Some Background Concepts

CHAPTER II.1.1 INTRODUCTION: BIOLOGY AND MEDICINE – KEY CONCEPTS IN THE USE OF BIOMATERIALS IN SURGERY AND MEDICAL DEVICES

Buddy D. Ratner

Professor, Bioengineering and Chemical Engineering, Director of University of Washington Engineered Biomaterials (UWEB), Seattle, WA, USA

Biomaterials Science: *An Introduction to Materials in Medicine* directly addresses the multidisciplinary nature of the biomaterials field by providing concise tutorials in the key concepts essential for practitioners of biomaterials science. The word "biomaterials" implies biology and materials. This section addresses the fundamental "bio" science relevant to biomaterials (Section I.2 serves a similar function for the fundamental materials science relevant to biomaterials). The background biology is important, because this scientific foundation will help us to understand, predict, and engineer the *in vivo* bioresponses observed by the biomaterials scientist, the physician, and the patient.

When a synthetic material is placed in a biological milieu (implantation in a living organism, for example), a series of reactions is initiated almost instantaneously. Water molecules (and H^+ and OH^-), being the lowest molecular weight species, should reach the biomaterial surface first (in milliseconds). Their considerable impact on subsequent reactions is elaborated upon in Chapters I.1.6 and I.2.10. Although water is not considered a biomolecule, it sets the stage for the biological reactions to follow.

Proteins, dissolved in serum at a concentration of approximately 7 g/dL, arrive next at the surface by diffusion or in some cases by convection. There are 700 or more proteins in blood. Some are relatively non-bioreactive, such as albumin, and others have numerous biological activities, such as fibrinogen or fibronectin. When proteins diffuse to a biomaterial interface, they will arrive in order of molecular weight (small proteins like thrombin, 35 kDa, arrive before heavier proteins like IgG, at 160 kDa). Once at the surface, proteins can adsorb, desorb, exchange with other proteins, denature,

increase their biological activity or decrease their biological activity. This complex landscape, comprised of many proteins in many states of organization and elaborated upon in Chapter II.1.2, becomes the environment to which cells will respond (and cells do indeed respond to proteins).

The fundamentals of *in vitro* cell interaction with surfaces (or more accurately, interactions with the protein layer on biomaterial interfaces in water) are described in Chapter II.1.3. This chapter is particularly relevant for surface diagnostic devices (ELISA assays, DNA microarrays, protein microarrays), cell culture, and for biosensors, but also pertains to many reactions observed *in vivo*.

Chapter II.1.4 discusses the biology of cells, with an emphasis on what the cells do under various conditions and what happens when they are injured (you can't have a surgical site without cell injury; also rubbing and mechanical forces associated with medical implants can induce cell injury).

Single cell types rarely exist alone. They aggregate or interact to form tissues (Chapter II.1.5). Some principles that govern tissue formation from individual cell types are relatively simple and have been elaborated upon by researchers such as Malcolm S. Steinberg, who demonstrated that a cell membrane surface tension associated with cell surface cadhedrin molecules can drive cell aggregation into organized multicellular structures. Other aspects of tissue formation are governed by the complex mechanisms observed in studying the developmental biology of organisms. Biomaterials and medical devices are interfaced against tissues, so understanding tissues, their organization, and their properties is important. Furthermore, the cells in tissues make a "grout" that holds them together; this material is called extracellular matrix (ECM). ECM serves a mechanical function in stabilizing the tissues but is, in its own right, highly biologically active. For example, it has been shown that triple-helical collagen I, the primary component of ECM, can bind in a biospecific manner to more than 50 other biomolecules, including some with high biological activity such as fibronectin. Thus, the ECM presents to the cells bioactive biomolecules in optimal conformation and orientation, and thus

directs their functions and actions. This concept is particularly important to tissue engineering (Section II.6). Also, the degradation products of ECM can be highly bioactive. For example, the work of Judah Folkman and colleagues demonstrated that degradation fragments of some collagens are inhibitory to angiogenesis. Since ECM is synthesized by tissue cells and is broken down by cells such as the macrophage, the bioactive fragments from the breakdown can impact tissue formation and biological reaction.

Chapter II.1.6 addresses mechanical forces, their effects on cells and tissues, and their importance for biomaterials (Chapter I.1.4 on biomechanics provides some of the concepts needed to appreciate Chapter II.1.6). Living organisms move, and blood flows. Thus, all implants in living organisms are subjected to mechanical forces. Although Chapter II.1.6 focuses on the liquid–biomaterial interface (e.g., blood interactions), the concepts of force communication from the environment external to the cell, to the cell membrane, particularly from an engineering standpoint, are elaborated upon. The work of Donald Ingber and others helps us to understand how this mechanical trigger at the cell membrane can signal to the cell nucleus, leading to downregulation or upregulation of specific genes, which then leads to expression of new cytokines and/or other signaling molecules.

Mechanical forces can impact cells macroscopically, but also impact at a microscopic level. In 1965, S. B. Carter published a paper in *Nature* in which he showed that cells follow micron-dimension scratches in a plastic film, a phenomenon he named contact guidance. We use that term to this day to describe this mechanically-induced response of cells to micron scale features. Chapters I.2.13 and I.2.15 give us patterning, texture, and porosity tools to manipulate cell–mechanical interactions at the micro- and even the nanolevel.

Section II.1 ends with Chapter II.1.7, which is on key concepts relating to stem cells. When the second edition of this textbook was being assembled, one could hardly imagine the importance that stem cells would assume for biomaterials and tissue engineering. Now, some 10 years later, stem cells are seen to be of critical importance to tissue engineering, but are also important for wound healing, tissue development, and even for the evolution of cancerous tumors. Furthermore, stem cell differentiation to specific tissue cells seems to be significantly impacted by mechanical forces communicated to the cells by surface modulus and surface topographies (textures and porosities) at the micron scale (surface chemical composition can also impact differentiation). Thus, we see relationships between this chapter and Chapter II.1.6 (effects of mechanical forces on cells) and Section II.6 (tissue engineering).

CHAPTER II.1.2 ADSORBED PROTEINS ON BIOMATERIALS

Thomas A. Horbett
Bioengineering and Chemical Engineering, University of Washington, Seattle, WA, USA

INTRODUCTION

The replacement of injured or diseased tissues with devices made from materials that are not of biologic origin is the central approach in current biomaterials science and clinical practice. The prevalence of this approach is due largely to the fact that these materials are not attacked by the immune system, unlike donor tissues or organs. This fundamental difference arises from the presence of immunologically recognizable biologic motifs on donor tissue, and their absence on synthetic materials.

Nonetheless, there are other types of biological responses to implanted biomaterials that often impair their usefulness, including the clotting of blood and the foreign-body reaction. Clearly, the body does recognize and respond to biomaterials. The basis for these reactions is the adsorption of adhesion proteins to the surface of the biomaterials that are recognized by the integrin receptors present on most cells. The adsorption

of adhesion proteins to the biomaterial converts it into a biologically recognizable material, as illustrated in Figure II.1.2.1. The protein adsorption event is rapid (seconds) and happens on all materials implanted into biological systems. Note: familiarity with protein structure is essential to appreciate the content of this chapter. All introductory biochemistry textbooks can provide this critical background material.

The interaction of adhesion receptors with adhesion proteins thus constitutes a major cellular recognition system for biomaterials. Therefore, the role of adsorbed adhesion proteins in mediating cellular interactions with biomaterials will be the primary focus of this chapter. Examples illustrating the ability of adsorbed adhesion proteins to influence cellular interactions with foreign materials are presented first. Then, some of the major physicochemical characteristics of protein adsorption are illustrated and discussed, including rapid kinetics, monolayer adsorption, and competitive adsorption. Molecular spreading events related to the conformational stability of the protein are presented at some length, as background for a section on how the biological activity of adsorbed adhesion proteins is affected by the substrate. The final section summarizes the principles underlying the role of adsorbed proteins in mediating platelet response to biomaterials, as an illustrative case study representative of many other types of cellular responses.
FIGURE II.1.2.1 Cell interactions with foreign surfaces are mediated by integrin receptors with adsorbed adhesion proteins that sometimes change their biological activity when they adsorb. The cell is shown as a circular space with a bilayer membrane in which the adhesion receptor protein molecules (the slingshot-shaped objects) are partly embedded. The proteins in the extracellular fluid are represented by circles, squares, and triangles. The receptor proteins recognize and cause the cell to adhere to only the surface bound form of one protein, the one represented by a solid blue circle. The bulk phase of this same adhesion protein is represented by a blue triangle, indicating that the solution and solid phase forms of this same protein have a different biological activity. The figure is schematic and not to scale.

This chapter emphasizes the biological effects of adsorbed adhesion proteins, and includes material that is discussed in greater detail in several previous review articles by the author (Horbett 1993, 1994, 1996, 1999, 2003; Horbett and Brash 1995). Those articles also give citations to all the work discussed here. A useful recent review that emphasizes thermodynamic and other physicochemical aspects of protein adsorption has been provided by Latour (2008).

Most studies of protein interactions with biomaterials and their effects on cells have been done *in vitro* after relatively short contact periods, leading to the focus here on effects in the shorter-term that involve undegraded adhesion proteins that mediate cell interactions. However, the adsorbed protein layer on biomaterials implanted in humans or animals for longer times includes smaller size fragments (observed on breast implants (Backovic et al., 2007), glucose sensors (Gifford et al., 2006), and kidney dialyzers (Cornelius and Brash, 1993)) that are presumably due to proteolytic attack. The functional role of any of these changes to the adsorbed proteins on the interaction of biomaterials with the body remains to be elucidated.

EXAMPLES OF THE EFFECTS OF ADHESION PROTEINS ON CELLULAR INTERACTIONS WITH MATERIALS

Protein adsorption to materials can be performed with a single protein, typically in a buffer solution, or from complex, multi-protein solutions, such as blood plasma which can contain hundreds of proteins. Experiments done with single proteins in buffer can be used to study fundamental aspects of protein adsorption, such as adsorption rates or conformational changes, and to study biological responses such as cell adhesion to each protein. Adsorption from complex media approximates the adsorption conditions encountered by implanted biomaterials, and thus provides a more realistic insight into the functional role of adsorbed proteins. Examples of the effects on cellular responses of protein adsorption done under both conditions are presented.

The Effects of Preadsorption with Purified Adhesion Proteins

Preadsorption of certain proteins onto a solid substrate, such as tissue culture polystyrene, greatly increases its adhesiveness to many kinds of cells, and such proteins are called adhesion proteins. The increased adhesiveness is due to the fact that many cells have receptors in their cell membrane that bind specifically to these specialized proteins. The adhesion receptors involved in cell adhesion to biomaterials and extracellular matrices such as collagen are called integrins. For example, fibronectin preadsorption greatly increases the adhesion of fibroblasts, while albumin preadsorption prevents it. Experiments of this type have been done with a wide variety of cells and adhesion proteins, with basically similar results. Adhesion proteins also promote the flattening out or spreading of the cell onto the surface. A specific example is provided by measuring the percentage of attached cells that spread on polystyrene surfaces pretreated with increasing concentrations of fibronectin. Spreading is only about 5% on albumin coated surfaces, but increases to nearly 100% as the fibronectin concentrations in the preadsorption solution are increased from 0.03 to 3 μg/ml.

In studies of protein-mediated cell adhesion, it is necessary to eliminate or reduce the role of non-specific adhesion directly to the uncoated surfaces, as this is often high, so that the special ability of adhesion proteins compared to other proteins would be masked. Thus, when testing for the ability of a protein to specifically cause cell adhesion, any residual uncoated sites left after preadsorption with the putative adhesion protein are filled by a second adsorption step with a protein such as albumin, which is commonly used to block surfaces because it greatly reduces most cell adhesion. The results for this surface are compared to a control surface that is only adsorbed with albumin. Under these conditions, any elevation in cell adhesion compared to the albumin control can be ascribed to the test protein, rather than non-specific adhesion due to direct contact with the surface.

An example of the effect of fibronectin adsorption is shown in Figure II.1.2.2, which also contrasts it with the effects of the non-adhesive protein immunoglobulin G. As shown in the figure, the adhesion of

3T3 Cell Adhesion to HEMA–EMA/Glass
FIGURE II.1.2.2 3T3 cell adhesion to HEMA–EMA copolymers varying from hydrophilic (HEMA-rich) to hydrophobic (EMA-rich): effect of no adsorbed protein, preadsorption with fibronectin (designated CIG in the figure) or preadsorption with immunoglobulin G (IgG). The data is from the author's laboratory.

the fibroblast-like 3T3 cells to a series of polymers and copolymers of 2-hydroxyethyl methacrylate (HEMA) and ethyl methacrylate (EMA) not previously adsorbed with protein (and without proteins in the cell suspension) varies, being much less on the hydrophilic polyHEMA-rich surfaces than on the hydrophobic polyEMA-rich surfaces. These data are an example of direct or non-specific cell adhesion in which the cells adhere directly to the surfaces, rather than to adsorbed proteins. The preadsorption of the surfaces with immunoglobulin G (IgG) greatly reduces the adhesion of the cells to all the surfaces, because this protein effectively blocks the non-specific adhesion of the cells to the surfaces. In the presence of IgG, the high non-specific adhesion to EMA rich surfaces cannot occur, as the cells do not have direct contact with the surfaces. In contrast, surfaces preadsorbed with fibronectin (designated CIG in the figure) are much more adhesive than the same surface adsorbed with IgG. After fibronectin coating, even surfaces rich in HEMA that are not adhesive become adhesive, as the cells now interact not with HEMA, but with the adhesive protein.

Preadsorption of adhesion proteins also affects cell interactions with surfaces studied under *in vivo* conditions. For example, blood platelet deposition onto polymeric arteriovenous shunts in dogs is greatly increased when fibrinogen or fibronectin are preadsorbed to the surfaces in comparison to albumin coated surfaces (see Chapters II.2.6 and II.3.5).

Depletion Studies

Although adsorption of purified adhesion proteins to a surface is one way to see their effect on cell adhesion, as presented in the section "The Effects of Preadsorption with Purified Adhesion Proteins," it does not mimic

very well what occurs with implanted biomaterials. This is because implants are exposed to complex mixtures of proteins such as plasma or serum, so the adhesion protein must compete with many others for adsorption to the biomaterial. Under those conditions, a given adhesion protein present in the bulk phase protein mixture may really play little or no role. It is possible that very little of the adhesion protein may adsorb to the surface, as it is "out-competed" by other proteins for the limited surface sites. Thus, a more biologically relevant way to understand the role of an adhesion protein in reactions to implants is to study the effect of their selective depletion from the complex mixture. The observations presented in this section, and the articles they are based on, are presented in greater detail in a review article (Horbett, 1999).

Selective depletion means that only one of the proteins is removed from the mixture at a time, either by immunoadsorption chromatography, by use of plasma from mutant individuals lacking the adhesion protein of interest, or by selective enzymatic degradation. Thus, the more important role of adsorbed vitronectin, as opposed to fibronectin, in mediating attachment and spreading of cells on many surfaces has emerged from immunoadsorption studies. Several studies illustrate the important role that adsorbed fibrinogen plays in the adhesion of platelets, neutrophils, and macrophages.

The effects of removal of fibronectin or vitronectin or both proteins from serum on the adhesion of endothelial cells depend on surface chemistry. On tissue culture polystyrene (TCPS) fibronectin removal has little effect, while vitronectin removal greatly reduces adhesion. The results clearly show the primary role of adsorbed vitronectin in supporting endothelial cell adhesion to TCPS. In contrast, adhesion to a surface modified by ammonia in a glow discharge (see Chapter I.2.12) requires fibronectin, since removal of that protein greatly reduces adhesion to this surface, while vitronectin removal has little effect. However, the results for TCPS are more typical, i.e., on most surfaces studied by this method it appears that vitronectin, not fibronectin, is the primary agent responsible for cell adhesion.

Platelet adhesion to surfaces preadsorbed with plasma deficient in fibrinogen is much less than to the same surface preadsorbed with normal plasma, as illustrated in Figure II.1.2.3. Most of the adhesion supporting activity can be restored to fibrinogen deficient plasma by addition of exogenous fibrinogen at concentrations well below that in normal plasma. Platelets are very sensitive to fibrinogen as they adhere to some surfaces at fibrinogen adsorption levels of only 5 ng/cm^2, in comparison with adsorption values in the range of 100–200 ng/cm^2 in the presence of normal fibrinogen concentrations. In contrast, removal of fibronectin or vitronectin or von Willebrand's factor from plasma has little effect on platelet adhesion (data not shown), even though these other plasma proteins act as adhesion proteins when adsorbed
FIGURE II.1.2.3 Platelet adhesion to Immulon I® preadsorbed with normal plasma (triangles) or afibrinogenemic plasma (squares). The solid line represents the platelet adhesion to Immulon I® preadsorbed with a series of dilutions of normal plasma, whereas the dotted line represents the platelet adhesion to Immulon I® preadsorbed with a series of dilutions of afibrinogenemic plasma. The arrow at the lower right corner indicates platelet adhesion to Immulon I® preadsorbed with 2% BSA only (BSA is bovine serum albumin). (Source: Figure 4 in Tsai and Horbett, 1999. Copyright permission received.)

as single proteins to surfaces. It appears that too little of these other proteins adsorb from plasma to make much difference, i.e., competition from fibrinogen and other proteins keeps their surface concentration too low, and so their removal has no effect.

The apparently negligible role of von Willebrand's factor in platelet adhesion discussed above only applies when platelet adhesion from static suspensions is measured. At higher wall shear rates (e.g., $500 \; sec^{-1}$), platelet adhesion to biomaterials is highly dependent on the presence of adsorbed von Willebrand's factor. This dependence is most clearly illustrated by the effects of increasing the shear rate on platelet adhesion. On surfaces preadsorbed with normal plasma (i.e., containing von Willebrand's factor, fibrinogen, and the other proteins), platelet adhesion is much higher at higher shear rates than low shear rates, because of the enhanced transport of the platelets to the surface, i.e., the greater number of platelet–surface encounters at high shear rate allows for an increase in the number of adhesive outcomes. On surfaces preadsorbed with plasma deficient in von Willebrand's factor only, raising the shear rate not only does not result in an increase in adhesion, but the adhesion at high shear is actually lower than at low shear, exactly the opposite of what happens in the presence of von Willebrand's factor. Thus, von Willebrand's factor adsorption plays a major role in platelet adhesion at higher shear rates. The special role of von Willebrand's factor in high shear adhesion is thought to be due to the ability of the platelet receptor GPIb-IX to form and break bonds very rapidly with immobilized von Willebrand's factor, causing the platelets to roll along the surface until they are activated and

can form a permanent bond that stops the rolling. The role of von Willebrand's factor in shear-mediated adhesion was documented in several recent studies (summarized in Zhang et al., 2008). Interestingly, the adsorbed von Willebrand's factor molecule is itself subject to distortion by both mechanical and fluid shear (Siedlecki et al., 1996). That may play a role in the surface activation of von Willebrand factor by exposing platelet binding sites on the molecule.

When mice are depleted of fibrinogen by treatment with an enzyme that degrades it, the adhesion of neutrophils and macrophages to a polymer implanted in their peritoneal cavity is greatly reduced. The fibrinogen depleted animals exhibited near normal neutrophil and macrophage adhesion to the implants, if the implants are preadsorbed with fibrinogen. These studies clearly illustrate the power of the depletion method. Previously, it had been thought that either complement or IgG would be the main adhesion proteins for neutrophils and monocytes, due to the presence of receptors on these cells that bind these proteins. Instead, it appears that an integrin receptor for fibrinogen (CD11b/CD18, also known as Mac-1) plays a major role, at least during the initial or acute phase of the foreign-body response in the mouse peritoneal cavity.

Inhibition of Receptor Activity with Antibodies

Another way to show the role of adhesion proteins in cell interactions with biomaterials is to add specific inhibitors of their function. Adhesion proteins cause cell adhesion by binding to integrin receptors that specifically recognize the adhesion protein. One way to inhibit this reaction is to add an antibody that binds to the adhesion receptor or adhesion protein. Examples of these approaches are now presented.

Platelet receptor-mediated interactions appear to be the primary mechanism of platelet interaction *in vivo* with certain vascular grafts, because platelet deposition is largely inhibited by antibodies to the glycopro IIb/IIIa receptor, the major integrin on the surface of platelets. *In vitro* platelet adhesion to surfaces preadsorbed with blood plasma is also inhibited by anti-glycoprotein IIb/IIIa in a dose-dependent manner, as illustrated in Figure II.1.2.4. In this study, samples of the polyurethane Biomer were preadsorbed with plasma and then exposed to platelets in an albumin containing buffered saline suspension that had increasing amounts of the antibody. As shown in the figure, adhesion declined to very low values when high concentrations of the anti-integrin antibody were present.

There is currently much interest in the ability of biomaterials to regulate stem cell differentiation, including the role of proteins adsorbed to the biomaterials. Thus, antibodies to vitronectin and fibronectin were used to study the role of these two proteins in osteogenic

differentiation of mesenchymal stem cells on polycap-rolactone. The vitronectin antibody selectively blocked adhesion and differentiation, but the fibronectin anti-body did not, showing the importance of vitronectin-mediated adhesion in the behavior of this type of stem cell (Chastain et al., 2006). Combinatorial screening methods to find biomaterials that promote neural stem cell differentiation found a role for adsorbed fibronectin and other adhesion factors in combination with immo-bilized growth factors (Nakajima et al., 2007). A much broader combinatorial screen (3456 assays) for bio-materials conducive to human mesenchymal stem cell adhesion has also been done (Anderson et al., 2005). Modification of biomaterials with various adhesion pro-moting peptides to promote stem cell adhesion and dif-ferentiation has also come under active study, because it is thought to be a good way to "provide a microenvi-ronment where adhesive moieties are expressed in a spa-tial and temporal manner to control cellular behaviors" (Hwang et al., 2008).
FIGURE II.1.2.4 Effect of anti-IIb/IIIa antibody on platelet adhe-sion to Biomer preadsorbed with plasma. Adhesion of platelets incubated in monoclonal antibody CP-8 (monovalent Fab' fragment directed against the glycoprotein (GP) IIb/IIIa complex) to Biomer. Substrates were contacted with 1.0% plasma for 2 hours, then with washed, antibody-treated platelets for 2 hours. (From: Chinn J.A., Horbett T.A., Ratner B.D. (1991). THE ADSORPTION BEHAVIOR OF PROTEINS AT SOLID–LIQUID INTERFACES

Adsorption Transforms the Interface

Figure II.1.2.5 illustrates an experiment that is per-formed by the author to demonstrate the adsorption of proteins to surfaces. As illustrated in part (A), water droplets sprayed on the surface of an unused polysty-rene cell culture dish are easily visible because they bead up, i.e., the contact angle between the droplet and the polystyrene surface is very high due to the water repel-lent, hydrophobic nature of polystyrene (Chapter I.1.5). If a cell were placed on a polystyrene dish instead of the water droplet, it would also encounter a very non-wettable surface. Part (B) of the figure illustrates the results of spraying water droplets on the surface of a polystyrene dish that had first been exposed to a protein solution for a short time, and then rinsed extensively with water. As illustrated, no water droplets can be seen on this surface, reflecting the fact that in this case the added drop of water completely spread out over the surface of the preadsorbed dish. This happens because the water in part (B) was not able to interact with the polystyrene surface, because the surface had become coated with a layer of the hydrophilic protein adsorbate. Similarly, cells that come into contact with surfaces adsorbed with proteins do not directly "see" the substrate, but instead they interact with the intervening protein adsorbate.

Rapid Adsorption Kinetics and Irreversibility

The kinetics of adsorption of proteins to solid surfaces typically consists of a very rapid initial phase, followed by a slower phase upon approach to the steady-state value. Initially, proteins adsorb as quickly as they arrive at the largely empty surface. In this phase, adsorption is linear when plotted against $time^{1/2}$, characteristic of a diffusion-controlled process. In the later, slower phase, it is more difficult for the arriving proteins to find and fit into an empty spot on the surface.

Figure II.1.2.6 shows the time course of adsorp-tion of lysozyme on silica measured with a high speed,
FIGURE II.1.2.5 The conversion of non-wettable polystyrene surface (A) into one completely wettable by water (B) is due to the adsorption of proteins (simulated images based son actual observations).
FIGURE II.1.2.6 The adsorption kinetics of lysozyme to a silica surface as studied with ellipsometry. The adsorbed amount versus time for adsorption of lysozyme to silica followed by buffer rinsing after 1800 seconds, addition of surfactant (sodium dodecyl sulfate) after 3600 seconds, and a final rinse with buffer after 5400 seconds (open circles). Adsorption from a mixture of the protein and surfactant for 1800 seconds followed by rinsing is also included (closed circles). The experiments were carried out at 25°C in 0.01 M phosphate buffer, 0.15 M NaCl, pH 7. (Reprinted with permission from: Arnebrandt and Wahlgen, 1995. Copyright © 1995 American Chemical Society.)

automated ellipsometer capable of very rapid measurements (Arnebrant and Wahlgen, 1995). At the earliest measurement time, less than a second into the study, the adsorption has reached almost half of the steady-state value. At 2000 seconds, the protein solution was replaced with a buffer, resulting in some removal of loosely bound protein, but the adsorption stabilizes and would have remained at this value for much longer than shown, due to the tight, irreversible binding. At 4000 seconds, a solution of the detergent sodium dodecyl sulfate (SDS) was infused, leading to complete removal of the protein. Thus, this experiment illustrates the rapid adsorption of proteins. It also illustrates that most of the adsorbed protein is irreversibly bound, as indicated by the fact that washing the surface with buffer does not remove the protein. The adsorbed protein is only removed when a strong surfactant (SDS in this example) is used. All these features are characteristic of protein adsorption to solid surfaces.

Figure II.1.2.7 provides an example from modeling studies illustrating the complex array of interactions possible for a protein interacting with a surface (Agashe et al., 2005). The illustrations are for the gamma chain of fibrinogen interacting with either a CH_3 or a COOH terminated self-assembled monolayer (SAM) (Chapter I.2.12), and shows that many atoms in the protein's amino acid side chains come near the surface, and could thus contribute to bonding. These modeling studies start with high resolution protein structures, and apply molecular dynamic calculations that allow the protein molecule and its atoms to move in space, in order to find

favorable interactions with surfaces. It is found that the protein rolling over the surface eventually oriented itself with several residues near the surface, as shown.

For the CH_3-terminated SAM, the position of the protein illustrated is a stable orientation that has hydrophobic groups, namely the side chains of alanine and leucine, and the CH_2 of a lysine side chain, lying close to the surface forming hydrophobic interactions with the methyl surface. In this orientation, the hydrophilic functional groups of the protein residues remained hydrated and well separated from the surface.

For the COOH surface, the position of the molecule that is a preferred orientation is quite different than for the CH_3 surface, as comparison of the overall shapes of the molecule against the two surfaces indicates. A clearer indication of these differences is the types of amino acid side chains found near the COOH interface. As shown, the near neighbors are three lysines, a glutamine, and an arginine, providing favorable interactions with the COOH. The COOH-terminated SAM was modeled as 50% deprotonated/50% protonated to represent pH 7.4.

The Monolayer Model

The existence of a close packed monolayer of adsorbed protein is suggested by studies with single protein solutions, in which a saturation effect can often be observed in the adsorption isotherm (Figure II.1.2.8). Adsorption to surfaces exposed to different concentrations of protein until steady-state adsorption is achieved (2 hours or more) increases steeply at low bulk phase concentrations, but typically reaches a plateau or saturation value at higher bulk concentrations. This behavior is called a Langmuir isotherm, and has the form shown in the following equation:

$$\theta = \frac{[P]}{K_D + [P]}$$

where θ is the fractional occupancy of the surface (with a range of 0 to 1), i.e., Γ/Γ_{max} where Γ is the adsorption of a particular bulk protein concentration ($[P]$) and Γ_{max} is the maximum adsorption in the saturation or plateau region. The constant K_D is the dissociation constant for the protein–surface interaction:

$$P + S \rightleftarrows P - S$$

$$K_D = \frac{[P] \cdot [S]}{[P - S]}$$

where S is an absorption site on the surface.

Despite the fact that protein adsorption to biomaterials is an irreversible process, the concentration dependence of adsorption for pure protein solutions often follows the Langmuir isotherm that is only applicable for reversible adsorption processes such as gas adsorption. One explanation for this is that the space occupied per protein molecule in a close packed layer
FIGURE II.1.2.7 Molecular interactions of the 30 kDa C-terminus γ-chain fragment of fibrinogen with self-assembled monolayers with terminal CH₃ (left) and COOH (right) groups. Spacefill and wireframe models were newly created by R. Latour from the trajectory data for simulations described by Agashe et al., (2005). The models for the CH₃ surface show the interactions of the side chains of two alanines residues (A), one leucine (L), and the CH₂ groups of a lysine residue (K). The models for the COOH surface show the interactions of the side chains of three lysines (K), a glutamine (Q), and an arginine (R). Color code: Green = C; Red = O; Blue = N; White = H; Yellow = S. For clarity, interactions not easily seen in the full molecule views are not labeled.

(its "footprint") varies depending on the adsorption conditions. Thus, at low concentrations, the proteins have time to molecularly spread onto the surface and form a larger footprint, i.e., a packed layer of more spread protein molecules is formed. In contrast, when adsorption is done at higher concentrations, the adjacent sites are rapidly filled with other proteins, and so the spreading of each molecule into these sites on the surface is inhibited. In this case, a packed layer of protein is also formed, but the molecules are less spread so that there can be more of them per unit area than when adsorption occurs at lower concentration (Wertz and Santore, 2001). Support for the existence of variations in molecular spreading and protein footprints is provided by the fact that proteins adsorbed at lower concentrations tend to be more tightly bound, as judged by lower desorption upon exposure to buffer or other proteins or detergents.

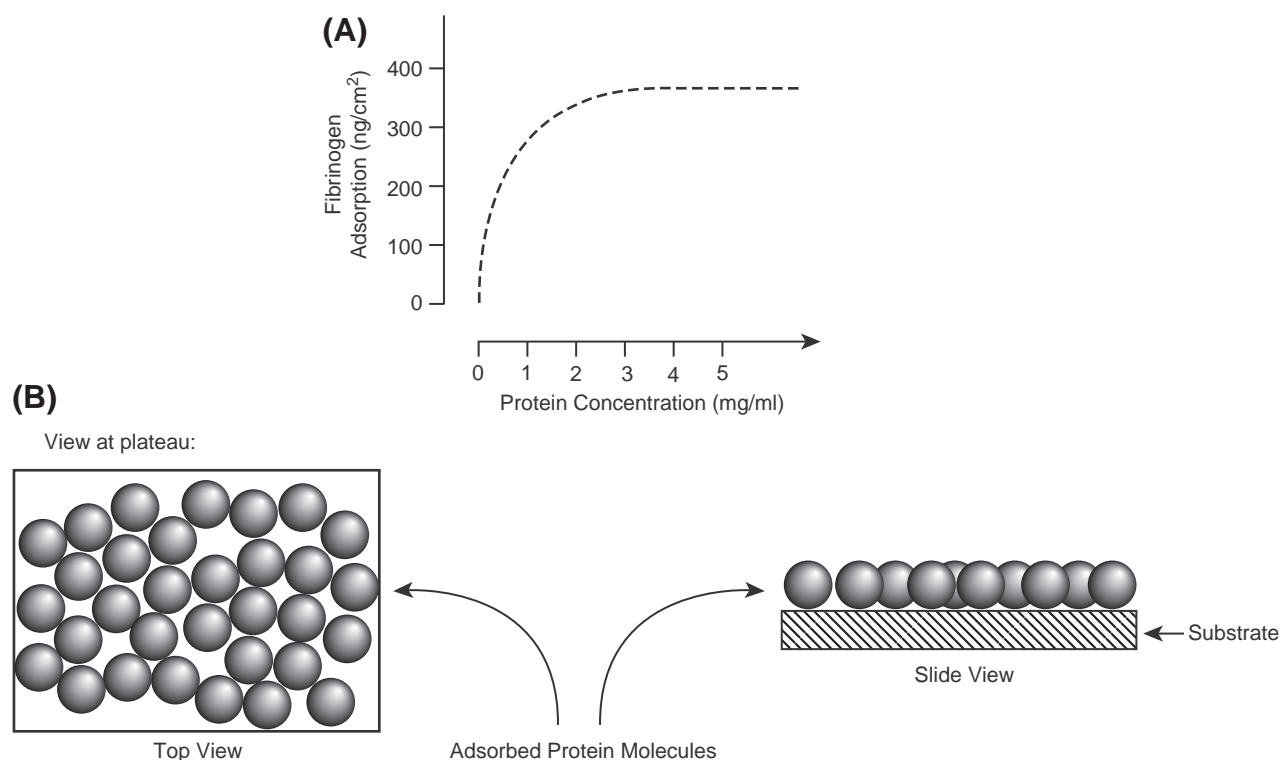
Usually, the plateau adsorption value observed in measured adsorption isotherms falls within the range expected for a close-packed monolayer of protein (about 0.1–0.5 μg /cm², depending on the diameter and orientation assumed for the protein). The adsorption values from complex protein mixtures are also typically in the monolayer range. For example, the sum total of the amount of adsorption of the three major proteins in plasma (albumin, IgG, and fibrinogen) on the HEMA-EMA series of surfaces is also in the range 0.1–0.5 μg/cm². In addition, the fact that competition exists between proteins for adsorption to a surface (see section


FIGURE II.1.2.8 Adsorption isotherms (A) and the monolayer concept (B).

"Competitive Adsorption of Proteins to Surfaces from Protein Mixtures," below) also indicates the existence of limited sites. Thus, when a monolayer is the limit, there must be some selection for which proteins are present in the adsorbed film. It should be noted that well-defined plateaus are not always observed, but instead adsorption rises much more slowly at higher bulk phase concentrations than at low concentrations, i.e., Freundlich isotherms do occur.

Competitive Adsorption of Proteins to Surfaces from Protein Mixtures

Adsorption from mixtures of proteins is selective, leading to enrichment of the surface phase in certain proteins. In this context, enrichment means that the fraction of the total mass of the adsorbed protein layer corresponding to a given protein is often much higher than the fraction of this protein in the bulk phase mixture from which it adsorbed. Since the solid can accommodate only a small fraction of the total protein present in the bulk phase, and proteins vary greatly in their affinity for surfaces, some adsorbed proteins are present in greater amounts than others. Studies of surfaces exposed to plasma have shown that many different proteins are present in the adsorbed film.

The competitive phenomena underlying differential enrichment from multi-protein mixtures are most clearly illustrated in binary mixtures of proteins. Figure II.1.2.9 has three separate curves in it, which overlap at the high and low ends. These curves represent the typical outcome
FIGURE II.1.2.9 Competitive adsorption of two proteins from a mixture. (From: Horbett, 1993.)

of binary mixture studies, but for three different conditions. For example, when a radiolabeled protein such as fibrinogen ("A" in the figure) is mixed with various amounts of an unlabeled protein such as albumin ("B" in the figure), the adsorption of fibrinogen ("A") always declines when sufficiently high amounts of albumin ("B") are present. However, the amount of competing protein needed to inhibit the adsorption of the labeled protein is different in each curve. This is meant to illustrate that, for a given pair of competing proteins, the competition curves will be different if the surfaces they are competing for are different. In addition, if the surfaces are kept the same, but the competition of different pairs of proteins are studied, the curves will differ because the ability of proteins to compete for surface sites is quite different for different proteins. A convenient way to characterize
FIGURE II.1.2.10 Differential affinity of proteins to a series of polymers: adsorption of Fg (green line); IgG (purple line); Alb (red line); and Hb (blue line) from plasma to hydroxyethyl methacrylate – ethyl methacrylate copolymers. (Redrawn version of a figure from: Horbett, 1981.)

these binary competition curves is the ratio of competing protein it takes to cause 50% inhibition of the adsorption of the labeled protein. If this ratio is 1, it reflects the fact that the proteins are equal in affinity for the surface; if the ratio is much less (or much greater) than one, it signifies that much less (or much more) of the competing protein is needed to reduce the adsorption, and so the competitor has a much higher (or much lower) affinity for the surface.

For example, inhibition of fibrinogen adsorption to polyethylene requires roughly 10-fold excess by weight of lower affinity competing proteins such as albumin, but is effectively inhibited by the higher affinity protein hemoglobin, even when hemoglobin is present at only 10% of the mass of fibrinogen. However, the amounts needed for this inhibition will depend on the surface chemistry, because the affinity of proteins changes with surface chemistry. Affinity variation is thus a major principle determining the outcome of the competitive adsorption processes.

An experimental example of surface chemistry-dependent selective adsorption of proteins from a complex protein mixture is shown in Figure II.1.2.10. In these studies, a radiolabeled protein (e.g., 125I-fibrinogen) added to blood plasma enabled measurement of the protein's adsorption to a series of polymers and copolymers of 2-hydroxyethyl methacrylate (HEMA) and ethyl methacrylate (EMA). This series varies greatly in its surface properties, from water swollen hydrophilic HEMA to water repelling hydrophobic EMA. The studies were repeated four times, once each with 125I labeled fibrinogen, albumin, IgG or hemoglobin. The dependence of the adsorption of each protein on the changes in surface chemistry in this series is different for each protein, as reflected in the very different shape of lines for each protein. For example, albumin displayed preferential adsorption to both HEMA and EMA, in that adsorption to these polymers was much greater than to any of the HEMA–EMA copolymers. Conversely, fibrinogen adsorption was maximal at intermediate HEMA–EMA

compositions. Another behavior is shown by the adsorption of hemoglobin and IgG, both of which display maximal adsorption to EMA, with minimal adsorption on surfaces made with about 20% EMA. Another way to look at this data is to consider that the very different trends in adsorption across the series for each protein means that the relative amount of each protein is unique to each surface, and varies quite a bit among the surfaces. On HEMA, the adsorption is seen to be in the order albumin>hemoglobin>fibrinogen>IgG, while on EMA the order is quite different: IgG, hemoglobin, and albumin are all about the same, but much greater than fibrinogen adsorption. On the 50–50 HEMA–EMA copolymer, the order is also different: fibrinogen and hemoglobin adsorption are about the same, but much greater than albumin or IgG. Examination of the amounts of adsorption for each protein on each surface shows that the overall composition of the adsorbed layer is different on each and every polymer in the series. The differences seen in these studies are typical for many other polymers that have been studied. Namely, the relative enrichment of a given protein when adsorbed from a complex mixture such as plasma is unique to each polymer studied. The effect of surface chemistry in causing differences in the relative enrichment of proteins adsorbed from the complex mixture of proteins in plasma is due to differences in the relative competitive affinity of the proteins for each surface that were discussed above in regard to binary competitive adsorption studies.

Other examples of surface enrichment from complex protein mixtures are readily available. The examples presented in this paragraph emphasize protein affinity differences, in contrast to the surface affinity examples presented in the previous paragraph. Although fibrinogen is only the third most concentrated protein in plasma, after IgG and albumin, biomaterials exposed to plasma are enriched in fibrinogen in the adsorbed phase. Hemoglobin is present in very low concentrations in plasma (0.01 mg/mL or less), but it is still adsorbed in amounts similar to the more predominant proteins because of its high surface affinity. Albumin, a lower affinity protein, presents a counter example. Albumin concentration in plasma is much higher than fibrinogen, yet the surface concentration of albumin adsorbed from plasma is typically about the same as fibrinogen. The high concentration of albumin in the plasma drives it onto the surface according to the law of mass action. Similarly, fibrinogen adsorption is higher from plasmas that contain higher concentrations of fibrinogen. Thus, mass concentration in the bulk phase is the second major factor determining competitive adsorption behavior.

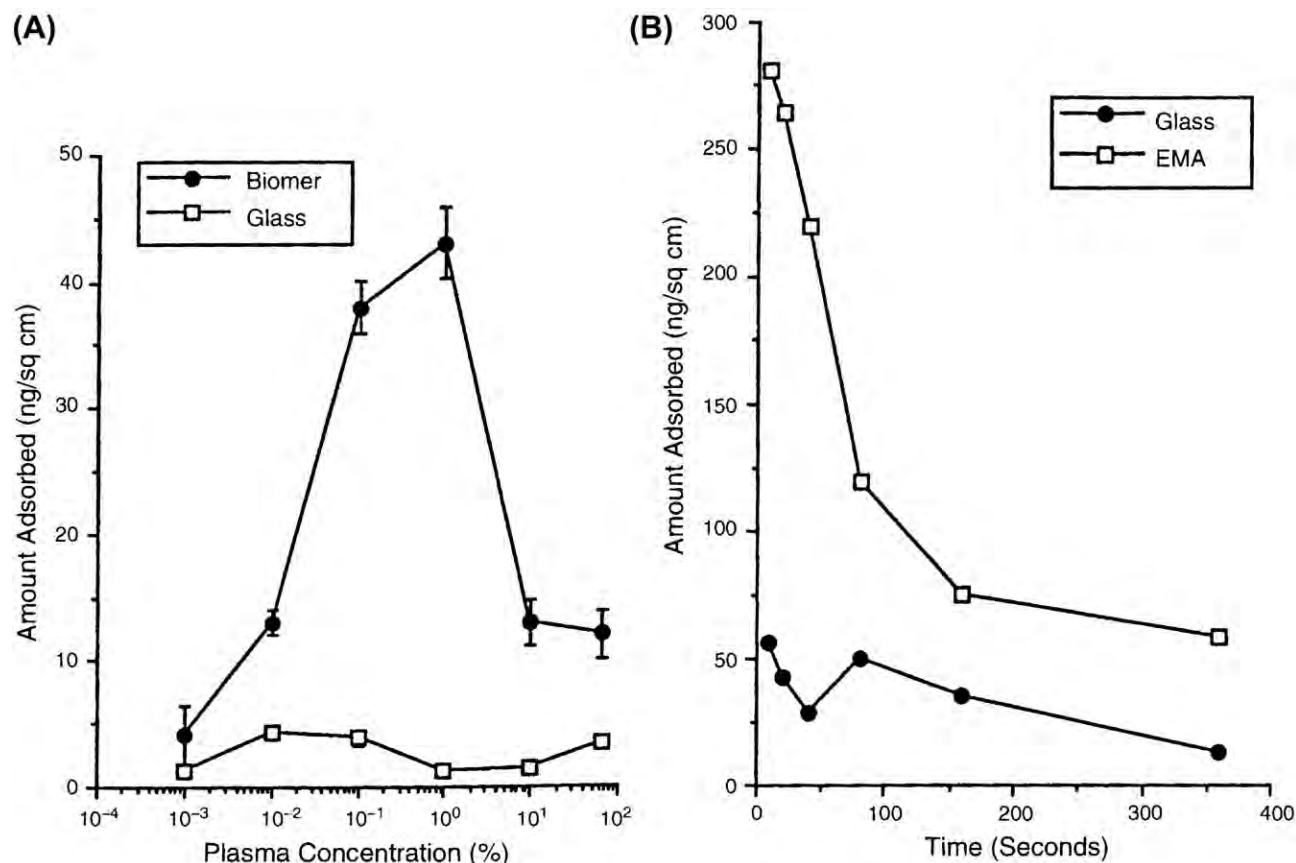
The adsorption of fibrinogen from plasma exhibits some unusual behavior. On some surfaces, fibrinogen adsorption is maximal at intermediate dilutions of plasma (see example in Figure II.1.2.11A). In addition, fibrinogen adsorption from full-strength or moderately diluted plasma is higher at very early adsorption times than at


FIGURE II.1.2.11 The Vroman effect: (A) fibrinogen adsorption to Biomer and glass from various concentrations of blood plasma; (B) time course of fibrinogen adsorption to glass and poly(ethyl methacrylate) (PEMA) from undiluted plasma. (Reprinted with permission from Slack and Horbett, 1995. Copyright © 1995 American Chemical Society.)

later times (example shown in Figure II.1.2.11B). These are examples of the Vroman effect for fibrinogen. This phenomenon is a clear example of the unique effects of competitive adsorption on both the steady-state and the transient composition of the adsorbed layer that forms from plasma. The Vroman effect appears to involve displacement of initially adsorbed fibrinogen by later arriving, more surface-active plasma proteins, especially high molecular weight kininogen, and transitions in the adsorbed fibrinogen which make it less displaceable with adsorption time (reviewed in Slack and Horbett, 1995). Vroman effects, i.e., peaks in adsorption at intermediate dilution, are also observed for fibronectin adsorption from serum, and even for binary protein mixtures under certain conditions.

MOLECULAR SPREADING EVENTS: CONFORMATIONAL AND BIOLOGICAL CHANGES IN ADSORBED PROTEINS

Proteins that adsorb to solid surfaces can undergo conformational changes, because of the relatively low structural stability of proteins and the tendency to unfold to allow further bond formation with the surface. Conformational changes can be detected with many types of

physicochemical methods, and also by measuring changes in the biological activity of the adsorbed proteins.

