concentration. The system also has to be biocompatible and it should biodegrade when the insulin delivery is completed, avoiding the need to retrieve it. The smart hydrogel must have rapid response, be reliable and reproducible over the term of use, and not induce any immunogenic responses.

hormones, is significantly different from delivery of other therapeutic protein drugs. Most protein drugs are released at a predetermined dose at a predetermined rate for a predetermined time period. Delivery of peptide hormones, however, requires a different mode from a predetermined release profile. The human body has multiple oscillation mechanisms to maintain metabolic homeostasis, and it is the hormone that tightly regulates each body function. An optimum amount of hormone results in a harmony between many functions of the body. Because of this, a lack of fine control in a DDS designed to deliver a hormonal peptide or protein drug could induce significant side effects, which could alter the desired clinical outcome. For instance, insulin should be delivered only when the blood glucose level is increased, and an accurate dose of insulin has to be delivered in a matter of minutes. Otherwise, either hyperglycemia or continued hypoglycemia will result in the body. Figure II.5.16.1 shows an example of how an ideal smart hydrogel insulin sensor with feedback delivery would be specifically designed to meet all the requirements for accurate and reproducible insulin delivery on demand.

> Numerous smart hydrogels have been prepared for the self-regulated delivery of insulin in response to changes in glucose level in the blood. While such smart hydrogels can recognize the change in the glucose level in the environment and alter the rate of insulin release accordingly, one of the main problems of such systems is their gradual decrease in reproducibility.

Numerous smart hydrogels have been prepared for the self-regulated delivery of insulin in response to changes in glucose level in the blood (Kataoka, Miyazaki, Bunya, Okano, and Sakurai, 1998; Kim and Park, 2001). While such smart hydrogels can recognize the change in the glucose level in the environment and alter the rate of insulin release accordingly, one of the main problems of such systems is their gradual decrease in reproducibility. The ability

of the hydrogels to respond to glucose changes decreases gradually, and thus, maintaining the original property for an extended period of time is critical for the successful development of clinically useful smart hydrogel systems.

The lack of truly smart hydrogels that can be used for self-regulated insulin delivery indicates that our current approach needs reevaluation. It is all too common to develop new materials first and then to look for applications. Quite often, finding the right application from the known properties of the new material is not easy. A more effective way to develop clinically useful smart hydrogels may be to understand the physiological requirements for a specific application and then design the new smart hydrogels. Smart hydrogels that need to be used for self-regulated insulin delivery need to take into consideration the requirements first, instead of making the hydrogels first, without understanding the physiological needs. Smart hydrogels can be translated into clinical products much faster and more efficiently if the physiological requirements are understood first before developing any new smart hydrogels. One of the best ways to make ideal smart hydrogels is to make biomimetic systems, e.g. smart hydrogels that function as islet cells. Making such islet cell biomimetic systems requires much more complexity than is currently available in smart hydrogels.

SMART HYDROGELS AS BIOMIMETIC SYSTEMS

Recent progress on smart hydrogels has been indeed remarkable, and this improved technology should be used effectively in developing better DDS. While there is no doubt that the future of smart hydrogels is bright (Kopecek, 2007), the future development of smart hydrogels may have to consider many fundamental differences between artificial and natural nanomaterials.

Natural systems are made by association of molecules (i.e. the bottom–up approach) resulting in the simplest and

yet most efficacious systems for survival (Park, Yui, and Mrsny, 2004, pp. 427–437). On the other hand, synthetic systems are usually prepared by the top–down approach. Although self-assembly and layer-by-layer composition are common in synthetic systems, their microscopic structures and biological functions are worlds apart from natural systems. The truly biomimetic smart hydrogels will be those that can act like a natural system in its speed, function, and repeatability. Developing such smart hydrogels is the key to the successful formulation of self-regulated DDS, especially feedback insulin delivery systems. Another important point to consider in developing smart hydrogels for pharmaceutical and biomedical applications is their ultimate use in humans. The smart hydrogels must be made of materials that can be proven to be safe. For this reason, the GRAS (generally regarded as safe) materials are preferred, but new materials can be used, especially when they provide unique and useful properties, through proper testing of the safety.