Physicochemical Studies of Conformational Changes

"Soft" proteins are found to adsorb more readily and more tenaciously than "hard" proteins. In this context, a "soft" protein is one with a low thermodynamic stability, while a "hard" protein is more stable to unfolding in solution in response to denaturing conditions, such as elevated temperature. This concept and the articles supporting the following discussion are presented in detail elsewhere (Horbett and Brash, 1995).

Comparison of the adsorptive behavior of different proteins to their molecular properties indicates that less stable proteins are more adsorptive. The important role of structural stability in adsorption is also supported by recent studies with engineered mutant proteins with single amino acid substitutions that vary in stability. Lysozyme adsorption at the solid–liquid interface, and tryptophan synthase occupation of the air–water interface are greater for less stable mutants, and more stable lysozyme variants tend to be displaced by less stable mutants (Lee et al., 2004).

Several studies with differential scanning calorimetry (DSC) methods seemed to indicate that adsorbed proteins may lose much of their structure, depending on how "soft" they are. Heat is taken up at a certain elevated temperature for proteins in solution, due to unfolding of the native protein at the transition temperature. An absence or reduction of this effect for an adsorbed protein suggests that the adsorbed protein has already undergone the transition, i.e., that it has already unfolded upon adsorption. The transition enthalpy of lysozyme adsorbed to negatively charged polystyrene was much less than for the protein in solution (0–170 kJ/mol for the adsorbed protein versus about 600 kJ/mol for the native protein depending on the pH). However, for lysozyme adsorbed on hematite, the unfolding enthalpy is only about 20% less than for the native protein, indicating that changes in the enthalpy of unfolding depend on the adsorbing surface. Furthermore, for lactalbumin the heat released is nearly zero when adsorbed on either the polystyrene or the hematite surface, suggesting complete unfolding of lactalbumin on both surfaces. These observations are consistent with the lower stability of lactalbumin in comparison to lysozyme. Several proteins adsorbed to pyrolytic carbon do not show any release of heat at the expected transition temperature, suggesting that pyrolytic carbon induces complete unfolding; a result that is consistent with the tenacious binding of proteins to this surface. It has also been shown that albumin and lysozyme adsorbed to polystyrene exhibit no unfolding enthalpy, while lysozyme adsorbed to a hydrophilic contact lens still exhibits about 50% of the heat released by the native protein. Streptavidin adsorbed to polystyrene displays an unfolding enthalpy that is very similar to that for the native protein in solution, probably because of the greater stability of streptavidin in comparison to lysozyme or albumin.

However, more recent studies of adsorbed proteins by the DSC method in conjunction with other, more direct conformational measurements such as circular dichroism (CD), show that at least some adsorbed proteins that appear to be completely denatured, as judged by DSC, still have considerable amounts of their native structure, as measured by CD. It thus appears that some proteins become somewhat more stable after adsorption, and thus do not show heat release at the normal melting temperature.

The concept of molecular spreading of the adsorbed protein suggested by these observations has been used to explain differences in the amount of IgG adsorbed during stepwise adsorption. When the final concentration of bulk protein is achieved in a series of smaller concentration steps, as opposed to bringing the bulk concentration to its final value in one step, adsorption is smaller. This result is thought to be due to spreading and an enlarged footprint of a protein molecule that can occur at lower bulk concentrations, and is similar to the explanation of Langmuir isotherms given earlier. Conformational

changes upon adsorption of fibronectin to polystyrene beads and Cytodex® microcarrier beads have been detected using electron spin resonance spectroscopy. Many other physicochemical studies are consistent with partial unfolding of the adsorbed proteins (Andrade, 1985; Lundstrom, 1985; Horbett and Brash, 1995).

Changes in Biological Properties of Adsorbed Proteins

While physicochemical studies sometimes suggest complete denaturation of adsorbed proteins, most probes for biological activity suggest the changes are more limited (reviewed with citations in Horbett, 1993). Thus, enzymes retain at least some of their activity in the adsorbed state, especially when the surfaces are more fully loaded with enzyme. Measurements of enzyme activity or retention times during passage over hydrophobic chromatography matrices have shown that the degree of denaturation is highly dependent on the protein, the length of time the protein has spent on the matrix, the solvent, and other conditions, and is not necessarily complete.

Changes in the binding of a monoclonal antibody to fragment D of fibrinogen upon fibrinogen adsorption to polystyrene have been attributed to changes in the conformation of fibrinogen after adsorption. Thus, solution-phase fibrinogen does not bind the antibody raised to fragment D, but the surface-adsorbed fibrinogen does. Furthermore, bulk fibrinogen does not compete for the binding of the antibody to the surface-adsorbed fibrinogen. The RIBS (receptor-induced binding site) antibodies are similar: they bind to fibrinogen only after the fibrinogen has bound to either a solid surface or to the platelet IIb/IIIa receptor. The binding of the RIBS antibodies and others that bind to the platelet binding regions of fibrinogen varies with the length of time after adsorption of the fibrinogen. Platelet adhesion to polymethacrylates has been correlated with the amount of antifibrinogen binding, suggesting that the adsorbed fibrinogen is in different conformations on the various polymethacrylates.

Fibrinogen undergoes a time-dependent transition after its adsorption to a surface that results in reduced platelet and antibody binding to the adsorbed fibrinogen, as well as reduction in the SDS and plasma displaceability, and changes in amide II frequency of the adsorbed fibrinogen. The losses in platelet binding, antibody binding, and SDS elutability are prevented if albumin is included in the storage buffer. An example showing time dependent losses in antibody binding to fibrinogen and its prevention by albumin is shown in Figure II.1.2.12. Vitronectin also appears to undergo conformational changes upon adsorption that affect its ability to bind heparin and its infrared spectra.

Modulation of the biologic activity of fibronectin has been shown in several studies in which the ability of fibronectin adsorbed to various surfaces to support cell attachment or spreading was found to differ. For
FIGURE II.1.2.12 Transitions in adsorbed fibrinogen. The effect of three-day residence in buffer or buffered albumin solution upon anti-fibrinogen binding to fibrinogen adsorbed from dilute plasma to Biomer polyurethane is shown. BSA: bovine serum albumin. (From: Fig. 3A in Chinn et al., 1992.)

example, fibronectin adsorbed to tissue culture grade polystyrene was able to support cell attachment and spreading, whereas fibronectin adsorbed to ordinary polystyrene does not support spreading very well, unless some albumin is added to the fibronectin solution. Fibronectin adsorbed to self-assembled monolayer (SAM) films with various functional end groups also varies in its ability to interact with cells. On hydrophobic SAMs there is poor cell spreading unless albumin is coadsorbed (albumin "rescuing"). The albumin "rescuing" phenomenon observed for SAMs is similar to the albumin effect on fibronectin's ability to promote cell spreading on polystyrene, and to the effect of albumin addition in preventing losses in platelet adhesion to fibrinogen adsorbed surfaces discussed above. The ability of fibronectin adsorbed to a series of polymers to support the outgrowth of corneal epithelial cells has also been found to vary a great deal, despite the presence of similar amounts of fibronectin on the surfaces.

The effect of albumin addition in enhancing the adhesivity of fibronectin-coated surfaces is opposite to what one might expect, because the added albumin should reduce the amount of adsorbed fibronectin as albumin competes for sites on the surfaces. The explanation for the albumin effect is thought to be that by adsorbing along with the fibronectin to the surface, the albumin molecules occupy surface sites near the fibronectin molecules. The adsorbed albumin molecules thus keep the adsorbed fibronectin molecules from undergoing structural changes that they would otherwise do in trying to spread into formerly empty surface sites, but they cannot do so if albumin molecules fill those sites.

Highly uniform SAM surfaces with different terminal functional groups have proved useful in showing how surface chemistry modulates the biologic properties of adsorbed fibronectin. When increasing amounts of fibronectin were adsorbed to SAMs with terminal OH, COOH, NH_2 or CH_3 functional groups, it was found that

the amount of adsorbed fibronectin required to cause cell adhesion varied widely. Thus, on the CH_3 surface it took far higher amounts of fibronectin to obtain equivalent maximal adhesion than on the OH surfaces (Keselowsky et al., 2003). Similarly, the binding affinity of antibodies that bind to the cell binding domain and of the integrin $\alpha_5\beta_1$ was much higher for fibronectin on the OH surface than on the CH_3 surface. Thus, there are significant differences in the functional presentation of the central cell-binding domain of fibronectin upon adsorption to different surface chemistries. The theoretical predictions of differences in preferred orientation of adsorbed molecules on surfaces with different chemistry (see Figure II.1.2.7) suggest that these biological effects are also due to orientational effects. With an osteogenic cell line, genes that mark osteoblastic differentiation and actual mineralization were both elevated in the cells on the fibronectin-coated OH and NH_2 surfaces compared with the COOH and CH_3 SAMs (Keselowsky et al., 2005). Myoblast differentiation on fibronectin adsorbed to this same series of SAMs also varied greatly, in the order OH> CH_3> NH_2 = COOH (Lan et al., 2005). The ability of myoblasts to rearrange adsorbed fibronectin and deposit new fibronectin was also much greater on the CH_3 surface than on the OH surface.

Figure II.1.2.13 shows an experimental example of the modulation of the biologic activity of adsorbed fibrinogen, namely its ability to mediate platelet adhesion. In these studies, both fibrinogen adsorption and binding of a fibrinogen specific antibody were measured from plasma diluted to various degrees on a series of chemically modified polystyrene surfaces. Platelet adhesion to the plasma preadsorbed surfaces was also measured. The left part of Figure II.1.2.13 shows that there was no obvious correlation between platelet adhesion and fibrinogen adsorption, despite the fact that we know that fibrinogen adsorption is required for adhesion, as shown in Figure II.1.2.3. However, when the availability of the platelet binding region in fibrinogen adsorbed to these surfaces was measured using a monoclonal antibody (M1) that binds to the C-terminal region of the gamma chain of fibrinogen, it was found to vary greatly. Platelet adhesion was well correlated with the antibody binding, as shown in the right panel in Figure II.1.2.13. The poor correlation with total fibrinogen adsorption, and the greatly improved correlation with platelet binding site availability, is strong support for the idea that the functional activity of adsorbed fibrinogen in supporting platelet adhesion depends on the surface to which it is adsorbed. Thus, fibrinogen's bioadhesive activity is modulated by the surface chemistry.

The studies with platelets, fibroblasts, epithelial cells, osteocytic cells, and myoblasts show that substrate properties somehow modulate the ability of adsorbed proteins to interact with cells. These differences may arise, at least in part, from differences in the availability of epitopes on adhesive proteins for the cell surface receptor. That
FIGURE II.1.2.13 Cross plots of platelet adhesion against the amount of fibrinogen (FGN) adsorption or M1 antibody binding on five different surfaces. (From: Tsai et al., 2003.)

is, both the amount of the adsorbed adhesive protein, as well as its "bioreactivity," are actively influenced by the properties of the surface to which it is adsorbed.

THE IMPORTANCE OF ADSORBED PROTEINS IN BIOMATERIALS

Table II.1.2.1 summarizes the principles underlying the influence of adsorbed proteins in biomaterials used in contact with the blood. All of the principles listed also apply in other environments, such as the extravascular spaces, albeit with other proteins and other cell types (e.g., macrophages in the peritoneum adhere via other receptors and other adhesion proteins). The blood platelets therefore provide a "case study," and we close this chapter by considering this case.

The high sensitivity of platelet–surface interactions to adsorbed proteins is fundamentally due to the presence of adhesion receptors in the platelet membrane that bind to certain plasma proteins. There are only a few types of proteins in plasma that are bound by the adhesion receptors. The selective adsorption of these proteins to synthetic surfaces, in competition with the many nonadhesive proteins that also tend to adsorb, is thought to mediate platelet adhesion to these surfaces, which in turn leads to platelet activation events such as their ability to catalyze the formation of thrombin. However, since the dissolved plasma-phase adhesion proteins do not bind to adhesion receptors unless the platelets are appropriately stimulated, while unstimulated platelets can adhere to adsorbed adhesion proteins, it appears that adsorption of proteins to surfaces accentuates and modulates the adhesion receptor–adhesion protein interaction. The type of surface to which the adhesion protein is adsorbed affects the ability of the protein to support platelet adhesion, due to variations in the amount of adsorbed fibrinogen (Horbett, 1993), and in the availability of the platelet binding regions in the fibrinogen molecule (Tsai et al., 2003). The principles that determine protein

TABLE II.1.2.1	**Principles Underlying the Influence of Adsorbed Plasma Proteins on Blood Platelet Interactions with Biomaterials**

1. Synthetic foreign materials acquire bioreactivity only after first interacting with dissolved proteins. The principal means by which the transformation from an inert, nonthrombogenic polymer to a biologically active surface takes place is the interaction of the proteins with the surface that then mediates cell adhesion.
2. Platelets are an important example of why and how adsorbed proteins are influential in cell–biomaterials interactions.
3. Sensitivity of platelets to adsorbed proteins is due to:
   a. Some proteins in plasma are strongly adhesive for platelets: fibrinogen, fibronectin, vitronectin, and von Willebrand factor.
   b. Concentrating, localizing, immobilizing effects of adsorbing the proteins at the interface accentuates the receptor–adhesion protein interaction.
   c. Platelets have receptors (IIb/IIIa and Ib/IX) that bind specifically to a few of the plasma proteins, mediating adhesion.
4. Principles of protein adsorption to biomaterials:
   a. Monolayer adsorption and consequent competition for available adsorption sites means that not all proteins in the plasma phase can be equally represented on the surface.
   b. Driving forces for adsorption are the intrinsic surface activity and bulk phase concentration of the proteins.
   c. Surfaces vary in selectivity of adsorption.
   d. Biological activity of the adsorbed protein varies on different surfaces.

adsorption to biomaterials include monolayer adsorption, the intrinsic surface activity and bulk concentration of the protein, and the effect of different surfaces on the selectivity of adsorption and biologic activity of the adsorbed protein.

More generally, all proteins are known to have an inherent tendency to deposit very rapidly on surfaces as a tightly bound adsorbate that strongly influences subsequent interactions of many different types of cells with the surfaces. It is therefore thought that the particular

properties of surfaces, as well as the specific properties of individual proteins, together determine the organization of the adsorbed protein layer, and that the nature of this layer in turn determines the cellular response to the adsorbed surfaces.

The importance of adsorbed proteins in biomaterials science is also well-illustrated by the amount of effort that has been expended to develop protein "non-fouling" or protein repellent materials in recent years (see Chapter I.2.10 and Horbett, 2003). Since fibrinogen adsorption is required for platelet adhesion, an obvious approach to improve blood compatibility is to produce biomaterials that reduce fibrinogen adsorption, and thus much recent research has focused on finding protein repellent materials. For example, many studies show that fibrinogen adsorption can be reduced with poly(ethylene oxide) (PEO) coatings of various types (e.g., PEO/polylactide copolymers, PEO grafted polyurethanes (PUs), PEO grafted PU/polystyrene, ethylene glycol terminated SAMs or glow discharge deposited polymers of the low molecular weight polyether tetraglyme to make PEO-like coatings), and that platelet adhesion is reduced, both *in vitro* and *in vivo*. However, since even low amounts of adsorbed fibrinogen (ca. 5 ng/cm^2; Tsai and Horbett, 1999) are sufficient to support nearly full-scale platelet adhesion, and many of the surfaces tested fail to reduce fibrinogen adsorption to that degree, it has proved difficult to make biomaterials that fully achieve this design criterion.

INTRODUCTION

There is no doubt that *in vitro* methods have been and will continue to be of great value to the progression of medical science. The culture of mammalian cells and the study of their behavior *in vitro* has led to new understandings of cell physiology (Neher and Sakmann, 1976), molecular biology (Mello, 2007), and many disease processes (Schwarz et al., 1985). In many experimental settings, the ability to extract and grow cells from host tissues is a powerful tool since experimental question(s) can be evaluated under standardized conditions without the many complicating influences from the host physiology.

As science has progressed, new *in vitro* techniques have developed beyond the culture of cells in glass or plastic dishes. Cell–substrate interactions are of particular interest since cells interact physically with the extracellular matrix (ECM) and often modify it in response to various stimuli. As a result, efforts to examine and recapitulate the *in vivo* environment *in vitro* often require modification of the cell culture substrates. Cell–substrate interactions at the micro- and nanoscales have been facilitated by new techniques, applications, and approaches that have emerged from the combination of engineering and biology. In practice, the chemistry, topography, and elasticity of the culture surface may be altered, and mechanical forces can also be applied to cells by physical deformation of the culture substrate.

With respect to tissue engineering and organ regeneration, advances in our understanding of cell–substrate interactions are essential to controlling cell behavior. For example, the ability to pattern cells with micron scale precision on a variety of substrates presents new opportunities to study and recreate cell–cell interactions required to generate functional tissues *in vitro* for subsequent implantation *in vivo*. This is of primary importance, since organs contain multiple cell types that are precisely arranged in close proximity to form complex structures.

This chapter provides a basic understanding of *in vitro* principles, beginning with a fundamental overview of the culture of cells and their interactions with surfaces. We then describe a number of techniques employed to manipulate the *in vitro* environment at the micro- and nanoscale and then discuss how these fundamental techniques can be applied to investigate and influence cell behavior.

A BASIC OVERVIEW OF CELL CULTURE

Tissue culture is a general term for the harvest of cells, tissues or organs, and their subsequent growth or maintenance in an artificial environment. Mammalian cells cultured *in vitro* have the same basic requirements as cells growing within an organism. Specialized approaches have been developed to replace a number of mammalian systems essential for life. *In vitro*, blood is replaced by the culture media, which bathes the cells and provides an energy source (glucose), essential nutrients (salts and amino acids), proteins and hormones (from added serum), and a buffer (to maintain pH balance). During culture, the byproducts of cellular metabolism are released into the media as its constituents are depleted. Since the culture media is not continually circulated and purified, it must be changed regularly to maintain optimal conditions for cell function. Not surprisingly, these culture conditions are also favorable for the growth of unwanted organisms such as fungi and bacteria. Since there is no immune system to control infection *in vitro*, anti-fungal and anti-bacterial agents can be added to the media on a prophylactic basis. To further reduce the likelihood of contamination by microorganisms, cells are manipulated under a laminar flow hood using strict aseptic (sterile) techniques. Laminar hoods control and direct filtered air to facilitate a sterile working environment by reducing the contact of air-borne bacteria and particulates with the culture dish and hood surfaces.

Cells in media are contained in culture dishes or flasks and incubated in a temperature-controlled (37°C) and humidified (95%) chamber. While the lids of the culture dishes cover and protect the media, they are not sealed and enable gas exchange within the incubator. The exchange of gas at the media surface acts like the lungs to maintain

TABLE II.1.3.1	Examples of Some Commonly Used Cell Lines		
Cell Line	**Organism**	**Tissue of Origin**	**Further Cell Information**
3T3	Mouse	Embryonic fibroblast	Fibroblasts
AML-12	Mouse	Liver	Liver cells
HeLa	Human	Cervical cancer	Epithelium (first cell line reported)
HUVEC	Human	Umbilical cord vein	Endothelium (stem cells)
MC3T3-E1	Mouse	Calvarial fibroblast	Differentiate to osteoblast

the gas balance necessary for metabolism. CO_2 is usually added to the incubator at a low concentration (5%). The CO_2 interacts with the bicarbonate buffer in the media to help maintain a pH of 7.0–7.4. Buffering counteracts pH changes in the media as it accumulates waste from cellular activity. Phenol red is commonly added as an indicator to monitor pH, and a change in the color of the media is often a sign of poor culture conditions. Since the culture dishes are not sealed they are prone to evaporation. To reduce evaporation, and prevent a subsequent change in media concentration, a water dish (with an anti-fungal/anti-bacterial agent) is usually placed in the bottom of the incubator to maintain a high level of ambient humidity.

Primary Culture

Cells for *in vitro* work may be obtained from tissue (primary culture) or from cell lines. Cells for primary culture are obtained by surgical dissection of living tissues. Cells can be obtained by passing media through the marrow cavities of the long bones, by collecting cells that grow out from a piece of tissue (*explant culture*) or by enzymatic digestion of tissue that contains cells. Enzymatic digestion of small pieces of tissue immersed in collagenase at 37°C breaks down the surrounding ECM and releases entrapped cells (*enzymatic dissociation*). After harvest, cells may be cultured in suspension or on culture substrates. Anchorage dependent cells are plated for a few days to remove dead or unwanted (non-adherent) cell types. Cells anchored to the surface of the culture plate are "released" by adding a mixture of trypsin, a protease found in the digestive system, and ethylenediaminetetraacetic acid (EDTA). Trypsin degrades proteins, including important cell adhesion proteins (CAPs) that anchor the cell to the culture surface. Over short treatment times, trypsin is generally not harmful to cells. EDTA is a chelating agent that binds calcium and magnesium ions. EDTA increases the effectiveness of trypsin and prevents cell aggregation after release from the culture dish.

Harvested cells are often filtered to produce a suspension of single cells. The single cell suspension is counted, and portions of the initial cell population are transferred to new culture dishes for expansion. Expansion is also referred to as *sub-culturing* or *passaging* the cells. Passaging cells ensures that cells are plated at a low density so they have space around them to proliferate. Under appropriate conditions, most cells proliferate and form a monolayer on the culture surface. The point at which cells completely cover the culture surface is referred to as *confluence*. At confluence, proliferation will generally cease because cell–cell contact results in *contact inhibition*. Unlike cell lines, primary cells are often used without passaging or passaged only a few times, since passaging can result in loss of cell characteristics (phenotype).

Cell Lines

Generating primary cultures by continually harvesting and isolating cells is a time-consuming task. As a result, it is often preferable to utilize cells that are obtained from stock maintained in the laboratory. Cell lines refer to cells that can be passaged many times without loss of their phenotype. Physiologically, these cells can divide repeatedly, without shortening of their telomeres (Hayflick, 1965). Cell lines differ from other cells in that they have escaped the Hayflick limit and are *immortalized* (Hayflick, 1985). Examples of a handful of commonly used cell lines, from a large number of existing cell lines, are presented in Table II.1.3.1.

Cell lines also offer an experimental advantage. In terms of strict experimental uniformity, primary cultures may contain unwanted cell types unintentionally included during harvest. Primary cultures may also contain slight genetic variations due to genetic differences arising from the harvest of cells from different animals. Since cell lines are derived from the same cell they are all genetic clones of the parent cell.[*] As a result, experiments using cell lines can be reproduced by different laboratories using the same cell, with obvious advantages for collaboration, verification, and reproducibility.

A large number of cell lines are derived from tumors or cells that have undergone spontaneous mutation or some form of manipulation. The HeLa cell line is an example that has been in use since the early 1950s and was derived from cervical cancer cells taken from Henrietta Lacks (Scherer et al., 1953). It is helpful to recognize that while cell lines may behave similarly to normal cells, they have been obtained by repeated culture and selection (Puck and Marcus, 1955; Browne and Al-Rubeai, 2007),

---

[*] If the cell line has not been contaminated or has not undergone spontaneous genetic change.

by treating or transforming normal cells (using viruses, oncogenes, radiation, drugs or chemicals) (Prasad et al., 1994; Eiges et al., 2001; Groger et al., 2008), from transgenic mice (Connelly et al., 1989; Wu et al., 1994) or isolated from tumors (Riches et al., 2001; Yasuda et al., 2009). For example, transformed cells may present different morphologies and altered metabolisms (Priori et al., 1975; Wittelsberger et al., 1981), and often do not exhibit robust contact inhibition (Bell, 1977; Erickson, 1978). These behaviors strongly suggested that cell lines have the inherent potential to demonstrate responses that may not be typical of primary cells (Steele et al., 1991; Heckman, 2009). Therefore, when establishing new experimental protocols using cell lines it is recommended that the results of the protocol be validated with primary cells.

Cell lines can be obtained from nonprofit organizations such as the American Type Culture Collection (ATCC), the European Collection of Cell Cultures (ECACC), and the Coriell Institute for Medical Research (CIMR). The ATCC (www.atcc.org), ECACC (www.hpacultures.org.uk), and the CIMR (www.coriell.org) provide high-quality cell lines which are subject to careful testing and validation. The testing process ensures that cells provided are free of unwanted organisms such as mycoplasma or that other unwanted cell types are not present. Cell lines obtained from tissue banks are usually meticulously characterized and preserved to maintain these materials in a manner that permits reproducibility of results across time and among laboratories around the world. In some cases, cell lines can be obtained from other research laboratories; however, caution should be exercised since the possibility exists that the cell lines may be contaminated with microorganisms or unwanted cell types.

Characteristics of Cultured Cells

Cultured cells often display characteristic behaviors and growth patterns. A well-known characteristic is *contact inhibition*. In 1954, Abercrombie and Heaysman proposed that cells do not form multilayers because they do not move over or under their neighbors (Abercrombie and Heaysman, 1954). Cells exhibiting contact inhibition will preferably migrate to unoccupied areas of the culture substrate, and will not use the upper surface of a confluent cell monolayer as substrate. Contact inhibition is closely related to the cessation of cell proliferation (Timpe et al., 1978), and is one reason why most cells cultured *in vitro* produce monolayers of cells (Garrod and Steinberg, 1973). When cultured cells are in complete contact with each other, plasma membrane ruffling and cell motility are inhibited, resulting in an overall cessation of cell growth (Heckman, 2009). For this reason, cells maintained in culture are frequently replated at lower densities so that growth and proliferation may continually occur.

Detecting Cancerous Cells *In Vitro*

The phenomenon of contact inhibition has diagnostic implications for assessing the malignancy of cells (Amitani and Nakata, 1977; Abercrombie, 1979). A predominant behavior of malignant cells is uncontrolled cell growth. The natural phenomenon of contact inhibition has been used as a test to distinguish cancerous from noncancerous cells (Dehner, 1998). Interestingly, unlike normal cells, malignant cells will also proliferate in agar (a three-dimensional matrix) where no suitable binding sites for cell attachment exist (Whang-Peng et al., 1986).

Cultured cells also often display characteristic shapes that can be used as visual cues to assess the health and differentiation of a culture population. For example, pre-osteoblastic cells are fibroblastic in shape, possessing a long "drawn out" morphology. Upon subsequent differentiation into mature osteoblasts, cells display a cuboidal appearance. Dead or non-adherent cells are often spherical in shape and float in the culture media.

UNDERSTANDING CELL–SUBSTRATE INTERACTIONS

In vivo, cell–surface interactions are often explored as a means to enhance or control peri-implant tissue formation. Surface chemistry, topography, and elastic modulus (stiffness) of the substrate are all means to control and guide cell activity, and ultimately modulate tissue formation. This triad of properties is important for tissue engineering and organ regeneration where multiple cell types must be directed to form complex structures all in close proximity, and often with micron scale precision. In terms of three-dimensional scaffolds, tuning of scaffold chemistry, topography, and stiffness are all means to selectively guide cell development and differentiation within the bulk material.

Since most cells interact with a substrate (e.g., within the ECM) it is often desirable to control the interaction of cells with substrates *in vitro*. Modulation of the culture surface by fabrication of "engineered surfaces" comprised of micro- and nanosized chemical and topographical patterns or coatings have been used to investigate cell behavior such as adhesion, morphology, migration, proliferation, cell–cell communication, gene expression, production of ECM, differentiation, and responsiveness to extracellular signaling.

Surfaces for Cell Culture

It has long been established that most mammalian cells respond favorably to culture conditions that promote cell attachment. Cell attachment is often characterized by a change in cell morphology. Adherent cells possess a "flattened" appearance, often with an irregular cell shape and the extension of cellular processes (Figure II.1.3.1). Regular observation of cells *in vitro* is essential for successful

culture as cell density, state, and contamination can all be readily assessed visually. In this regard, optically clear materials are practical as they permit simple assessment of cell growth and morphology during culture, and are well suited to many histological techniques that involve staining for quantification of cell activity. Glass, once a common form of culture ware, has been replaced by tissue culture polystyrene (TCP). While TCP is most widely used as a culture substrate, other polymers such as polyvinyl-chloride, polycarbonate, and polytetrafluoroethylene have been used. Advantages of TCP are that it is inexpensive, clear, easily formed and treated to modify surface groups, and unlike glass, it can be embedded and sectioned.

Process of Cell Attachment *In Vitro*

Cell attachment is the initial step in a cascade of cell–biomaterial interactions, and is important to cellular processes such as cell guidance, proliferation, and differentiation (Ruoslahti, 1996). For many adherent cells, cell
FIGURE II.1.3.1 Scanning electron microscopy image of MC3T3-E1 cells at various stages of adherence on polished titanium substrate demonstrating changes in cell morphology during attachment. Attached cells have a flattened morphology and form intimate contact with the substrate. Detached cells are round. SEM 1800X.

proliferation can only occur on a substrate. As a result, cell–surface interactions are fundamental to understanding cell behavior, and provide an important means to control and quantify cell activity.

The process of cell attachment is largely understood (Ruoslahti and Pierschbacher, 1987; Ruoslahti and Reed, 1994; Ruoslahti, 1996; Garcia, 2005). *In vitro*, when hydrophilic surfaces like TCP are exposed to culture media containing serum, they are rapidly coated by a thin (~20 nm) layer comprised mainly of proteins (Andrade and Hlady, 1987; Kasemo and Lausmaa, 1994; Nakamura et al., 2007) that adsorb to the culture surface in a monolayer. The process of cell attachment to TCP (and many other materials) is indirect, since cells do not bind directly to TCP but instead bind to the adsorbed protein monolayer (Fredriksson et al., 1998). Cells make contact with, and anchor to, the adsorbed proteins at discrete peptide regions referred to as focal contacts (Gallant and Garcia, 2007). Cells possess heterodimeric transmembrane proteins composed of α and β subunits called *integrins*. Integrins are receptors that recognize and bind to specific anchoring proteins present on the conditioned TCP surface (Peter and Ma, 2006). The adsorbed proteins present short but specific peptide sequences (Table II.1.3.2) that are recognized by integrins as binding sites. Integrins recognize and bind to specific ligands such as fibronectin, vitronectin, collagen, and laminin. Over 18 α and 8 β receptor subunits have been identified, and these subunits combine to produce a wide variety of receptor types (Hynes, 2002). Of these combinations, the $\alpha_v\beta_3$ integrin is one of the most abundant and binds to vitronectin, fibronectin, von Willebrand factor, osteopontin, tenascin, bone sialoprotein, and thrombospondin (Hynes, 2002). A common peptide receptor for $\alpha_v\beta_3$ integrin is the RGD (arginine–glycine–aspartic acid) sequence (Ruoslahti and Pierschbacher, 1987). For the majority of cells cultured *in vitro*, fibronectin and vitronectin are important for cell attachment to TCP (Massia and Hubbell, 1991a; Steele et al., 1993).

In their capacity as adhesion receptors, integrins play an important role in controlling various steps in the

signaling pathways that regulate processes as diverse as cytoskeletal organization, cell proliferation, differentiation, apoptosis, and migration. In most cell types certain biochemical signals necessary for cell growth, function, and survival are triggered by integrins upon attachment. Without attachment, the cell eventually undergoes *apoptosis*, which is also known as programmed cell death (Ruoslahti and Reed, 1994).

Commercial and Experimental Modifications of Culture Surfaces

Polystyrene is a hydrophobic material that is not well suited to the attachment of most mammalian cells (Curtis et al., 1983). For the culture of non-adherent cells, untreated polystyrene dishes are routinely used. As previously described, most cells require modified surfaces that are suitable for protein adsorption before attachment can occur.

A variety of treatment methods have been employed to improve cell attachment and growth on the TCP surface (Table II.1.3.3). TCP treatments used to enhance cell adhesion are often proprietary and vendor specific, but some methods such as chemical treatment in sulfuric acid (Curtis et al., 1983), chemisorption (Shen and Horbett, 2001; Bain and Hoffman, 2003a), ionizing radiation (Callen et al., 1993) or exposure to plasma-based ionizing processes such as glow discharge (Amstein and Hartman, 1975; Koller et al., 1998) have been described in the literature. It is generally understood that these treatments impart a charge to the TCP surface that enhances its ability to interact with and bind specific CAPs present in the serum added to the culture media (Jacobson and Ryan, 1982; Lee et al., 1997).

It is important to recognize that the preparation of culture surfaces can have profound effects on the behavior of cultured cells (Shen and Horbett, 2001; Bain and Hoffman, 2003b). For some cell types, commercially available surfaces may be far from optimal, and identification of optimized substrates can be a laborious task, especially for cells that are difficult to culture *in vitro*. One approach has been the generation of culture surfaces comprised of mixtures of protein-adhesive and "protein-repellant" molecules or groups. Bain and Hoffman used a combination of protein adhesive diamine groups (N_2) and hydrophobic trifluoropropyl groups (F3) to generate a large number of culture surfaces by varying the ratio of monomers in a silanization bath (Bain and Hoffman, 2003a). The different surfaces produced possessed varying affinities for protein adhesion and, as a result, cell adhesion. A surprising finding of the work was that the growth and activity of insulin-secreting cells was best supported by the most hydrophobic (F3) surfaces in the study (Bain and Hoffman, 2003b).

More direct approaches to tune substrate chemistry can be achieved by anchoring specific adhesion molecules to the culture substrate. In such investigations, it is often advantageous to retain only the molecule(s) of interest, while reducing or excluding non-specific protein adhesion as might occur with cells grown in normal, serum-enriched media (Koepsel and Murphy, 2009). Self-assembled monolayers (SAMs) are a versatile and valuable tool that has been used to study protein adhesion (Prime and Whitesides, 1991; Li et al., 2007). SAMs are comprised of long alkane thiols anchored at the thiol end to the gold-coated substrate, while the other end is derivatized with small functional groups such as cell adhesion peptides or "protein-repellant" oligo(ethylene oxide) sequences. The functional groups can also be conjugated to specific proteins, such as monoclonal antibodies, or can interact with proteins in the media. SAMs can be tailored to exhibit specific amounts of protein adsorption, by controlling the composition of the monolayer (mixture of functional groups).

The control of ligand density and type provides another means to modify substrate chemistry and cell behavior. Gradients of immobilized ECM components and growth factors have also been shown to direct cell migration and shape (Liu et al., 2007; Inoue et al., 2009). Such experimental aspects can also be explored efficiently with microfluidic systems where the facile and reproducible generation of gradients utilizing small reagent volumes has been applied to the study of cell behavior *in vitro* (Du et al., 2009).

Dynamic Control of Cell Culture Surfaces

Controllable surfaces for cell culture have been generated that enable a predictable change in the adhesive or morphological characteristics of the surface. Changes in surface characteristics may be achieved by mechanical or physico-chemical methods, and the latter methods

	Radiation grafting (thermo-sensitive polymers)	(Yamato et al., 2001; Yamato et al., 2002)

are the focus of this section. A wide variety of dynamic surfaces have been fabricated from SAMs with specific functional groups that are responsive to thermal, chemical, electrical or electromagentic (UV or visible light) stimuli. Dynamic culture surfaces can be used as a means to control cell adhesion. More sophisticated applications have been used to selectively pattern surfaces to generate a culture environment with multiple cell types specifically arranged in groups in close proximity to each other.

Dynamic culture surfaces have also been used to detach cells from substrates. Cell sheets have been spontaneously detached by cooling a thermally-sensitive, radiation- or plasma-polymerized poly(N-isopropylacrylamide) (poly[NIPAAm]) polymer (Cheng et al., 2004). Okano's group in Japan has pioneered in this method, using electron beam radiation grafting of NIPAAm monomer on the surfaces of cell culture dishes. (Yamato et al., 2001, 2002) (see Table II.1.3.3). At temperatures suitable for cell culture (above 32°C) the poly[NIPAAm] surface is hydrophobic and readily adsorbs cell adhesive proteins (CAPs), leading to the growth of a cell monolayer to confluence. However, when the temperature is reduced below a critical temperature (32°C) the poly[NIPAAm] surface becomes hydrophilic, and the cell sheet detaches as a contiguous, confluent monolayer, carrying with it the CAP monolayer. Such dynamic thermal control of cell adhesion can be particularly useful for the intact removal of a sheet of cells by avoiding the use of proteolytic enzymes such as trypsin that can disrupt natural cell–cell networks and compromise cellular integrity. Cell sheets have a variety of applications in tissue engineering (Elloumi-Hannachi et al., 2010; Gauvin et al., 2010), and the Okano group has applied them clinically as monolayers of corneal cells for repairing damaged or diseased eye surfaces.

Methods that switch surfaces from cell-adhesive to non-adhesive have also been reported using photo-responsive SAMs. These approaches generally modify the presentation of CAPs making them less accessible to the cell. Upon exposure to UV light, surfaces based on a combination of azobenzene groups and RGD ligands will "hide" the RGD groups by UV-induced conversion of the azobenzene functional group from polar to non-polar character (Auernheimer et al., 2005). Exposure to UV light reduced the exposed length of the azobenzene-RGD segments, and reduced cell adhesiveness by 17%. Nitro-spiropyran and methyl methacrylate polymer coatings have also been employed as photo-responsive surfaces (Higuchi et al., 2004). Nitro-spiropyran is a photo-responsive polymer that switches from a cell adhesive state to a non-adhesive (hydrophilic) state upon exposure to UV light.

Investigating Cell–Substrate Interactions

The cellular microenvironment consists of a myriad of signals arising from surrounding cells, the ECM, and soluble molecules. The ability to control and modulate cell behavior, through the cell environment, is important for understanding cell behavior as well as controlling a wide range of biomaterial interactions. In general, cell behavior can be modified by controlling substrate chemistry, topography, and elasticity, and investigations have traditionally focused on broad changes to the cell culture surface, such as those obtained by application of a coating. However, cell–cell and cell–ECM interactions in nature usually occur over very small, nanoscale distances.

New insights into cell behavior and physiology have been gained by utilizing and extending a variety of techniques and materials that can be used to influence the cell environment at the microscale. The following sections examine some of the fundamental concepts learned from examining cell behavior in response to substrate chemistry, topography, elasticity, and strain, alone and in combination at macro-, micro-, and nanoscales.

Limitations of Biomaterial Evaluation *In Vitro*

It is important to recognize that the *in vitro* evaluation of biomaterials is subject to specific constraints arising from the reduced complexity of the *in vitro* environment. First and foremost, there is no immune or inflammatory response *in vitro*. Nor is there the same cascade of events resulting from implantation, e.g., the interaction with components of blood, formation of a clot, vascularization, and recruitment of a variety of cells that participate in the wound healing response.

CELL RESPONSE TO SUBSTRATE CHEMISTRY

Surface chemistry is perhaps the most obvious, and in some cases, the most accessible parameter to control when modifying *in vitro* conditions to assess their effects on cell behavior. At the macroscale, a variety of strategies can be employed to modify culture surface chemistry. Most coating strategies aim to increase cell adhesion or to preferentially select for certain cell types. Uniform coatings may be achieved by either spin coating a solution of it on the substrate surface, or by immersion of the substrate in a solution of it, followed by draining and drying. Substrates have been coated in these ways with a variety of organic and inorganic compounds, such as collagen (Chlapowski et al., 1983; Kataropoulou et al., 2005), fibronectin (Klein-Soyer et al., 1989), gelatin (Aframian et al., 2000), and poly-L-lysine (Jensen and Koren, 1979). Culture surfaces have also been broadly coated with specific adhesion-related peptides. The peptide sequence arginine–glycine–aspartate (RGD) has been immobilized on a number of materials as a means of enhancing two-dimensional cell attachment (Massia and Hubbell, 1990a, 1991b; Cutler and Garcia, 2003; Petrie et al., 2008). Studies suggest that 1 pmol/mm^2 of RGD may be required as a minimal surface density (Chollet et al., 2009), and that an increase in RGD density is generally beneficial to cell attachment (Massia and Hubbell, 1991b). However, it is worth noting that there may be an

optimum ligand density for maximum cell attachment. The spatial organization of various cell ligands may also be achieved on some surfaces. This approach has been used to enhance the initial number of attached cells, to increase their proliferation or to preferentially select for specific cell types (Zemljic Jokhadar et al., 2007).

There are, however, instances where substrate coatings are of limited benefit, and examples of such include cultures where the applied coating may rapidly degrade or detach from the culture substrate. A common strategy to enhance cell adhesion is to modify the substrate chemistry to encourage the adsorption and presentation of certain CAPs or ligands (Keselowsky et al., 2003). Ligands are present on CAPs in the serum added to culture media. As previously discussed with TCP, a number of processes have been developed to enable modification of large culture surface areas to enhance CAP protein adsorption.

Micrometer-Scale Chemical Patterns

Patterning at the microscale is associated with the control of cell shape, position, and density, and presents a powerful tool to examine and control the cell microenvironment. A common approach is to generate a pattern of CAPs on a two-dimensional surface and then to plate with cells that adhere preferentially to the patterned, adhesive regions. Usually the non-adhesive regions are PEGylated. A multitude of patterns in various configurations have been attained using printing methods, as well as methods including dynamic surfaces as previously discussed.

Cells and proteins have been previously patterned on various substrates using SAMs (Mrksich and Whitesides, 1996), metal templates (O'Neill et al., 1990), stamped proteins, peptides (Hyun et al., 2001), and biopolymers (Bhatia et al., 1997), microfluidic channels (Takayama et al., 1999), membranes (Folch et al., 2000; Ostuni et al., 2000), polysaccharides (Khademhosseini et al., 2004; Suh et al., 2004), and cross-linked poly(ethylene glycol) (PEG) (Khademhosseini et al., 2003). Non-contact methods can also be used to generate protein patterns and include films that are cross-linked by photolithography that selectively promote or exclude cell adhesion (Chien et al., 2009). In this manner, non-specific biological molecules can be used to create patterns of adhesive and/or non-adhesive regions. Short chains of PEG have been assembled on surfaces to form a brush-like layer that resists protein adsorption and, as a consequence, cell attachment.

Protein patterning has also been used to produce regions of preferential adhesion for specific cell types, to alter cell shape, to cluster cells together, to restrict their proliferation or to position different cell types in close proximity. Components of the ECM which participate in cell adhesion *in vivo* are candidates for studies involving chemical patterning *in vitro*. Fibronectin, laminin, vitronectin, and collagen are examples of ECM molecules commonly used for patterning cell adhesive regions. Such proteins may also be classified as CAPs.

Direct transfer of proteins or cells from a stamp to the substrate can also be used to generate micro- and nanoscale patterns. Microstamping or microcontact printing (*μ*CP) is a technique whereby polydimethylsiloxane (PDMS) molds are used to pattern substrates by the selective transfer of materials of interest (Mrksich and Whitesides, 1996). In one approach, the relief patterns on a PDMS stamp can be used to form patterns of SAMs on the surface of a substrate through conformal contact. Alkane thiols are used to pattern gold-coated surfaces by forming densely packed SAMs. The thiol end groups strongly interact with the gold surfaces, and the rest of the molecule can then be used to control surface chemistry, wetting, and protein and cell adhesion. For example, alkane thiols can be PEGylated at the opposite end from the –SH group to render gold-coated surfaces "nonfouling," or protein and cell resistant. To micropattern surfaces using alkane thiols, a variety of methods have been employed such as *μ*CP. In this approach, PDMS molds are "inked" with the alkanethiol solution, and transferred to the gold surface by conformal contact between the relief pattern and the substrate. Using *μ*CP, micropatterns of SAMs terminated with PEG chains have been generated. These micropatterns have been used to immobilize proteins and cells on specific regions of a surface, and inhibit their contact with other regions by selectively modifying those regions with the non-fouling PEGs.

Using micropatterned fibronectin islands, Chen et al. reported that the area available for cell adhesion and the resultant cell shape governed whether individual cells grow or die, regardless of the type of matrix protein or antibody to integrin used to mediate adhesion (Chen et al., 1997, 1998) (Figure II.1.3.2). For bovine capillary cells, apoptosis significantly increased as fibronectin island size was reduced below 400 μm^2. Using micropatterned fibronectin McBeath et al. demonstrated that cell shape regulated the differentiation of human mesenchymal stem cells (hMSCs) (McBeath et al., 2004); hMSCs that were permitted to adhere, spread, and flatten, differentiated into osteoblasts, while those that were not permitted to attach formed spherical shapes and resulted in adipocytes.

Non-Fouling Surfaces in Cell Culture

As previously described, non-fouling surfaces may be created with PEGylated alkane thiols formed into SAMs. Other approaches include the generation and deposition of non-fouling coatings or films, such as plasma-deposited triglyme and tetraglyme films of the Ratner group (Johnston et al., 2005), plasma-deposited tetraglyme, and fluorocarbon-based films (Goessl et al., 2001; Cao et al., 2007).

PEG has been used in many chemical variations to generate non-fouling surfaces. Polymerization of PEG monomers to form brush-like non-fouling coatings has been investigated. Beginning with surface-initiated atom

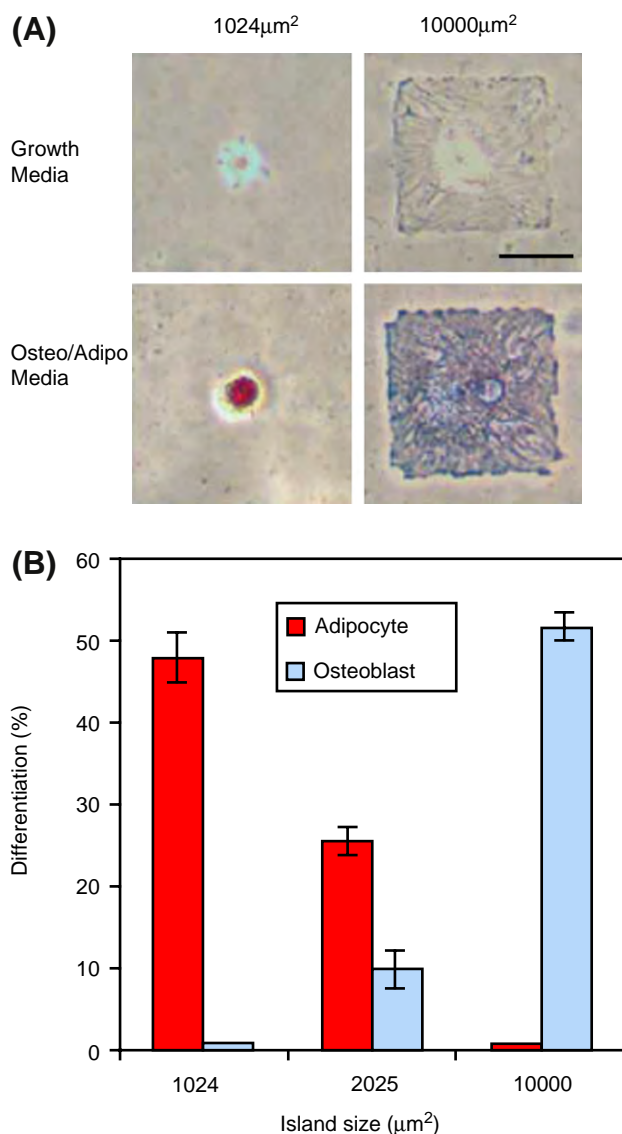

FIGURE II.1.3.2 Cell shape modulates hMSC differentiation: (A) Brightfield images of hMSCs plated onto small (1024 μm²) or large (10,000 μm²) fibronectin spots after 1 week. Fibronectin spots were patterned on a mixed SAM substrate by micro-contact printing. Large fibronectin spots supported osteogenesis (blue) while small fibronectin spots supported adipogenesis (red). Scale bar 50 μm. (B) Differentiation of hMSCs on 1024, 2025, or 10,000 μm² islands after 1 week of culture. Small fibronectin spots resulted in adipogenesis, medium fibronectin spots supported both adipogenesis and osteogenesis, and large fibronectin spots resulted in osteogenesis. (Reprinted from McBeath et al. (2004). Cell shape, cytoskeletal tension, and RhoA regulate stem cell lineage commitment, *Developmental Cell*, **6**(4), 483–495. Copyright (2004), with permission from Elsevier.)

transfer radical polymerization, Lavanant et al. grew robust brush-like polymers of poly(ethylene glycol) methacrylate (PEGMA) on low density PE by photobromination followed by polymerization (Lavanant et al., 2010). Functionalization of the peptide brushes with the RGD containing peptide ligand, GGGRGDS, increased cell adhesion compared to the polymerized PEGMA surface, as expected.

Changes in the structure of the component molecules of SAMs can also reduce cell adhesion. For example, SAMs comprised of oligo(ethylene glycol) (OEG) with EG side chain lengths of 4, 9, and 23 were grafted to titanium as a non-fouling surface. Surfaces were exposed to 3T3 fibroblast cells in media with 10% FBS, and uncoated titanium was used as a control. At four hours, cells were visible on the Ti surface, but there was no cell adhesion and no visible difference between the SAMs with different side chain lengths. At 35 days, cell adhesion on surfaces was related to side chain length, and longer side chains resulted in fewer adhered cells. Eventually cells covered all the surfaces; however, complete cell coverage was observed at 7, 10, and 11 weeks for samples with side chain lengths of 4, 9, and 23 (Fan et al., 2006).

For many patterning applications, the ability to isolate or sequester cell adhesive regions by surrounding them with surfaces that resist cell attachment is of great interest. The practical applications include the fabrication of arrays of cells for high throughput testing, as well as patterned co-cultures for investigating complex interactions between different groups of homogenous cell populations. Microarrays of captured molecules surrounded by non-fouling backgrounds are one approach that has been used to identify and screen combinations of cell adhesion peptides to develop bioactive surfaces. Monchaux and Vermette grafted RGD and RGE (a non-adhesive control) as well as other known endothelial ligands (REDV and SVVYGLR) on a low-fouling carboxymethyl dextran background (Monchaux and Vermette, 2007). They concluded that RGD was necessary for cell adhesion, and that endothelial cells could discriminate against and would not adhere to RGE. Co-immobilization of the RGD peptide with VEGF or SVVYGLR significantly enhanced endothelial cell adhesion, while co-immobilization of RGD with either REDV or SVVYGLR induced a reduction in endothelial cell spreading.

The development of non-fouling surfaces from biodegradable or biologically relevant compounds is of great interest. Biodegradable ultra-low fouling peptide surfaces have been generated from natural amino acids that offer new and innovative means to control cell adhesion (Chen et al., 2009). Amino acids (H2N-CH-R-COOH) are molecules that possess an amine group (H2N), a carboxylic acid group (COOH), and an organic side chain (R) of varying length and composition. Amino acids are the building blocks of proteins, and are the ubiquitous components of many organisms. Ultra-low fouling surfaces based on net neutral zwitterionic amino acids have been developed that can "catch and release" molecules of interest (Mi et al., 2010), potentially enabling a new generation of *in vitro* surfaces for diagnostic and assay-based testing.

Chemical Patterning for the Co-Culture of Cells

Cell–cell interactions are important for tissue development and function. During embryogenesis, the temporal

and spatial signaling between cells of different origins is part of the cascade of events that support tissue growth and development (Yu et al., 2008). However, the process of harvesting tissue and isolating cells, as well as the purification of specific cell types, disrupts many of the cell–cell interactions found *in vivo*, resulting in a loss of cell–cell contact, signaling, structure, and general heterogeneity.

The co-culture of different cell types is one approach to enhance the *in vitro* environment and maintain cell phenotype *in vitro* (Nandkumar et al., 2002; Chang Liu and Chang, 2006). Co-cultures can be established by simply mixing two or more cell populations prior to plating; however, this provides little control over cell–cell contact, spacing or interaction. Greater control can be obtained through the use of patterned co-cultures which primarily control homotypic and heterotypic cell–cell contact. Using patterning techniques, co-cultures can be established where cell–cell contact, spacing, and interaction can be controlled with high resolution. Both cells and cell adhesive proteins may be patterned using selective adhesion to micropatterned substrates (Folch and Toner, 2000; Hui and Bhatia, 2007), by flow through a microfluidic channel (Chiu et al., 2000; Takayama et al., 2001), by stamping with a stencil-based approach (Chen et al., 1998; Folch and Toner, 2000) or by seeding on surfaces that dynamically switch from cell-adhesive to cell-repulsive (Edahiro et al., 2005; Kikuchi et al., 2009). A common requirement of most co-culture (and patterning) applications is the ability to selectively control and limit cell adhesion to specific areas of the substrate. As a result, non-fouling surfaces can be of considerable benefit.

A practical application of co-culturing is the study of cells from the liver (hepatocytes). Hepatocytes rapidly lose their ability to generate a characteristic protein (albumin) when cultured *in vitro*. Using mask-to-mask registration and photolithography, Hui and Bhatia (2007) generated surfaces with three distinct chemistries for the co-cultures of hepatocytes and 3T3-J2 fibroblasts. Hepatocytes preferentially adhered to collagen coated regions, and fibroblasts to serum coated glass regions (Figure II.1.3.3). A non-fouling PEG region was included that separated the two cell types and controlled the amount of contact or interaction between co-cultured populations for up to seven days (Figure II.1.3.3). At eight days, hepatocytes retained the ability to produce albumin.

High-Throughput Screening

Microarrays represent a specific type of chemical patterning. The arrays consist of a large number of small spots, each with a defined location and a unique chemical composition. This approach is suitable for testing biomaterials and microenvironments to enable the screening of large numbers of chemical combinations in a high-throughput manner. A high-throughput microarray that probes the cell–cell, cell–ECM, and cell–biomaterial interactions can be useful for studying cell

adhesion, proliferation, and differentiation (Khademhosseini, 2005; Khademhosseini et al., 2006).

Typically, cell–ECM interactions are studied by using purified matrix proteins adsorbed to cell culture substrates. This approach requires large amounts of protein per 96- or 384-well plate, and can be prohibitively expensive. To address these challenges, new methods have been developed using pin tools (Cleveland and Koutz, 2005), piezo tips (Niles and Coassin, 2005), ultrasound (Strobl et al., 2004), and microarray (Flaim et al., 2005) technology for nanoliter liquid handling. Recently, robotic spotters capable of dispensing and immobilizing nanoliters of materials have been used to fabricate microarrays, where cell–matrix interactions can be tested and optimized in a high-throughput manner. For example, synthetic biomaterial arrays have been fabricated to test the interaction of stem cells with various extracellular signals (Anderson et al., 2004). Using this approach, thousands of polymeric materials were synthesized and their effect on the differentiation of human embryonicstem (ES) cells (Anderson et al., 2004) and human mesenchymal stem cells (hMSC) (Anderson et al., 2005) were evaluated. These interactions have led to unexpected and novel cell–material interactions. Although the molecular mechanisms associated with the biological responses have yet to be clarified, such technology may be widely applicable in cell–microenvironment studies, and in the identification of cues that induce desired cell responses. Also, the materials which yield desired responses could be used as templates for tissue engineering scaffolds. Such an approach is a radical change from traditional methods of developing new biomaterials, where polymers have been individually developed and tested for their effect on cells. In addition to the screening of libraries of synthetic materials, the effect of natural ECM molecules on cell fate can be similarly evaluated in a high-throughput manner. In one example, combinatorial matrices of various natural ECM proteins were tested for their ability to maintain the function of differentiated hepatocytes, and to induce hepatic differentiation from murine ES cells (Flaim et al., 2005). A peptide and small molecule microarray made by a DNA microarray spotter was also used to study high-throughput cell adhesion (Falsey et al., 2001). A microarray of immobilized ligands was analyzed with three different biological assays such as protein-binding assay, functional phosphorylation assay, and cell adhesion assay. This array can be used to rapidly screen and analyze the functional properties of various ligands.

Nanometer-Scale Chemical Patterning

Nanosized chemical patterns generally do not direct cell shape or orientation as a result of their extremely small size relative to the cell. However, surfaces with chemical features on the nanoscale do modulate cell functions such as adhesion, proliferation, migration, differentiation, and gene expression.

CELL RESPONSE TO SUBSTRATE TOPOGRAPHY

All cells are exposed to some type of physical environment *in vivo*. Cell–cell interactions, the ECM, and biomaterials all present a surface to the cell that is quantifiable in terms of its surface features (Abrams et al., 2003; Liliensiek et al., 2009). As a field of study, surface topography defines the specific morphological characteristics of a surface. Surface topography may be generally described as isotropic (uniformity in all directions) or anisotropic (uniformity in one direction).

Surface topography may be quantified by a number of techniques such as atomic force microscopy (AFM) or white light interferometry (WLI).

Unlike periodic surfaces typically fabricated for *in vitro* investigation (Clark et al., 1987; Chou et al., 1998; Brunette and Chehroudi, 1999), most biological surfaces present non-ordered features at the macro- and microscale which generally become more ordered at the nanoscale (Fratzl, 2008). Fibers in the ECM and pores in basement membranes are just a few examples of prevalent and quantifiable topographical features (Abrams et al., 2003; Liliensiek et al., 2009). Thus, it is not surprising that cells respond to topographical cues, and that surface topography of the culture surface presents another means to control and study cell behavior *in vitro*. Micro- and nanosized features are known to influence cell behavior, and both generally coexist in many biological surfaces. Accurate quantification of these surfaces is challenging, since most tools are optimized for quantifying micro- or nano-features individually, but not both at the same time (Guruprasad Sosale and Vengallatore, 2008).

In terms of cell activity, surface topography has been reported to affect proliferation, gene expression (Carinci et al., 2003), cell adhesion (Hamilton et al., 2006), motility (Clark et al., 1987), alignment (Clark et al., 1991), differentiation (Martinez et al., 2009), and matrix production (Hacking et al., 2008). In sensing and interacting with the topographical environment, evidence suggests that cells extend fine processes termed *filopodia* (Morris et al., 1985; Dalby et al., 2003a, 2004; Choi et al., 2007). While the specific mechanisms are poorly understood, changes in cell activity resulting from interaction with surface features have been linked to changes in cytoskeletal arrangement (Wojciak-Stothard et al., 1995) including actin filaments (Gerecht et al., 2007), nuclear shape (Dalby et al., 2003b), and ion channels (Tobasnick and Curtis, 2001). It is likely that these effects represent a small portion of the cellular events relating to interactions with surface topography, and different mechanisms or combinations of mechanisms may be activated by different feature sizes and shapes (Ball et al., 2007).

Micrometer-Scale Topography

Investigations concerning the response of cells to precisely patterned, microfabricated surfaces began decades ago. Fibroblasts (Brunette, 1986a), osteoblasts (Hamilton and Brunette, 2007), macrophages (Wojciak-Stothard et al., 1996), neutrophils (Tan and Saltzman, 2002), epithelial (Brunette, 1986b), endothelial (Bettinger et al., 2006), cardiomyocytes (Kim et al., 2005), and neuronal cells (Clark et al., 1991), have all demonstrated a reproducible response to surface texture on the microscale (Ireland et al., 1987; Britland et al., 1992; Curtis and Wilkinson, 1998; Fitton et al., 1998; Dalby et al., 2002b; Berry et al., 2004). Polarization or

cell alignment along the direction of ridged surfaces is a phenomenon that is commonly observed when cells are cultured on linearly patterned substrates. Cell alignment to topographical features is referred to as contact guidance (Wood 1988; Wojciak-Stothard et al., 1996; Brunette and Chehroudi, 1999). With microscale-sized features, cell alignment generally increases with increasing groove depth and decreasing groove spacing (Bettinger et al., 2006); however, cell response to topography is highly dependent upon cell type (Figure II.1.3.4). For example, epithelial cells and fibroblasts are differently affected by surfaces with micron-sized grooves (Clark et al., 1987, 1990).

Nanometer-Scale Topography

It has been demonstrated that cells can sense and respond to features as small as 10–30 nm (Wojciak-Stothard et al., 1996; Dalby et al., 2002b). Compared to the microscale, where cells may be profoundly affected by a single feature, at the nanoscale a repetition of similar features has the greatest effect and provides the most predictable results regarding cell behavior (Curtis et al., 2004; Ball et al., 2007). Once again, cell response to topography is highly dependent upon cell type. Using surfaces of aligned ridges possessing a constant ridge spacing of 260 nm and depths varying from 100–400 nm, Clark demonstrated that neuronal cells were highly oriented in the ridge direction for all depths, epithelial-like cells were highly oriented for all depths, whereas the orientation of fibroblast-like cells increased with increasing depth from 50% orientation at 100 nm to nearly 95% orientation at 400 nm (Clark et al., 1991).

At the microscale, increasing the depth and decreasing the width of grooved or stepped surface features increases the probability of cell alignment with the topographical feature(s). At the nanoscale, it appears that a finite limit in feature sizes exists with respect to cell alignment to surface topography. By culturing fibroblasts on linearly patterned surfaces fabricated by e-beam lithography, it was determined that groove depths below 35 nm or ridge widths smaller than 100 nm did not result in cell alignment, and that 35 nm may be the threshold for whole cell fibroblast alignment (Loesberg et al., 2007). Similarly Teixeira et al. demonstrated a finite limit in the response of human corneal epithelial cells to surfaces with linearly patterned surfaces with groove spacing ranging from 400 to 4000 nm (groove width 330 to 2100 nm) (Teixeira et al., 2006). At groove spacings greater than 400 nm, cells were oriented in an increasingly parallel manner to the linear pattern (Figure II.1.3.4); however, at groove spacings less than 400 nm, cells were perpendicularly arranged. These findings further demonstrate a cell-specific sensitivity with regard to cell alignment to surface topography, and also imply that a limit exists in feature sizes that cells are able to recognize.
FIGURE II.1.3.4 Effect of micro and nano patterns on corneal epithelial cell alignment. (A) Cells were aligned perpendicularly to ridges that were 70 nm wide and 330 nm apart. (B) Expanded view of (A) showing filopodia also aligned perpendicularly to the patterns. (C) With increasing width and spacing (1900 nm ridge width, 2100 nm spacing), cells were aligned with the ridges; and (D) filopodia were guided by the topographic pattern. (Reprinted from Teixeira et al. (2006). The effect of environmental factors on the response of human corneal epithelial cells to nanoscale substrate topography. *Biomaterials*, **27**(21), 3945–3954. Copyright (2006), with permission from Elsevier.)

The effects of nano-topography on cell differentiation have also been reported. Proteomic-based studies have also shown that cells respond to nm-sized pits and pores in irregular patterns, leading to increased differentiation and matrix production by human osteoprogenitor cells (Kantawong et al., 2008). Likewise, studies with surfaces fabricated by the arrangement of titanium nanotubes have demonstrated that the nanotube diameter affects both hMSC differentiation and adhesion (Oh et al., 2009). Smaller diameter nanotubes (30 nm) increased adhesion, while larger diameters (100 nm) increased differentiation. Other authors using different cell lines and culture conditions have reported optimal nanotube diameters and spacing as low as 15 nm (Park et al., 2007). Topography at the nanoscale can also be used to effectively reduce cell adhesion. Kunzler et al. generated a constant gradient of nano-features (65 nm diameter and height) with the spacing as the only changing parameter along the gradient (Kunzler et al., 2007). This study demonstrated that the spacing or density of non-adhesive nanoscale features can disrupt cell adhesion, likely by restricting receptor–ligand interaction.

High-Throughput Screening of Surface Topography

Like microarrays used to test many chemical compounds at one time in a high-throughput manner, topographical arrays have been developed to assess the effects of systematic variances in surface topography. Lovmand et al. developed a topographical array consisting of 504 topographically distinct surface structures fabricated on silicon wafers that were coated with tantalum prior to cell seeding (Lovmand et al., 2009). Each structure consisted of a topographical pattern comprised of a series of circles, squares or rectangles that varied systematically in height from 0.6 to 2.4 μm, and feature size and spacing from 1.1 to 6.6 μm. Murine osteoblast cells (MC3T3-E1) were cultured on the array for up to 28 days to assess proliferation, cell area, and mineralization. It was determined that the height of the features had the greatest effect on mineralization, followed by feature size, then the gap size. The combined effects of feature size and gap size became important as feature height decreased.

Clinical Applications of Surface Morphology

Osteoblasts are substrate-dependent cells that have been widely used for investigating responses to surface topography. A considerable amount of work has been produced concerning the response of osteoblast cells to surface topography, and the end result of this work has been widely applied clinically to enhance the long-term fixation of dental and orthopedic implants by bone (Hacking et al., 1999, 2003). Mechanical fixation of an implant by the direct apposition of bone is referred to as osseointegration (Branemark et al., 1977; Albrektsson et al., 1981). Irregularly textured surfaces on titanium implants have been created by blasting the surface with small hard particles (Al_2O_3) that deform the relatively ductile titanium surface and produce a distinctly unordered micron-sized surface texture. It is common with dental implants that these surfaces are further processed by immersion in acid that superimposes a finer secondary nanosized structure upon the textured surface, and increases osseointegration.

A Note about Cell Lines in the Study of Surface Topography

To enhance optical clarity, the TCP surface is very smooth ($R_a \sim 1.2$ nm) (Chang et al., 2007), and this has certain ramifications for the growth and development of cells *in vitro*. Adherent cell lines are selected preferentially for their ability to proliferate and differentiate on glass or tissue culture plastic. As a result, many cell lines have been selected based on their behavior on smooth, flat surfaces that are rarely found *in vivo*. Studies comparing the response of primary cells to cell lines derived from similar tissue sources have reported significant differences in cell activity (Fisher and Tickle, 1981; McCartney and Buck, 1981). This point becomes especially salient when working with surfaces where the effects of surface topography are the subject of primary interest (Clark et al., 1991; Hacking et al., 2008).

CELL RESPONSE TO SUBSTRATE ELASTICITY

While surface chemistry and topography modulate cell function, it is increasingly evident that cells respond to the physical or mechanical properties (stiffness) of the substrate. Stiffness can be described as the resistance of a solid material to deformation, and is commonly defined by elastic modulus (*E*) and reported in units referred to as a "pascal" (Pa). Excluding bone ($10-20 \times 10^9$ Pa), most tissues have an elastic moduli in the range of 10^1 to 10^6 Pa, substantially lower than the elastic moduli of most culture surfaces like TCP ($3-3.5 \times 10^9$ Pa).

Hydrogels are well-suited to the study of cell substrate interactions since their stiffness can be varied by controlling the water content of the gel, which is controlled by modifying the polymer concentration or the relative extent of cross-linking. Hydrogels can also be made from a very diverse variety of natural and synthetic materials, such as hyaluronic acid (HA), fibrin, alginate, agarose, chitosan, polyacrylamide, and PEG. In terms of collagen hydrogels, gel stiffness may be increased by increasing the collagen concentration (Brigham et al., 2009) or

reducing the thickness of the gel and immobilizing it on a glass substrate (Arora et al., 1999).

The stiffness of the substrate affects cell adhesion, spreading, and migration, especially the last two. In two-dimensional cultures, cells preferentially migrate towards surfaces of greater stiffness, a phenomenon referred to as mechanotaxis (Lo et al., 2000). In two-dimensional systems endothelial and fibroblast cells cultured on collagen-coated substrates that were classified as compliant ($\sim 5 \times 10^3$ Pa) or stiff ($\sim 70 \times 10^3$ Pa) demonstrated remarkably different behaviors (Opas, 1994). Cells cultured on compliant substrates had reduced spreading, increased lamellipodia activity, and greater migration. Cells cultured on stiffer substrates generally increased in proliferation; however, the specific effect seen is cell-type dependent (Pelham and Wang, 1997). There is substantial evidence that substrate stiffness also affects cell proliferation in two-dimensional as well as three-dimensional culture systems (Wong et al., 2003).

Substrate elasticity can also be used to direct the differentiation of certain cell types. MSCs cultured on collagen-coated substrates of varying stiffness can be directed toward neuronal, myogenic, and osteogenic lineages (Engler et al., 2006). For example, adult neural stem cells will selectively differentiate to neurons on softer substrates ($1 \times 10^2 - 5 \times 10^2$ Pa) or glial cell types on stiffer substrates ($1 \times 10^3 - 1 \times 10^4$ Pa) (Saha et al., 2008). These findings suggest that stem cells are able to recognize and differentiate according to physiologically relevant substrate stiffness.

CELL RESPONSE TO MECHANICAL DEFORMATION (STRAIN)

There has been considerable work assessing the response of cells to mechanical strain or deformation (Buckwalter and Cooper, 1987). Forces can be applied directly to adherent cells *in vitro* by either elongation or compression of their substrate (two-dimensional) or matrix (three-dimensional). With respect to cyclic tensile loads, in both two-dimensional and three-dimensional cultures, cells predominantly align in the direction of the applied load and assume an elongated morphology (Toyoda et al., 1998; Henshaw et al., 2006; Haghighipour et al., 2007).

Because of the loadbearing function and well-known adaptation to load of the musculoskeletal system, cells of this system have been evaluated on surfaces under conditions of tensile and compressive strain. Toyoda et al. cultured cells harvested from the anterior cruciate ligament (ACL) and synovium (Toyoda et al., 1998). Cells were subjected to cyclic tensile load for 24 hours on culture plates with flexible rubber bases. For both cell types, tensile load increased cell alignment and elongation; however, tensile load only increased the production of collagen type I in cells derived from the ACL (Toyoda et al., 1998). These results have been supported by similar studies where fibroblasts subjected to cyclic

tensile strain increased the formation of organized ECM, increased collagen production, and increased metabolic activity compared to unloaded controls (Hannafin et al., 2006; Joshi and Webb, 2008).

Bone is another well-known loadbearing tissue, and the extent of mineralization and bone mineral density is load dependent (Rodionova and Oganov, 2003). *In vitro*, cyclic strain in both tensile (Hanson et al., 2009) and compressive (Goldstein, 2002) loading enhances osteoblast mineralization. Thus, strain appears to be an important stimulus for the generation of mineralized and tendon-like tissues *in vitro*. These findings have led to the fabrication of bioreactors that can apply physiologic loads to developing tissue to enhance the production and alignment of ECM in a number of tissues including cardiac (Kortsmit et al., 2009), bone (van Griensven et al., 2009), cartilage (Preiss-Bloom et al., 2009), and tendon (Riboh et al., 2008).

COMPARISON AND EVALUATION OF SUBSTRATE CUES

As previously discussed, cells respond to a number of surface cues such as chemistry, topography, elasticity, and strain (sometimes cyclic strain). Evaluating cell response to multiple cues is inherently difficult, since substrate properties are often interrelated. In many *in vitro* investigations of biomaterials it may be difficult to clearly separate the effects of surface chemistry from those of morphology and elasticity. This is particularly problematic in cases where the unique properties of a material may arise from the manufacturing process (Bobyn et al., 1999; Hacking et al., 2002). In such investigations, it is important to recognize that subtle changes in biomaterial properties can have profound effects on cellular response, and ultimately *in vivo* function. This is especially true, for example, of implant coatings where responses to surface morphology need to be dissociated from other factors, such as surface chemistry. Experimental controls must not just approximate surface morphology, but must match it precisely, since subtle changes in surface morphology have the potential to confound experimental findings. In many cases, however, it may not be practical or even possible to produce an exact morphological control from a different biomaterial. A morphological control may be generated by coating the surface of interest with a thin-film that is dense, durable, homogenous, and does not alter the surface morphology. There are a variety of thin-film deposition techniques collectively referred to as physical vapor deposition (PVD) that have been employed by several research groups (Hacking et al., 2002, 2007; Meredith et al., 2007). While other coating methods exist, PVD is advantageous since samples can be processed at lower temperatures in a relatively inert environment.

Control of substrate elasticity can be achieved by varying the composition and curing conditions. PDMS, for example, can be prepared with a range of elasticity (2.8–1882 kPa) by varying the ratio of base to curing agent (Cheng et al., 2009). Since PDMS can be cast into many shapes, patterned surfaces with varying elasticity can be created. These surfaces can be subsequently coated to achieve uniform and comparable surface chemistry. Similarly, by progressively reducing the thickness of a gel to a thin film, chemical composition can be maintained while substrate elasticity changes.

While the contributions of topography, chemistry, elasticity, and strain to cell behavior have been evaluated and documented for a wide variety of cell types, much of the literature has evaluated the effects of only one stimulus in each experimental setting. *In vivo*, however, it is reasonable to expect that cells experience a wide range of stimuli simultaneously. Since physical cues such as chemistry, topography, elasticity, and strain can produce both synergistic and opposing effects on cell behavior, it is of interest to evaluate their simultaneous effect on cell behavior, and if possible describe a hierarchy of cellular cues. However, since the cellular response to physical stimuli is often dependent upon cell phenotype, and is further influenced by soluble factors, broad exploration of these phenomena presents a challenging combinatorial experimental environment.

Chemistry and Topography

Using a combination of patterning techniques including photolithography, Curtis established that fibroblasts respond to both chemical and topographic patterns (Curtis and Wilkinson, 1999). However, when both chemical and topographical stimuli were combined and orthogonally opposed on the same surface, cells aligned with nanosized topographical patterns. Curtis coined the term "topographic reaction" to describe these events (Curtis and Wilkinson, 1999). Similarly, a preference of cellular alignment on chemical patterns versus response to topographic cues in the presence of both topographic and chemical patterns has been demonstrated in a number of studies (Charest et al., 2006; Gomez et al., 2007).

Chemistry and Strain

Hyun et al. developed a system to evaluate the combined effects of chemical patterning and strain on cell alignment (Hyun et al., 2006). Thin paraffin films were patterned with adhesive regions of fibronectin to which NIH 3T3 fibroblasts adhered and aligned. After cells aligned in the direction of the chemical patterning, the paraffin films with the adherent cells were subjected to cyclical stretch. Mechanical force was applied perpendicular to the cell alignment resulting from chemical patterning, and the actin cytoskeleton realigned along the axis of applied mechanical stress. Stretched cells showed altered gene expression of cytoskeletal and matrix proteins in response to mechanical deformation.

Topography and Strain

Cheng et al. (2009) fabricated patterned PDMS substrates consisting of parallel microchannels (2 μm wide, 2 μm separation, and 10 μm deep) that were subjected to cyclic compressive strain applied perpendicular to the direction of the channels. After six hours of compression, fibroblasts cultured on the patterned PDMS substrate aligned in the direction of the microchannels (topographical cue) and perpendicular to the direction of compression. Elastic microgrooved surfaces have also been utilized to maintain the cellular orientation of mesenchymal stem cells (MSCs) while subjected to cyclic tensile strain (Kurpinski et al., 2006).

SUMMARY

In vivo, cells are responsive to a myriad of substrate-related signals within the environment. At the micro- and nanoscale, interactions with the ECM expose the cell to a variety of chemical moieties and topographical features. Micro- and nanoscale technologies have provided many new tools to manipulate the *in vitro* environment. Cell behavior may be modified by patterns of cell adhesive ligands and topographical features. Further modification of cell behavior can be achieved by altering substrate mechanical properties, such as elasticity, or by deformation of the cell shape. With respect to generating complex tissue structures, substrate cues like topography, chemistry, and matrix elasticity are promising candidates for controlling cell differentiation. Unlike soluble factors, substrate cues can provide specific information for directing and controlling cell behavior. The combination of multiple physical cues presents new and potentially useful methods to direct and control cell development and behavior.

GLOSSARY OF TERMS

ACL: anterior cruciate ligament
AFM: atomic force microscopy
Al$_2$O$_3$: alumina oxide
ATCC: American Type Culture Collection
CAPs: Cell adhesive proteins
CIMR: Coriell Institute for Medical Research
DNA: deoxyribonucleic acid
E: elastic modulus
ECM: extracellular matrix
EDTA: ethylenediaminetetraacetic acid
HA: hyaluronic acid
hMSCs: human mesenchymal stem cells
MSCs: mesenchymal stem cells
NIPAAm: N-isopropylacrylamide
Pa: pascal
PE: polyethylene
PDMS: polydimethylsiloxane
PEG: poly(ethylene glycol)
PVD: physical vapor deposition
REDV: Arginine-Glutamic Acid-Aspastic Acid Valine

RGD: arginin–glycine–aspartate, adhesion-related peptide sequence
RGE: Arginine-Glycine-Glutamic Acid
SAMs: self-assembled monolayers
SVVTGLR: Serie-Valine-Valine-Tyrosine-Glycine-Leucine-Arginine
Ta: Tantalum
TCP: tissue culture polystyrene
Ti: Titanium
VEGF: Vascular Endotthelial Growth Factor
WLI: white light interferometery

CHAPTER II.1.4 CELL FUNCTION AND RESPONSE TO INJURY

Richard N. Mitchell and Frederick J. Schoen
Department of Pathology, Brigham and Women's Hospital and Harvard Medical School, Boston, MA, USA

Composed of nucleic acids, proteins, and other large and small molecules, *cells* constitute the basic structural building blocks of all living matter. Except for the circulating elements in blood and lymph, cells are joined via cell–cell junctions to form *tissues* comprising a handful of general types: *epithelium*; *connective tissue*; *muscle*; and *nerve*. *Hematopoietic* and *lymphoid* tissues – responsible for producing red and white blood cells and platelets – also exhibit similar features as they generate their final circulating progeny. Organs are assembled from the basic tissue types, and are "glued" together within an *extracellular matrix* (ECM) composed of myriad proteins, glycoproteins, mucopolysaccharides (sugar polymers) and proteoglycans (polymeric sugars attached to a protein core) synthesized by the individual cells. The organs, in turn, perform the various functions required by the intact living organism, including circulation, respiration, digestion, excretion, movement, and reproduction.

A major goal in this and the following chapter is to describe how biological structure is adapted to perform physiologic function. This general and overarching concept extends from cells (and their *subcellular*

constituents) to the organization of tissues, and of organs. Beginning with the smallest subunits of cellular organization, we will build to progressively more complex systems. In the following chapter, we will extend the concepts of structure–function correlation beyond cells to include extracellular matrix and complex tissues, and will also describe the technologies by which histologists and pathologists examine normal and abnormal tissues. In these chapters, we also provide an introduction to the physiologic responses to environmental stimuli, the mechanisms of cell injury, cell–materials interactions, and the methodologies by which these are all studied.

In this chapter on function and response to injury, and in the following chapter on tissues and the extracellular matrix, we will highlight the following fundamental concepts of cells and the tissues they form.

CELLS: FUNCTION AND RESPONSE TO INJURY

- General characteristics and functions of cells
- Compartmentalization of regionally specialized function by membranes
- Cellular specialization to facilitate unique functions
- Regulation and coordination of cell function
- Cellular differentiation
- Response of cells to injury, including mechanisms of cell death.

TISSUES AND THE EXTRACELLULAR MATRIX

- Structure and function of the extracellular matrix (ECM)
- Organization of cells into tissues
- Integration of tissues into organs
- Remodeling of the extracellular matrix
- Interaction of cells, tissues, and foreign materials
- Basic methods used to study cells and tissues.

NORMAL CELL HOUSEKEEPING

In very broad strokes, we will first outline the general organization of a prototypical cell, using it to identify the functional considerations required for maintaining viability. We will then revisit each of these structural features to illustrate important concepts in *homeostatic maintenance* (keeping the cell within certain functional boundary conditions) and response to the environment.

Conceptually, cells may be viewed as independent collections of self-replicating enzymes and structural proteins that carry out certain general functions. The most essential cell attributes are:

- protection from the environment
- acquisition of nutrients

- movement
- communication
- catabolism of extrinsic molecules
- degradation and renewal of senescent intrinsic molecules
- energy generation
- self-replication.

Intracellular constituents exist in a microcosm of water, ions, sugars, and small molecular weight molecules called the *cytosol* or *cytoplasm*. Within the cytosol is also a source of energy, typically *adenosine triphosphate* (ATP). Although long conceptualized as a randomly diffusing bag of soluble molecules, the cell is, in fact, a structurally highly-ordered and functionally integrated assembly of organelles, cytoskeletal elements, and enzymes.

The cytosol is delimited and protected from the environment by a phospholipid bilayer, the *plasma membrane*, which permits the cell to maintain cytosolic constituents at concentrations different than those in the surrounding environment. Due to its hydrophobic inner core, the plasma membrane is impermeable to charged and/or large polar molecules; however, it is rendered selectively permeable (i.e., permits specific passage) to incoming or outgoing material (ions, sugars, amino acids, etc.) by pore or transport proteins inserted through it. Most nutrient acquisition is accomplished by the movement of desired substrates either through *protein channels* (driven by electrochemical gradients) or by energy-driven transport through *carrier proteins*. Cells also have the capacity to internalize material by capturing solute or even particles from the extracellular environment in invaginated folds of the plasma membrane called *vesicles*. Depending on the volume and size of the ingested material, the process is denoted *phagocytosis* ("cell eating") or *pinocytosis* ("cell drinking"). *Transcytosis* denotes the movement of pinocytic vesicles from one side of a cell to the other (typically across endothelial cells lining blood vessels); this process clearly permits bulk fluid transport and can play an important role in mediating the increased vascular permeability ("leaky vessels") that occurs around tumors or at sites of inflammation. Plasma membranes also characteristically express a variety of specific surface molecules that facilitate interactions with other cells, soluble ligands (e.g., insulin), and/or with the extracellular matrix (communication).

Many of a cell's normal "housekeeping" functions are compartmentalized within membrane-bounded intracellular organelles (Figure II.1.4.1), thus permitting adjacent regions of the cell to have vastly different chemistries. By isolating certain cellular functions within distinct compartments, potentially injurious degradative enzymes or toxic metabolites can be kept at usefully high concentrations locally, without causing damage to more delicate intracellular constituents. Moreover, compartmentalization also allows the creation of unique intracellular environments (e.g., low pH, high calcium
FIGURE II.1.4.1 General schematic of a typical mammalian cell, demonstrating the general organization and major organelles. Note that each compartment has distinct functions made possible by selectively permeable membranes. (Reproduced by permission from Bergman, A. R., Afifi, A. K. & Heideger, P. M. (Eds.). (1996). *Histology.* Saunders: Philadelphia, PA.)

or containing reactive oxygen species or proteases) that permit more efficient functioning of certain chemical processes, enzymes or metabolic pathways.

The enzymes and structural proteins of the cell are constantly being renewed by ongoing synthesis tightly balanced with intracellular degradation. Oversight for the new synthesis of macromolecules, including

deoxyribonucleic acid (DNA) and *ribonucleic acid* (RNA) is provided by the *nucleus*. New proteins destined for the plasma membrane or for secretion into the extracellular environment are synthesized and packaged in the *rough endoplasmic reticulum* (RER) and *Golgi apparatus*; proteins intended for remaining in the cytosol are synthesized on free *ribosomes*.

Smooth endoplasmic reticulum (SER) may be abundant in certain cell types where it is used for steroid hormone and lipoprotein synthesis, as well as for the modification of hydrophobic compounds into water-soluble molecules for export, or in some cases adapted to store intracellular calcium. Degradation of internalized molecules or senescent self-molecules into their constituent amino acids, sugars, and lipids (catabolism) is the primary responsibility of the lysosomes and proteasomes. Peroxisomes play a specialized role in the catabolism of fatty acids, generating hydrogen peroxide in the process. Intracellular vesicles busily shuttle internalized material to appropriate intracellular site(s) for catabolism or direct newly-synthesized materials to the plasma membrane or relevant target organelle. The three-dimensional architecture of the cell is maintained by a scaffolding of intracellular proteins collectively called the cytoskeleton, analogous in some ways to the support provided by the bones of our bodies. Directed movement of organelles, and even selected proteins, within the cell is accomplished by using the cytoskeleton as a connected network of guide wires; molecular motors (called *dyneins* and *kinesins*) literally "walk" attached organelles from one site to another along these tightropes. These structural proteins also provide basic cellular shape and intracellular organization, which are necessary for the maintenance of *cell polarity* (differences in cell structure and function at the top of a cell versus its side or base). For example, in many cell types, and particularly in epithelial tissues, it is critical for cells to distinguish – and keep separated – the top (*apical*) versus the bottom and side (*basolateral*) surfaces.

Cell movement within its environment is accomplished through rearrangement of the cytoskeleton; the various protein networks have to be disassembled and re-established in a coordinated fashion to allow directed motion. The direction of motion is typically determined by external concentration gradients of chemotactic agents that differentially signal one edge of a cell more than another. The major energy currency for macromolecular synthesis, metabolite degradation, and intra- and extracellular transport is ATP, which is generated in the *mitochondrion* using oxidative phosphorylation. Finally, all of these organelles must be replicated (organellar biogenesis) and correctly apportioned in daughter cells following mitosis.

The Specific Function(s) of a Given Cell are Reflected by the Relative Amounts and Types of Organelles it Contains. The relative predominance of specific types of organelles can be inferred by examination of tissue sections prepared by standard histologic techniques, and can be confirmed by transmission electron microscopy. For example, cells with substantial energy requirements can be expected to have a significantly greater capacity to generate energy. Thus, kidney tubular epithelial cells (which reabsorb sodium and chloride against concentration gradients), and cardiac myocytes (which rhythmically contract 50–100 times per minute) have a generous complement of mitochondria. In comparison, cells specifically adapted to synthesize and export selected proteins (e.g., insulin in a pancreatic islet cell or antibody produced by a plasma cell) have a well-developed rough endoplasmic reticulum. A corollary to this general concept is that the nutritional and extracellular structural needs of a cell can also be inferred from the organellar constituents and the presumed cellular function. Thus, cells with substantial energy demands, but little in the way of intracellular reserves (e.g., myocardial cells), will need a continuous source of oxygen and glucose – provided by a dense capillary supply with minimal diffusion distance from blood to mitochondria. Conversely, cells that absorb from one surface but export products at a different interface will require an extracellular basement membrane and specific cell–cell connections to provide the proper orientation.

THE PLASMA MEMBRANE: PROTECTION, NUTRIENT ACQUISITION, AND COMMUNICATION

Plasma membranes, as well as all other organellar membranes, are dynamic, fluid, and inhomogeneous lipid bilayers containing a variety of embedded proteins. Biologic membranes are composed of phospholipids that are *amphipathic*; i.e., they have a polar head-group that prefers to interact with water (*hydrophilic*), and non-polar fatty acid chains that resist interaction with water (*hydrophobic*). These phospholipids spontaneously assemble to form two-dimensional sheets with their hydrophilic head groups facing towards the aqueous cytoplasm or extracellular fluid, and their hydrophobic lipid tails interacting to form a central core that largely excludes water. Since the lipid core of plasma membrane is intrinsically resistant to the movement of large or polar molecules, continued cell function requires that specific protein channels or transport mechanisms be in place to facilitate uptake of ions and metabolites (Figure II.1.4.2). In addition, the plasma membrane is also the interface between the extracellular environment and the inner cellular domains; cell surface proteins can link extracellular matrix with the intracellular cytoskeleton or can act as receptors for extracellular ligands that can trigger intracellular signaling events.

The lipid confers structural integrity and barrier function to the membrane, and the inserted proteins provide specialized membrane functions (see below). In addition, the specific composition of the lipid bilayer, e.g., relative amounts of various phospholipids, cholesterol, and glycolipids, will alter the physico-chemical properties of the membrane, as well as the functioning of associated proteins. Although the various lipid and protein constituents can move about easily in the plane of the membrane, certain components have a predilection for each other, and different domains with distinct lipid compositions
FIGURE II.1.4.2 Model of a prototypical cell membrane. Note the lipid bilayer with outer, hydrophilic headgroups (exposed to an aqueous environment) and inner, hydrophobic tailgroups (maintaining a barrier to solute movement). Inserted through the membrane or attached to either inner or outer planes are various proteins that permit transport, cell–cell and signal molecule interactions, and linkage of the membrane to the intracellular cytoskeleton or extracellular matrix. (Reproduced by permission from Bergman, A. R., Afifi, A. K. & Heideger, P. M. (Eds.). (1996). *Histology*. Saunders: Philadelphia, PA.)

are thereby created. Since inserted membrane proteins have different solubilities in these various lipid domains, the membrane lipid inhomogeneities result in functionally distinct islands and patches of protein molecules. This has significance in terms of cell–cell and cell–matrix interactions, as well as in intracellular signaling. The lipid component of the plasma membrane is also asymmetric, that is, the inner and outer leaflets have different general compositions. The asymmetry has functional significance in that gangliosides, conferring a net negative charge, and glycolipids – both of which are on the outer face of the bilayer – are important for cell–cell and cell–matrix interactions, local electrostatic effects, and creation of barriers to infection. In contrast, inositol-containing phospholipids are primarily arrayed on the inner face, presumably because they play an important role in intracellular signaling.

How Proteins Associate with Membranes Reflects their Function. Most proteins inserted into membranes are *integral* or *transmembrane* proteins, having one or more relatively hydrophobic α-helical segments that traverse the lipid bilayer and securely anchor the protein. Proteins involved in forming pores or transporting other molecules will typically be transmembrane. In other cases, proteins are attached to the membrane via weaker lipid–protein or protein–protein interactions. Non-integral proteins can potentially interact with a variety of membrane molecules, can mediate cytoskeletal interactions that permit movement or can be used to transduce transient signals.

Plasma Membrane Proteins Frequently Function Together as Large Complexes. These complexes may be primarily assembled as the proteins are synthesized in the RER or may arise by lateral diffusion in the plasma membrane. Such *de novo* complex formation, followed by signal cascade inside the cell, is a typical paradigm

employed to translate ligand–surface receptor binding into an intracellular response. Large complexes also form the basis for intercellular connections such as *tight junctions* (see below). Similar interactions between like proteins on adjacent cells (*homotypic interactions*) create a zone that separates the apical versus basolateral aspects of cells in epithelial layers, and thereby establish cell polarity.

The Hydrophobic Lipid Core of Plasma Membranes is an Effective Barrier to the Passage of Most Polar Molecules. Small, nonpolar molecules, such as O_2 and CO_2, readily dissolve in lipid bilayers, and therefore rapidly diffuse across them. Large hydrophobic molecules, such as steroid hormones (testosterone and estrogen, for example), also readily cross lipid bilayers. Even polar molecules, if sufficiently small (e.g., water, ethanol, and urea at molecular weights of 18, 46, and 60 daltons, respectively) rapidly cross membranes. In contrast, glucose, at a molecular weight of only 180 daltons is effectively excluded, and lipid bilayers are completely impermeable to ions, regardless of size, due to their charge and high degree of hydration. Therefore, to facilitate the entrance or egress of most molecules, specific transport proteins are required. For small molecular weight molecules (ions, glucose, nucleotides, and amino acids up to approximately 1000 daltons) there are two main categories: *carrier proteins* and *channel proteins*. For larger molecules or even particles, uptake is mediated by specific receptors, internalized via *endocytosis*. Large molecules destined for export are packaged in *secretory vesicles* that fuse with the plasma membrane and expel their contents in a process called *exocytosis*.

Each type of transported molecule (ion, sugar, nucleotide, etc.) requires a unique membrane transport protein to facilitate passage. These transporters typically exhibit strong specificity. Thus, a particular transporter
FIGURE II.1.4.3 Schematic of receptor-mediated endocytosis, enabling large molecules (e.g., transferrin with bound iron) and extracellular solutes to enter the cell. After binding to specific receptors, proteins are internalized on *clathrin-coated pits*, which pinch off to form *clathrin-coated vesicles*. The clathrin coat is then removed and the vesicle fuses with *endosomes* delivering its bound contents. Acidification of the endosome releases ligands; the receptors can be reutilized by vesicles pinching off from the endosome and recycling to the plasma membrane (*exocytosis,* not shown). (Reproduced by permission from Bergman, A. R., Afifi, A. K. & Heideger, P. M. (Eds.). (1996). *Histology*. Saunders: Philadelphia, PA.)

will move glucose but not galactose; another transporter will move potassium but not sodium. Carrier proteins bind their specific ligand and undergo a series of conformational changes to transfer it across the membrane; their transport is relatively slow. In comparison, channel proteins create hydrophilic pores; when open, these permit rapid movement of selected solutes. In most cases, a concentration and/or electrical gradient between the inside and outside of the cell drives solute movement by passive transport (virtually all plasma membranes have an electrical potential difference across them, with the inside of a cell negative relative to the outside). In some cases, active transport against a concentration gradient is accomplished by carrier molecules (never channels) and requires energy expenditure (provided by the breakdown of ATP). Transporters also include the multidrug resistance (MDR) protein, which pumps polar compounds (for example, chemotherapeutic drugs) out of cells, and may render cancer cells more resistant to treatment. Similar transport mechanisms also regulate intracellular and intraorganellar pH; human beings and most of their cytosolic enzymes prefer to work at pH 7.2, while lysosomes function best at pH 5 or less.

Because the plasma membrane is freely permeable to water, water will move into or out of cells along its concentration gradient (by osmosis). Extracellular salt in excess of that seen in the cytoplasm (hypertonicity) will cause a net movement of water out of cells; conversely, hypotonicity will cause a net movement of water into cells. Since the intracellular environment is rich in charged molecules that attract a large number of charged counter-ions (tending to increase osmolarity), cells need to constantly and actively regulate their intracellular osmolarity by pumping out small inorganic ions (typically sodium and chloride). The loss of the ability to generate energy (e.g., in a cell injured by toxins or lacking oxygen), therefore results in an osmotically swollen cell which may eventually rupture if normal homeostatic mechanisms do not soon supervene.

Uptake and Metabolism of Large Extracellular Molecules Requires Vesicle Targeting and Membrane Recycling. Proteins, large carbohydrates, and other macromolecules cannot enter cells by either channels or carriers. Instead, they are internalized by endocytosis (see Figure II.1.4.3). Endocytosis typically begins at a specialized region of the plasma membrane called the *clathrin-coated pit*, which rapidly invaginates and pinches off to form a *clathrin-coated vesicle* (about 2500 per minute in the average fibroblast). *Clathrin* is a hexamer of proteins that spontaneously assemble into a basket-like lattice to drive the budding process of endocytosis. Trapped within the vesicle will be a minute gulp of the extracellular milieu, as well as any molecules specifically bound to receptors on the internalized bit of plasma membrane (*receptor-mediated endocytosis*). This is the pathway, for example, by which cells internalize iron from the circulation: ionized iron, bound to a protein called *transferrin*, interacts with cell surface *transferrin receptors* which are then internalized via receptor-mediated endocytosis. The same pathway – but using a different receptor – is responsible for the binding and uptake of low-density lipoproteins (LDL) or any of a variety of other extracellular macromolecules. Notably, the same clathrin-coated pit or vesicle can contain many different receptors; all it takes to localize receptors to the clathrin endocytic pathway are specific amino acid motifs expressed on the cytosolic tails of the relevant proteins.

The vesicles rapidly lose their clathrin coat and then fuse with an acidic intracellular structure called the *endosome* where the lower pH causes dissociation of ligands from their receptors. This allows released ligands to be shuttled to the lysosome (or other locations) while receptors can either return to the plasma membrane for another cycle (e.g., the transferrin receptor) or can be degraded themselves (e.g., the LDL receptor) (Figure II.1.4.4 and below). Degradation of a receptor after internalization (*receptor down-regulation*) provides an important control for receptor expression and
FIGURE II.1.4.4 Schematic demonstrating the pathways by which internalized material is degraded. There is convergence of *endocytic*, *phagocytic*, and *autophagic* vesicles as they fuse with newly synthesized catabolic enzyme-containing vesicles or with pre-existing *lysosomes*. The contents are nearly completely degraded to constituent amino acids, sugars, and lipids; non-degradable material will accumulate in residual bodies. (Reproduced by permission from Bergman, A. R., Afifi, A. K. & Heideger, P. M. (Eds.). (1996). *Histology*. Saunders: Philadelphia, PA.)

receptor-mediated signaling. Endocytosis can also deliver material completely across a cell, i.e., from the apical surface to the basolateral face (*transcytosis*), forming, for example, the basis for transport of nutrients from the gastrointestinal tract to the bloodstream. *Endocytosis* is an ongoing process, with constant recycling of vesicles back to the plasma membrane (*exocytosis*). Endocytosis and exocytosis must be tightly coupled, since a cell can internalize 10–20% of its own cell volume each hour or about 1–2% of its plasma membrane each minute.

Cell Communication is Critical in Multicellular Organisms. At the most basic level, extracellular signals may determine whether a cell lives or dies, whether it remains quiescent, proliferates, migrates or otherwise becomes active to perform its specific function(s).

Intercellular signaling is critical in the developing embryo in order for cells to appear in the correct quantity and location, and to maintain tissue organization. Intercellular signaling is also important in the intact organism, ensuring that all tissues act in appropriate concert in response to stimuli as divergent as food or threat to life. Loss of communication may be reflected in a congenital structural defect, in unregulated cell growth (cancer) or an ineffective response to an extrinsic stress.

Cells Communicate Over Short and Long Distances. Adjacent cells can communicate via *gap junctions* – hydrophilic cylindrical pores that effectively connect the two cells' cytoplasm, formed by hexamers of proteins called *connexins*. These pores permit movement of small ions (e.g., Ca^{++}), various metabolites, and potential second messenger molecules, but not larger macromolecules. *Extracellular signaling* by soluble mediators occurs in three different forms: (1) *paracrine*, meaning that it affects cells only in the immediate vicinity. To accomplish this, there can be only minimal diffusion, with the signal rapidly degraded, taken up by other cells or trapped in the ECM; (2) *synaptic*, classically where activated neural tissue secretes *neurotransmitters* at a specialized cell junction (*synapse*) onto target cells; (3) *endocrine*, where a regulatory substance, such as a hormone, is released into the bloodstream and acts on target cells at a distance.

Since most signaling molecules are present at extremely low concentrations ($\leq 10^{-8}$ M), binding to the appropriate target cell receptor is typically a high affinity and exquisitely specific interaction. Receptor proteins may be on the cell surface or they may be intracellular; in the latter case, ligands must be sufficiently hydrophobic to enter the cell (e.g., vitamin D or steroid and thyroid hormones). For intracellular receptors, ligand binding leads to formation of a receptor–ligand complex that directly associates with nuclear DNA, and subsequently either activates or turns off gene transcription. For cell-surface receptors, the binding of ligand can: (1) open ion channels (e.g., at the synapse between electrically-excitable cells); (2) activate an associated GTP-binding regulatory protein (*G protein*); or (3) activate an associated enzyme. Secondary intracellular downstream events frequently involve phosphorylation (via *kinases*) or dephosphorylation (via *phosphatases*) of target molecules, with subsequent changes in enzymatic activity, intracellular localization or the ability to bind to DNA and induce transcription (see Figure II.1.4.5).

Besides *soluble signals* that arrive through cell surface (and intracellular) receptor–ligand interactions (as in Figure II.1.4.5), cell behavior and differentiation are also regulated by mechanical forces – so-called *mechanotransduction*. Fluid shear, pressure or tension on a tissue modulates cellular activity through transmembrane proteins called *integrins* that link extracellular matrix molecules with the intracellular actin cytoskeleton. Tugging
FIGURE II.1.4.5 Overview of intracellular and cell surface receptor signaling pathways. Binding of ligands to cell surface receptors can open ion channels, activate associated G proteins or activate associated enzymes, many of which have kinase activity (the ability to phosphorylate other protein substrates). Kinase activity may activate additional kinases that may in turn phosphorylate other proteins (e.g., the JAK-STAT pathway). Subsequent intracellular downstream mediators (e.g., calcium, IP_3, cAMP) or events (e.g., the translocation of a phosphorylated protein to the nucleus) eventually induce changes in the transcriptional activity of specific genes. Ligand binding to intracellular receptors (e.g., estrogen and estrogen receptor; not shown) leads to formation of complexes that can directly associate with nuclear DNA to activate or turn off transcription. PI3 kinase, phosphoinositide-3 kinase; PLC-γ, phospholipase C- γ; JAK, Janus kinase; MAP kinase, mitogen activated protein kinase; IP_3, inositol trisphosphate; cAMP, cyclic adenosine monophosphate; STAT, signal transducers and activators of transcription. (Reproduced by permission from Kumar, V., Abbas, A. K. & Fausto, N. (Eds.). (2005). *Robbins and Cotran Pathologic Basis of Disease,* 7th edn. Saunders: Philadelphia, PA.)

on the extracellular matrix will thereby elicit cytoskeletal and nuclear conformation changes that can alter genetic expression. A cell membrane complex of proteins associated with the integrins (the *focal adhesion complex*) can also transduce extracellular forces through the mechanical activation of cell membrane kinases and ion channels (Figure II.1.4.6).

An individual cell is exposed to a remarkable cacophony of signals which it must sort through and integrate into a rational response. Some ligands or forces induce a given cell type to differentiate, others signal proliferation, and yet others direct the cell to perform a specialized function. Multiple signals at once, in a certain ratio, may induce yet another totally unique response. Many cells require certain signals just to continue living; in the absence of appropriate exogenous ligand – or even simple connection to the extracellular matrix – they may undergo a form of cellular suicide (programmed cell

death) called apoptosis (discussed in detail later in this chapter).

THE CYTOSKELETON: CELLULAR INTEGRITY AND MOVEMENT

The ability of cells to adopt a particular shape, maintain cell polarity, organize the relationship of intracellular organelles, and move depends on the intracellular scaffolding of proteins called the cytoskeleton. In eukaryotic cells there are three major classes of cytoskeletal proteins: 6–8 nm diameter actin microfilaments; 10 nm diameter intermediate filaments; and 25 nm diameter microtubules. Although these proteins can impart intracellular structure and cell shape (especially the intermediate filaments) it should also be emphasized that they are all dynamic. In particular, actin and microtubules enable movement and cellular locomotion.
FIGURE II.1.4.6 Soluble and mechanotransduction pathways by which a variety of cell behaviors – e.g., proliferation, differentiation, protein synthesis, locomotion or shape change – can be modified. Note that soluble mediators can act through plasma membrane receptors (or intracellular receptors – not shown) to affect changes in nuclear transcription, as depicted in greater detail in Figure II.1.4.5. Extrinsic mechanical forces can also lead to changes in cellular phenotypes by protein–protein interactions linking matrix proteins (e.g., fibronectin, and laminin) with cell surface integrins that are in turn connected to the nucleus through cytoskeletal elements such as actin microfilaments. Integrins are also important components of focal adhesion complexes, which can provide soluble secondary signals (e.g., through protein phosphorylation) when external mechanical forces are applied to proteins connected to them. PDGF, platelet-derived growth factor; EGF, epidermal growth factor; IL-1/TNF, interleukin-1/tumor necrosis factor; TGF-β, transforming growth factor-β; TIMPs, tissue inhibitors of metalloproteinases (Reproduced by permission from Kumar, V., Abbas, A. K. & Fausto, N. (Eds.). (2005). *Robbins and Cotran Pathologic Basis of Disease,* 7th edn. Saunders: Philadelphia, PA.)

Actin microfilaments: the **g**lobular protein actin (**G**-actin) is the major subunit of microfilaments, and is the most abundant cytosolic protein in cells. The monomers polymerize into long double-stranded helical filaments (**F**-actin), with a defined polarity (one end is stable; the other end grows or shrinks). In muscle cells, the filamentous protein *myosin* binds to actin, and moves along it – driven by ATP hydrolysis – forming the basis of muscle contraction. In non-muscle cells, F-actin and an assortment of *actin-binding proteins* form coordinated bundles and networks that control cell shape and surface movements.

Intermediate filaments comprise a large and heterogeneous family of closely related structural proteins.

Although they generally perform similar functions, each member of the family has a relatively restricted expression in specific cell types. These rope-like fibers are found predominantly in a stable polymerized form within cells; they are not usually actively reorganizing like actin and microtubules. Intermediate filaments impart strength and carry mechanical stress, e.g., in epithelia where they connect *spot desmosomes* (see below). They also form the major structural proteins of skin and hair (i.e., keratin).

Microtubules consist of polymerized dimers of α- and β-*tubulin* arrayed in constantly elongating or shrinking hollow tubes. These have a defined polarity with ends designated "+" or "–." In most cells, the "–" end is embedded in a microtubule organizing center (MTOC

or centrosome) which lies near the nucleus; the "+" end elongates or recedes in response to various stimuli by the addition or subtraction of the tubulin dimers. Within cells, microtubules may serve as mooring lines for protein "molecular motors" that hydrolyze ATP to move vesicles, organelles or other molecules around cells; the polarity of the microtubules allows cells to direct whether attached structures are "coming" or "going" relative to the nucleus. In neurons, microtubules are critical for the delivery of molecules synthesized in the nuclear area to the far-flung axonal cytosol, which may be as far away as 10,000 times the width of the cell body (indeed, the nucleus of some motor neurons in the spinal cord have axons extending to the muscles of the great toe over 3 feet away!). Microtubules are also used to pull chromosome pairs apart during mitosis, and thus play a basic role in cellular proliferation. Finally, in certain cells, microtubules and their associated molecular motors have been harnessed to facilitate cellular motility – they form cilia to move mucus and dust out of the airways, and flagella to propel sperm.

Maintaining cellular and tissue integrity requires cell–cell and cell–ECM interactions, mediated through the proteins embedded in the plasma membrane and connected to the cytoskeleton. The organization of tissues requires attaching cells together and to the underlying ECM scaffolding. The mechanical connections between extracellular elements and the intracellular cytoskeleton – mediated by transmembrane proteins – also means that extracellular forces on a tissue (e.g., torsion or tension) can be translated into intracellular events. Indeed, we have learned that "normal" cell behavior can critically depend on external physical forces, such as laminar shear stress on endothelial cells that line blood vessels.

As discussed above, the external face of a cell membrane is diffusely studded with carbohydrate-modified (*glycosylated*) proteins and lipids. This cell coat (or *glycocalyx*) functions primarily as a chemical and mechanical barrier, but also serves an important role in cell–cell and cell–matrix interactions, including sperm–egg attachment, blood clotting, lymphocyte recirculation, and inflammatory responses. For example, neutrophils (cells involved in acute inflammation) are recruited to sites of infection or injury by localized endothelial cell expression of lectin-like molecules (*selectins*) that bind the sugar motifs expressed on the neutrophil surface glycoproteins.

Cell–cell connections include *occluding junctions* (*tight junctions*) and *anchoring junctions* (*desmosomes*) (Figure II.1.4.7) (gap junctions (described above) function primarily in cell-to-cell communication and do not materially contribute to cellular adhesiveness). Tight junctions seal cells together in a continuous sheet, preventing even small molecules (but not water) from leaking from one side to the other. These junctions are the basis of the high electrical resistance of many epithelia,
FIGURE II.1.4.7 Diagram of two prototypical epithelial cells (as part of a larger planar sheet) demonstrating attachments to the underlying basal lamina (*hemidesmosomes*), and to each other (*tight junction*, *adhesion belt*, and *spot desmosomes*). Note the cytoskeletal elements underlying each attachment point giving structural integrity to the individual cells as well as to the larger epithelial structure. *Gap junctions* do not confer intercellular adhesion, but are responsible for direct cell–cell signaling. (Reproduced by permission from Bergman, A. R., Afifi, A. K. & Heideger, P. M. (Eds.). (1996). *Histology.* Saunders: Philadelphia, PA.)

as well as the ability to segregate apical and basolateral spaces. It is important to remember, however, that these junctions (as well as the desmosomes) are also dynamic structures that intermittently dissociate and reform. This allows processes such as the healing of an epithelial wound or passage of inflammatory cells across vascular endothelium to sites of infection. Intracellular actin microfilaments can stretch across cells, connecting tight junctions on different faces of the same cell; such spanning creates a circumferential band (*adhesion belt*) of cytoskeleton that provides structural integrity and shear strength to sheets of interconnected cells (Figure II.1.4.7).

Desmosomes mechanically attach cells (and their cytoskeletons) to other cells or to the ECM. When they occur in broad belts or bands between cells they are referred to as *belt desmosomes*; when they are small and rivet-like they are denoted as *spot desmosomes*. Desmosomes are formed by a homotypic association (two proteins of the same type) of transmembrane glycoproteins called *cadherins*. The cytosolic ends of cadherins are associated with cytoskeletal actin microfilaments and intermediate filaments. *Focal adhesion complexes* or *hemidesmosomes* (literally, half a desmosome) are "spot welds" that connect cells to the extracellular matrix; in the case of epithelial tissues, the connections are to a dense ECM meshwork called the *basal lamina* or *basement membrane* (see Chapter II.1.5). The plasma membrane proteins forming the basis of these interactions are called *integrins*; like cadherins, they attach to intracellular actin microfilaments. These focal adhesion complexes,

connecting cells to the ECM, also act to generate intra-cellular signals when cells are subjected to abnormal shear stress (such as endothelium in a turbulent area of the bloodstream).

THE NUCLEUS: CENTRAL CONTROL

With the exception of the terminally-differentiated hematopoietic cells (erythrocytes and platelets), every human cell has a central regulatory nucleus containing nucleic acids (DNA and RNA) and proteins that determine the sequence and rate of macromolecular synthesis. The full complement of DNA in a cell is called its *genome*.

The Nucleus is not a Uniform Static Repository of Molecules. At any given time, and depending on the functional state of the cell, there is *replication* (duplication of DNA) or *transcription* (conversion of DNA into messenger RNA) of selected subsets of the genome. Clearly, proliferating cells need to generate an entire copy of all nuclear material so that daughter cells can each be afforded a complete set of chromosomes. In mitotically-quiescent cells, however (those in G_0 of the cell cycle), there is no DNA replication; nuclear activity is essentially all devoted to gene transcription. While certain housekeeping functions must be constitutively active to maintain normal cellular viability, in differentiated cells only a small fraction of all possible genes is transcribed.

Nuclear Proteins and Nucleic Acids are Organized into Clumps and Clusters Called Chromatin. Two basic forms of chromatin are recognizable by light microscopy and routine staining correlating with the activity of the gene. When genes are transcriptionally inactive, they are tightly coiled in compact aggregates wrapped around protein *histones*, and are not accessible to transcription machinery; this results in a cytochemically dense appearance called *heterochromatin*. In actively transcribing genes, the nuclear material uncoils into a more extended linear form, which is cytochemically disperse and called *euchromatin*. The degree of cellular activation or gene transcription may thus be inferred from the general staining characteristics of nuclei (Figure II.1.4.8). The nucleolus is a subcompartment of the nucleus dedicated to ribosomal RNA synthesis and ribosome assembly. Its size may also reflect the translational activity of the cell; the greater the protein synthesis, the more prominent the nucleolus.

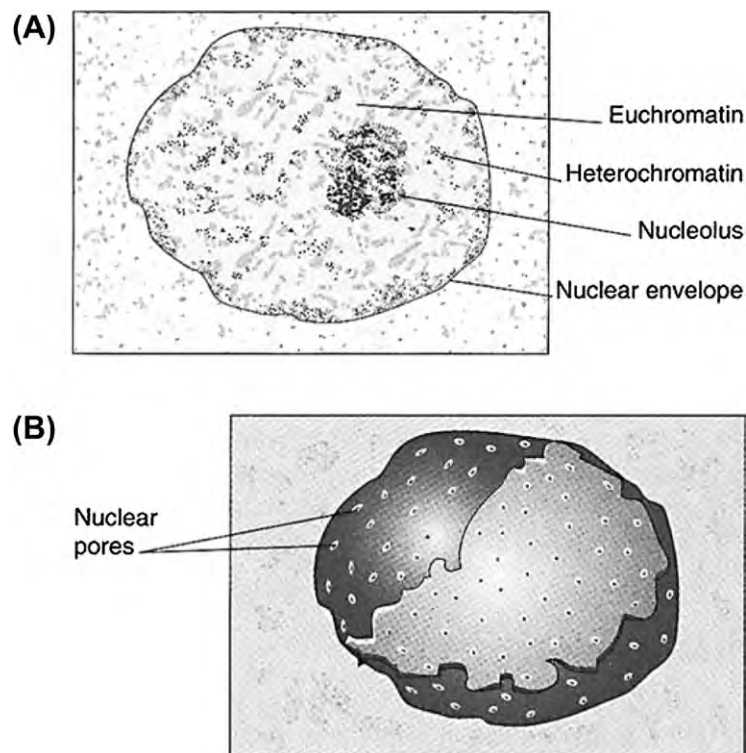
Movement of Molecules into and Out of the Nucleus is Restricted and Tightly Regulated. The nucleus is surrounded by a *nuclear envelope* formed by two concentric membranes supported by networks of intermediate filaments. The outer membrane is continuous with the endoplasmic reticulum, and is joined to the inner membrane at numerous *nuclear pores* that punctuate the envelope. The pores are elaborate, gated structures which permit the active transport of molecules to and from the cytosol. Since the pores are readily permeable


FIGURE II.1.4.8 Diagram of the nucleus and nuclear pore system. (A) Illustration of *heterochromatin* (clumped non-transcribing nuclear material), *euchromatin* (dispersed, transcribing nuclear material), and *nucleolus* (site of ribosome synthesis); (B) Schematic representation of nuclear pores; note that they are not passive openings in the nuclear envelope, but rather represent selective active transporters. only to globular proteins ≤50,000 daltons, the process of moving large molecules and complexes (e.g., ribosomes out of the nucleus or histones and polymerase complexes into the nucleus) is accomplished by specific receptor proteins. Macromolecules destined for the nucleus are identified by specific nuclear localization signals (typically certain amino acid sequences) that permit binding to the pore receptor proteins. Of note, these localization signals may be cryptic, as in some inactive steroid receptor proteins. Subsequent binding of the steroid ligand causes a conformational change that uncovers the localization signal; the receptor can then be translocated to the nucleus.

ROUGH AND SMOOTH ENDOPLASMIC RETICULUM, AND GOLGI APPARATUS: BIOSYNTHETIC MACHINERY

The endoplasmic reticulum (ER) is the site for the synthesis of all the transmembrane proteins and lipids for most of a cell's organelles, including the ER itself. It is also the initial site for the synthesis of the majority of molecules destined for residence in the lumens of ER, Golgi, and lysosomes or for export out of the cell. The ER is organized into a mesh-like maze of interconnecting branching tubes and flattened vesicles (see Figure II.1.4.1) forming a continuous sheet around a single highly convoluted space topologically equivalent to the extracellular environment. The ER is composed of contiguous but distinct domains, distinguished by the presence (rough ER or RER) or absence (smooth ER or SER) of ribosomes.

Membrane-bound ribosomes on the cytosolic face of RER are actively translating mRNA into proteins, which are folded and edited in the lumen of the ER (Figure II.1.4.9). This process, called translation, is directed by amino acid signal peptides generally present on the N-termini of nascent proteins; if a new protein with a signal peptide is produced on a free ribosome, the signal peptide directs the entire complex to attach to the ER membrane. Proteins synthesized in this way are directly inserted into the ER as they are being made. Within the ER lumen, the proteins fold and form multi-subunit complexes under the scrutiny of ER chaperone molecules. These chaperones interact with a variety of proteins within the ER, ensuring that they are completely assembled and functional. Failure to appropriately fold results in retention and eventually degradation within the ER; thus the ER has an editing function for safeguarding the fidelity of the transcriptional apparatus. In some cases where unfolded proteins overwhelm the editing capacity, a so-called ER "stress response" (also called the unfolded protein response) triggers the affected cell to undergo apoptotic cell death.

For proteins lacking a signal sequence, the translation apparatus remains on free ribosomes in the cytosol, frequently forming *polyribosomes* as multiple translation units attach to the mRNA; the resulting protein remains within the cytoplasm and is not exported from the cell.

After leaving the RER, proteins and lipids are modified in the Golgi apparatus and sorted for intracellular delivery (Figure II.1.4.10). In the Golgi proteins are glycosylated – modified by a step-wise addition of various sugars. These modifications are important in subsequent sorting of molecules to various intracellular sites, and also because glycosylation is critical for surface molecules
FIGURE II.1.4.9 Schematic demonstrating the general steps in the synthesis of proteins on *rough endoplasmic reticulum* (RER). (A) Peptide synthesis from mRNA begins on free ribosomes in the cytosol; (B) Signal peptide sequences on the nascent proteins direct the entire complex to attach to the ER membrane with insertion of the synthesizing protein into the RER lumen; (C) The signal sequence is cleaved and the protein is completely synthesized, eventually detaching from the ribosome; (D) The protein is folded and assembled (if necessary) into multi-subunit complexes; the ribosome detaches from the ER surface and returns to the cytoplasm. (Reproduced by permission from Bergman, A. R., Afifi, A. K. & Heideger, P. M. (Eds.). (1996). *Histology.* Saunders: Philadelphia, PA.)
FIGURE II.1.4.10 Functional, schematic diagram of the relationship between the *rough endoplasmic reticulum* (RER), *smooth endoplasmic reticulum* (SER), and the *Golgi apparatus*. Proteins destined for export or for other intracellular organelles pass from the RER to the SER where they form vesicles for transport to the Golgi; there they are progressively modified and sorted, eventually leaving in transport vesicles for their appropriate final destination. (Reproduced by permission from Bergman, A. R., Afifi, A. K. & Heideger, P. M. (Eds.). (1996). *Histology.* Saunders: Philadelphia, PA.)

involved in cell–cell or cell–matrix interactions. In addition to the step-wise glycosylation of lipids and proteins, the trans-Golgi network sorts molecules for dispatch to other organelles (including the plasma membrane) or secretory vesicles destined for extracellular release. The Golgi complex is especially prominent in cells specialized for secretion, including goblet cells of the intestine or bronchial epithelium (making large amounts of polysaccharide-rich mucus), and plasma cells (secreting antibodies).

The SER has a Role in Steroid Hormone Synthesis, Modification of Certain Metabolites, and Intracellular Calcium Regulation. The *SER* in most cells is relatively sparse. However, in cells that synthesize steroid hormones (e.g., the adrenal cortex or gonads) or that catabolize lipid-soluble molecules (e.g., liver cells make certain drugs more water-soluble so that they may be excreted), the SER may be particularly conspicuous. The SER is also responsible for sequestering intracellular Ca++; release of Ca++ from the SER is a mechanism by which cells can rapidly respond to extracellular signals. Finally, in muscle cells, specialized SER called *sarcoplasmic reticulum* regulates the successive cycles of myofiber contraction (Ca++ released into the cytosol) and relaxation (Ca++ pumped back into the SER).

LYSOSOMES, PROTEASOMES AND PEROXISOMES: WASTE DISPOSAL

To digest internalized macromolecules or senescent organelles, cells primarily rely upon lysosomes. *Lysosomes* are membrane-bounded organelles containing a large assortment (>40) of acid hydrolase enzymes including proteases, nucleases, lipases, glycosidases, phosphatases, and sulfatases. Each have an optimal activity at pH 5, which is a protective feature since these enzymes will do less damage should they leak into the pH 7.2 cytosol. Materials destined for catabolism arrive in the lysosomes by one of three pathways:

(1) internalized by *fluid-phase* or *receptor-mediated endocytosis*. Material passes from plasma membrane to early endosome to late endosome, and ultimately into the lysosome (see Figure II.1.4.4).
(2) obsolete organelles within cells (the average mitochondrion, for example, only lives 10 days) are shuttled into lysosomes by a process called *autophagy*. The resultant *autophagosome* then fuses with lysosomes and the organelle is catabolized. Besides normal organellar turnover, this pathway may be important in pathologic settings leading to cellular and tissue atrophy (e.g., disuse atrophy of skeletal muscle); it has also been increasingly recognized as another mechanism of programmed cell death distinct from apoptosis.
(3) *phagocytosis* of microorganisms or large fragments of matrix or debris occurs primarily in professional phagocytes (*macrophages* or *neutrophils*). The material is engulfed to form a *phagosome* that subsequently fuses with a lysosome.

Proteasomes degrade cytosolic molecules that are senescent or require constant turnover to regulate their activity. The cytosol also needs a mechanism by which misfolded proteins can either be refolded or degraded, and to regulate the longevity of certain other proteins that turn over at discrete rates. Chaperones (also known as heat shock proteins) are intracellular proteins that are upregulated following cell stress, and have the capacity to refold partially denatured molecules (Figure II.1.4.11). Failing successful reconstitution of normal structure or in cases where a protein has outlived its usefulness, molecules are marked for destruction by covalently binding one or more 76-amino acid
FIGURE II.1.4.11 Mechanism of intracellular protein repair and degradation. The normal activity of damaged and denatured proteins can be recovered through the action of chaperones (also called *heat shock proteins*). If the proteins cannot be successfully refolded, proteasome degradation will occur. This is also a mechanism by which cytoplasmic proteins that are no longer required (e.g., signaling molecules) can be regulated. Senescent or damaged cytoplasmic proteins are marked for destruction by the proteasome by ubiquitination. The proteasome is a cylinder composed of several different proteases, each with its active site pointed at the hollow core; proteins are degraded into small (6–12 amino acids) fragments. (Reproduced by permission from Kumar, V., Abbas, A. K. & Fausto, N. (Eds.). (2005). *Robbins and Cotran Pathologic Basis of Disease,* 7th edn. Saunders: Philadelphia, PA.)

proteins called ubiquitin. Ubiquitin-tagged molecules are then targeted to polymeric protein complexes called proteasomes; hundreds to thousands of proteasomes are present in any given cell. Each proteasome is a cylinder composed of several different proteases, each with its active site pointed at the hollow core; proteins are degraded into small (6–12 amino acids) fragments. This degradative mechanism is thought to be a holdover from prokaryotes (i.e., primitive cellular organisms) that lack lysosomes (Figure II.1.4.11).

Peroxisomes are probably the vestiges of ancient eukaryotic structures that catabolized oxygen when it would have been a highly toxic molecule, and not necessarily useful in generating energy. These organelles derive their name from the numerous enzymes they contain to remove hydrogen ions from various substrates and transfer them to oxygen, forming *peroxide* in the bargain. In addition, they contain large quantities of oxidative enzymes such as catalase (which breaks down hydrogen peroxide) and urate oxidase. A major function of peroxisomes in mammalian cells (shared by mitochondria) is the β-*oxidation* of fatty acids, whereby two-carbon blocks are successively removed, converted to acetyl CoA, and shuttled to the cytoplasm to undergo additional biosynthetic reactions. Peroxisomes are also the only organelle capable of catabolizing *very long chain fatty acids* (≥20 carbons). An interesting sidelight is that no ATP is generated by peroxisomes in the course of their fatty acid breakdown; the energy is released in the form of heat. Interestingly, these are self-replicating organelles; new peroxisomes can only derive from preexisting peroxisomes. They self-assemble from selected proteins (marked by a serine-lysine-leucine triple amino acid motif) synthesized in the cytosol and imported through binding to specific peroxisome membrane receptors.

MITOCHONDRIA: ENERGY GENERATION

Energy to run intracellular processes is (mostly) provided by adenosine triphosphate (ATP) generated by mitochondria. ATP hydrolysis, the chemical reaction that removes a terminal phosphate from ATP to form adenosine diphosphate (ADP), is accompanied by the release of a large amount of energy. The energy derived from this hydrolysis is the essential currency used for such activities as ion and macromolecular transport across membranes, synthesis of molecules for cell housekeeping and for export, and specialized cell functions such as contraction of muscle.

ATP production begins with cytosolic glycolysis (e.g., metabolizing glucose to pyruvate or lactate), followed by the mitochondrial conversion of pyruvate to carbon dioxide and water through the Krebs cycle, with subsequent oxidative phosphorylation. These reactions – particularly oxidative phosphorylation (the process of generating ATP from substrate oxidation) – are critically

dependent on the availability of oxygen. When oxygen is present, 38 ATP are generated from metabolism of one glucose molecule; in the absence of oxygen, only two molecules of ATP are generated. Although carbohydrate metabolism is the primary source of ATP (in the brain, glucose is essentially the *only* energy source), fat and protein breakdown can also contribute to ATP production.

Each mitochondrion has two separate and specialized membranes. There is a core *matrix space* (containing most of the enzymes to catabolize glucose and its primary metabolites) surrounded by an *inner membrane* (containing the enzymes to transfer electrons to oxygen) folded into *cristae*; these constitute the major working parts of the organelle. The inner membrane is enclosed by the *intermembrane space* (site of ADP-to-ATP phosphorylation) which is in turn surrounded by the *outer membrane*; the latter is studded with a transport protein called *porin*, which forms aqueous channels permeable to low molecular weight substrates (Figure II.1.4.12). Interestingly, mitochondria are also central to the pathways leading to *apoptosis* (see later).

Mitochondria probably evolved from ancestral prokaryotes engulfed by primitive eukaryotes about 1–2 billion years ago. This explains why mitochondria contain their own DNA (circularized, about 1% of the total cellular DNA) encoding for approximately one-fifth of the proteins involved in oxidative phosphorylation. Although the mitochondrial DNA codes for only a very small number of proteins, mitochondria have the machinery necessary to carry out all the steps of DNA replication, transcription, and translation. Consistent with its evolutionary origin, mitochondrial translational machinery is similar to present-day bacteria. For example, protein synthesis is initiated with the same modified amino acid
FIGURE II.1.4.12 Schematic diagram of the mitochondrion demonstrating the functional segregation of the enzymatic machinery required to generate ATP. TCA: tricarboxylic acid. (Reproduced by permission from Bergman, A. R., Afifi, A. K. & Heideger, P. M. (Eds.). (1996). *Histology.* Saunders: Philadelphia, PA.)

as bacteria (N-formyl methionine), and is sensitive to the same antibiotics. It is noteworthy that – like peroxisomes – new mitochondria can only derive from pre-existing mitochondria. Thus, since only the ovum contributes the cytoplasmic organelles in the fertilized zygote, mitochondrial DNA is *maternally inherited*.

CELL SPECIALIZATION AND DIFFERENTIATION

As discussed above, basic functional attributes of cells include protection, signaling, nutrient absorption and assimilation, energy generation, macromolecule synthesis, growth, and reproduction. Without these basic activities, cells cannot live. However, most cells also exhibit specialization – that is, they have additional capabilities, such as irritability, conductivity, absorption or secretion of molecules. Multicellular organisms are thus composed of individual cells with marked specialization of structure and function. These differentiated cells allow a division of labor in the performance and coordination of complex functions carried out in architecturally distinct and organized tissues.

Determining a Cellular Phenotype

In many cases, the nature of well-differentiated tissues can be readily identified by routine histologic staining – that is putting thin sections on a glass slide and dipping them in *hematoxylin* (which stains negatively charged molecules such as DNA blue) and *eosin* (a counter-stain that stains virtually everything else pink), so-called *H&E* stain. Thus, skeletal muscle can be easily distinguished from liver; and brain from fat (just as examples). Histologists have also developed a variety of other stains to highlight various tissue components (e.g., calcium, elastin, collagen, etc.) that can further help to identify tissue differentiation. However, immature or poorly differentiated tissues – and especially individual cells – can be extremely difficult to identify by observation alone. The following techniques take advantage of some characteristic feature of targeted cells and tissues, most commonly a specific protein or mRNA made only by a specific cell to establish the phenotype; occasionally, a functional characteristic (e.g., excitability of a neuron or secretion of insulin by β-islet cells) can also be used to determine cellular identity. Note that techniques can typically distinguish the *location* of a particular cell or tissue within an organ or can *quantify* how much of a particular product is being made, but *cannot do both.*

- *Immunofluorescence or immunohistochemistry*: antibodies to a specific cell surface or intracellular molecule are applied to tissue slices or to individual cells. Presence of bound antibody is assessed by fluorescent or enzymatic tags on the antibodies. This demonstrates which cell in a tissue (or even which tissue) is making a particular constituent, but is generally not quantitative.
- *Western blot or enzyme-linked immunosorbent assay* (ELISA): tissues are ground up or otherwise solubilized by detergent extraction or other means. The protein constituents are separated by electrophoretic techniques on the basis of molecular weight and/or charge (Western blot) or are simply incubated in the presence of antibodies adsorbed onto a plastic plate (ELISA). In the Western blot, the presence of specific molecules is detected by the binding of antibodies to the separated protein bands, as assessed by enzymatic or radioactive tags on the antibodies. In the ELISA, protein bound to the plate-adsorbed antibodies is detected by a second set of antibodies linked to an enzyme. These techniques are quantitative, but will not typically identify which cell out of a mixture is making the molecule of interest.
- *Polymerase chain reaction* (PCR): messenger RNA is extracted from a cell population or tissue of interest and specific sequences representing the transcripts that are translated into a particular protein are subjected to enzymatic amplification; amplified fragments are detected by electrophoretic techniques that separate the mRNA based on size. The presence of a selected mRNA band is therefore taken as evidence of a particular cell phenotype. Although the technique is typically quite sensitive and can be quantitative for the mRNA, it does not necessarily equate to the quantity of a protein produced. Also, note that the technique will not determine which cell in a mixture is making the mRNA of interest.
- In-situ *hybridization*: complementary DNA sequences (labeled with fluorescent or other tags) that bind to a particular mRNA are applied to tissue sections. Binding is detected by fluorescence or enzymatic assays. This technique allows identification of which cell in a tissue is making a particular message, but is generally not quantitative.
- *Gene array technology*: mRNA from cells or tissues of interest is converted to complementary DNA (cDNA) fragments, typically using fluorescently-tagged nucleotides of a particular color (e.g., green or red). These are then bound to a panel of different DNA transcripts, where each sequence in the panel – representing a particular gene – is adsorbed to a discrete location on a plastic grid or "chip" (thousands of genes can be represented on each chip). Binding of a cDNA is detected by fluorescence imaging, and the *pattern* of mRNA expression (i.e., multiple mRNA species can be discerned) by the original cell or tissue can be inferred. A particular strength of the technique is that such labeled cDNAs can also be prepared from cells or tissues treated with different reagents, and then compared on the same chip. For example, a stem cell population can be treated with one kind of drug (drug A) with the cDNAs prepared from it being labeled with green nucleotides. The same stem cell population can also be treated with a different drug (drug B) with the cDNAs being labeled with red nucleotides. Equal amounts of the red and green cDNAs are then put on the same chip and the relative binding of red versus green cDNA can be quantitated. If a particular gene on the chip glows red it indicates that drug B induced that message; if green, then drug A induces it. If both drugs induce a message comparably, the result is yellow fluorescence, and if neither induces a particular mRNA, the result is black.

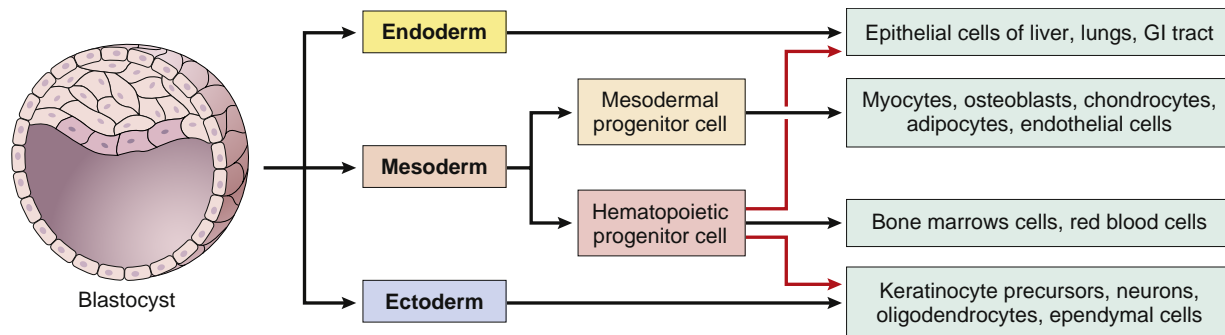
Differentiated cells have developed well-defined structural and/or functional characteristics associated with increasing specialization. For example, striated muscle cells have well-organized actin and myosin filaments that slide over one another, facilitating cellular contraction. Gastric (stomach) epithelial cells have large numbers of mitochondria to generate the ATP necessary to pump hydrogen ions out of the cell against a concentration gradient and acidify the stomach contents. Skin keratinocytes function as a protective barrier by undergoing autophagic programmed cell death and becoming scale-like structures filled with durable, non-living keratin (an intermediate filament). Specialized phagocytic cells of the immune system must detect infectious microorganisms


FIGURE II.1.4.13 Differentiation of mature cell lineages from the totipotential blastocyst. Cells in the early embryo have the capacity to proliferate and differentiate into all adult tissues. As the embryo acquires more cells, distinct layers form from the original sphere (endoderm, mesoderm, and ectoderm – based on general location of the cells within the developing fetus) that will become three general pluripotential lineages with more limited cellular differentiation repertoires. Eventually, after multiple rounds of replication and additional differentiation, the final adult tissues develop. Adult stem cells derived from the original three lineages typically persist within the organs they formed, with the capacity to regenerate cells of that tissue. Moreover, adult hematopoietic progenitors from the original mesoderm have the relatively unique capacity to generate tissues of the endoderm and ectoderm in addition to making marrow-derived blood cells. (Reproduced by permission from Kumar, V., Abbas, A. K. & Fausto, N. (Eds.). (2005). *Robbins and Cotran Pathologic Basis of Disease,* 7th edn. Saunders: Philadelphia, PA.)

(e.g., bacteria, parasites, and viruses), actively migrate to them, and then ingest and destroy them. *Polymorphonuclear leukocytes* (also called *PMNs* or *neutrophils*) are particularly active against bacteria, and *macrophages* react to other types of organisms and foreign material. B-lymphocytes are not phagocytic, but contribute to immunity by producing antibodies that can bind and neutralize infectious agents.

All specialized cells derive originally from the totipotential cells that comprise the early blastocyst. As the fetus grows and develops, subsets of these totipotential cells differentiate and assume specific functions that will eventually lead to the formation of mature tissues, e.g., bone, muscle, liver, skin, and brain (Figure II.1.4.13). To some extent, even in fully developed organisms, there persist populations of multipotential cells variably able to repopulate adult tissues where there is an ongoing balance between cellular proliferation, programmed cell death (*apoptosis*), and differentiation into end-stage cells with special "talents" but no further ability to reproduce (Figure II.1.4.14). This next section will briefly describe the concepts of stem cells and cellular differentiation.

Cellular Differentiation Involves an Alteration in Gene Expression. Every cell in the body has the same complement of genes (called the *genotype*). With progressive differentiation, selected subsets of genes are preferentially expressed, yielding a distinct biological profile (called the *phenotype*). As cells progressively specialize, more and more of the "unnecessary" genes in the differentiating cell are turned off (usually irreversibly). Some genes are active at all times (*constitutively expressed*); others may be selectively activated or *modulated* depending on external influences (e.g., injury). Thus, from a pluripotent cell, differential activation of specific genes can engender the development of endothelial cells, skeletal muscle, fat, bone or cartilage (Figure II.1.4.15).
FIGURE II.1.4.14 Achieving steady-state populations of cells. Total cell numbers in a baseline tissue population can be regulated by changes in stem cell input, loss of cells through programmed cell death (apoptosis), cellular proliferation or differentiation. (Reproduced by permission from Kumar, V., Abbas, A. K. & Fausto, N. (Eds.). (2005). *Robbins and Cotran Pathologic Basis of Disease,* 7th edn. Saunders: Philadelphia, PA.)

The structural and functional changes that occur during cellular differentiation are usually irreversible. Moreover, increasing specialization results in a loss of cell potentiality, as well as a loss in the capacity for cell division. For example, the newly fertilized ovum is absolutely undifferentiated and has the capacity to divide extensively, ultimately giving rise to progeny that comprise all the cells of the body. Cells with the capacity to both divide and yield differentiated cells of one or more types are called stem cells. "Stemness" can be
FIGURE II.1.4.15 Differentiation of pluripotent mesodermal progenitor cells. The same stromal cell can differentiate down different developmental pathways depending on the activation of specific genes; this can occur through exogenous soluble factors or cell–matrix interactions. Thus, vascular endothelial growth factor (VEGF) and fibroblast growth factor-2 (FGF2) are extrinsic signals that induce endothelial differentiation. Sox9, CBFA1, PPARγ, and myo D are intracellular transcription factors whose activities will induce the specific lineages shown. (Reproduced by permission from Kumar, V., Abbas, A. K. & Fausto, N. (Eds.). (2005). *Robbins and Cotran Pathologic Basis of Disease,* 7th edn. Saunders: Philadelphia, PA.)

functionally understood as the capacity for asymmetric division: one progeny cell maintains totipotentiality (it can still potentially become any cell type) while the other daughter cell transcribes selected subsets of genes to generate more differentiated tissues.

The stem cells in early embryos (found only rarely in adult cell populations) are *totipotential* and have virtually limitless replicative capacity. As cells differentiate along particular specialization or tissue pathways, they lose the ability to interconvert and develop into all cell types, although they may be able to form most or all the cells of a particular tissue. Thus, gastrointestinal stem cells in the small bowel can differentiate into absorptive epithelial cells, mucus-producing epithelial cells, and Paneth crypt cells that produce bacteriocidal proteins; however, they cannot differentiate into smooth muscle cells or even other types of epithelium. Stem cells in these lineages are said to be *pluri-* or *multipotential*; they may also have slightly limited replicative capacity. With further terminal differentiation, cells typically lose the ability to replicate at all. In the example of the small bowel, the terminally-differentiated absorptive cells actually divide no further and undergo programmed cell death within 3–4 days of their genesis. Classically, cardiac

muscle cells and neurons have also been considered as terminally-differentiated cells without replicative capacity. Obviously, this has clinical significance when these very important terminally-differentiated cells are injured (e.g., by heart attack or stroke). Nevertheless, there is increasing evidence that there may be small populations of cardiac and neuronal stem cells that we can tap into to regenerate these tissues; moreover, we are increasingly adept at isolating and cultivating totipotential stem cells – and coaxing them to differentiate into desirable cell lineages. Finally, there is also accumulating evidence to suggest that cells of end-stage, highly differentiated tissues can, under very limited conditions (e.g., some forms of injury), de-differentiate into multipotent stem cells.

CELL REGENERATION AND PROLIFERATION

At a tissue level, the ability to regenerate is a function of the level of differentiation of the stem cells within that tissue and their overall replicative potential; these fall into three broad general categories: labile; stable; and permanent tissues.

Labile tissues have pluripotent stem cells that are constantly in cell cycle, and thus are constantly generating new cells that will differentiate into the final population comprising the parenchyma of that particular organ. As those final differentiated cells senesce, they typically undergo programmed cell death (apoptosis, discussed later); nevertheless, they are continuously being replaced by the "next generation," and thus the integrity of the tissue is maintained. These tissues include many epithelia such as the stratified squamous surfaces of the skin, oral cavity, vagina, and cervix; the cuboidal epithelia of the ducts draining exocrine organs (e.g., salivary glands, pancreas, biliary tract); the columnar epithelium of the gastrointestinal tract, uterus, and fallopian tubes; and the transitional epithelium of the urinary tract. The hematopoietic cells of the bone marrow are also continuously replenishing the circulating peripheral blood cell elements. As a corollary of their ongoing proliferation, labile tissues typically repopulate sites of injury relatively quickly. However, they are also most sensitive to extrinsic insults such as radiation or chemotherapy for tumors – which is why patients being treated for cancer lose their hair (hair follicle epithelium), malabsorb food (gastrointestinal epithelium), and are anemic and prone to infections and bleeding (bone marrow).

Stable tissues have pluripotent stem cells that typically rest in the G_0 stage of the cell cycle and are not actively turning over. However, these cells can be kick-started into cell cycle, and have substantial regenerative capacity. They include the parenchymal cells of organs such as liver, kidney, and pancreas, as well as endothelial cells, and mesenchymal cells such as fibroblasts and smooth muscle.

Permanent tissues include neurons and cardiac myocytes. Classically, these cells cannot replicate, and irreversible injury results only in scarring. Skeletal muscle is also generally placed in this category, although this tissue does have a limited regenerative capacity, largely due to the proliferation and transformation of a small population of stem cells associated with endomysial sheaths. Moreover, we are also learning that terminally differentiated permanent cells – previously thought to be irreplaceable once destroyed (e.g., nerve and muscle) – may be potentially repopulated by bone marrow-derived stem cells or even small populations of tissue-endogenous stem cells. While exciting, the extent to which we can utilize this replacement process appears to be very limited; for all practical purposes (for now), dead permanent cells become scar.

These concepts have important ramifications not only for embryogenesis, but also for the budding tissue engineer. For applications that require large numbers of differentiated cells, expansion of terminally-differentiated cell populations may work for some cell types (e.g., skin). However, cells such as heart or nerve will probably require directed differentiation from expanded stem cells.

CELL INJURY AND REGENERATION

Cells constantly adjust their structure and function to accommodate alterations in their environment, particularly responding to chemical and mechanical stressors; inability to successfully adapt results in cell injury and ultimately cell death (Figure II.1.4.16).

Cells attempt to maintain their intracellular milieu within relatively narrow physiologic parameters; that is, they maintain *normal homeostasis*. For relatively small changes in the environment, subtle modifications of cell behavior will likely permit normal "business as usual." However, as cells and tissues encounter more challenging physiologic stresses or pathologic stimuli, they undergo more extensive changes (*adaptation*) designed to achieve a new steady-state, but in all cases to *preserve viability*. The principal significant adaptive responses are:

hypertrophy: an increase in size of individual cells;
hyperplasia: an increase in cell number;
atrophy: a decrease in size, without appreciable change in cell number;
metaplasia: transformation from one mature cell type to another.

There may also be more subtle changes in the expression of selected genes that are functionally beneficial but are not necessarily reflected in alterations of morphology.

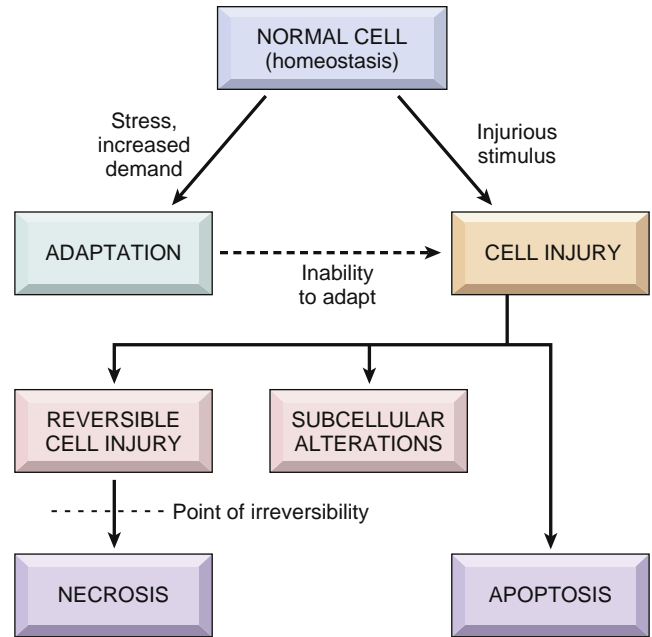
Usually, if the extracellular stressors recede, the cells and tissues will revert to their prestressed state. However,


FIGURE II.1.4.16 General overview of potential cellular responses to stressors and injurious stimuli. (Reproduced by permission from Kumar, V., Abbas, A. K., Fausto, N. & Aster, J. C. (Eds.). (2010). *Robbins and Cotran Pathologic Basis of Disease,* 8th edn. Saunders: Philadelphia, PA.)

if the stressors persist and a cell's adaptive capability is exceeded, *cell injury* develops. Up to a point, cell injury itself is *reversible*, and with normalization of the stimulus the cell returns to its baseline state, usually no worse for wear. However, with severe or persistent stress, the cell suffers *irreversible* injury and dies.

For example, when heart muscle cells are subjected to persistent increased load (e.g., high blood pressure), the cells adapt by undergoing *hypertrophy* (enlargement of the individual myocytes, and eventually the entire heart) to compensate for the higher pressures they must pump against. Conversely, in periods of prolonged starvation (as can happen in prolonged illness or with malignant tumors), all myocytes (and thus the heart) will undergo *atrophy*. The same myocytes, subjected to an imbalance between blood supply and energy demand due to an occluded coronary artery (*ischemia*), may be *reversibly injured* if the occlusion is incomplete or sufficiently brief; alternatively, they may undergo *irreversible injury* (i.e., cell death, also called *necrosis*, as in *myocardial infarction*) following complete or prolonged occlusion (Figure II.1.4.17).

Beyond adaptive responses, environmental stimuli can also induce genetic changes which can trigger abnormal proliferation and differentiation. Such behavior is uncoordinated relative to normal tissues, has lost its responsiveness to normal growth controls, and persists after cessation of the stimuli that initiated it. This condition is called "*neoplasia*;" in its malignant form, it is more commonly called *cancer*.
FIGURE II.1.4.17 Schematic of the cellular responses and morphologic changes to reversible and irreversible injury, the latter eventually culminating in necrotic cell death. Reversible injury is characterized by a generalized cell and organellar swelling due to a loss of ATP-driven mechanisms to maintain normal ionic gradients; there will also be plasma membrane blebbing (as cytoskeletal elements degrade), ribosome detachment from the ER with diminished protein synthesis, and nuclear chromatin clumping with reduced transcription. As the cells transition to irreversible injury, the changes become more severe, and eventually the cell cannot recover normal function – even after oxygen and glucose are restored to generate ATP. In that case, necrosis supervenes with lysosomal rupture, swollen mitochondria with amorphous densities within them, membrane fragmentation, and condensation of the nucleus (*pyknosis*), fragmentation of the nucleus (*karyorrhexis*), and dissolution of the nucleus (*karyolysis*). (Reproduced by permission from Kumar, V., Abbas, A. K. & Fausto, N. (Eds.). (2005). *Robbins and Cotran Pathologic Basis of Disease,* 7th edn. Saunders: Philadelphia, PA.)

CAUSES OF CELL INJURY

Hypoxia and Ischemia

Recall that the efficient production of ATP by mitochondria – and therefore the energy needed to run all cell activities – is critically dependent on oxygen. *Hypoxia* is decreased O_2 supply relative to the needs of a particular cell or tissue. *Anoxia* is the complete absence of oxygen. Tissue hypoxia can occur in any setting where there is reduced oxygen tension including causes as diverse as high altitude, anemia, and carbon monoxide poisoning

(the latter diminishes the oxygen carrying capacity of hemoglobin). However, far and away the most common cause of tissue hypoxia is diminished blood flow, called *ischemia*; irreversible tissue injury (*necrosis*) due to ischemia is called *infarction*. It bears repeating that although diminished blood flow will invariably lead to hypoxia, oxygen deficiency can occur in the setting of adequate tissue perfusion. It is also important to note that diminished blood flow will also affect the ability to remove waste products from a metabolizing tissue so that, all things considered, *ischemia is far worse than simple hypoxia*.

Chemical Injury

Chemical agents include components of food, naturally occurring toxins, hormones, neurotransmitters, synthetic drugs, environmental pollutants, poisons, ethanol, tobacco, and even toxic biomaterials. Although almost any cellular constituent can be affected by chemical modification, agents that poison mitochondrial function (e.g., cyandide) will obviously wreak substantial havoc. Chemicals induce cell injury by one of two general mechanisms:

- by combining directly with a critical molecular component or cellular organelle and thereby inhibiting its normal activity (chemotherapeutic drugs generally fall into this category).
- chemicals that are not intrinsically biologically active may be converted to toxic metabolites during normal physiologic breakdown. Such modification is usually accomplished by the P-450 mixed function oxidases in the smooth endoplasmic reticulum (SER) of the liver, and the most important mechanism of cell injury is by formation of *free radicals* (see below). Acetaminophen and carbon tetrachloride belong to this category of compounds.

Biologic Agents

Infectious agents run the gamut from virus and bacteria to fungi, protozoans, and helminths (worms). There is generally a preferred cell or tissue of invasion (called a *tropism*), and therefore each agent tends to have a defined spectrum of potential injury. *Viruses* multiply intracellularly, appropriating host biosynthetic machinery in the process; cell lysis may occur directly or as a result of the immune system's recognition and destruction of infected cells. More insidiously, viruses may compromise the ability of a cell or tissue to perform its normal functions; worse still, viruses may play a role in transformation to malignant neoplasms. *Bacteria* have toxic cell wall constituents (e.g., endotoxin), and can release a variety of exotoxins. Moreover, the very process of eradicating infections by the host immune system can also cause injury – and in many cases constitutes the bulk of the pathology.

Physical Injury

Injury can result by direct mechanical force (trauma, pressure), temperature extremes (burn, frostbite), electric shock or ionizing radiation.

Genetic Defects

Mutations in a variety of cellular proteins can lead to cellular dysfunction and eventually irreparable cellular injury. Congenital defects generally manifest as progressive disorders; examples include: lysosomal storage diseases where progressive accumulation of certain non-degradable metabolites eventually causes cell rupture; disorders of muscle (*myopathies*) due to defective energy synthesis by mitochondria; and sickle cell anemia caused by mutated hemoglobin which results in stiff, non-deformable red blood cells.

PATHOGENESIS OF CELL INJURY

There are three basic mechanisms of cell injury:

(1) *Loss of adequate ATP production.* Ischemia, hypoxia, or mitochondrial dysfunction will all cause a precipitous drop in ATP synthesis; unfortunately, compensatory anaerobic pathways that suffice for yeast and other single-celled organisms cannot begin to satisfy the energy demands of the mammalian cell. The resulting depletion of ATP has widespread effects:

- the plasma membrane ATP-driven "sodium pump" cannot keep up with the influx of counter-ions and water driven by the high intracellular charge density and osmolarity. Consequently, there is a marked accumulation of intracellular sodium and its accompanying water of hydration, producing *acute cellular swelling*. Changes in solute concentrations and in the intracellular ionic environment will negatively impact normal enzymatic activities.
- anaerobic glycolysis increases due to decreased ATP and associated increases in adenosine monophosphate (AMP) that stimulate the enzyme phosphofructokinase. Evolutionarily designed to maintain the cell's energy by generating ATP from glycogen, activation of this pathway leads to rapid *depletion of glycogen stores*. Increased glycolysis also results in accumulation of lactic acid and inorganic phosphates from hydrolysis of phosphate esters, and lowers the intracellular pH, in addition to exacerbating the already increased osmotic load.
- dropping pH and ATP levels cause ribosomes to detach from the rough endoplasmic reticulum (RER) and polysomes to dissociate into monosomes, with a resultant *reduction in protein synthesis*.
- if ATP generation is not restored the cytoskeleton disperses, resulting in loss of ultrastructural features such as microvilli, and the formation of cell surface "blebs." Mitochondria, endoplasmic reticulum, and indeed whole cells usually appear swollen owing to loss of osmotic regulation. If ATP synthesis is recovered (usually by restoration of oxygen), all the above disturbances are reversible; if not, irreversible injury (cell death) follows (Figure II.1.4.17).

(2) *Oxygen and oxygen-derived free radicals.* Lack of oxygen (and loss of ATP production) obviously underlies the pathogenesis of ischemic cell injury. In

addition, *partially-reduced*, *activated oxygen* species are important mediators of cell death. *Free radicals* are chemical species with a single unpaired electron in an outer orbital; they are extremely unstable and readily react with inorganic or organic chemicals. The most important free radicals in biological systems are oxygen-derived and include: *hydroxyl* ($OH\bullet$) radicals (from the hydrolysis of water, e.g., by ionizing radiation); *superoxide radicals* ($O_2-\bullet$); and nitric oxide radicals ($NO\bullet$). Free radicals initiate autocatalytic reactions; molecules that react with free radicals are in turn converted into free radicals, further propagating the chain of damage. When generated in cells, free radicals cause single-strand breaks in DNA, fragment lipids in membranes via lipid peroxidation, and fragment or cross-link proteins, leading to accelerated degradation or loss of enzymatic activity. Free radical damage is a pathogenic mechanism in such varied processes as chemical and radiation injury, oxygen and other gaseous toxicity, cellular aging, microbial killing by phagocytic cells, inflammatory damage, and tumor destruction by macrophages, among others.

It is important to note that besides being a consequence of chemical and radiation injury, free radical generation is also a normal part of respiration and other routine cellular activities, including microbial defense. It therefore makes sense that cells and tissues have developed mechanisms to degrade free radicals and thereby minimize any injury. Fortunately, free radicals are inherently unstable, and generally spontaneously decay; superoxide, for example, rapidly breaks down in the presence of water into oxygen and hydrogen peroxide. The rate of such decay is significantly increased by the action of superoxide dismutases (SOD) found in many cell types. Other enzymes, e.g., glutathione (GHS) peroxidase, also protect against injury by catalyzing free radical breakdown, and catalase directs the degradation of hydrogen peroxide. In addition, endogenous or exogenous antioxidants, e.g., vitamin E, may either block free radical formation or scavenge them once they have formed.

(3) *Failure of intracellular calcium homeostatic mechanisms.* Cytosolic free calcium is normally maintained by ATP-dependent calcium transporters at extremely low concentrations (less than 0.1 μM), while extracellular calcium and sequestered mitochondrial and endoplasmic reticulum calcium stores are typically at roughly 10^4-fold higher concentrations. Consequently, any cell ischemia or injury potentially looses a flood-gate of calcium. Increased cytosolic calcium in turn activates a variety of *phospholipases* (promoting membrane damage), *proteases* (catabolizing structural and membrane proteins), *ATPases* (accelerating ATP depletion), and *endonucleases* (fragmenting genetic material).

Ischemia-Reperfusion Injury

If cells are reversibly injured in ischemic circumstances, restoration of blood flow should theoretically result in cell recovery. However, in many cases, restoration of blood flow to ischemic but otherwise viable tissues results in paradoxically exacerbated and accelerated injury. As a result, tissues experience additional cell loss and dysfunction in excess of that which occurs in just the irreversibly damaged areas. This so-called *ischemia/ reperfusion injury* is a clinically important process that significantly contributes to tissue damage in myocardial and cerebral infarctions. Although the exact mechanisms are unclear, reperfusion into ischemic tissues may cause further damage by the following:

- Restoration of blood flow bathes compromised cells in high concentrations of calcium when they are not able to fully regulate their ionic environment; increased intracellular calcium activates the pathways described above and causes loss of cellular integrity.
- Restoration of blood flow into an area that is already irreversibly injured results in activation of innate immunity pathways (including complement) and a locally augmented inflammatory cell recruitment. These cells release high levels of potentially deleterious oxygen-derived reactive species and cytokine inflammatory mediators.
- Damaged mitochondria yield incomplete oxygen reduction and therefore increased production of free radical species; in addition, ischemically-injured cells have compromised antioxidant defense mechanisms.

RESPONSES TO CELL INJURY

Whether a specific form of stress induces adaptation or causes reversible or irreversible injury depends not only on the nature and severity of the stress, but also on several other cell-specific variables including vulnerability, differentiation, blood supply, nutrition, and previous state of the cell.

- *Cellular response to injurious stimuli depends on the type of injury*, *its duration*, *and its severity*. Thus, low doses of toxins or a brief period of ischemia may only lead to reversible cell injury, whereas larger toxin doses or longer ischemic intervals may result in irreversible injury and cell death.
- *Consequences of an injurious stimulus are dependent on the type of cell being injured*, its *current status* (nutritional, hormonal, etc.), and its *adaptability*. For example, striated skeletal muscle in the leg can tolerate complete ischemia for 2–3 hours without suffering irreversible injury, while cardiac muscle will die after only 20–30 minutes, and central nervous system (CNS) neurons are dead after 2–3 minutes. Similarly, a well-nourished liver (with reserves of intracellular glycogen) can withstand an ischemic or anaerobic

challenge far better than a liver without any potential energy stockpile.

REVERSIBLE VERSUS IRREVERSIBLE INJURY

Regardless of the nature of a particular cellular insult, four cell systems are particularly vulnerable: (1) cell membrane integrity; (2) ATP generation, largely via mitochondrial aerobic respiration; (3) protein synthesis; and (4) the integrity of the genetic apparatus.

Within limits, cells can compensate for disturbance of any of these, and if the injurious stimulus abates will return to normalcy. Persistent or excessive injury, however, causes cells to pass the threshold into *irreversible injury*. In other words, they die; pathologically, the cells become *necrotic* or are said to undergo *necrosis* (Figure II.1.4.17).

An important concept on the spectrum from normal to reversible injury, and thence onto irreversible injury, relates to cellular and tissue function. The specialized activities relating to cell function may shut down relatively early in the setting of injury, and in most cases long before there is any cell death. For example, myocardial cells become non-contractile after 1–2 minutes of ischemia, although they will not die until 20–30 minutes of ischemia have elapsed. Consequently, if injury can be reversed before cells become irretrievably damaged, then restoration of function can be anticipated. Of course, lack of cardiac function may lead to death of other important structures (e.g., the brain) even before the heart cells themselves reach the point of no return.

NECROSIS

Two phenomena consistently characterize irreversible injury. The first is the *inability to reverse mitochondrial dysfunction* (lack of oxidative phosphorylation and ATP generation) even upon restoration of oxygen; the second is the development of *profound disturbances in membrane function*. Massive calcium influx into the cell occurs, particularly if ischemic tissue is reperfused after the point of irreversible injury, with broad activation of calcium-dependent catabolic enzymes. In addition, proteins, essential coenzymes, and ribonucleic acids seep out through the newly permeable membranes, and the cells also lose metabolites vital for the reconstitution of ATP. Injury to the lysosomal membranes results in leakage of their enzymes into the cytoplasm; the catabolic enzymes are activated in the reduced intracellular pH of the ischemic cell, and will further degrade cytoplasmic and nuclear components.

Since necrotic tissue is a potential nidus for secondary infections, the body rapidly mobilizes inflammatory cells to clean up the resulting debris, and initiates the process of either rebuilding the dead tissue or laying down a fibrous scar (see Chapter II.1.5). As mentioned previously, the recruited inflammation can in itself be a cause of further local injury. Moreover, having to replace a specialized tissue with a non-functional matrix scar is also a less than optimal outcome.

APOPTOSIS

The cell death that has been thus far described is the consequence of irreversible injury; in a way, this can be thought of as cellular "homicide." However, there is also an important form of controlled or *programmed* cell death that can be conceptualized as cellular "suicide." *Apoptosis* (from root words meaning "a falling away from") is a distinctive and important mode of cell death that must be differentiated from standard *necrosis* (Figure II.1.4.18 and Table II.1.4.1). Apoptosis is responsible for programmed cell death in several important physiologic (as well as pathologic) processes, including:

- the programmed destruction of cells during embryogenesis, including implantation, organogenesis, and developmental involution.
- hormone-dependent physiologic involution, such as the endometrium during the menstrual cycle or the lactating breast after weaning, or pathologic atrophy, as in the prostate after castration.
- cell deletion in proliferating populations such as intestinal crypt epithelium or cell death in tumors.
- deletion of autoreactive T cells in the thymus, cell death of cytokine-starved lymphocytes or cell death induced by cytotoxic T cells.
- a variety of mild injurious stimuli (heat, radiation, cytotoxic cancer drugs, etc.) that cause irreparable DNA damage that in turn triggers cell suicide pathways (e.g., via the tumor-suppressor protein *p53*).

Indeed, failure of cells to undergo physiologic apoptosis may result in unimpeded tumor proliferation, autoimmune diseases or aberrant development.

Apoptosis usually involves single cells or clusters of cells with condensed nuclear chromatin or chromatin fragments. The cells rapidly shrink, form *cytoplasmic buds*, and fragment into *apoptotic bodies* composed of membrane-bound vesicles of cytosol and organelles (see Figure II.1.4.18). These fragments are quickly extruded, and then phagocytosed and degraded by neighboring cells, and *do not elicit an inflammatory response*. The nuclear changes are due to fragmentation of DNA into histone-sized pieces through the activation of endonucleases.

The mechanisms underlying apoptosis are roughly schematized in Figure II.1.4.19. The basic mechanisms comprise four separable but overlapping components:

(1) *Signaling pathways*. The process may be triggered by a variety of signals ranging from an intrinsic
FIGURE II.1.4.18 The cellular structural changes of *necrosis* (left) and *apoptosis* (right). In necrosis, there is chromatin clumping, organelle swelling, and eventual membrane damage; dead cells are typically degraded and digested by recruited inflammatory cells. In apoptosis, there is nuclear chromatin condensation and fragmentation, followed by cytoplasmic budding of *apoptotic bodies*, which are phagocytized by adjacent cells. programmed event (e.g., in development), a lack of growth factor, specific receptor–ligand interactions, release of granzymes from cytotoxic T cells or selected injurious agents (e.g., radiation). Transmembrane signals may either suppress pre-existing death programs (and are thus survival stimuli) or may initiate a death cascade. The most important in this latter group are those that belong to the tumor necrosis factor receptor (TNFR) superfamily of plasma membrane molecules (includes the FAS surface molecule). These plasma membrane receptors share an intracellular "death domain" protein sequence which, when oligomerized (typically trimerized) leads to a cascade of enzyme activation culminating in cell death.

(2) *Control and integration.* This is accomplished by specific proteins that connect the original death signals to the final execution program. These proteins are important because their actions may result in either "commitment" or abortion of potentially lethal signals. There are two broad schemes for this stage:

- direct transmission of death signals *adapter proteins* to the execution mechanism
- members of the *Bcl-2 family of proteins* that *regulate mitochondrial permeability.*

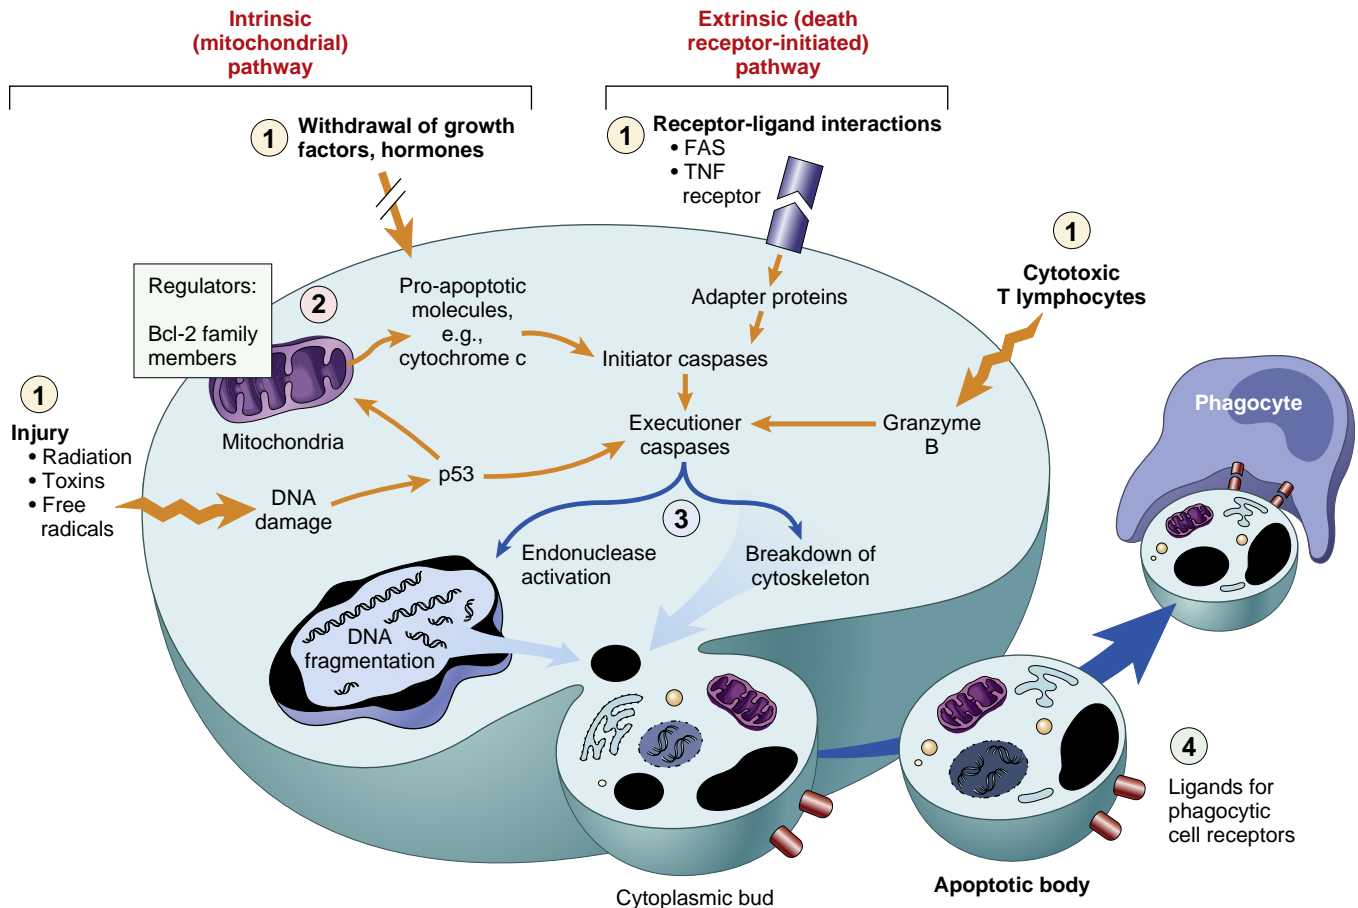
Various intracellular agonists (Ca^{+2}, free radicals, etc.) can affect mitochondria by causing *mitochondrial permeability transitions*. These are pores within the inner mitochondrial membrane that


FIGURE II.1.4.19 Schematic of events occurring in apoptosis. Items labeled (1) are various stimuli for apoptosis; some involve direct activation of caspases (cytotoxic T cells) while others act via adaptor proteins (e.g., surface receptors such as FAS or the tumor necrosis factor (TNF) receptor) or via mitochondrial release of cytochrome c. Items labeled (2) are inhibitors (e.g., Bcl-2) or promoters that modulate whether or not mitochondria will develop membrane permeability transitions to release cytochrome c; cytochrome c interacts with additional cytoplasmic proteins (e.g., *Apaf-1*) to induce caspase activation. Executioner caspases (3) activate endonucleases that degrade nuclear chromatin, and intracellular proteases that degrade the cytoskeleton. The end result (4) is extruded apoptotic bodies containing various organelles and cytosolic components that express surface phosphatidylserine residues which induce their uptake by adjacent phagocytic cells. (Reproduced by permission from Kumar, V., Abbas, A. K. & Fausto, N. (Eds.). (2005). *Robbins and Cotran Pathologic Basis of Disease,* 7th edn. Saunders: Philadelphia, PA.)

result in reduced membrane potential and diminished ATP production; increased permeability of outer mitochondrial membranes also releases an apoptotic trigger, *cytochrome c*, into the cytosol. Released cytochrome c binds certain cytosolic proteins (e.g., *pro-apoptotic protease activating factor* or *Apaf-1*), and activates them, triggering in turn caspase activation (see below) and setting in motion proteolytic events that will eventually allow the cell to kill itself. *Bcl-2* (found in the mitochondrial membrane) suppresses apoptosis by preventing increased mitochondrial permeability, and by stabilizing proteins to prevent caspase activation. Other members of the Bcl-2 family bind to Bcl-2 and modulate its antiapoptotic effect; thus Bcl-XL inhibits apoptosis while Bax and Bad promote programmed cell death.

(3) *Execution.* The final pathway of apoptosis, resulting from the synthesis and activation of a number of cytosolic catabolic enzymes, and culminating in

the morphologic changes described above. Although there are subtle variations, the final execution pathways exhibit common themes generally applicable to all forms of apoptosis:

- *Protein cleavage* by a class of proteases named *caspases*, so-called because they have an active site cysteine, and cleave after aspartic acid residues. Activation of one or more such caspase enzymes putatively leads to a cascade of activation of other proteases, inexorably culminating in cell suicide. Downstream *endonuclease* activation results in the characteristic DNA fragmentation of apoptosis, while cell volume and shape changes may in part be attributable to cleavage of components of the cytoskeleton.

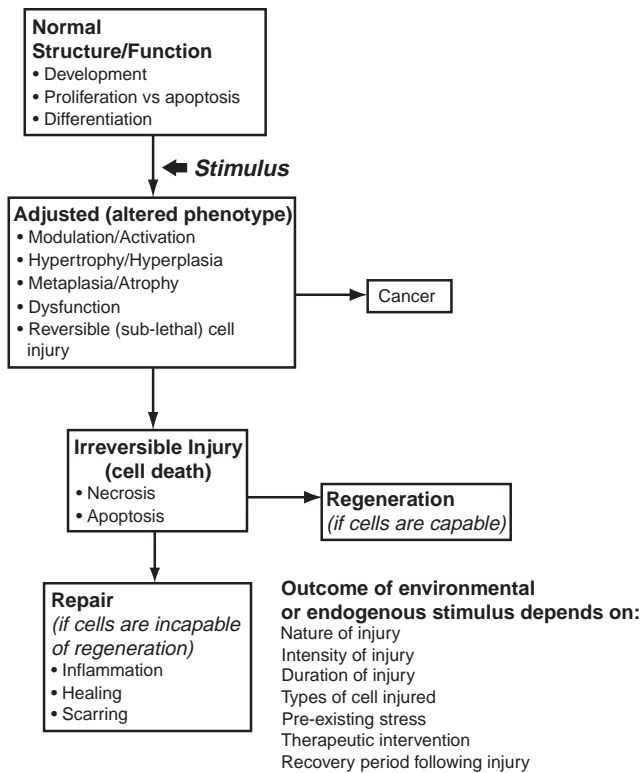
- *Extensive protein cross-linking* via *transglutaminase* activation converts soluble cytoplasmic proteins, and particularly cytoskeletal proteins, into a covalently-linked condensed shell that readily fragments into apoptotic bodies.


FIGURE II.1.4.20 Cellular mechanisms of disease, emphasizing the general concepts of activation and other phenotypic alterations, reversible and irreversible cell injury, and the various possible outcomes of cell injury.

- *DNA breakdown* into 180–200 base pair fragments (the distance between nucleosomes) occurs through the action of Ca^{+2} and Mg^{+2} dependent endonucleases. This may be visualized as a distinctive "laddering" of DNA into discrete sized pieces on agarose gel electrophoresis; this pattern is different from the random DNA fragmentation (forming a "smear" on agarose gels) typically seen in necrotic cells.

(4) *Removal of dead cells.* Apoptotic cells and their fragments have marker molecules on their surfaces that signal uptake and disposal by adjacent cells or phagocytes. This occurs by the flipping of phosphatidylserine from the inner cytoplasmic face of the apoptotic cells to the extracellular face. This (and other) alterations allow the early recognition and phagocytosis of apoptotic cells without release of pro-inflammatory mediators. The process is so efficient that dead cells typically disappear without leaving a trace, and inflammation is virtually absent.

The general framework of cell injury is summarized in Figure II.1.4.20. In the following chapter, we will extend the concepts of structure–function correlation beyond cells to include the extracellular matrix and complex tissues, examine what happens following cell and tissue injury, and describe how histologists and pathologists examine normal and abnormal tissues.

CHAPTER II.1.5 TISSUES, THE EXTRACELLULAR MATRIX, AND CELL–BIOMATERIAL INTERACTIONS

Frederick J. Schoen and Richard N. Mitchell
Department of Pathology, Brigham and Women's Hospital and
Harvard Medical School, Boston, MA, USA

This chapter will extend the concepts discussed previously in Chapter II.1.4 (Cells, Cell Function and Cell Injury) to describe how cells are organized to form specialized tissues and organs, how environmental stimuli affect tissue structure and function, how tissues respond to various insults, including those related to the insertion of biomaterials, and how cells interact with extracellular matrix and biomaterials. Four general areas will be covered:

1. Principles governing the structure and function of normal tissue, organs, and systems;
2. Processes leading to and resulting from abnormal (injured or diseased) tissues and organs;
3. Concepts in cell–biomaterials interactions;
4. Approaches to study the structure and function of tissues.

Germane to this discussion are two basic definitions: *histology* is the microscopic study of tissue structure; *pathology* is the study of the molecular, biochemical, and structural alterations and their consequences in diseased tissues and organs, and the underlying mechanisms that cause these changes. The mainstay of both histology and pathology is microscopic examination of tissues, aided by stains and other methods that enhance tissue contrast, indicate specific chemical and molecular moieties present, and convey structural and functional information.

Cells and *extracellular matrix* comprise the structural elements of the tissues of the body. The structure of cells, tissues, and organs comprise the morphologic expression of the complex (and dynamic) activities that comprise body function. The underlying theme is that *structure is adapted to perform specific functions* (*conversely, changes in function may alter structure*). Some excellent general references on tissue biology and pathology are available (Rubin and Strayer 2012; Kumar et al., 2010).

Cells and *extracellular matrix* are the structural elements of the tissues of the body. The structure of cells, tissues, and organs comprise the morphologic expression of the complex (and dynamic) activities that comprise body function. The underlying theme is that *structure is adapted to perform specific functions* (*conversely, changes in function may change and alter structure*).

STRUCTURE AND FUNCTION OF NORMAL TISSUES

Cells, the living component of the body (as discussed in detail in the Chapter II.1.4), are surrounded by and obtain their nutrients and oxygen, and discharge wastes via blood, tissue fluid (also known as extracellular fluid), and lymph. *Blood* consists of blood cells suspended in a slightly viscous fluid called *plasma*; *serum* results when the coagulation proteins are removed from plasma, Capillaries exude a clear watery liquid called tissue fluid that permeates the amorphous intercellular substances lying between capillaries and cells. More tissue fluid is produced than can be absorbed back into the capillaries; the excess is carried away as lymph by a series of vessels called lymphatics, which ultimately empty the lymph into the bloodstream.

In all tissues and organs, cells are assembled during embryonic development into coherent groupings by virtue of specific cell–cell and cell–matrix interactions (Ingber, 2010a). Each type of tissue has a distinctive and genetically-determined pattern of structural organization adapted to its particular function; each pattern is strongly influenced by both metabolic (Carmeliet, 2003) and/or mechanical factors (Wozniak and Chen, 2009). *Homeostasis*, a normal process by which cells adjust their function to adapt to minor changes in day-to-day physiological demands, is regulated by:

1. Genetic programs of metabolism, differentiation, and specialization;
2. Influences of neighboring cells, the extracellular matrix, and signals that trigger specific cellular responses;
3. Environmental conditions, such as mechanical forces, temperature, and ionic content;
4. Availability of oxygen and metabolic substrates.

When normal limits of homeostasis are exceeded, pathological changes may result.

The Need for Tissue Perfusion

Since all mammalian cells require perfusion (i.e., blood flow bringing oxygen and nutrients, and carrying away wastes) for their survival, most tissues have a rich vascular network. Thus, the circulatory (also known as the cardiovascular) system is a key feature of tissue and organ structure and function (Figure II.1.5.1). Perfusion (i.e., delivery of blood) to a tissue or an organ is provided by the cardiovascular system, composed of a pump (the *heart*), a series of distributing and collecting tubes (*arteries* and *veins*), and an extensive system of thin walled vessels (*capillaries*) that permit exchange of substances between the blood and the tissues. Circulation of blood transports and distributes essential substances to the tissues, and removes byproducts of metabolism. Implicit in these functions are the intrinsic capabilities of the cardiovascular system to buffer pulsatile flow in order to ensure steady flow in the capillaries, regulate blood pressure and volume at all levels of the vasculature, maintain circulatory continuity while permitting free exchange between capillaries/venules and the extravascular compartments,

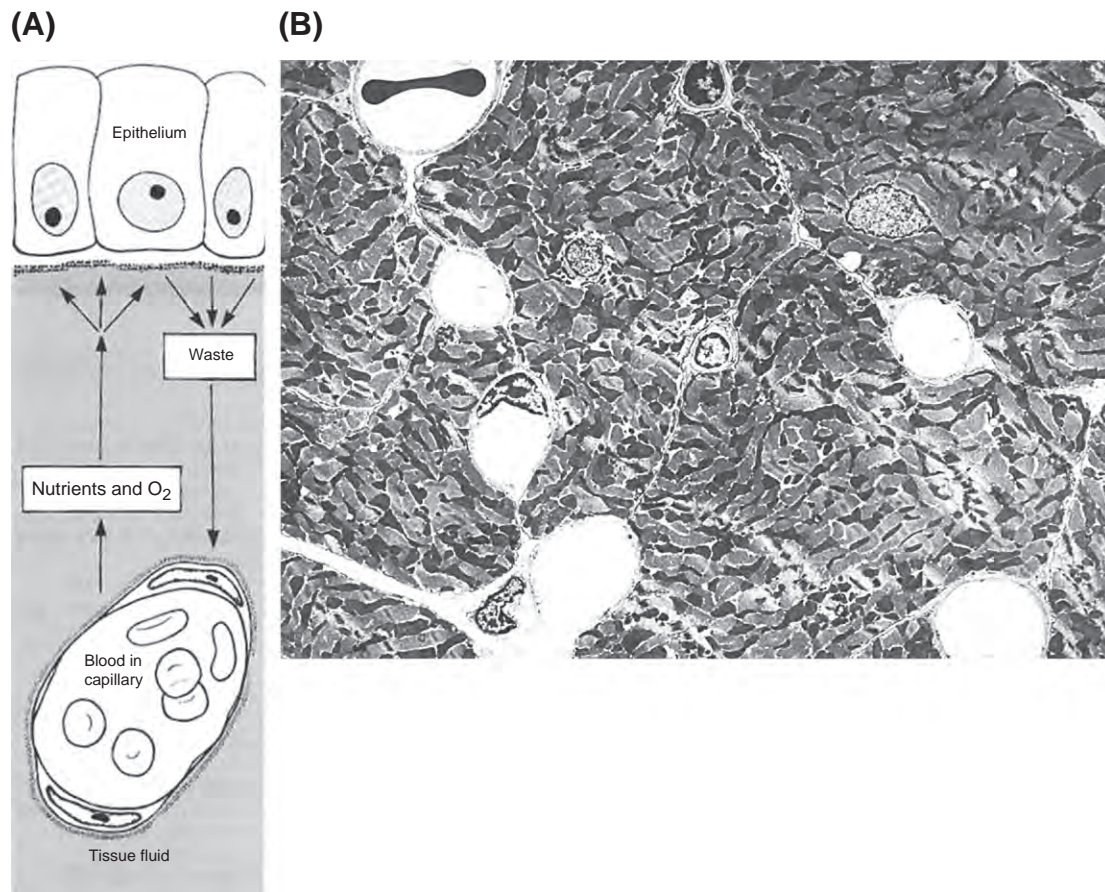
(A)   **(B)**


FIGURE II.1.5.1 Role of the vasculature in tissue function. (A) Schematic diagram of the route by which the cells in a tissue obtain their nutrients and oxygen from underlying capillaries. Metabolic waste products pass in the reverse direction and are carried away in the bloodstream. In each case, diffusion occurs through the tissue fluid that permeates the amorphous intercellular substances lying between the capillaries and the tissue cells. (B) Myocardium, a highly metabolic tissue, has a rich vascular/capillary network, as demonstrated by transmission electron microscopy. The six open round spaces are capillaries. A red blood cell is noted in the capillary at upper left. ((A): Reproduced by permission from Cormack, D. H. (1987). *Ham's Histology,* 9th Edn. Lippincott: Philadelphia, PA.)

and control hemostasis (managing hemorrhage by a coordinated response of vasoconstriction and plugging of vascular defects by coagulation and platelet clumps). Other functions of the circulation include such homeostatic (control) mechanisms as regulation of body temperature, and distribution of various regulating substances (e.g., hormones, cytokines and other inflammatory mediators, growth factors). Moreover, the circulatory system distributes immune and inflammatory cells to their sites of action, and the endothelial cells that line blood vessels have important immunological and inflammatory functions (Mitchell and Schoen, 2010).

Although the cardiac output is intermittent owing to the cyclical nature of the pumping of the heart, continuous flow to the periphery occurs by virtue of distention of the aorta and its branches during ventricular contraction (*systole*), and elastic recoil of the walls of the aorta and other large arteries with forward propulsion of the blood during ventricular relaxation (*diastole*). Blood moves rapidly through the aorta and its arterial branches, which become narrower and whose walls become thinner and change histologically toward the peripheral tissues. By adjusting the degree of contraction of their circular

muscle coats, the distal arteries (*arterioles*) control the distribution of tissue blood flow to various tissues, and also permit regulation of local and systemic blood pressure. Blood returns to the heart from the *capillaries*, the smallest and thinnest walled vessels, by passing through *venules* and then through veins of increasing size.

Blood entering the right ventricle of the heart via the right atrium is pumped through the pulmonary arterial system at mean pressures about 1/6 of those developed in the systemic arteries. The blood then passes through the lung capillaries in the alveolar walls, where carbon dioxide is released across the pulmonary alveolar septa to, and oxygen taken up from, the alveoli. The oxygen-rich blood returns through the pulmonary veins to the left atrium and ventricle to complete the cycle.

Large diameter blood vessels are effective in delivering blood. Smaller vessels are most effective in regulating blood flow, and the smallest (the capillaries) regulate diffusional transport to and from the surrounding tissues. Thus, owing to their very thin walls and slow velocity of blood flow, which falls to approximately 0.1 cm/sec from 50 cm/sec in the aorta, capillaries are the sites of most exchange of oxygen, nutrients, and cellular wastes.

Capillary density is determined by the diffusion limit of oxygen; approximately 100–200 µm in most highly metabolic tissues (recall Figure II.1.5.1). Thus, highly metabolic tissues (e.g., heart muscle) have a dense network of blood vessels, and three-dimensional tissue formation and growth requires the formation of new blood vessels, a process called *angiogenesis*. It also follows that tissues that require less nutrition (e.g., cartilage and resting skeletal muscle) and those that are relatively thin (e.g., heart valve leaflets) may either require a sparse vascular network or none at all.

In the following sections we will cover the general functional principles of tissue organization and response to various types of injury, highlighted by specific illustrative examples.

Extracellular Matrix

Extracellular matrix (ECM) comprises the biological material produced by, residing in-between, and supporting cells. ECM, cells, and capillaries are physically and functionally integrated in tissues and organs (Figure II.1.5.2). The ECM provides physical support and a matrix in which cells can adhere, signal each other, and interact. However, the ECM is more than a scaffold that maintains tissue and organ structure. Indeed, the ECM regulates many aspects of cell behavior, including cell proliferation and growth, survival, change in cell shape, migration, and differentiation (the so-called "cell fate decisions"). (See Figures II.1.5.3 and II.1.5.4.)

The principal functions of the ECM are:

- Mechanical support for cell anchorage
- Determination of cell orientation
- Control of cell growth
- Maintenance of cell differentiation
- Scaffolding for orderly tissue renewal
- Establishment of tissue microenvironments
- Sequestration, storage, and presentation of soluble regulatory molecules.

Some extracellular matrices are specialized for a particular function, such as strength (tendon), filtration (the basement membranes in the kidney glomerulus) or adhesion (basement membranes supporting most epithelia). To produce additional mechanical strength in bones and teeth, the ECM is calcified. Even in a tissue as "simple" as a heart valve leaflet, the coordinated interplay of several ECM components, and the spatial and temporal dynamics of these interactions, are critical to function (Schoen, 2008). Moreover, the scaffolds used in tissue engineering applications often replicate the several functions of, and are intended to stimulate the production of, natural ECM (Lutolf and Hubbell, 2005; Lutolf et al, 2009).

ECM components are synthesized, secreted, and remodeled by cells in response to environmental cues. Virtually all cells secrete and degrade ECM to some extent. Certain cell types (e.g., fibroblasts and smooth muscle cells) are particularly active in production of interstitial ECM (i.e., the ECM between cells). Epithelial cells also
FIGURE II.1.5.2 Main components of the extracellular matrix, including collagen, proteoglycans, and adhesive glycoproteins. Both epithelial cells and fibroblasts interact with ECM via integrins. Basement membranes and interstitial ECM have differing architecture and general composition, although there is some overlap. Some ECM components (e.g., elastin) are not included for the sake of simplification. (Reproduced by permission from Kumar, V., Abbas, A. K., Fausto, N. & Aster, J. C. (eds.). (2010). *Robbins and Cotran Pathologic Basis of Disease*, 8th Edn. Saunders: Philadelphia, PA.)

synthesize the ECM of their basement membranes (see Figure II.1.5.5D).

Determinants of Tissue Form and Function

The mechanical forces that cells experience from their surroundings markedly influence the maintenance of cellular phenotypes, and affect cell shape, orientation, and differentiated function through interaction with receptors for specific ECM molecules on cell surfaces (such as *integrins*) (Chen, 2008; Mammoto and Ingber, 2010; Reilly and Engler, 2010). The resultant changes in cytoskeletal organization and in the production of second messengers can modify gene expression. ECM plays a critical role in cell differentiation, organogenesis, and as a scaffold allowing orderly repair following injury. The reciprocal instructions between cells and ECM are termed *dynamic reciprocity*.

> The ECM provides physical support and a matrix in which cells can adhere, signal each other, and interact. However, the ECM is more than a scaffold that maintains tissue and organ structure. Indeed, the ECM regulates many aspects of cell behavior, including cell proliferation and growth, survival, change in cell shape, migration and differentiation (the so-called "cell fate decisions").

ECM consists of large molecules synthesized by cells, exported to the intercellular space, and structurally linked. Present to some degree in all tissues, and particularly abundant as an intercellular substance in *connective tissues*, ECM is composed of: (1) fibrous structural and adhesive proteins (e.g., collagen, laminins, fibronectin, vitronectin, and elastin); (2) specialized proteins (including growth factors); and (3) a largely amorphous interfibrillary matrix (mainly proteoglycans, solutes, and water). The precise composition varies from tissue to tissue. The large fibrous molecules are interlinked within an expansile glycoprotein–water gel, resembling a fiber-reinforced composite. The specific components are described below.

Fibrillar Proteins: Collagens and Elastin

Collagen comprises a family of closely related but genetically, biochemically, and functionally distinct molecules, which are responsible for tissue tensile strength. The most common protein in the animal world, collagen provides the extracellular framework for all multicellular organisms. The collagens are composed of a triple helix of three polypeptide α chains; about 30 different α chains form approximately 20 distinct collagen types. Types I, II, and III are the *interstitial* or *fibrillar collagens*; they are the most abundant and the most important for the present discussion. Type I is ubiquitous in hard and soft tissues; Type II is rich in cartilage, intervertebral disk, and the vitreous of the eye; and Type III is prevalent in soft tissues, especially those regions that are healing following injury, and in the walls of hollow organs. Types IV and V are nonfibrillar and are present in basement membranes, and soft tissues and blood vessels, respectively. Collagens are: (1) synthesized in cells as soluble procollagen precursors in discrete protein subunits; (2) secreted
FIGURE II.1.5.3 Integrin-ECM interaction. Schematic showing the mechanisms by which ECM (e.g., collagen, fibronectin, and laminin) and growth factors interact with cells, activate signaling pathways, and can influence gene expression, growth, motility, differentiation, and protein synthesis. Integrins bind ECM and interact with the cytoskeleton at focal adhesion complexes. This can initiate the production of intracellular messengers, or can directly mediate nuclear signals. Cell surface receptors for growth factors also initiate second signals. (Reproduced by permission from Kumar, V., Abbas, A. K., Fausto, N. & Aster, J. C. (eds.). (2010). *Robbins and Cotran Pathologic Basis of Disease*, 8th Edn. Saunders: Philadelphia, PA.)
FIGURE II.1.5.4 Individual cell behavior and the dynamic state of multicellular tissues is regulated by reciprocal molecular interactions between cells and their surroundings. (Reproduced by permission from Lutolf, M. P. & Hubbell, J. A. (2005). Synthetic biomaterials as instructive extracellular microenvironments for morphogenesis in tissue engineering. *Nature Biotechnology*, **23**, 47–55.)

into the extracellular environment self-assembled; and (3) matured insoluble collagen molecules in the extracellular space (called "post-translational modification").

During collagen synthesis, the α chains are subjected to a number of enzymatic modifications, including hydroxylation of proline and lysine residues, providing collagen with a high content of hydroxyproline (10%). Vitamin C is required for hydroxylation of the collagen propeptide; a requirement that explains inadequate wound healing in vitamin C deficiency (scurvy). After the modifications,

but still inside the cell, the procollagen chains align and form the triple helix. However, the procollagen molecule is still soluble and contains N-terminal and C-terminal propeptides. During or shortly after secretion from the cell, procollagen peptidases clip the terminal propeptide chains, promoting formation of fibrils, often called *tropocollagen*, and oxidation of specific lysine and hydroxylysine residues occurs by the extracellular enzyme lysyl oxidase. This results in cross-linkages between α chains of adjacent molecules stabilizing the array that is characteristic of collagen. The mechanical properties of collagen reflect this structure; collagen fibrils are both non-extensible even at very high loads, and incompressible.

Elastic fibers are composed of the protein elastin. They confer passive recoil to various tissues, are critical components of vascular tissues (especially the aorta where repeated pulsatile flow would cause unacceptable shears on non-compliant tissue and elastic recoil is important), and of intervertebral disks (where the repetitive forces of ambulation along the spine are dissipated). Unlike collagen, elastin can be stretched). The stretching of an artery every time the heart pumps blood into an artery is followed by the recoil of elastin which restores the artery's former diameter between heartbeats.

Amorphous Matrix: Glycosaminoglycans (GAGs), Proteoglycans, and Hyaluronan

Amorphous intercellular substances contain carbohydrate bound to protein. The carbohydrate is in the form of long chain polysaccharides called *glycosaminoglycans* (GAGs). When GAGs are covalently bound to proteins, the molecules are called *proteoglycans*. GAGs are highly charged (usually sulfated) polysaccharide chains up to 200 sugars long, composed of repeating unbranched disaccharide units (one of which is always an amino sugar – hence the name glycosaminoglycan). GAGs are divided into four major groups on the basis of their sugar residues:

- Hyaluronic acid: a component of loose connective tissue and of joint fluid, where it acts as a lubricant;
- Chrondroitin sulfate and dermatan sulfate;
- Heparan sulfate and heparin;
- Keratin sulfate.

With the exception of hyaluronic acid (not sulfated and thereby unique among the GAGs), all GAGs are covalently attached to a protein backbone to form proteoglycans, with a structure that schematically resembles a bottle brush. Proteoglycans are diverse, owing to different core proteins and different glycosaminoglycans. Proteoglycans are named according to the structure of their principal repeating disaccharide. Some of the most common are heparan sulfate, chondroitin sulfate, and dermatan sulfate. Proteoglycans can also be integral membrane proteins, and are thus modulators of cell growth and differentiation. The syndecan family has a core protein that spans the plasma membrane and contains a short cytosolic domain,

as well as a long external domain to which a small number of heparan sulfate chains are attached. Syndecan binds collagen, fibronectin, and thrombospondin in the ECM, and can modulate the activity of growth factors. Hyaluronan consists of many repeats of a simple disaccharide stretched end-to-end and binds a large amount of water, forming a viscous hydrate gel, which gives connective tissue turgor pressure and an ability to resist compression forces. This ECM component helps provide resilience, as well as a lubricating feature to many types of connective tissue, notably that found in the cartilage in joints.

Adhesive Molecules

Adhesive proteins, including fibronectin, laminin, and entactin permit the attachment to, and movement of, cells within the ECM.

- *Fibronectin* is a ubiquitous, multi-domain glycoprotein possessing binding sites for a wide variety of other ECM components. It is synthesized by many different cell types, with the circulating form produced mainly by hepatocytes. Fibronectin is important for linking cells to the ECM via cell surface integrins. Fibronectin's adhesive character also makes it a crucial component of blood clots, and of pathways followed by migrating cells. Thus, fibronectin-rich pathways guide and promote the migration of many kinds of cells during embryonic development and wound healing.
- *Laminin* is an extremely abundant component of the basement membrane; it is a tough, thin, sheet-like layer on which epithelial cells sit, and is important for cell differentiation, adhesion to the substrate, and tissue remodeling. Laminin polypeptides are arranged in the form of an elongated cross, with individual chains held together by disulfide bonds. Like fibronectin, laminin has a distinct domain structure; different regions of the molecule bind to Type IV collagen (an important component of the basement membrane), heparin sulfate, entactin (a short protein that cross-links each laminin molecule to Type IV collagen), and cell surface integrins.

Extracellular Matrix Remodeling

The maintenance of the extracellular matrix requires ongoing remodeling of collagen, itself dependent on ongoing collagen synthesis and catabolism. Connective tissue remodeling, either physiological or pathological, is in most cases a highly organized and regulated process that involves the selective action of a group of related proteases that collectively can degrade most, if not all, components of the extracellular matrix. These proteases are known as the matrix metalloproteinases (MMPs). Subclasses include the interstitial collagenases, stromelysins, and gelatinases.

In many tissues, cells degrade and reassemble the ECM in response to external signals as part of physiological

homeostasis in mature, healthy tissues. Although matrix turnover is generally quite low in normal mature tissues, rapid and extensive remodeling characterizes embryological development (which involves branching morphogenesis, and stem cell homing, proliferation and differentiation), and wound repair, as well as various adaptive and pathologic states, such as tumor cell invasion and metastasis. ECM remodeling is mediated (and regulated) by signaling through ECM receptors, including the integrins and the ECM-modifying proteins, such as matrix metalloproteinases (MMPs), serene proteases (e.g., plasmin, plasminogen activator), and cysteine protease (e.g., cathepsins) (Page-McCaw et al., 2007; Daley et al., 2008). An understanding of cell–substrate interactions and matrix remodeling are central to the application of next-generation biomaterials technology, tissue engineering, and regenerative therapeutics (Gurtner et al., 2008).

Enzymes that degrade collagen are synthesized by macrophages, fibroblasts, and epithelial cells. Collagenases are specific for particular types of collagens, and many cells contain two or more different such enzymes. For example, fibroblasts synthesize a host of matrix components, as well as enzymes involved in matrix degradation, such as MMPs and serine proteases. Particularly important in tissue remodeling are myofibroblasts, a particular phenotype of cells that are characterized by features of both smooth muscle cells (e.g., contractile proteins such as α-actin) and features of fibroblasts (e.g., rough endoplasmic reticulum in which proteins are synthesized) (Hinz et al., 2007). These cells may also be responsible for the production of (and likely respond to) tissue forces during remodeling, thereby regulating the evolution of tissue structure according to mechanical requirements.

Evidence suggests that growth factors and hormones (autocrine, paracrine, and endocrine) are pivotal in orchestrating both synthesis and degradation of ECM components. Cytokines such as TGF-β, PDGF, and IL-1 clearly play an important role in the modulation of collagenase and tissue inhibitors of metalloproteinases (TIMPs) expression. MMP enzymatic activities are regulated by TIMPs, which are especially important during wound repair. As natural inhibitors of the MMPs, TIMPS are multifunctional proteins with both MMP inhibitor activity and cell growth modulating properties. Degradation of the extracellular matrix is mediated by an excess of MMP activity over that of TIMPs. Distortion of the balance between matrix synthesis and turnover may result in altered matrix composition and amounts.

Cell–Cell and Cell–Matrix Interactions. Like cell–cell interactions, cell–matrix interactions have a high degree of specificity, requiring recognition, adhesion, electrical and chemical communication, cytoskeletal reorganization, and/or cell migration. Moreover, adhesion receptors may also act as transmembrane signaling molecules that transmit information about the environment to the inside of cells, in some cases all the way to the nucleus, and mediate the effects of signals initiated by growth factors

or compounds controlling gene expression, phenotypic modulation and cell replication, differentiation and apoptosis (Figure II.1.5.3). Although many of the components of the extracellular matrix (*ligands*) with which cells interact are immobilized and not in solution (e.g., the integrin adhesion receptors and the vascular selectins (the latter modulate interaction of circulating inflammatory cells with the endothelium)), some soluble (secreted) factors also modulate cell–cell communication in the normal and pathologic regulation of tissue growth and maturation. Indeed, the array of specific binding of specialized cues with cell-surface receptors induces complex interactions that regulate tissue formation, homeostasis, and regeneration (Figure II.1.5.4). Moreover, the scaffolds used in tissue engineering applications often replicate the several functions of, and are intended to stimulate the production of, natural ECM (Lutolf et al., 2009).

The *integrins* comprise a family of cell receptors with diverse specificity that bind ECM proteins, other cell surface proteins and plasma proteins, and control cell growth, differentiation, gene expression, and motility (Bokel and Brown, 2002). Some integrins bind only a single component of the ECM, e.g., fibronectin, collagen, or laminin (see above). Other integrins can interact with several of these polypeptides. In contrast to hormone receptors, which have high affinity and low abundance, the integrins exhibit low affinity and high abundance, so that they can bind weakly to several different but related matrix molecules. This property allows the integrins to promote cell–cell interactions as well as cell–matrix binding.

BASIC TISSUES

Humans have over a hundred distinctly different types of cells allocated to four types of basic tissues (Table II.1.5.1 and Figure II.1.5.5): (1) epithelium; (2) connective tissue;

TABLE II.1.5.1	The Basic Tissues: Classification and Examples
Basic Tissues	**Examples**
Epithelial tissue	
Surface	Skin epidermis, gut mucosa
Glandular	Thyroid follicles, pancreatic acini
Special	Retinal or olfactory epithelium
Connective tissue	
Connective tissue proper	
Loose	Skin dermis
Dense (regular, irregular)	Pericardium, tendon
Special	Adipose tissue
Hemopoietic tissue, blood and lymph	Bone marrow, blood cells
Supportive tissue	Cartilage, bone
Muscle tissue	
Smooth	Arterial or gut smooth muscle
Skeletal	Limb musculature, diaphragm
Cardiac muscle	Heart
Nerve tissue	Brain cells, peripheral nerve
FIGURE II.1.5.5 Photomicrographs of basic tissues, emphasizing key structural features. (A)–(D) Epithelium; (E), (F) connective tissue; (G) muscle; and (H) nervous tissue. (A) Skin. Note the thin stratum corneum (c) and stratum granulosum (g). Also shown are the stratum spinosum (*s*), stratum basale (b), epidermal pegs (ep), dermal papilla (dp), and dermis (d). (B) Trachea, showing goblet cells (g), ciliated columnar cells (c), and basal cells (*b*). Note the thick basement membrane (bm) and numerous blood vessels (v) in the lamina propria (lp). (C) Mucosa of the small intestine (ileum). Note the goblet (g) and columnar absorbing (a) cells, the lamina propria (lp), and crypts (arrows). (D) Epithelium of a kidney collecting duct resting on a thin basement membrane (arrows). (E) Dense irregular connective tissue. Note the wavy unorientated collagen bundles (c) and fibroblasts (arrows), (p), plasma cells. (F) Cancellous bone clearly illustrating the morphologic difference between inactive bone lining (endosteal, osteoprogenitor) cells (bl) and active osteoblasts (ob). The clear area between the osteoblasts and calcified bone represents unmineralized matrix or osteoid. (cl), Cement lines; (o), osteocycles. (G) Myocardium (cardiac muscle). The key features are centrally placed nuclei, intercalated discs (representing end-to-end junctions of adjoining cells) and the sarcomere structure visible as cross-striations in the cells. (H) Small nerve fascicles (n) with perineurium (p) separating it from two other fascicles (n). ((A)–(F) and (H) reproduced by permission from Berman, I. (1993). (eds.). *Robbins Pathologic Basis of Disease*, 7th Edn. Saunders: Philadelphia, PA.)
FIGURE II.1.5.5 cont'd

(3) muscle; and (4) nervous tissue. The different basic tissues have distinctive microscopic appearances that belie their specific functional roles. The basic tissues have their origins in embryological development; early events include the formation of a tube with three *germ layers* in its wall: (1) an outer layer of ectoderm (which gives rise to skin and the nervous system); (2) an inner layer of endoderm (from which the lining membranes of the gut, respiratory tract, and genitourinary system, and the liver and pancreas derive); and (3) a middle layer of mesoderm (which is the origin of muscle, bone, blood cells, and the blood forming organs and the heart).

Epithelia cover the internal and external body surfaces and accommodate diverse functions. An epithelial surface can be: (1) a protective dry, cutaneous membrane barrier (as in skin); (2) a moist, mucous membrane, lubricated by glandular secretions and variably absorptive (digestive and respiratory tracts); (3) a moist membrane lined by mesothelium, lubricated by fluid that derives from blood plasma (peritoneum, pleura, pericardium); (4) the inner lining of the circulatory system, called endothelium; and (5) the source of internal and external secretions (e.g., endocrine and sweat glands,

respectively). Epithelium derives mostly from ectoderm and endoderm, but also from mesoderm.

Epithelial cells play fundamental roles in the directional movement of ions, water, and macromolecules between biological compartments, including absorption, secretion, and exchange. Therefore, the architectural and functional organization of epithelial cells includes structurally, biochemically, and physiologically distinct plasma membrane domains that contain region-specific ion channels, transport proteins, enzymes and lipids, and cell–cell junctional complexes. These components help integrate multiple cells to form an interface between biological compartments in organs. Subcellular epithelial specializations are not apparent to the naked eye – or even necessarily to light microscopy; they are best studied by transmission electron microscopy (TEM) and by functional assays (e.g., assessing synthetic products, permeability, and transport).

Supporting the other tissues of the body, connective tissue arises from embryonic mesenchyme, a derivative of mesoderm. Connective tissue also serves as a scaffold and conduit, through which course the nerves and blood vessels that support the various epithelial tissues. Other

types of tissue with varying functions are also of mes-
enchymal origin. These include dense connective tissue,
adipose (fat) tissue, cartilage and bone, circulating cells
(blood cells and their precursors in bone marrow), as
well as inflammatory cells that defend the body against
infectious organisms and other foreign agents.

Muscle cells develop from mesoderm and are highly
specialized for contraction. They have the contractile
proteins *actin* and *myosin* in varying amounts and con-
figuration, depending on cell function. Muscle cells are
of three types: smooth muscle; skeletal muscle; and car-
diac muscle. The latter two have a striated microscopic
appearance, owing to their discrete bundles of actin and
myosin organized into sarcomeres. Smooth muscle cells,
which have a less compact arrangement of myofilaments,
are prevalent in the walls of blood vessels and the gastro-
intestinal tract. Their slow, non-voluntary contraction
regulates blood vessel caliber, and proper movement of
food and solid waste, respectively.

Nerve tissue, which derives from ectoderm, is highly
specialized with respect to irritability and conduction.
Nerve cells not only have cell membranes that gener-
ate electrical signals called action potentials, but also
secrete neurotransmitters, molecules that trigger adja-
cent nerve or muscle cells to either transmit an impulse
or to contract.

Organs

Several different types of tissues arranged into a func-
tional unit constitute an organ. These have a compos-
ite structure in which epithelial cells typically perform
the specialized work of the organ, while connective tis-
sue and blood vessels support and provide nourishment
to the epithelium. There are two basic organ patterns:
tubular (or hollow) and compact (or solid) organs.
Tubular organs include the blood vessels and the diges-
tive, urogenital, and respiratory tracts; they have similar
architectures in that each is composed of layers of tissue
arranged in a specific sequence. For example, each has
an inner coat consisting of a lining of epithelium, a mid-
dle coat consisting of layers of muscle (usually smooth
muscle) and connective tissue, and an external coat con-
sisting of connective tissue, often covered by epithelium
(for example, the intestines or vascular walls) (Figure
II.1.5.6). Specific variations in architecture reflect organ-
specific functional requirements. While the outer coat of
an organ that blends into surrounding structures is called
the *adventitia*, the outside epithelial lining of an organ
suspended in a body cavity (e.g., thoracic or abdominal)
is called a *serosa*.

The histologic composition and organization, as well
as the thickness, of these three layers of tubular systems
varies characteristically with the physiologic functions
performed by specific regions. The structure/function
correlations are particularly well-demonstrated in the
cardiovascular system (Figure II.1.5.7). Blood vessels

have three layers: an *intima* (primarily endothelium);
a *media* (primarily smooth muscle and elastin); and an
adventitia (primarily collagen). The amounts and rela-
tive proportions of layers of the blood vessels are influ-
enced by mechanical factors (especially blood pressure,
which determines the amount and arrangement of mus-
cular tissue), and metabolic factors (reflecting the local
nutritional needs of the tissues). Three features will
illustrate the variation in site-specific structure–function
correlations:

- As discussed above, capillaries have a structural
  reduction of the vascular wall to only endothelium
  and minimal supporting structures to facilitate
  exchange (i.e., the metabolic function dominates).
  Thus, capillaries are part of the tissues they supply
  and, unlike larger vessels, do not appear as a separate
  anatomical unit.
- Arteries and veins have distinctive structures. The
  regional structural changes are primarily controlled
  by mechanical factors. The arterial wall is gener-
  ally thicker than the venous wall, in order to with-
  stand the higher blood pressures that prevail within
  arteries compared with veins. The thickness of the
  arterial wall gradually diminishes as the vessels
  themselves become smaller, but the wall–to–lumen
  ratio becomes greater in the periphery. Veins have
  a larger overall diameter, a larger lumen, and a nar-
  rower wall than the corresponding arteries with
  which they course.
- In essence, the heart is a blood vessel specialized for
  rhythmic contraction; its media is the *myocardium*,
  containing muscle cells (*cardiac myocytes*).

The blood supply of an organ comes from its outer
aspect. In tubular organs, large vessels penetrate the
outer coat, perpendicular to it, and give off branches
that run parallel to the tissue layers (Figure II.1.5.8).
These vessels divide yet again to give off penetrating
branches that course through the muscular layer, and
branch again in the connective tissue parallel to the
layers. The small blood vessels have junctions (*anas-
tomoses*) with one another in the connective tissue.
These junctions may provide collateral pathways that
can allow blood to bypass obstructions. Compact,
solid organs have an extensive connective tissue frame-
work, surrounded by a dense, connective tissue capsule
(Figure II.1.5.9). Such organs have an area of thicker
connective tissue where blood vessels and other con-
duits (e.g., airways in the lungs) enter the organ; this
region is called the *hilus*. From the hilus, strands of con-
nective tissue extend into the organ and may divide it
into lobules.

In both tubular and compact organs, the dominant
cells comprising specialized tissues are the *parenchyma*
(e.g., epithelial cells lining the gut, thyroglobulin-hormone
producing epithelial cells in the thyroid or cardiac muscle

(A)

cells in the heart). Parenchyma occurs in masses (e.g., endocrine glands), cords (e.g., liver), or tubules (e.g., kidney). Parenchymal cells can be arranged uniformly in an organ, or they may be segregated into a subcapsular region (*cortex*) and a deeper region (*medulla*), each performing a distinct functional role. The remainder of the organ has a delicate structural framework, including supporting cells, extracellular matrix, and vasculature (essentially the "service core"), which constitutes

the *stroma*. After entering an organ, the blood supply branches repeatedly to small arteries, and ultimately capillaries in the parenchyma; veins and nerves generally follow the course of the arteries.

Parenchymal cells are generally more sensitive to chemical, physical, or ischemic (i.e., low blood flow) injury than stroma. Moreover, when an organ is injured, orderly repair and regrowth of parenchymal cells requires an intact underlying stroma.
FIGURE II.1.5.7 Regional structural variations in the cardiovascular system. Although the basic organization is constant, the thickness and composition of the various layers differ, as a functional response to differential hemodynamic forces and tissue metabolic requirements. TISSUE RESPONSE TO INJURY: INFLAMMATION, REPAIR, AND REGENERATION

A key protective response of an organism is its ability to eliminate damaged tissues and foreign invaders, such as microbes or exogenous non-biological materials (the latter including therapeutic biomaterials). Elimination of the intruder rids the organism of both the cause and the consequences of cell and tissue injury. Without this protective process, tissue wounds would not heal and infections would go unchecked. However, inappropriately triggered or uncontrolled inflammation can also be deleterious. Inflammation is usually a highly coordinated response involving proteins, leukocytes, and phagocytic cells (macrophages) that are derived from circulating cells, all of which travel in the blood and are recruited to a site where they are needed.

The outcome of tissue injury depends primarily on the tissue type affected, the extent of the injury, and whether it is persistent (Figure II.1.5.10). When an environmental perturbation or injury is transient or short-lived, tissue destruction is small, and the tissue is capable of homeostatic adjustment or regeneration; the outcome is restoration of normal structure and function. However, when tissue injury is extensive or occurs in tissues that do not regenerate, inflammation and repair occur, and the result is scarring (Singer and Clark, 1999). When an infection or foreign material cannot be eliminated, the body "controls" the foreign body or infection by creating a wall around it (and thereby isolating it as much as possible from healthy tissue). Thus, most inert biomaterials elicit an early inflammatory response, followed by a late tissue reaction characterized by encapsulation by a relatively thin fibrous tissue capsule (composed of collagen and fibroblasts, and similar to a scar). The nature of the reaction is largely dependent on the chemical and physical characteristics of the implant.

As described above, inflammation and repair follow cell and tissue injury induced by various exogenous and endogenous stimuli, both eliminating (i.e., diluting, destroying or isolating) the cause of the injury (e.g., microbes or toxins), and disposing of necrotic cells and tissues that occur as a result of the injury. In doing so, the inflammatory response initiates the process that heals and reconstitutes the tissue, by replacing the wound with native parenchymal cells or by filling up the defect with fibroblastic scar tissue, or some combination of both (such as skin reconstituting the epidermis and scarring the dermis) (Figure II.1.5.11). Inflammation and repair constitute an overlapping sequence of several processes (Figure II.1.5.12):

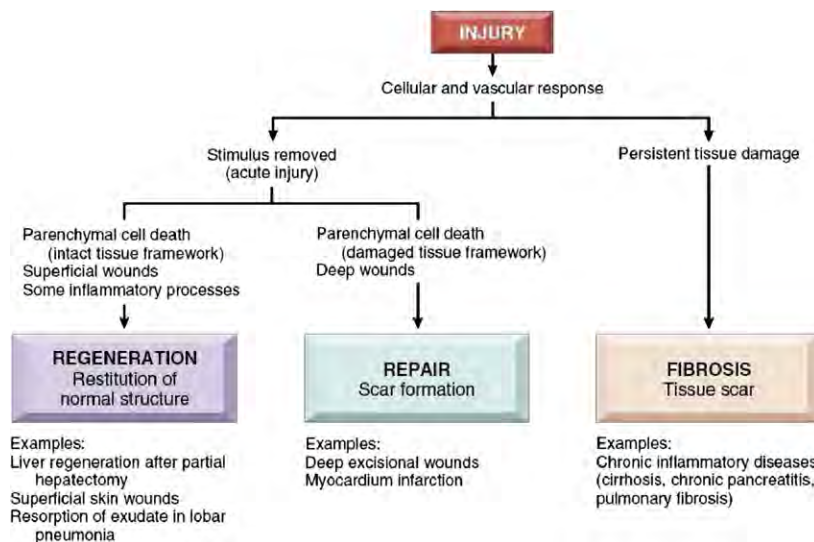
- Acute inflammation: The immediate and early response to injury, of relatively short duration, characterized by fluid and plasma protein exudation into the tissue, and by accumulation of neutrophils (polymorphonuclear leukocytes). In the case of an infection that cannot be easily eliminated, an abscess (i.e., a localized collection of acute inflammation and infectious organisms) is the outcome.
- Chronic inflammation: This phase is manifested histologically as lymphocytes and macrophages, often with concurrent tissue destruction, and can evolve into repair involving fibrosis and new blood vessel proliferation. A special type of chronic inflammation characterized by activated macrophages and often multinucleated giant cells, organized around an irritating focus, is called a *granuloma* or *granulomatous inflammation*. The pattern also occurs in pathologic states where the inciting agent is not removable, including the foreign body reaction (see below).


FIGURE II.1.5.10 Regeneration, repair, and fibrosis after injury and inflammation. (Reproduced by permission from Kumar, V., Abbas, A. K., Fausto, N. & Aster, J. C. (2010). *Robbins and Cotran Pathologic Basis of Disease*, 8th Edn. Saunders: Philadelphia, PA.)

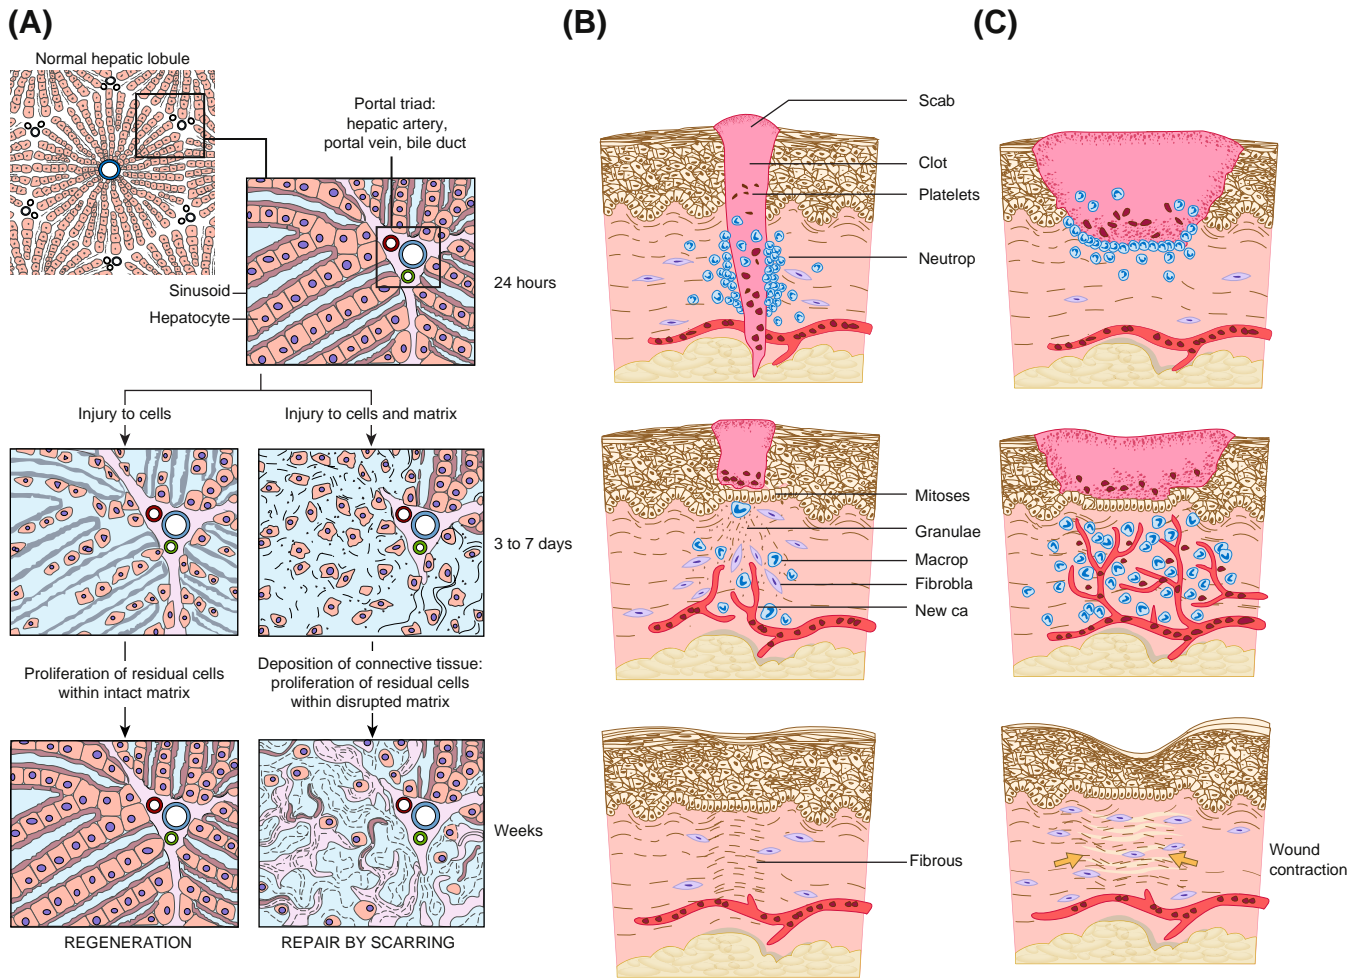
(A)   **(B)**   **(C)**


FIGURE II.1.5.11 Key concepts in tissue responses following injury. (A) Role of the extracellular matrix in regeneration versus repair, illustrated for liver injury. Regeneration requires an intact matrix and persistence of cells capable of proliferation. If both cells and matrix are damaged, repair occurs by fibrous tissue deposition and scar formation. (B) and (C) Wound healing and scar formation in skin. (B) Healing of a wound that caused little injury leads to a thin scar with minimal contraction. (C) Healing of a large wound causes substantial scar and more contraction and distortion of the tissue. (Reproduced by permission from Kumar, V., Abbas, A. K., Fausto, N. & Aster, J. C. (2010). *Robbins and Cotran Pathologic Basis of Disease*, 8th Edn. Saunders: Philadelphia, PA.)
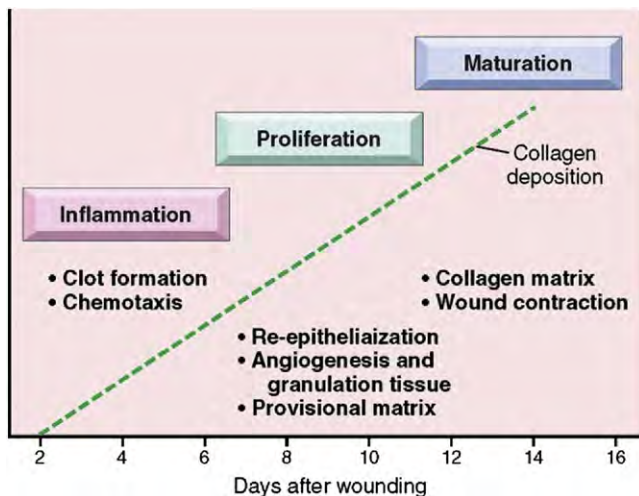

FIGURE II.1.5.12 Phases of cutaneous wound healing: Inflammation, proliferation, and maturation. (Reproduced by permission from Kumar, V., Abbas, A. K., Fausto, N. & Aster, J. C. (2010) *Robbins and Cotran Pathologic Basis of Disease*, 8th Edn. Saunders: Philadelphia, PA.)

Synthetic biomaterials are generally not immunogenic, and are therefore generally not "rejected" like a transplanted organ. However, they typically elicit the *foreign body reaction* (*FBR*), a special form of non-immune inflammation. The most prominent cells in the FBR are macrophages, which presumably attempt to phagocytose the material, but degradation is difficult. Depending on the local milieu and the resultant chemical signals, microphages will differentiate (activate) in different ways, either pro-inflammatory or pro-healing and fibrosis (Mosser and Edwards, 2008; Brown et al, 2012). Multinucleated *giant cells* in the vicinity of a foreign body are generally considered evidence of a more severe FBR in which the material is particularly irritating. This reaction is frequently called a *foreign body granuloma*. The more "biocompatible" the implant, the more quiescent is the ultimate response.

- Scarring: In situations where repair cannot be accomplished by regeneration, scarring occurs as a composite of three sequential processes: (1) formation of new blood vessels (*angiogenesis*); (2) deposition of collagen (*fibrosis*); and (3) maturation and remodeling of the scar (*remodeling*). The early healing tissue rich in new capillaries and proliferation of fibroblasts is called *granulation tissue* (not to be confused with granuloma, above). The essential features of the healing process are usually advanced by 4–6 weeks, although full scar remodeling may require much longer.

Inflammation is also associated with the release of chemical mediators from plasma, cells or extracellular matrix, which regulates the subsequent vascular and cellular events, and may modify their evolution. The chemical mediators of inflammation include the vasoactive amines (e.g., histamine), plasma proteases (of the coagulation, fibrinolytic, kinin, and complement systems), arachidonic acid metabolites (eicosinoids) produced in the cyclooxygenase pathway (the prostaglandins) and the lipoxygenase pathway (the leukotrienes), platelet-activating factor, cytokines (e.g., interleukin1 [IL-1], tumor necrosis factor-α [TNF-α] and interferon-γ [IFN-γ]), nitric oxide and oxygen-derived free radicals, and various intracellular constituents, particularly the lysosomal granules of inflammatory cells. Polypeptide growth factors also influence repair and healing by affecting cell growth, locomotion, contractility, and differentiation. Growth factors may act by endocrine (systemic), paracrine (stimulating adjacent cells) or autocrine (same cell carrying receptors for their own endogenously produced factors) mechanisms. Growth factors involved in mediating angiogenesis, fibroblast migration, proliferation, and collagen deposition in wounds include epidermal growth factor (EGF, important in proliferation of epithelial cells and fibroblasts), platelet-derived growth factor (PDGF, involved in fibroblast and smooth muscle cell migration), fibroblast growth factors (FGFs), transforming growth factor-β (TGF-β, with a central role in fibrosis), and vascular endothelial growth factor (VEGF, with a central role in angiogenesis).

TECHNIQUES FOR ANALYSIS OF CELLS AND TISSUES

Cells in culture (*in vitro*) often continue to perform many of the normal functions they have in the body (*in vivo*). Through measurement of changes in secreted products under different conditions, for example, culture methods can be used to study how cells respond to certain stimuli. However, since cells in culture do not have the usual chemical and physical environment that they have in tissues, normal physiological function may not always be present.

Techniques commonly used to study the structure of either normal or abnormal tissues, and the purpose of each mode of analysis, are summarized in Table II.1.5.2 and Figure II.1.5.13. The most widely used technique (historically and presently) for examining tissues is light microscopy, described below. Several advanced tissue analysis techniques are also increasingly being used to answer more detailed questions concerning cell and tissue function.

Light Microscopy

The conventional light microscopy technique involves obtaining the tissue sample, followed by fixation, paraffin embedding, sectioning, mounting on a glass slide, staining, and examination. Photographs of conventional tissue sections taken through a light microscope (photomicrographs) were illustrated in Figure II.1.5.5. Photographs of a tissue sample, paraffin block, and resulting tissue section on a glass slide are shown in Figure II.1.5.14. The tissue is obtained by either surgical excision (removal), biopsy (sampling) or autopsy (postmortem examination). A sharp instrument is used to dissect the tissue to avoid distortion from crushing. The key processing steps are summarized in the following paragraphs.

To preserve the structural relationships among cells, their environment, and subcellular structures in tissues, it is necessary to cross-link and preserve the tissue in a permanent, non-viable state called *fixation*. Specimens should be placed in fixatives as soon as possible after removal. Fixative solutions prevent degradation of the tissue when it is separated from its source of oxygen and nutrition (i.e., autolysis) by coagulating (i.e., cross-linking, denaturing, and precipitating) proteins. This prevents cellular hydrolytic enzymes (which are released when cells die) from degrading tissue components and spoiling tissues for microscopic analysis. Fixation also immobilizes fats and carbohydrates, reduces or eliminates enzymic and immunological reactivity, and kills microorganisms present in tissues.

A 37% solution of formaldehyde is called *formalin*; thus, 10% formalin is approximately 4% formaldehyde. This solution is the routine fixative in pathology for light microscopy. For TEM and scanning electron microscopy (SEM), glutaraldehyde preserves structural elements better than formalin. Adequate fixation in formalin and/or glutaraldehyde requires tissue samples less than 1.0 and 0.1 cm, respectively, in largest dimension. For adequate fixation, the volume of fixative into which a tissue sample is placed should generally be at least 5 to 10 times that of the tissue volume.

Dehydration and Embedding

In order to support the specimen during sectioning, specimen water (approximately 70% of tissue mass) must be

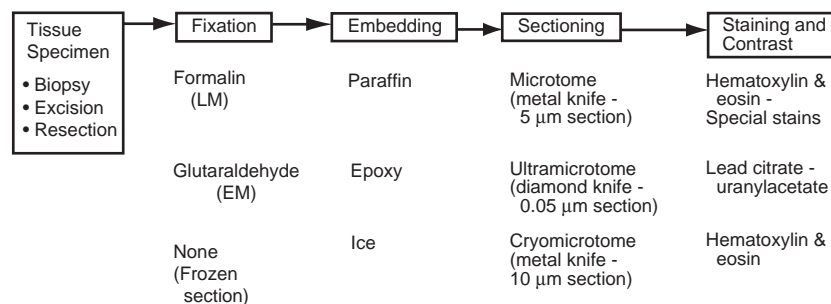
TABLE II.1.5.2	Techniques Used to Study Tissue
Technique	**Purpose**
Gross examination	Determine overall specimen configuration; many diseases and processes can be diagnosed at this level
Light microscopy (LM)	Study overall microscopic tissue architecture and cellular structure
Transmission electron microscopy (TEM)	Study ultrastructure and identify cells and their and environment
Enzyme histochemistry	Demonstrate the presence and location of enzymes in gross or microscopic sections
Immunohistochemistry	Identify and locate specific molecules, usually proteins, for which a specific antibody is available as a probe
Microbiologic cultures	Diagnose the presence of infectious organisms
Morphometric studies (at gross, LM or TEM levels)	Quantitate the amounts, configuration, and distribution of specific structures
Chemical, biochemical and spectroscopic analysis	Assess bulk concentration of molecular or elemental constituents
Energy dispersive x-ray analysis (EDXA)	Perform site-specific elemental analysis in sections
In-situ hybridization	Identify presence and location of mRNA or DNA within cells and tissues in histological sections
Northern blot	Detect the presence, amount, and size of specific mRNA molecules
Western blot	Identify the presence and amount of specific proteins
Southern blot	Detect and identify specific DNA sequences
Polymerase chain reaction (PCR)	Cyclical amplification of DNA to produce sufficient material for analysis
Tissue microarray	Permits study of multiple lesions simultaneously using tissue from multiple patients or blocks on the same slide; produced using a needle to biopsy conventional paraffin blocks and placing the cores into an array on a recipient paraffin block


FIGURE II.1.5.13 Key features of tissue processing for examination by light and electron microscopy.
FIGURE II.1.5.14 Tissue processing steps for light microscopy. (A) Tissue section. (B) Paraffin block. (C) Resulting histologic section.

replaced by paraffin wax or other embedding medium, such as glycolmethacrylate. This is done through several steps, beginning with dehydration of the specimen through increasing concentrations of ethanol (eventually to absolute ethanol). However, since alcohol is not miscible with paraffin (the final embedding medium), xylol (an organic solvent) is used as an intermediate solution.

Following dehydration, the specimen is soaked in molten paraffin and placed in a mold larger than the specimen, so that tissue spaces originally containing water, as well as a surrounding cube, are filled with wax. The mold is cooled, and the resultant solid block containing the specimen (see Figure II.1.5.14B) can then be easily handled.

Sectioning

Tissue specimens are sectioned on a microtome (which has a blade similar to a single-edged razor blade), that is progressively advanced through the specimen block. The shavings are picked up on glass slides. Sections for light microscopic analysis must be thin enough to both transmit light and avoid superimposition of various tissue components. Typically sections are approximately 5 μm thick – slightly thicker than a human hair, but thinner than the diameter of most cells. If thinner sections are required (e.g., approximately 0.06 μm thick ultrathin sections are necessary) for TEM analysis, a harder supporting (embedding) medium (usually epoxy plastic) and a correspondingly harder knife (usually diamond) are used. Sections for TEM analysis are cut on an ultramicrotome. Because the conventional paraffin technique requires overnight processing, frozen sections are often used to render an immediate diagnosis (e.g., during a surgical procedure that might be modified according to the diagnosis). In this method, the specimen itself is frozen, so that the solidified internal water acts as a support medium, and sections are then cut in a cryostat (i.e., a microtome in a cold chamber). Although frozen sections are extremely useful for immediate tissue examination, the quality of the appearance is inferior to that obtained by conventional fixation and embedding methods. Frozen sections may also be used to section specimens that contain a component of interest that would be dissolved out or otherwise altered by processing with the organic solvents required by paraffin embedding (e.g., some polymers).

Staining

Tissue components have no intrinsic contrast, and are of fairly uniform optical density. Therefore, in order for tissue to be visible by light microscopy, tissue elements must be distinguished by selective adsorption of dyes (Luna, 1968). Since most stains are aqueous solutions of dyes, staining requires the paraffin in the tissue section to be removed and replaced by water (rehydration).

The stain used routinely in histology involves sequential incubation in the dyes hematoxylin and eosin (H&E). Hematoxylin has an alkaline (basic) pH that stains blue–purple; substances stained with hematoxylin typically have a net negative charge and are said to be "basophilic" (e.g., cell nuclei containing DNA). In contrast, substances that stain with eosin, an acidic pigment that colors positively-charged tissue components pink–red, are said to be "acidophilic" or "eosinophilic" (e.g., cell cytoplasm, collagen). The tissue sections shown in Figure II.1.5.5 were stained with hematoxylin and eosin.

Special Staining and Immunohistochemistry

There are special staining methods for highlighting components that do not stain well with routine stains (e.g., microorganisms) or for indicating the chemical nature or the location of a specific tissue component (e.g., collagen, elastin; Table II.1.5.3). There are also special techniques for demonstrating the specific chemical activity of a compound in tissues (e.g., enzyme histochemistry). In this case, the specific substrate for the enzyme of interest is reacted with the tissue; a colored product precipitates in the tissue section at the site of the enzyme. In contrast, immunohistochemical staining takes advantage of the immunological properties (antigenicity) of a tissue component to demonstrate its nature and location by identifying sites of antibody binding. Antibodies to the particular tissue constituent are attached to a dye, usually a compound activated by a peroxidase enzyme, and reacted with a tissue

TABLE II.1.5.3	Stains for Light Microscopic Histology[a]
To Demonstrate	**Stain**
Overall morphology	Hematoxylin and eosin (H&E)
Collagen	Masson's trichrome
Elastin	Verhoeff-van Gieson
Glycosoaminoglycans (GAGs)	Alcian blue
Collagen–elastic–GAGs	Movat
Bacteria	Gram
Fungi	Methenamine silver or periodic acid-Schiff (PAS)
Iron	Prussian blue
Calcium phosphates (or calcium)	von Kossa (or alizarin red)
Fibrin	Lendrum or phosphotungstic acid hematoxylin (PTAH)
Amyloid	Congo red
Inflammatory cell types	Esterases (e.g., chloroacetate esterase for neutrophils, nonspecific esterase for macrophages)

section (immunoperoxidase technique) or the antibody is attached to a compound that is excited by a specific wavelength of light (immunofluorescence). Although some antigens and enzymatic activity can survive the conventional histological processing technique, both enzyme activity and immunological reactivity are often largely eliminated by routine fixation and embedding. Therefore, histochemistry and immunohistochemistry are frequently done on frozen sections. Nevertheless special preservation and embedding techniques now available often allow immunological methods to be carried out on carefully fixed tissue.

Electron Microscopy

Contrast in the electron microscope depends on relative electron densities of tissue components. Sections are stained with salts of heavy metals (osmium, lead, and uranium), which react differentially with different structures, creating patterns of electron density that reflect tissue and cellular architecture. An example of an electron photomicrograph is shown in Figure II.1.5.1B.

It is often possible to derive quantitative information from routine tissue sections using various manual or computer-aided methods. Morphometric or stereologic methodology, as these techniques are called, can be extremely useful in providing an objective basis for otherwise subjective measurements (Loud and Anversa, 1984). Techniques for sampling information from small amounts of tissue include laser microdissection, confocal microscopy, two-photon microscopy, etc.

Three-Dimensional Interpretation

Interpretation of tissue sections depends on the reconstruction of three-dimensional information from two-dimensional observations on tissue sections that are usually thinner than a single cell. Therefore, a single section may yield an unrepresentative view of the whole. A particular structure (even a very simple one) can look very different, depending on the plane of section. Figure II.1.5.15 shows how multiple sections must be examined to appreciate the actual configuration of an object or a collection of cells.

Artifacts

Artifacts are unwanted or confusing features in tissue sections that result from errors or technical difficulties in obtaining, processing, sectioning or staining the specimen. Recognition of artifacts avoids misinterpretation. The most frequent and important artifacts are autolysis, tissue shrinkage, separation of adjacent structures, precipitates formed by poor buffering or by degradation of fixatives or stains, folds or wrinkles in the tissue sections, knife nicks or rough handling (e.g., crushing) of the specimen.
FIGURE II.1.5.15 Considerations for three-dimensional interpretation of two-dimensional information. Sections through a subject in different levels and orientations can give different impressions about its structure, here illustrated (A) for a hard-boiled egg, and (B) for a section through cells of a uniform size that suggests that the cells are heterogenous. (Modified by permission from Cormack, D. H. (1993). *Essential Histology*. Copyright 1993, Lippincott.)

Identification, Genotyping, and Functional Assessment of Cells, Including Synthetic Products, in Cells or Tissue Sections

It is frequently necessary to accurately ascertain or verify the identity of a cell, or to determine some aspect of its function, including the production of synthetic molecules. For such an assay, either isolated cells or whole tissues are used, depending on the objective of the study. Isolated cells or minced tissue have the advantage of allowing molecular and/or biochemical analyses on the cells and/or products, and often allow the acquisition of quantitative data. Nevertheless, the major advantage of whole tissue preparations is the ability to spatially localize molecules of interest in the context of architectural features of the tissue. Methods for identification and determination of

the function of cells and identification of extracellular components in situ are summarized in Table II.1.5.4. New techniques are available. Cellular apoptosis and proliferation can be quantified (Watanabe et al., 2002). Immunohistochemical markers allow detection of proteins that are highly expressed in a tissue section. However, the relevant antibodies to proteins expressed in high concentration must be available, and the expense of such studies limits their usefulness. In-situ hybridization permits similar investigation of gene expression but, as with immunohistochemistry, only a discrete panel of previously predicted genes can be probed.

Advanced Tissue and Cell Analysis

Several very exciting new and evolving techniques are available to assay the anatomy and function of tissues and cells with extraordinary precision and/or spatial localization. These can be used individually or coupled. Very exciting are various forms of functional genomic and proteomic analyses (Chen et al., 2009). In particular, gene expression profiling shows the complete array of genes expressed in cells or tissues; the technology may identify pathogenetically distinct subtypes of any lesion and search for fundamental mechanisms even when candidate genes are unknown (Duggal et al., 2009). Confocal microscopy helps localize a particular component in a living cell by observing a series of optical sections (planes) which are reconstructed into a three-dimensional image (Watson et al., 2000; Howell et al., 2002). Tissue microassays permit the comparative examination of potentially hundreds of individual specimens in a single paraffin block (Hewitt, 2012). In addition, laser-assisted microdissection techniques permit isolation of an individual or a homogenous population of cells on selected cell populations under direct visualization from

a routine histological section of complex, heterogeneous tissue (Edwards, 2007; Kurkalli et al., 2010). Very exciting new imaging technologies may permit analysis of viable tissues *in vivo* (Pinaud et al., 2006; Georgakoudi et al., 2008; Weissleder and Pittet, 2008).

REGENERATIVE CAPACITY OF CELLS AND TISSUES

Organs are theoretically capable of renewing via three routes: (1) proliferation and differentiation of resident stem cells; (2) dedifferentiation of resident cells followed by proliferation/differentiation; and (3) homing and differentiation of circulating stem cells. Most types of cell populations can undergo turnover, but the process is highly regulated, and the production of cells of a particular kind generally ceases until some are damaged or another need arises. Rates of proliferation are different among various cell populations, and are frequently divided into three categories: (1) renewing (also called labile) cells have continuous turnover, with proliferation balancing cell loss that accrues by death or physiological depletion; (2) expanding (also called stable) cells, normally having a low rate of death and replication, retain the capacity to divide following stimulation; and (3) static (also called permanent) cells, not only have no normal proliferation, but they have also lost their capacity to divide. The relative proliferative (and regenerative) capacity of various cell types is summarized in Table II.1.5.5.

In normally renewing (labile) cell populations (e.g., skin, intestinal epithelium, bone marrow), tissue-specific (often called "adult") stem cells proliferate to form daughter cells that can become differentiated and repopulate the damaged cells. A particular stem cell produces many such daughter cells, and, in some cases, several different kinds of cells can arise from a common multipotential ancestor cell (also called multipotency, e.g., bone marrow stem cells lead to several different types of blood cells). In epithelia (such as the

TABLE II.1.5.5	Regenerative Capacity of Cells Following Injury		
Category	**Normal rate of Replication**	**Response to Stimulus/ Injury**	**Examples**
Renewing/ labile	High	Modest increase	Skin, intestinal mucosa, bone marrow
Expanding/ stable	Low	Marked increase	Endothelium, fibroblasts, liver cells
Static/ permanent	None	No replication; replacement by scar	Heart muscle cells, nerves

epidermis layer of skin), the stem cells reside at the base of the tissue layer, away from the surface; differentiation and maturation occur as the cells move toward the surface. Regenerative tissues, especially those with high proliferative capacity, such as the hematopoietic system (e.g., bone marrow) and the epithelia of the skin and the gastrointestinal tract, renew themselves continually and can regenerate following injury, providing that the stem cells of these tissues have not been destroyed. Expanding (stable) populations can increase their rate of replication in response to suitable stimuli. Stable cell populations include glandular epithelial cells, liver, fibroblasts, vascular smooth muscle cells, osteoblasts, and endothelial cells. Cells that die are generally replaced by new ones of the same kind. In contrast, permanent (static) cells have minimal, if any, normal mitotic capacity and, in general, cannot be induced to regenerate. Following injury, they are replaced by scar. The inability to regenerate large, functional amounts of certain tissue types following injury can result in a clinically important deficit, since the function of the damaged tissue is irretrievably lost. For example, an area of heart muscle or brain which is damaged by ischemic injury (e.g., myocardial infarction) cannot be effectively replaced by viable cells; the necrotic area is repaired by scar has no functional potential. Therefore, in heart the remainder of the heart muscle must assume the workload of the lost tissue. In brain, the majority of function is lost in the cells damaged by a stroke.

While the classical concepts enumerated above continue to hold true from a practical standpoint, recent evidence suggests that some regeneration of neural tissue and heart muscle cells can occur under certain circumstances following injury. Both the extent to which this can occur and effective strategies to harness this potential and exciting source of new tissue are as yet unknown (Orive et al., 2009; Hosoda et al., 2010; Yi et al., 2010).

CELL/TISSUE–BIOMATERIALS INTERACTIONS

For most applications, biomaterials are in contact with cells and tissues (either hard tissue, including bone; soft tissue, including cardiovascular tissues; and blood in the case of cardiovascular implants or extracorporeal devices), often for prolonged periods. Thus, rational and sophisticated use of biomaterials and design of medical devices requires some knowledge of the general concepts concerning the interaction of cells with non-physiological surfaces. This discussion complements that described in Chapter II.1.2. and II.1.3.

Most tissue-derived cells require attachment to a solid surface for viability, growth, migration, and differentiation. The nature of that attachment is an important regulator of those functions. Moreover, the behavior and function of adherent cells (e.g., shape, proliferation, synthetic function) depend on the characteristics of the

substrate, particularly its adhesiveness and mechanical properties (Reilly & Engler, 2010).

Following contact with tissue or blood, a bare surface of a biomaterial is covered rapidly (usually in seconds) with proteins that are adsorbed from the surrounding body fluids. The chemistry of the underlying substrate (particularly as it affects wettability and surface charge) controls the nature of the adherent protein layer. For example, macrophage fusion and platelet adhesion/aggregation are strongly dependent on surface chemistry. Moreover, although cells are able to adhere, spread, and grow on bare biomaterial surfaces *in vitro*, proteins absorbed from the adjacent tissue environment or blood and/or secreted by the adherent cells themselves markedly enhance cell attachment, migration, and growth.

Cell adhesion to biomaterials and the ECM is mediated by cytoskeletally-associated receptors in the cell membrane, which interact with cell adhesion proteins that adsorb to the material surface from the surrounding plasma and other fluids (Figure II.1.5.16). Cell adhesion triggers multiple functional biochemical signaling
FIGURE II.1.5.16 Progression of anchorage-dependent cell adhesion. (A) Initial contact of cell with solid substrate. (B) Formation of bonds between cell surface receptors and cell adhesion ligands. pathways within the cell (Chen, 2008). The interactions are critical to cell-growth control responsive to mechanical forces mediated through associated changes in cell shape and cytoskeletal tension (Ingber, 2010b). Focal adhesions are considered to represent the strongest such interactions. They comprise a complex assembly of intra- and extracellular proteins, coupled to each other through transmembrane integrins. Cell-surface integrin receptors promote cell attachment to substrates, and especially those covered with the extracellular proteins fibronectin and vibronectin. These receptors transduce biochemical signals to the nucleus by activating the same intracellular signaling pathways that are used by soluble growth factor receptors. The more cells spread, the higher their rate of proliferation. The importance of cell spreading on their proliferation has been emphasized by classical experiments that used endothelial cells cultured on microfabricated substrates containing fibronectin-coated islands of various defined shapes and sizes of a micrometer scale (Figure II.1.5.17) (Chen et al., 1997). Cells spread to the limits of the islands containing a fibronectin substrate; cells on circular islands were circular while cells on square islands became square in shape and had 90° corners. When the spreading of the cells was restricted by small adhesive islands (10–30 μm), proliferation was arrested, while larger islands (80 μm) permitted proliferation. When the cells were grown on micropatterned substrates with 3–5 μm dots, comprising multiple adhesive islands that permitted the cells to extend over multiple islands while maintaining the total ECM contact similar to that of one small island (that was associated with inhibited growth), they proliferated. This confirmed that the ability of cells to proliferate depended directly on the degree to which the cells were allowed to distend physically, and not on the actual surface area of substrate binding. Thus, cell distortion is a critical determinant of cell behavior.

Interactions of cells with ECM differ from those with soluble regulatory factors owing to the reciprocal interactions between the ECM and the cell's actin cytoskeleton (Ingber, 2010b). For example, rigid substrates promote cell spreading and growth in the presence of soluble mitogens; in contrast, flexible scaffolds that cannot resist cytoskeletal forces promote cell retraction, inhibit growth, and promote differentiation. Thus, the properties of the nature and configuration of the surface-bound ECM on a substrate, and the properties of the substrate itself, can regulate cell–biomaterials interactions. The key

concept is that a biomaterial surface can contain specific chemical and structural information that controls tissue formation, in a manner analogous to cell–cell communication and patterning during embryological development.

The exciting potential of this strategy is exemplified by tissue engineering approaches that employ biomaterials with surfaces designed to stimulate biophysical and biochemical microenviromental use of highly precise spatial and temporal reactions with proteins and cells at the molecular level, to trigger cell fate decisions such as adhesion, proliferation, migration, and specific gene-expression profiles and differentiation patterns (Lutolf et al, 2009). Such materials provide the scientific foundation for molecular design of scaffolds that could be seeded with cells *in vitro* for subsequent implantation or specifically attract endogenous functional cells *in vivo*. A key challenge in tissue engineering is to understand quantitatively how cells respond to various molecular signals and integrate multiple inputs to generate a given response, and to control non-specific interactions between cells and a biomaterial, so that cell responses specifically follow desired receptor–ligand interactions. Understanding the principles regulating these responses, the means to chart them, and the ability to fabricate elaborate interfaces with carefully controlled ligand type, density, clustering, and spatial distribution (potentially in three dimensions) will ultimately permit novel biosensors, smart biomaterials, advanced medical devices, microarrays, and tissue regenerative approaches.

CHAPTER II.1.6 EFFECTS OF MECHANICAL FORCES ON CELLS AND TISSUES (THE LIQUID–CELL INTERFACE)

Daniel E. Conway[1], Suzanne G. Eskin[2], and Larry V. McIntire[2]

[1]Robert M. Berne Cardiovascular Research Center, University of Virginia, Charlottesville, Virginia, USA

[2]Department of Biomedical Engineering, Georgia Institute of Technology and Emory University School of Medicine, Atlanta, Georgia, USA

Mechanical properties of materials have already been covered in Chapter I.1.3 on "Bulk Properties of Materials." In this chapter, we will cover the effects of mechanical forces on cells within tissues, on the surfaces of biomaterials or within polymer scaffolds, focusing primarily on the effects of fluid forces. Because host cells interact with implanted materials or because cells are implanted as therapeutic entities in themselves, often within a biomaterial scaffold, the response of cells to mechanical forces is important to consider in order to predict the success of an implant. Cells that are particularly adapted for functioning in concert with physical forces are those of the cardiovascular and musculoskeletal systems, but all cells experience some mechanical forces. In fact, the appropriate local mechanical environment appears to be crucial for maintenance of proper cell phenotype. This chapter will focus on physiological and pathological flow-induced shear stress and fluid-induced strains that cells experience with emphasis on the effects of these forces on cell function. The key role of mechanical forces in tissue formation and maintenance of cell–extracellular matrix and cell–cell interactions will be discussed in Chapter II.6.5 in the context of micromechanical design criteria for tissue-engineered biomaterials.

CELLULAR DETECTION OF MECHANICAL FORCES

Mechanotransduction is the transduction of mechanical forces applied to a cell or tissue into chemical and biological responses. Sensors of mechanical forces include ion channels, G-protein-coupled receptors, intercellular junctions, and focal adhesions (Davies, 1995; Papadaki and Eskin, 1997). Most of these sensors have direct connections to the cytoskeleton, and often are unable to transduce physical forces when the attachment to the cytoskeleton is lost, suggesting that coupling of surface mechano-receptors to the cytoskeleton is required for mechanical transduction (Alenghat and Ingber, 2002). An additional indirect effect of mechanical force is in the redistribution of extracellular signaling molecules. Mechano-sensing cells, such as hair cells in the inner ear, are specialized for their role in sensing mechanical forces. However, most other cells with primary functions that do not include sensing mechanical forces are responsive to such forces if exposed to them.

> Cells that are particularly adapted for functioning in concert with physical forces are those of the cardiovascular and musculoskeletal systems, but all cells experience some mechanical forces. In fact, the appropriate local mechanical environment appears to be crucial for maintenance of proper cell phenotype.
>
> Mechano-sensing cells, such as hair cells in the inner ear, are specialized for their role in sensing mechanical forces. However, most other cells with primary functions that do not include sensing mechanical forces are responsive to such forces if exposed to them.

BLOOD VESSELS

Mechanical forces resulting from blood flow directly affect cellular functions and morphology and thus, the physiology of the cardiovascular system (Davies, 2009). The forces to which cells of the blood vessels are subjected directly include wall shear stress and circumferential strain (Figure II.1.6.1). Disruption or distortion of these forces affects local cellular homeostasis, and may prime the area for development of pathology. Sites of atherosclerosis in humans have been shown to be non-random, and are strongly correlated with curved or branched sites in the vasculature that, as a result of their geometry, experience

low time-averaged shear stress, shear stress reversal, and spatial and temporal gradients in shear stress (Glagov et al., 1988; Davies, 2008). Disturbances in mechanical forces due to implantation of medical devices can also alter cellular function. Small diameter arterial grafts (both synthetic and autologous vein) frequently fail because of compliance mismatch with the native vessel and resulting

FIGURE II.1.6.1 Schematic representation of the hemodynamic forces acting on the artery wall. (A) Cross-section through the artery, in which all layers are constantly subjected to tensile stress (cyclic strain) which arises from normal forces generated by the pusatility of blood flow. (B) Longitudinal section through the artery. Fluid flow profile (illustrated by the parabola) imparts tangential forces (shear stress) to the blood vessel wall. Endothelial cells lining the blood vessel wall respond first to this force.

flow and wall strain disturbances at the anastomoses (see Box 1) (Singh et al., 2007)

Blood vessels are comprised of three major cell types: endothelial cells; smooth muscle cells; and fibroblasts. A one-cell thick layer of endothelial cells forms the endothelium that lines the lumen of the entire vasculature. Large arteries also include a middle layer, the media, which consists of smooth muscle cells with secreted extracellular matrix, and an outermost layer, the adventitia, consisting primarily of fibroblasts and extracellular matrix, which also contains blood vessels and nerves supplying the artery itself.

Extensive studies that apply shear stress or cyclic strain to endothelial cells *in vitro* confirm that these cells actively participate in vascular physiology. Although only one cell thick, the endothelium provides a permeability barrier; controls thrombosis and hemostasis by maintaining an active thromboresistant surface, which no biomaterial has yet been able to match, and acts as a mechanosensor for the underlying tissue. Smooth muscle cells in the medial layer contract, relax, proliferate, synthesize matrix or migrate in response to shear stress, cyclic strain, and paracrine factors (biochemical signals) from endothelial cells. Vessels denuded of the endothelium expose the smooth muscle cells and matrix to blood flow, resulting in binding of platelets and, subsequently, thrombosis (Wagner and Frenette, 2008).

Effect of Shear Stress on Blood Vessels

The flow of blood over the endothelium generates viscous drag forces in the direction of flow. The resulting tangential force exerted per unit area of vessel surface at the blood–endothelium surface defines shear stress. Mathematically, the product between the viscosity (μ) and the

Box 1 Hemodialysis Access Fistulas
Placement of (A) and (B) fistulas, and (C) grafts for access to the blood for hemodialysis. (PTFE, polytetrafluoroethylene) (From: Singh et al. (2007). Successful angioaccess. *Surg. Clin. North Am.,* **87**, p. 1213. Elsevier.)

velocity gradient at the wall, also known as the wall shear rate (γ), equates to wall shear stress (τ_w) (Equation 1):

$$\tau_w = \mu\gamma \qquad (1)$$

With ventricular contraction, momentum propagates as waves down the aorta, but diminishes in amplitude on the arterial side of the circulation, with distance from the heart. Pulsatility is generated by the pumping action of the heart, and gives rise to pulsatile shear stress and cyclic strain. Typical mean arterial values of shear stress range from 6 to 40 dyn/cm^2, but can vary from 0 to well over 100 dyn/cm^2 elsewhere in the vasculature (Goldsmith and Turitto, 1986; Dobrin et al., 1989).

While pulsing down the arterial tree, blood flow remains mostly laminar; however, it often becomes complex and/or disturbed (reversing and/or recirculating) at areas of arterial branching, triggering spatial and/or temporal gradients in shear stress (e.g., Figure II.1.6.2).

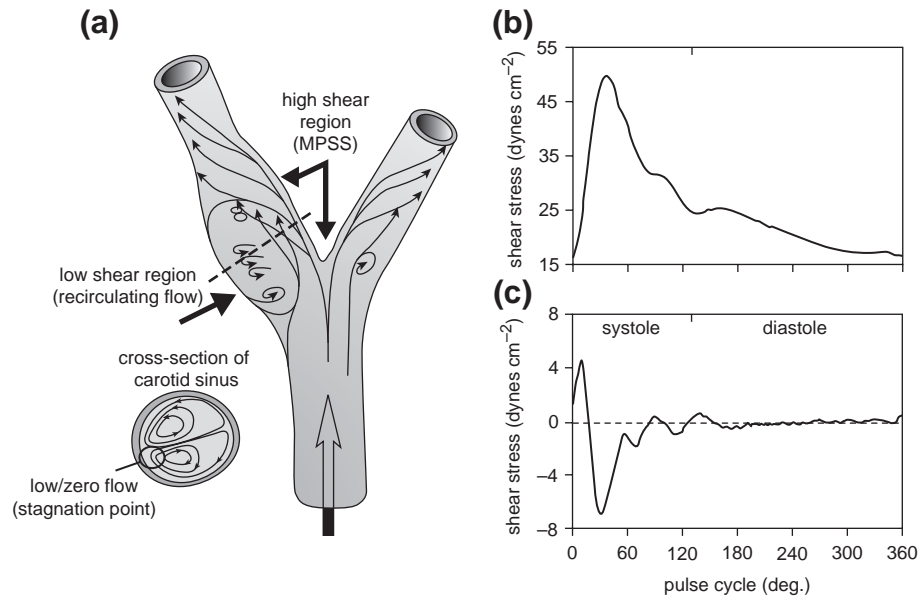
Endothelial cells have been studied extensively for their ability to respond to changes in shear stress. Two *in vitro* systems have been developed to characterize the response of endothelial cells to a variety of shear stresses: the parallel plate flow chamber; and the cone and plate system (Figure II.1.6.3). In the parallel plate model, cells are grown on a glass slide, which sandwiches a silicone gasket onto a polycarbonate parallel plate (Frangos


FIGURE II.1.6.2 Representation of flow features at the carotid bifurcation. (a) Change in wall shear stress throughout the course of the cardiac cycle at two locations within the carotid bifurcation, low shear (including recirculating flow) and high shear regions (MPSS, mean positive shear stress). (b) waveform of shear stress during one cardiac cycle (1 sec.) measured at the high shear stress region; (c) waveform of shear stress at the low shear stress region, showing reversing (recirculating) flow. (Reprinted with permission from the Royal Society; White and Frangos, (2007). *Philos. Trans. R. Soc. Lond. B. Biol. Sci.* **362**(1484), 1459–1467).
FIGURE II.1.6.3 *In vitro* systems for studying the effects of shear stress on cells. (A) In the parallel plate system cells are grown on glass slides and mounted onto a parallel plate chamber. The gasket provides a known gap height. Fluid flows in the inlet, across the deck, and out the exit slot (B). In the cone and plate system cells are grown on a circular dish, which forms a viscometer at the bottom. A small fixed angle cone is rotated at a constant angular velocity providing a constant shear stress across the cells.

et al., 1987). This creates a very small gap width through which tissue culture medium is circulated. The geometric dimensions are known, allowing for the calculation of the fluid shear stress from the flow rate. For a Newtonian fluid flowing through a parallel plate flow chamber with a rectangular geometry, the steady, laminar shear stress at the wall is:

$$\tau_w = \frac{6\mu Q}{bh^2} \qquad (2)$$

in which τ_w = wall shear stress, μ = viscosity, Q = flow rate, b = channel width, and h = channel height. By varying the chamber geometry, the flow rate or the viscosity, the entire physiological range of wall shear stresses can be investigated. The flow rate is varied using a syringe pump or gravity driven system to provide the desired wall shear stress across the cells. The cone and plate system consists of a tissue culture dish as the plate, and a fixed angle cone mounted to a motor that imparts an angular velocity. For small cone angles, the shear rate (and therefore the shear stress) is essentially constant throughout the flow field. Since the dimensions of this system are also characterized, the fluid shear stress can be calculated for a given angular velocity.

If the cell property studied responds to shear stress in a dose-dependent fashion (i.e., varies directly with the level of shear stress imposed), it is referred to as "shear stress-dependent." If the property under study responds to changes in shear rate, but not directly with the level of shear stress imposed, it is referred to as "transport-dependent." "Flow-dependent" can include both shear stress- and shear rate-dependent phenomena. The difference arises from inclusion of mass-transport phenomena (convection and diffusion) in flow-dependent processes, whereas the term "shear stress-dependent" refers to the mechanical force only. Differences between effects due to shear stress alone, and those due to mass and momentum transfer, can be examined by circulating media of different viscosities (e.g., with the addition of high molecular weight dextran).

Endothelial cells, in either of these *in vitro* shear stress systems, exposed to long-term (24 hours or greater) steady shear stress at arterial levels (10–25 dynes/cm²), as well as pulsatile non-reversing shear stress (Figure II.1.6.2b), have been shown to produce a more anti-inflammatory and anti-proliferative phenotype than when exposed to pulsatile reversing conditions or low shear stress or to static culture (Figure II.1.6.2c) (McCormick et al., 2001; Dai et al., 2004; Chien, 2008; Yee et al., 2008). Acute responses to arterial shear stress include release of signaling molecules such as nitric oxide and prostacyclin, phosphorylation of membrane proteins, and activation of GTPases and tyrosine kinases (Frangos et al., 1985; White and Frangos, 2007). Released signaling molecules, such as prostacyclin and nitric oxide, can in turn act on smooth muscle cells to mediate vasorelaxation. Response of endothelial cells to arterial level shear stresses of 24 hours or longer include alignment of the actin cytoskeleton, movement of the microtubule organizing center toward the direction of flow, and cell elongation and alignment in the direction of flow (Eskin and McIntire, 1988; Orr et al., 2006).

Endothelial cells respond differently to reversing or oscillatory shear stress as compared to non-reversing shear stress. Steady or non-reversing shear stress transiently induces proinflammatory and proliferative pathways, which are subsequently downregulated by long-term exposure to shear stress. However, oscillatory or reversing shear stress results in sustained activation of these pathways, leading to the hypothesis that under steady shear stress cells adapt and downregulate these pathways, whereas under disturbed flow the continued changes in flow magnitude and direction lead to sustained activation (Dai et al., 2004; Orr et al., 2006; Chien, 2008). A summary of the changes induced by reversing shear stress as compared to non-reversing shear stress are summarized in Table II.1.6.1. The increases in cell proliferation, lipid metabolism, and inflammation observed in endothelial cells exposed to reversing shear stress *in vitro* suggest that *in vivo* disturbed hemodynamics may prime local sites for atherosclerosis. Consistent with biochemical differences, cells do not elongate or align in the direction of flow at sites of atherosclerosis (Figure II.1.6.4).

TABLE II.1.6.1	Comparison of the effects of reversing flow to non-reversing flow on endothelial gene expression and function	
	Reversing Flow	**Non-reversing Flow**
Flow Pattern	Fluid reversal, small net flow	No reversal, large net flow
Location in Arteries	Bifurcations and high curvature	Straight regions
Endothelial Cell Alignment	Not aligned	Aligned parallel to flow
Inflammatory Genes	Up-regulated	Down-regulated
Monocyte Adhesion	Increased	Decreased
Cell Proliferation	Increased	Decreased
Anti-oxidant Genes	Decreased	Increased
Vasodilating molecules	Decreased	Increased
Effect on Atherogenesis	Pro-atherogenic	Anti-atherogenic

FIGURE II.1.6.4 Arterial endothelial cell alignment *in vivo* (porcine) and *in vitro* (human). (a) Endothelial cell alignment in undisturbed unidirectional laminar flow in the descending thoracic aorta (LSS, laminar shear stress), and (b) absence of transition from alignment in disturbed flow adjacent to a branch of the aorta. In (b), a region of cell alignment changes abruptly to polygonal cell morphology beyond a line of flow separation (curved arrows) that marks the boundary of a disturbed flow region in which oscillating, multidirectional flow typically occurs (double-headed arrow). Scale bar in each panel = 15 μm. (c) Endothelial cell alignment under *in vitro* steady shear stress (15 dynes/cm^2), and (d) reversing shear stress (modeled after the wall shear stress at the carotid sinus) is similar to *in vivo* alignment. ((a) and (b) reprinted with permission from Springer: Davies, P. F. (2008). Endothelial transcriptome profiles *in vivo* in complex arterial flow fields, *Annals of Biomedical Engineering,* **36**, 563–570, 2008; (c) and (d) unpublished data (D. E. Conway).)

There is evidence that endothelial cells respond to shear stress within seconds. Rapid changes occur through the activation of ion channels, G-proteins, and stimulation of protein kinases (Davies et al., 2003; White and Frangos, 2007). Shear stress may act directly on the cell membrane to deform the cell surface and activate unknown sensor proteins. However, recent evidence has suggested that shear stress forces are transmitted by the cytoskeleton to intracellular locations where signaling can occur, such as intercellular junctions, focal adhesions, the nuclear membrane, and lipid rich regions of the cell membrane known as caveolae (Stamatas and McIntire, 2001; Davies et al., 2003; Boyd et al., 2003). In addition to remodeling of the cytoskeleton in response to shear stress there is also evidence of focal adhesion remodeling and activation of proteins at these adhesion sites (Davies et al., 2003), supporting the hypothesis that the majority of shear stress sensing is directly coupled to the cytoskeleton.

More recently, the glycocalyx has re-emerged as an important mechanosensor of shear stress in endothelial cells. The glycocalyx is an extracellular membrane-bound layer of glycoproteins and plasma proteins that has been shown to extend up to 500 μm from the endothelial cell membrane (Figure II.1.6.5). *In vivo*, this structure is large enough to prevent cells and even large plasma proteins from reaching the surface of the cell.

Removal of key glycocalyx molecules results in a reduced response to shear stress (reduction in nitric oxide production, absence of cell elongation in response to flow, and loss of shear stress-induced suppression of cell proliferation), suggesting that the glycocalyx is an important mechano-sensor of fluid shear stress in endothelial cells (Tarbell and Pahakis, 2006). A reduction in the glycocalyx has also been observed in a number of disease states, including hypertension, inflammation, ischemia and reperfusion, hyperglycemia, and at known sites of atherosclerosis (internal carotid sinus). Furthermore, reduced glycocalyx expression has been correlated with increased leukocyte adhesion, suggesting that the glycocalyx may provide protection against atherogenesis (Van Teeffelen et al., 2007). Recently it has been suggested that *in vitro* endothelial cells do not form a hemodynamically relevant glycocalyx, highlighting the need for a better understanding of the formation and regulation of this potentially important mechano-sensitive extracellular structure (Potter and Damiano, 2008).

Animal models have further validated data generated from *in vitro* systems. Suo et al. used computational fluid dynamics to model the wall shear stress in the mouse aortic arch (Suo et al., 2007). Although the mouse vasculature has higher overall shear stresses than the human, inflammatory markers, such as intracellular adhesion molecule-1 (ICAM-1) and vascular cell adhesion molecule-1
FIGURE II.1.6.5 The endothelial glycocalyx can extend up to 0.5 µm into the vessel lumen. (A) Electron microscopic overview of an Alcian blue 8GX-stained rat left ventricular myocardial capillary (bar = 1 µm). (B) After hyaluronidase treatment, before Alcian blue staining (bar = 1 µm). (C) Detailed pictures of glycocalyx on normal (left) and hyaluronidase-treated (right) capillaries (bar = 0.5 µm). (Source: van den Berg, B. M. et al. (2003). *Circ. Res.*, **92**, 592–594.)

(VCAM-1), were upregulated at sites with low time-averaged shear stress and changes in shear stress direction (Figure II.1.6.6) (Suo et al., 2007). Microarray analysis of disturbed flow and undisturbed flow regions in the porcine aorta showed increased inflammatory cytokines and receptors in regions of disturbed flow (Passerini et al., 2004). These *in vivo* studies suggest that shear stress at sites of atherosclerosis may prime the endothelium toward

an inflammatory state, which then may be exacerbated by additional risk factors (e.g., cholesterol, smoking, exercise).

Effect of Cyclic Strain on Blood Vessels

Along with momentum, pressure propagates as waves down the arterial tree, leading to a periodic circumferential tensile stress in the vessel lumen (Figure II.1.6.1). *In vivo*, blood pressure measures the variation in force against the blood vessel wall as the blood is ejected from the heart during each heartbeat (each cardiac cycle). In measuring blood pressure in humans, the brachial artery is occluded by a pressure cuff (attached to a sphygmomanometer), while the sound of the blood flow is measured downstream with a stethoscope. The pressure cuff is slowly loosened, allowing the pressure to decrease and the blood to flow downstream. The pressure at which the blood flow begins is the systolic pressure. As the pressure continues to decrease, the value at which the sound disappears is the diastolic pressure. Since the arterial wall is compliant, this periodic pressure difference gives rise to a cyclic wall strain. Since arteries and some synthetic substrates on which cells are cultured are elastic, cyclic strain can be measured as the percentage change in diameter between the systolic and diastolic pressures. In normal circulation, the internal diameter and, thus, circumference of large mammalian arteries increases cyclically between 2% and 18% over the cardiac cycle at a frequency of approximately 1 Hz (60 cycles/min) (Dobrin, 1978). The arterial cyclic strain can increase by 15% in hypertension (Gupta and Grande-Allen, 2006). Typical systole/diastole values in large human arteries range from 90/60 mmHg to 120/80 mmHg.

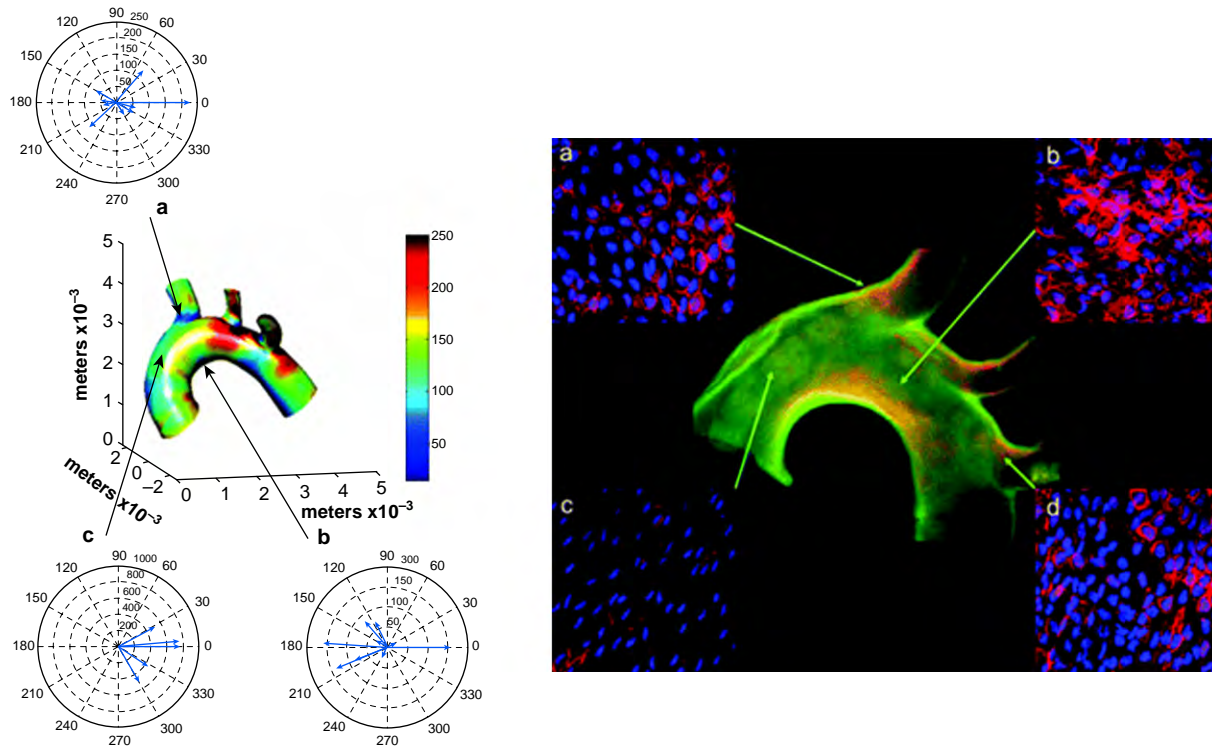
To study cyclic strain effects *in vitro*, cells must be cultured on a deformable substrate, usually silicone rubber or segmented polyurethane coated with extracellular matrix proteins, then subjected to cyclic deformation at a rate similar to the heart rate (1 Hz). Most frequently, custom built uniaxial strain devices are driven mechanically by an eccentric cam, which imposes a nearly uniform strain along the substrate at a frequency simulating the heart rate (1 Hz) (Frye et al., 2005; Yung et al., 2008). Custom built biaxial strain units have also been used (Kim et al., 1999). The mechanical forces generated in *in vitro* studies on uniaxial cyclic strain optimally include a "motion control" condition. "Motion control" controls for the reversing shear stress (less than 0.5 dyne/cm^2) from fluid motion accompanying cyclic strain of the membrane. Some endothelial cells are more responsive to motion control than to cyclic strain (Sung et al., 2007). Cultured cells have been exposed to cyclic strain in commercially available Flexercell Strain Units (Flexcell International, Corp.), which can deform in uniaxial or biaxial modes (Matheson et al., 2007). These units are driven by vacuum pressure beneath 6-well plates with flexible elastomeric bottoms, on which cells are cultured, thus deforming substrate and cells (Haseneen et al., 2003). It


FIGURE II.1.6.6 Regional differences in wall shear stress in the mouse aortic arch correlates with regional differences in VCAM-1 expression. Left: The computed, time-varying wall shear stress vectors are depicted at areas (a), (b), and (c) in one mouse aorta. The color coding indicates the mean wall shear stress distribution (defined as the wall shear stress magnitude averaged over the cardiac cycle). The vector diagrams indicate the time-varying changes in the direction and magnitude of wall shear stress throughout the cardiac cycle. There is a greater variation in the direction of the instantaneous wall shear stress vectors in areas (a) and (b), as can be seen in the polar plots of wall shear stress. Note that the relatively low mean wall shear stress zone at the inner curvature of the aortic arch (b), has instantaneous magnitudes of wall shear stress up to approximately 150 dynes/cm^2, whereas values exceeding 600 dynes/cm^2 were found along the lateral wall of the ascending aorta (c). Right: High expression of VCAM-1 protein correlates with areas of the aortic arch with low and time-varying shear stresses (a, b, and d) whereas VCAM-1 expression in the ascending aorta (c) is lower, consistent with unidirectional flow. (Source: Suo, J. et al. (2007). *Arteriosclerosis, Thrombosis, and Vascular Biology,* **27,** 346–351.)

should be noted that not only do the mechanical forces that impinge on a population of cultured cells alter their function, but also the substrate on which the cells are cultured may affect cell response. Cyclic strain has been shown to alter phenotype of cultured smooth muscle cells on polymeric scaffolds (Kim et al., 1999), and to cause differentiation of embryonic stem cells into smooth muscle cells (Shimizu et al., 2008).

Although the effects of shear stress and cyclic strain are most frequently studied independently of each other, recent work has suggested that the synchronization of the two forces when applied simultaneously can affect gene expression and morphology (Owatverot et al., 2005). The stress phase angle has been defined as the temporal phase angle between cyclic strain and wall shear stress (Figure II.1.6.7) (Dancu et al., 2004). The stress phase angle has been shown to be most negative at sites prone to atherosclerosis when compared to other regions of the vasculature, and can be made even more negative with hypertension (Dancu et al., 2004). Cells exposed to identical wall shear stress and cyclic strain, but at a stress phase angle of –180° instead of 0°, had reduced endothelial nitric oxide production and
FIGURE II.1.6.7 Stress phase angle (SPA) is the phase shift between cyclic strain and wall shear stress. (D. E. Conway drawing.)

increased endothelin-1 production (Dancu et al., 2004), suggesting that asynchronous wall shear stress and cyclic strain could lead to endothelial cell dysfunction.

INTERSTITIAL FLUID

Twenty percent of the mass of the human body consists of interstitial fluid, the fluid that surrounds most cells (Swartz and Fleury, 2007). This fluid is constantly in motion, driven by lymphatic drainage, which returns plasma that has leaked out of capillaries to the blood

| **Mechanical Forces in the Embryonic-Cardiovascular System**

The embryonic circulatory system is highly dynamic, forming and remodeling while simultaneously providing blood flow to the developing organs. Until recently, the role of hemodynamic forces in the development of the heart and blood vessels was unknown. This case study shows the effects of hemodynamic forces on the vascular remodeling of the mouse embryo yolk sac (Lucitti et al., 2007). Endothelial cells in the yolk sac first assemble into a primitive vascular mesh network, but begin to remodel in the presence of flow into a network of branched, hierarchical network of large and small vessels that are surrounded by smooth muscle cells. Using a mouse knockout model (Mlc2a-null) that

had impaired cardiac contractility (resulting in impaired flow and red blood cell movement), the authors showed that reduced blood flow led to impaired vessel remodeling. Reductions in the red blood cells in normal mice also impaired the vessel remodeling. To determine if the impaired vessel remodeling is due to lowered oxygen transport or reduced blood viscosity, the plasma in the mice with reduced red blood cells was supplemented with synthetic sugars to restore the viscosity to normal levels, which resulted in the development of a normal vascular system. Their results show that mechanical forces are essential for proper blood vessel development.
Heterozygous (A,C,E) and knockout (B,D,F) mouse embryos with fluorescently labeled red blood cells. At embryonic day 8.5, blood islands have formed in both wild-type (A) and *Mlc2a*-null (B) embryos, and red blood cells begin to circulate in both wild-type (C) and *Mlc2a* mutant (D) embryos. However, the vascular network fails to remodel by embryonic day 9.5 in the mutant embryos (F), as compared with wild-type (E). (Reprinted with permission from The Company of Biologists, Lucitti, J. L., Jones, E. A., Huang, C., Chen, J., Fraser, S. E. & Dickinson, M. E. (2007). Vascular remodeling of the mouse yolk sac requires hemodynamic force. *Development,* **134***, 3317–3326.)

Lymph Capillaries in the Tissue Spaces
FIGURE II.1.6.8 Lymphatic vessels carry fluid away from the tissues. Lymphatic vessels start as blunt-ended capillaries and come together to form larger lymphatic vessels. (Source: National Cancer Institute http://training.seer.cancer.gov/module_anatomy/unit8_2_lymph_compo.html.)

through the lymphatic system (Figure II.1.6.8). The smallest lymphatic vessels are the lymph capillaries, which are found in most organs of the body, excluding the bone marrow and central nervous system. These capillaries start as blunt ends and come together to form larger contractile lymphatic vessels that have valves that prevent backflow, and smooth muscle cells that can provide contractility. The forces responsible for interstitial flow are hydrostatic and osmotic pressure differences (also known as Starling forces) between the blood, interstitium, and lymphatic system. Contractility by larger lymphatic vessels can further increase pressure gradients. The velocity of interstitial fluid is estimated to be 0.1 to 2 μm/s, but can be increased during inflammation (Swartz and Fleury, 2007). The resistance to interstitial fluid flow is affected by the specific composition of the extracellular matrix (ECM), cell density, and integrity of the lymphatic system; however, interstitial fluid pressure is also affected by external factors, such as movement, exercise, blood pressure, and hydration (Swartz and Fleury, 2007).

In addition to providing exchange of cell nutrients and wastes, interstitial flow has been shown to affect blood and lymphatic capillary morphogenesis, chondrocyte and osteocyte function, fibroblast differentiation, smooth muscle cell cytokine production, ocular function, morphogenesis in perfused three-dimensional cultures, and patterning in embryo development (see Box 2) (Nonaka, 2005; Swartz and Fleury, 2007). Interstitial flow can drive both mechanical and biochemical cellular responses by imparting mechanical forces, such as shear stress and cyclic strain, both on the cell surface and the extracellular matrix that is directly connected to the cellular cytoskeleton, and biochemical changes through redistribution of extracellular signaling molecules (Figure II.1.6.9) (Rutkowski and Swartz, 2007). In three-dimensional matrices with interstitial fluid flow of 1 μm/s, the shear stress at the cell surface has been estimated to average 6×10^{-3} dynes/cm^2, with a peak shear stress of 1.5×10^{-2} dynes/cm^2, over three orders of magnitude lower than the

wall shear stress in a large artery (Rutkowski and Swartz, 2007). It is unclear if cells can directly sense such a low shear stress, and therefore may rely on the surrounding extracellular matrix to amplify the signals through shear-induced strain or alternatively the effects may be due to convective mass transfer of signaling molecules.

Lymphatic flow has recently been shown to enable autologous chemotaxis, a mechanism whereby a cell can receive directional cues for cellular migration, but simultaneously can be the source of such cues (Fleury et al., 2006). Previously it was assumed that cells migrating towards a signaling concentration gradient were following a gradient secreted by an upstream cell or tissue. However, through autologous chemotaxis, subtle flows can create assymetrical pericellular protein concentrations and trancellular gradients that increase in the direction of fluid flow (Fleury et al., 2006). This mechanism could explain how leukocytes and tumor cells use gradients in interstitial fluid to locate and migrate to draining lymphatics (Rutkowski and Swartz, 2007).

In large arteries, the endothelial cells are the cells exposed directly to shear stress, while all the cell types in the vessel wall are exposed to cyclic strain. But when the endothelial cells are damaged, the hydraulic conductivity of an artery is dramatically increased. This increase in hydraulic conductivity leads to elevated interstitial flow through the artery wall. Models of interstitial flow in blood vessels with an intact endothelium have shown that medial smooth muscle cells are on average exposed to 1 dyne/cm^2 shear stress, but the smooth muscle cells closest to the endothelial cells can experience a shear stress of 10 dynes/cm^2, similar to the fluid shear stress directly imparted to the endothelial cells by blood flow (Tada and Tarbell, 2002). A study by Garanich et al. showed that increased shear stress enhanced the migratory properties of adventitial fibroblasts (Garanich et al., 2007). These fibroblasts have been reported to participate in the arterialization of capillaries, and also contribute to intimal hyperplasia (vessel thickening) that occurs in response to vessel injury. Changes in

Box 2 Interstitial Fluid Flow Affects Vertebrate Embryo Patterning

Interstitial fluid flow has also been shown to be important in development and tissue morphogenesis. Nonaka et al. showed that in the mouse embryo the nodal cilia generate a unidirectional leftward flow of extraembryonic fluid which is the first step in the generation left–right asymmetry (Nonaka et al., 1998). Recent work has shown that convection, not just diffusion alone, of such signaling molecules can drive left–right asymmetry of internal organs (e.g., determining that the heart is located on the left side of the body). Reversal of this flow direction resulted in reversal of the asymmetry (Nonaka et al., 2002).

It is currently unclear if nodal flow affects transport of signaling molecules or acts directly as a mechanical stress on the cells (Shiratori and Hamada, 2006). Morphological analysis of the nodal cilia has shown that the cilia are not completely perpendicular, but are instead tilted in the posterior direction (A and B) (Nonaka et al., 2005). This tilt, combined with the clockwise rotation of the cilia results in a more efficient stroke in the leftward direction, and a less efficient stroke in the rightward direction, resulting in a net flow in the left direction (C).
Left/right symmetry of vertebrate embryo. (A) Most cilia have a pattern consistent with the projection of a tilted cone (blue and green, see text) whereas some cilia move in a D-shape (orange). A, P, L, and R refer to anterior, posterior, left, and right sides of the node, respectively. The direction of cilia rotation was clockwise (arrows). (B) Relationship between movement of cilia and their projected images at various tilt angles. (C) Circular clockwise motion of a cilium can generate directional leftward flow if its axis is not perpendicular to the cell surface but tilted posteriorly. Due to distance from the cell surface, a cilium in the leftward phase (red arrow) drags surrounding water more efficiently than the rightward phase (blue arrow), resulting in a net leftward force (pink arrow). (Images are from Nonaka, S., Yoshiba, S., Watanabe, D., Ikeuchi, S., Goto, T., et al. (2005). *De novo* formation of left–right asymmetry by posterior tilt of nodal cilia. *PLoS Biol.* **3**(8): e268. This journal releases its work to the public domain).
TRENDS in Cell Biology

FIGURE II.1.6.9 The direct effects of interstitial flow on cells. Interstitial flow can induce (a) fluid shear stress, σ, on the cell surface; (b) forces normal to the cell surface (F); (c) shear and normal forces to the pericellular matrix that is mechanically coupled to the cytoskeleton; and (d) redistribution of pericellular proteins (autocrine and paracrine signals) that bind cell receptors. (Source: Rutkowski, J. M. & Swartz, M. A. (2007). A driving force for change: Interstitial flow as a morphoregulator. *Trends in Cell Biology,* **17**(1), 44–50. Elsevier.)

interstitial flow through the arterial wall may be important in mediating blood vessel wall remodeling.

Interstitial flow is important in the uptake of pharmaceuticals in local tissues or tumor delivery. Traditionally, therapeutics are given systemically, and therefore have been limited to small molecules with high diffusivities. However, the development of protein and antibody therapies and synthetic drug carriers, which are designed for selective uptake by a specific tissue, require a better understanding of the local interstitial transport in the target tissue. Tumors frequently have leaky blood vessels, in combination with a nonfunctional lymphatic system, resulting in increased interstitial fluid pressure compared to normal tissues (Swartz and Fleury, 2007). This can hinder anti-tumor therapies seeking to accumulate drugs selectively in tumor tissue. The increased interstitial pressure in the tumor leads to decreased convective forces across the blood vessel wall, as well as a decrease in pressure variation within in the tumor, resulting in decreased drug distribution in the tumor (Swartz and Fleury, 2007).

BONE AND CARTILAGE

Bone is made up of three types of cells: osteocytes, which maintain function; osteoblasts, which build bone; and osteoclasts which degrade bone. These cells reside in a matrix of collagen and hydroxyapatite, a complex tetracalcium phosphate, which is produced by osteoblasts. The osteocytes are mechanosensors, which release prostaglandins in response to mechanical forces, principally shear stress (Jiang et al., 2007). They transmit signals to other bone cells and the matrix through thin channels in the matrix to influence bone remodeling.

Bone is a tissue that is constantly undergoing remodeling in response to mechanical loading, forming new bone parallel to the loading direction, and losing density in unstressed regions. Bone loss from sedentary lifestyle, limb paralysis or microgravity during space flight has provided conclusive *in vivo* evidence for the positive effects of physiological loading of skeletal tissues (Orr et al., 2006). Mechanical loading generates fluid shear stress, hydrostatic compression, and stretch on bone cells. The dense bone matrix resists compressive forces, limiting the transfer of force to the cells (Orr et al., 2006). Physiological strains are only 0.04–0.3%; however, *in vitro* it has been shown that strains must be 1–10% to induce cellular responses (Orr et al., 2006). Unmineralized matrix around osteocytes is more permeable than mineralized bone, creating lacuno-canalicular porosities for interstitial fluid flow. As a result, compressive forces generate pressure gradients that drive interstitial fluid flow in the matrix; these shear stresses have been estimated to be 8–30 dynes/cm^2, similar to arterial wall shear stress (Orr et al., 2006). Interstitial fluid flow due to mechanical loading is thought to be the primary mechanism for action of mechanical forces on bone (Figure II.1.6.10) (Klein-Nulend et al., 2005). Although *in vitro* both osteoclasts and osteoblasts have been shown to respond to shear stress, the geometry of
FIGURE II.1.6.10 Model for the transduction of mechanical strain to osteocytes in bone. Left: The osteocyte-lining cell network of bone tissue under stress (large arrows). Loading results in flow of interstitial fluid in the canalicular non-mineralized matrix (horizontal arrow). (Source: Klein-Nulend, J., Bacabac, R. G. & Mullender, M. G. (2005). Mechanobiology of bone tissue. *Pathologie Biologie, **53**(10), 576–580. Elsevier.)

the lacuno-canalicular porosity suggests that interstitial fluid flow is preferentially sensed by the osteoclasts (Orr et al., 2006). Osteocytes respond to mechanical stimuli by secreting factors that can then, in turn, modulate both osteoblasts and osteoclasts (Klein-Nulend et al., 2005). Recent models, however, have suggested that the interstitial fluid flow applies drag forces to the pericellular matrix of the osteocyte that are 20 times larger than the fluid shear forces applied directly to the cell surface (Han et al., 2004). The fluid flow through the pericellular matrix induces strain on the actin filaments of the cytoskeleton, which results in strain amplification at the cellular level an order of magnitude greater than tissue-level strains. These recent models question the hypothesis that the regulatory mechanical force on osteocytes is fluid shear stress, and instead suggest that shear-induced strain may be the principal mechanotransducing force (Orr et al., 2006; Han et al., 2004).

> Bone is a tissue that is constantly undergoing remodeling in response to mechanical loading, forming new bone parallel to the loading direction, and losing density in unstressed regions. Bone loss from sedentary lifestyle, limb paralysis or microgravity during space flight has provided conclusive *in vivo* evidence for the positive effects of physiological loading of skeletal tissues.

Exercise-stimulated bone remodeling may be the response of osteoblasts to interstitial fluid flow (Reich et al., 1990; Hillsley and Frangos, 1994). Furthermore, temporal gradients in interstitial fluid flow, imposed by pulsatile shear stress (designed to simulate mechanical loading) stimulate osteoblast proliferation *in vitro* (Jiang et al., 2002), whereas steady shear stress does not stimulate osteoblast signal transduction or proliferation. Exposure of mouse osteocytes and mixed-population human bone cells to pulsating shear stress *in vitro* increased prostaglandin and nitric oxide release, similar to the effects of shear stress on vascular endothelial cells, suggesting that there may be some similar mechanisms for sensing fluid flow (Klein-Nulend et al., 2005). Strain rate has been shown to be more important than strain amplitude in inducing bone formation in response to loading, supporting the hypothesis that bone formation is stimulated by dynamic rather than static loads (Klein-Nulend et al., 2005).

Cartilage, located on the articulating surfaces of joints, provides low friction for freely moving joints. In the growing embryo, cartilage is the precursor to bone. Cartilage cells (chondrocytes) secrete a matrix of collagen fibers embedded in mucopolysaccharide (e.g., chondroitin sulfate). Although cartilage is relatively avascular compared with bone, cartilage responds to mechanical loading similarly to bone. Increased load leads to increased matrix production, resulting in stronger tissue. Cartilage must withstand tensile and shear forces in addition to compression (Kim et al., 1994). Most of the work on cartilage loading focuses on compression

and hydrostatic pressure. Cyclic compression of explants (0.1 Hz, 2–3% compression) stimulated matrix synthesis by chondrocytes (Shieh and Athanasiou, 2003).

SUMMARY

Nearly all mammalian cells and tissues are subject to mechanical forces. In the preceding pages we have highlighted the cardiovascular and skeletal systems adapted specifically to mechanical forces, to variations in blood flow and pressure, and to loadbearing, respectively. *In vitro* models have been employed to study how isolated endothelial and smooth muscle cells from arteries and veins respond to conditions of controlled shear stress and cyclic strain. Gene expression is sensitively regulated by alterations in shear stress and cyclic strain, which translates to functional changes in the cells. The elucidation of roles of different bone cell types has been clarified using *in vitro* models. We are just beginning to understand interstitial fluid flow in the lymphatic system, and the influence mechanical forces may have on cell migration and tumor growth.

In order to properly design biomaterials which successfully simulate native tissues, understanding the mechanical environment in which the biomaterial is implanted is important. Cells exposed to disturbed mechanical environments (e.g., reversing flow in blood vessels, compliance mismatch of blood vessel grafts, lack of weight-bearing on bone) typically have reduced function, and may promote the development of a pathological condition. In designing a biomaterial, we must attempt to recreate the mechanical environment that is to receive the implant for maximum success and long-term viability.

INTRODUCTION

Stem cells have become of increasing interest and relevance to the scientific community over the past 10–20 years as a result of the discovery and derivation of numerous types of stem cells that are now known to exist. Within the field of biomaterials research, stem cells have rightfully garnered more attention as it has been recognized that stem cell–material interactions can be critical to regulating cell fate, and that biomaterials may significantly improve the efficacy of therapeutic applications of stem cells currently being developed. Although stem cells are often broadly referred to as a single class of cells, in reality a wide variety of stem cells exist that exhibit a range of different molecular, cellular, and functional properties. Thus, it is imperative to the understanding of stem cell biology and the performance of stem cell research to be aware of the common nomenclature used to denote the similarities and differences among various types of stem cells. In this chapter, different classes of stem cells will be described and contrasted to one another based on functional definitions of their potential ("potency") to develop into mature cell types. This is followed by a discussion of the different physical factors comprising the environments ("niches") that regulate stem cell self-renewal and differentiation.

STEM CELL POTENCY

Historically, different types of stem cells have been classified according to the stage of development and/or tissue of origin from which they were originally isolated. This has resulted in frequent distinction between stem cells, without paying heed to the functional attributes of different stem cell populations. The misnomers "embryonic" and "adult" have been frequently used to convey different types of stem cells, whereas the reality is that a continuum of stem cells exists at all stages of mammalian development spanning varying levels of differentiation potential. It is generally accepted that stem cells derived from early stages of development (i.e., embryonic) can differentiate into a broader range of cells than stem cells isolated from more mature tissues formed during fetal and post-natal development. This hierarchical arrangement of stem cells has been classically depicted as immature cells giving rise to increasingly mature cells with more restricted differentiation potential.

In the simplest terms, stem cells are functionally defined by their dual capacity for self-renewal and differentiation (Figure II.1.7.1). Self-renewal is the process whereby cells stably maintain their phenotype and ability to differentiate as they undergo cell growth and division. Differentiation, on the other hand, results in an altered cell phenotype that typically has specialized functions, and that slows or loses ability for proliferation and undergoes a reduction in subsequent differentiation potential. The strictest functional test for a *bona fide* stem cell is for it to be clonogenic; that is for a single cell to demonstrate that it can give rise to phenotypically identical cells and differentiated progeny. Although most stem cells have traditionally been identified and referred to by their stage of development and tissue of origin, different classes of stem cells are more accurately categorized by the breadth of their capacity for differentiation – commonly referred to as "potency" (Figure II.1.7.2). Pluripotent stem cells have the ability to differentiate into cells from all three germ lineages (endoderm, mesoderm, and ectoderm), as well as germ cells that can give rise to viable offspring (i.e., sperm, ova). Pluripotent stem cells are thought to be normally found only during the earliest stages of embryogenesis, and become quickly depleted as tissue development proceeds. Embryonic stem cells (ESCs) are the classic example of a pluripotent cell, but more recently fully differentiated somatic cells from a variety of tissue sources have been successfully reverted to a pluripotent state and are referred to as "*induced*" pluripotent
FIGURE II.1.7.1 Stem Cell Definition. Stem cells are defined functionally by their ability to both self-renew and differentiate.
FIGURE II.1.7.2 Stem Cell Potency. Stem cells can be classified according to the breadth of their potential to differentiate into various progenitor and somatic cells.

FIGURE II.1.7.3 Stem Cells and Development. An inverse relationship exists between the potency of stem cells and the relative stage of development with which they are associated. Increasing numbers of different stem cells emerge over time that individually exhibit more restricted differentiation potential.

stem cells (iPS cells or iPSCs). Multipotent stem cells, in contrast, are capable of giving rise to multiple cell types, yet cannot differentiate into all somatic cell types (like pluripotent stem cells). Generally speaking, differentiation of multipotent stem cells is restricted to a single germ lineage from which the cells initially originated. Multipotent stem cells can be found widely distributed throughout the body in different physiological systems. Hematopoietic and mesenchymal stem cells are common examples of multipotent cells that exhibit the capacity to differentiate into various blood cells and connective tissue, respectively. Finally, unipotent stem cells, sometimes also referred to as "progenitor" cells, are generally restricted to differentiate to only a single cell type, yet also retain the ability to self-renew. Unipotent stem cells are commonly found in tissues of adult organisms that exhibit frequent turnover, such as the skin and the intestines. Situated within the respective tissues, unipotent stem cells locally serve to replenish cells in order to maintain tissue homeostasis.

Tissue-specific (also often called "adult") stem cells are also contained in many organs that do not turn over at a high rate, such as skeletal muscle, lungs, liver, kidney, etc. These cells are induced by specific injury to proliferate and provide more differentiated cells of one or

several very restricted subtypes of an organ. Recent studies have also suggested that cardiac and neural stem cells also exist in heart, but their capability for proliferation is yet uncertain. Although the plasticity of stem cells can be generally categorized as pluri-, multi- or unipotent, the full spectrum of differentiation potential exhibited by the various types of stem cells that have been identified and characterized is actually a continuum that can't be fully delineated presently by these general classifications. However, the notion of "potency" is important, in that it provides a general framework whereupon the functional attributes of different stem cells can be compared. As a result, it also conveys that the diversity of stem cells broadens as the potency of different types of stem cells decreases (Figure II.1.7.3). However, as stem cell research progresses the hierarchy among stem cells and distinguishing characteristics between different types of stem cells continue to become better defined.

Pluripotent Stem Cells

Pluripotent stem cells are distinguished from all other stem cells by their unique ability to differentiate into all 200-plus somatic cell types of mature mammalian organisms. Pluripotent stem cells are considered to have infinite self-renewal capacity when consistently maintained under optimal growth conditions *in vitro*, and normally grow at a faster rate than other stem or somatic cell types. Pluripotent stem cells are similar to epithelial cells, in that they express the cell adhesion marker E-cadherin, and remain closely associated with neighboring stem cells as they grow. As pluripotent stem cells differentiate, many of the cells undergo an epithelial-to-mesenchymal phenotypic transition whereby the cells decrease E-cadherin expression, become more spindle-shaped, and migrate away from one another coincident with the epigenetic changes that occur within the cells during differentiation.

Embryonic carcinoma cells (ECs) were the first class of pluripotent cells to be isolated and studied *in vitro* (Martin
FIGURE II.1.7.4 Derivation of Embryonic Stem Cells. Embryonic stem cells are derived from the inner cell mass of blastocysts and propagate indefinitely in culture.

and Evans, 1975). ECs are derived from teratocarcinomas, a malignant tumor that arises in the gonads from germ cells, and are capable of giving rise to cells from all three germ lineages both within the tumor, and following isolation and *in vitro* culture. Traditionally, ECs have been utilized as a model system for various aspects of tumor biology, including growth kinetics, drug resistance, and vascularization (Yuhas et al., 1977; Casciari et al., 1988; Shweiki et al., 1995; Helmlinger et al., 1997). Many of the methods and assays originally developed for EC culture were adopted for the subsequent cultivation and differentiation of the second class of pluripotent cells to be defined, *embryonic stem cells* (ESCs), discussed below.

ESCs, derived from the inner cell mass (ICM) during the blastocyst stage of embryonic development (Figure II.1.7.4), are the best known example of pluripotent stem cells (Evans and Kaufman, 1981; Martin, 1981; Doetschman et al., 1985). ESCs naturally give rise to all types of cells and tissues of the body. ESCs were originally derived from mice in the early 1980s, and largely used for the purpose of creating transgenic mice and to serve as an accessible *in vitro* model system for mammalian developmental biology studies (Baribault and Kemler, 1989). Nearly two decades later, ESCs were also successfully derived from primates; first rhesus monkeys (Thomson et al., 1995) and shortly thereafter, humans (Thomson et al., 1998). The establishment of human ESC lines heralded the prospect of not only developmental studies with human cells, but also the potential use of human pluripotent cells for regenerative cell therapies. Embryonic germ-like cells (EGCs), derived around the same time as human ESCs, are another example of a pluripotent cell type (Shamblott et al., 1998). EGCs are derived from primordial germ cells found within gonadal ridges and mesenteries. Human EGCs display similar phenotypic markers to those of ESCs, and when cultured as multicellular spheroids known as "embryoid bodies," give rise to cells from all three germ lineages (Shamblott et al., 2001). Although human ESC and EGC cell lines were originally derived at nearly identical times, researchers have more commonly worked with and published on ESCs, which have therefore served as the basis for most of what is currently known about human pluripotent biology.

The characterization of the genomic signature of pluripotent stem cell populations has recently led to the reprogramming of somatic cell types to induce pluripotency in terminally differentiated cells (iPS cells or iPSCs). The introduction of transcription factors found to be enriched in ESCs and other stem cells (i.e., Oct4, Sox2, c-Myc, and Klf4) into somatic cells has been shown to transform fully-differentiated cells into pluripotent cells (Takahashi and Yamanaka, 2006; Takahashi et al., 2007; Wernig et al., 2007; Yu et al., 2007; Okita and Yamanaka, 2011). Initially this novel proof-of-concept was demonstrated with different types of fibroblasts, but soon thereafter also performed with other somatic cells from various tissues, including peripheral blood, stomach, and liver (Aoi et al., 2008; Loh et al., 2009). Subsequent work has further demonstrated that different combinations of reprogramming factors in diverse cell types, or in conjunction with various co-factors, can be used to successfully produce iPS cells. Since the original creation of iPS cells, multiple approaches have been developed to introduce the necessary exogenous factors in the form of DNA, RNA or protein into cells to induce reprogramming (Okita et al., 2008; Zhou et al., 2009; Warren et al., 2010). Overall, independent of the particular method used, pluripotency appears to be re-established by the reactivation of endogenous genes (i.e., Oct4, Sox2, Nanog) that are normally permanently silenced by epigenetic mechanisms in somatic cells. The precise molecular mechanisms, signaling pathways, and transition points by which differentiated cells acquire a pluripotent state have yet to be defined, and remain the focus of many ongoing studies. The production of iPS cells is perceived to be advantageous over ESC isolation in that it does not require donated ova or blastocysts as a source of cells, but rather adult somatic cells. Furthermore, the ability to revert somatic cells to a pluripotent state provides a feasible route to the production of patient-specific iPS cells that could circumvent immunological issues associated with transplantation of ESC derivatives. Moreover, iPS cells provide a unique opportunity to examine developmental and mechanistic aspects of human cells for which viable sources are not readily accessible (i.e., heart muscle, neurons, islets). iPS cells derived from individuals with various congenital and familial diseases may also enable the study of progressive human disorders, such as Parkinson's, Huntington's, Alzheimer's, and diabetes (Park et al., 2008). However, many challenges remain in the realm of iPS cells; for instance, the efficiency of reprogramming remains quite low (typically <1%), although different somatic cells and methods display varying levels of reprogramming efficiency. It also remains unclear how similar/different iPSCs are compared to ESCs or how much heterogeneity exists amongst iPS cell lines created from different individuals or using different methods. In addition to creating iPS cells, as with other pluripotent stem cells, developing methods to efficiently direct iPSCs to specific differentiated cell types is a significant hurdle

that needs to be overcome in order to realize the envisioned clinical applicability of iPS cells to human diseases and regenerative therapies.

Multipotent Stem Cells

Multipotent stem cells include many cell types traditionally classified as adult stem cells, including hematopoietic, mesenchymal, and neural stem cells. Multipotent stem cells exhibit a variety of different types of morphologies that in many cases can be readily distinguished from one another, but are not necessarily uniquely identifiable from other types of differentiated cells. Multipotent stem cells tend to proliferate more slowly than pluripotent stem cells, and have a limited capacity for expansion, particularly *in vitro*. In culture, multipotent

stem cells tend to eventually senesce after a finite number of population doublings. Most types of multipotent stem cells have been successfully derived from pluripotent stem cells, in addition to being isolated from mature tissue sources. The proliferative ability and differentiation potential of multipotent stem cells in tissues generally declines with age; however, the exact reasons why remain unclear. The two most commonly held beliefs are that it is due to the gradual depletion of stem cells over time and/or the reduced potency of individual cells due to aging and disease.

Hematopoietic stem cells (HSCs) are rare populations of cells that give rise to all cell types of the blood that were initially identified by their colony-forming capacity in the spleens of irradiated mice after bone marrow transfer (Till and McCulloch, 1961; Becker et al., 1963). HSCs can differentiate into both lymphoid (B- and T-lymphocytes, natural killer cells) and myeloid cells (neutrophils, basophils, eosinophils, monocytes, macrophages, erythrocytes, and platelets). HSCs reside primarily in the bone marrow, but can also be found in the thymus, and the liver or spleen during fetal development. HSCs can exit the bone marrow compartment and transit in the circulatory system to distant sites within the body. The inherent ability of HSCs to be mobilized to the peripheral circulation allows for HSCs to be harvested directly from the blood by a process referred to as apheresis. HSC mobilization from the bone marrow into the circulation is stimulated by cytokines, such as G-CSF and/or GM-CSF. HSCs were the earliest stem cells to be discovered, and as a result more is known about the hierarchical distinctions and associated molecular markers for HSCs than any other stem cells. The low prevalence of HSCs in the blood makes it hard to recognize the cells accurately on a morphological basis, therefore isolation of HSCs is dependent on markers, particularly cell surface antigens, to identify and select HSCs away from other cells contained in the non-adherent fraction of blood or bone marrow aspirate. Of tremendous importance clinically, HSCs have the capacity to repopulate the entire hematopoietic system when transplanted into compromised recipients, such as following bone marrow

"Creating" Stem Cells

Prior to the discovery of iPS cells, stem cells could only be obtained by isolating, purifying/enriching and propagating cells from different tissue sources to ultimately arrive at either primary isolates or established cell lines. Reverting fully-differentiated (somatic) cells to a less mature state is a paradigm-shifting notion for cell biology and all related fields (Figure II.1.7.5). The origins of cellular reprogramming date back to the 1950s, when somatic frog nuclei were transplanted into enucleated eggs (Gurdon et al., 1958); a process that later became known as "cloning." The demonstration that cells can be reprogrammed indicates that differentiation should no longer be considered a uni-directional, irreversible path whereby cells progressively adopt more mature and restricted cell fates during the course of development. The results of reprogramming studies demonstrate that the traditional arrows depicting stem cell hierarchy can go in the opposite direction as well. Although the focus of most initial reprogramming studies was on reverting terminally differentiated cells to the most primitive (pluripotent) state, the concept of reprogramming has been extended to generate multipotent and progenitor cells from somatic cell sources, most often from the tissue the stem cells are most commonly associated with. It is anticipated that as the mechanisms of reprogramming become better understood, new technologies will be developed and new insights will be gained that will broadly impact the fields of biology and the biomedical sciences, including cancer, regenerative medicine, and disease modeling.
FIGURE II.1.7.5 Reprogramming of Somatic Cells. Somatic cells can be reverted to a pluripotent state by the influence of various types of reprogramming factors.

ablation. The transplantation of HSCs has been successfully employed as a therapeutic strategy for a variety of diseases, but is most common for the treatment of hematologic and lymphoid cancers. Hematopoietic stem cell transplantation has been performed clinically since 1957 (Appelbaum, 2007). According to the Center for International Blood and Marrow Transplant Research, in 2009 more than 30,000 autologous and 25,000 allogenic HSC transplants were performed worldwide, with the numbers steadily increasing each year. The therapeutic demand for HSCs prompted the need to explore alternative tissues sources, one of which, umbilical cord blood, has proven to be enriched with HSCs (Lu et al., 1993). The use of cord blood for HSC therapies has led to the creation of public cord blood banks and to the common practice of parents opting to cryopreserve their children's cord blood at the time of birth with private commercial entities. Current challenges associated with HSC transplantation include immune response to allogenic sources (termed graft versus host disease), variability in HSC sources (i.e., age, gender, race), and the often extensive and exhaustive preparative regimens that are necessary for many transplants.

Mesenchymal stem cells (MSCs) were first isolated from bone marrow based on their ability to adhere to culture substrates versus the rest of the non-adherent cell fraction, and largely resemble fibroblasts based on their morphology (Friedenstein et al., 1974). MSCs have subsequently been derived from a variety of other tissues of mesenchymal origin, including fat, umbilical cords, and dental pulp, to name just a few. MSCs have the proven capacity to differentiate into connective tissue cell types such as osteo-, adipo-, and chondrogenic cell lineages, making them of interest for many musculoskeletal studies and orthopedic tissue engineering efforts. It has been commonly reported that MSCs exhibit myogenic potential, although less frequently than other aforementioned phenotypes. In some cases, MSCs or sub-sets of cells within MSC populations have even been reported to differentiate into neuronal or cardiomyogenic cell fates; however, subsequent studies have failed to confirm such findings, thus consensus agreement on these latter, more distant phenotypes has not been reached. Some of the controversy over MSC differentiation potential could be due to the fact that MSC cell populations are known to be heterogeneous, consisting of morphologically similar but distinct sub-sets of cells expressing subtly different types or levels of phenotypic markers.

One of the more recently appreciated and functional characteristics of MSCs, independent of their differentiation potential, is their ability to secrete an array of trophic factors that can affect other cells in a paracrine manner. MSCs can produce molecules that impact tissue repair and remodeling processes, such as vasculogenesis and fibrosis, as well as immunomodulatory molecules that can act locally and systemically. Other aspects of MSCs are described in Chapter II.6.4 "Cell Sources

for Tissue Engineering"). Neural stem cells (NSCs) are found in the proliferating regions of fetal or adult brain tissues, typically in the subventricular zone (SVZ) or the hippocampus (Palmer et al., 1997; Doetsch et al., 1999; Martino et al., 2011). NSCs are therefore most commonly extracted from one of these two regions. NSCs have the capacity to self-renew and differentiate into neurons as well as glial cells, including astrocytes and oligodendrocytes both *in vitro* and *in vivo* (Gage, 2000). The use of NSCs and their functional derivatives has been of great clinical interest due to the incidence of neurodegenerative disorders that impair cognitive and motor function, including Parkinson's, Alzheimer's, and Huntington's diseases, Multiple Sclerosis, and Amyotrophic Lateral Sclerosis (ALS), as well as traumatic brain and spinal cord injuries (Kim and de Vellis, 2009).

The differentiation of various subtypes of motor and sensory neurons from NSCs, including those responsible for producing specific neurotransmitters, such as dopamine, has been achieved (Studer et al., 2000). In addition to molecular markers, the functional characterization of electrically excitable neurons created from NSCs *in vitro* has been confirmed using electrophysiological techniques, such as patch clamping and extracellular recordings. Transplantation of NSCs and neurons or glia derived from NSCs has been attempted for the treatment of Parkinson's disease, as well as ALS and spinal cord injury, with promising results.

Unipotent Stem Cells

Progenitor cells capable of self-renewal and differentiation, albeit it into only a single cell lineage, are referred to as unipotent stem cells. Unipotent stem cells, similar to multipotent stem cells in many respects, exhibit limited proliferative capacity and constitute a minority of the cells within any given tissue. In many cases, the similarities in morphology and marker expression make it technically difficult to readily discern stem cells from somatic cells in the surrounding tissue, but their spatial location can often be identified based on previous characterization studies. Depending on the tissue, some unipotent stem cells remain quiescent until activated by the need for tissue repair, such as skeletal myoblasts, whereas others are almost continuously generating progeny, such as epithelial stem cells of the intestines, to keep up with the high cell turnover of the tissues. As a result of their inherent specification for particular tissues, the heterogeneity and number of unipotent stem cells is much greater than for pluripotent or even multipotent stem cells.

Satellite cells are the precursors to skeletal myoblasts that reside in skeletal muscle located under the basal lamina immediately adjacent to mature muscle fibers. Upon traumatic injury or muscle degeneration, satellite cells are activated to proliferate, differentiate, and restore contractile muscle. Activation of the myogenic regulatory factors (MRFs) – MyoD, Myf5, myogenin, and MRF4

(Myf6) – initiates the myogenic differentiation of satellite cells into skeletal myoblasts, along with the myocyte enhancer factor 2 (MEF2) family of transcription factors that act cooperatively with MRFs. Myogenin and MRF4 expression are required for fusion of individual myoblasts to form multi-nucleated myotubes as terminal differentiation proceeds. During the course of differentiation, a sub-set of cells commit to replenishing the satellite cell compartment to permit continual repair of mucle tissue, whereas the majority of cells terminally differentiate into mature striated muscle fibers. Myoblasts have been investigated as a cell source for muscular dystrophy and cardiac regeneration, due to the fact that they are capable of producing contractile muscle.

Epithelial stem cells are among the most common types of stem cells, due to the abundance of epithelial tissues found throughout the body. Epithelial stem cells, such as those of the epidermis and intestine, are relatively long-lived compared to most other "adult" stem cells, due to the rapid turnover of these tissues. Epidermal stem cells and intestinal stem cells reside below the surface in the basal layers of their respective tissues, and although they are typically classified as unipotent under homeostatic conditions, they may exhibit multipotent differentiation potential, especially following tissue injury. Epithelial stem cells typically reside in a specific location, such as the "bulge" in skin or the "crypt" in the intestine, and proceed to transiently amplify and terminally differentiate as they move away from these sites of their normal residence.

STEM CELL NICHES

Controlling the proliferation, migration, and differentiation of stem cells is essential for proper tissue homeostasis and repair. The dynamic and complex microenvironment in which stem cells reside *in vivo* is a critical regulator of cell fate decisions, including quiescence, self-renewal, and differentiation. The components that make up this microenvironment are collectively referred to as the stem cell "niche" (Scadden, 2006). Neighboring cells, which provide direct cell–cell contacts, secreted paracrine factors, and extracellular matrix, are the key elements that comprise the niche. Stem cell niches are distinctly located within most tissues, and in many cases are distributed at a regular intervals or spacing. The specific role of different niche components has been studied for a variety of stem cell types, including MSCs, HSCs, and NSCs; however, much uncertainty remains as to how stem cell populations are precisely controlled within complex niche microenvironments throughout the lifespan of an organism.

Soluble Factors

Signaling molecules secreted by cells located within the niche play a critical role in directing the fate of stem cells.

Unlike cell adhesions, secreted molecules can diffuse over large distances within the niche, allowing interaction with many stem cells. The secretion of morphogens by cells comprising the niche also allows for concentration gradients to be established, which contribute to the precise control of stem cell fate. Although a wide range of secreted factors are important in regulation of specific stem cell niches, the Wnt/β-Catenin and TGF-β signaling families appear to be involved in regulating the action of stem cells in multiple niches. The canonical Wnt/β-Catenin signaling pathway plays a role in dictating cellular processes, including differentiation and proliferation, in a variety of cell types at different stages of development. The Wnt/β-Catenin pathway is conserved across species, yet plays different roles in controlling stem cell behavior in different niches. For example, Wnt signaling has been shown to promote self-renewal in HSCs (Reya et al., 2003), MSCs (Boland et al., 2004; Baksh and Tuan, 2007), and stem cells in the intestinal epithelium (van Es et al., 2005), yet induce differentiation in others, such as hair follicle precursors (Huelsken et al., 2001), skeletal myoblasts (Rochat et al., 2004), and NSCs (Muroyama et al., 2004). Bone morphogenetic proteins (BMPs), a sub-set of the transforming growth factor-β (TGF-β) superfamily, are another class of signaling molecules involved in regulation of multiple stem cell types. BMPs are large, dimeric, secreted proteins that contribute to various aspects of embryological development, as well as the maintenance of adult tissue. BMPs are involved in the regulation of the HSC niche; interestingly, studies suggest that rather than acting directly on HSCs, BMPs interact with osteoblasts within the HSC niche, which in turn signal to regulate HSC behavior. BMPs have also been implicated in the maintenance of the MSC niche (Zhang et al., 2003). Treatment of MSCs with different BMP isoforms *in vitro* has been shown to result in both osteogenesis (Friedman et al., 2006) and chondrogenesis (Gooch et al., 2002). BMP signaling is likewise important in neuro-induction, as well as differentiation of NSCs. Inhibition of BMP signaling via antagonists Noggin and Chordin is required for neuro-ectoderm formation during embryological development. In the late embryo and adult subventricular zone (SVZ), BMP signaling is required for glial cell differentiation, while Noggin potently induces neuronal differentiation (Lim et al., 2000).

Extracellular Matrix

The stem cell microenvironment consists not only of cells, but also of extracellular matrix, including proteins, glycoproteins, and glycosaminoglycans. The interaction of cells with the ECM is generally mediated by a class of membrane proteins called integrins. Integrins are heterodimeric proteins, consisting of an α and a β subunit. Integrins function to attach cells to the ECM, as well as in signal transduction from the ECM to the cells. The

interaction of integrins with ECM components has been studied in the context of many stem cell niches. Osteoblasts within the HSC bone marrow niche secrete the matricellular sialoprotein osteopontin (OPN), and the amount of OPN, in turn, can control the numbers of stem cells within the marrow in a dose-dependent manner (Nilsson et al., 2005; Stier et al., 2005). Tenascin C (TenC), an ECM glycoprotein, appears to be important in regulating NSC function in the SVZ. Mice lacking TenC exhibit increased numbers of NSCs, and a delayed progression of NSC differentiation from primarily neuronal to glial cells, suggesting that TenC is involved in coordinating NSC development (Garcion et al., 2004). Mice deficient in TenC also display reduced colony forming capacity of bone marrow cells, suggesting a role for TenC in the hematopoietic niche (Ohta et al., 1998). Laminins are a class of ECM proteins expressed in nearly all tissues and predominantly found as a component of basement membranes. Laminin-5 appears to play a role in MSC differentiation, as MSCs plated on laminin-5 displayed enhanced osteogenic differentiation (Klees et al., 2005, 2007). Laminins, as well as other common ECM molecules, such as collagens and fibronectin, are expressed by bone marrow stromal cells (Zuckerman and Wicha, 1983) and many other cell types, thus such molecules likely play a role in regulating not only the HSC niche, but many other stem cell niches as well.

Additionally, ECM stiffness may contribute to the regulation of stem cell niches. *In vitro* studies in which substrate stiffness on which MSCs were cultured was systematically varied, revealed that differentiation was a function of substrate modulus. Cells cultured on hard substrates displayed preferential osteogenesis; cells on soft substrates displayed neurogenesis, and cells on intermediate substrates were myogenic (Engler et al., 2006). Studies performed with adult neural stem cells cultured on interpenetrating polymer networks with variable moduli revealed that softer substrates supported neuronal differentiation, while substrates with higher moduli promoted differentiation to glial cells (Saha et al., 2008). The physical properties of substrates may also play a role in ESC differentiation, as stiffer matrices have been shown to enhance ESC spreading and proliferation, as well as specifically promote mesoderm induction and osteogenic differentiation (Evans et al., 2009). Altogether, these studies suggest that physiological changes in the mechanical properties of ECM, in addition to its biochemical composition, may play an important role in regulating stem cell behavior in various niches.

Cell–cell Interactions. The interaction of stem cells with neighboring cell types is critical for proper regulation of stem cell fate. While the role of secreted factors has been extensively studied, the role of direct adhesions of stem cells with neighboring cells is less well-understood. Direct cell–cell contacts are generally mediated by a class of calcium-dependant transmembrane proteins called cadherins. There are multiple subclasses of cadherins, including E-, P-, N-, and VE-cadherin, that typically interact with each other in a homophilic manner. Cadherins have been implicated in regulation of the HSC niche, as N-cad+ osteoblasts have been observed to play a role in supporting a subset of HSCs known as long-term HSCs (Zhang et al., 2003). Cadherins may play other roles in HSC niches, including the balance between proliferation and quiescence (Wilson et al., 2004), as well as influencing asymmetric division (Muguruma et al., 2006). Cadherins also play a role in embryonic development and in ESC differentiation. Proper embryo development requires an epithelial-to-mesenchymal transition (EMT), in which E-cadherin is downregulated, while N-cadherin expression increases (Thiery et al., 2009). Interestingly, the reverse process, mesenchymal-to-epithelial transition, also occurs during development, particularly in the kidneys and heart. ESCs, which characteristically express E-cadherin, undergo EMT during the course of differentiation in order to form mesenchymal cell lineages that express N- and VE-cadherin.

Additionally, the Notch signaling pathway is involved in the regulation of stem cell niches. Notch and its ligands, including Jagged and Delta-like, are each transmembrane proteins that require cell–cell contact in order to communicate. Osteoblasts in the bone marrow niche can express high levels of the Notch ligand jagged 1, which in turn can activate the Notch receptor on HSCs, suggesting a functional role for Notch signaling in HSC maintenance (Calvi et al., 2003). The role of Notch in NSC self-renewal and differentiation is not well-understood, as studies show that Notch is necessary for NSC maintenance (Chambers et al., 2001; Hitoshi et al., 2002), while others indicate that Notch activation accelerates glial cell differentiation of neural crest stem cells while inhibiting neuronal differentiation (Morrison et al., 2000). The Notch pathway is also a regulatory component of ESC fate, as mouse ESCs constitutively expressing Notch display enhanced neural differentiation efficiency upon removal of self-renewal stimuli, and Notch signaling activation in human ESCs is required to differentiate to all three germ layers (Lowell et al., 2006; Yu et al., 2008).

CONCLUSIONS

Stem cells are a unique class of cells that exist in most tissues of the body at all stages of development, from early embryogenesis all the way throughout adult life. The unique ability of stem cells to self-renew and differentiate distinguishes them functionally from other cell types, and the varying potency of stem cells to differentiate into different phenotypes establishes a hierarchical organization of different classes of stem cells. Multiple factors which comprise the physical environments, or

"niches," within which stem cells reside can significantly influence cell fate decisions. Thus, the engineering of biomaterial properties to control and direct stem cell fate *in vitro* and *in vivo* has tremendous potential to aid in the advancement of stem cell research, and translation of stem cells into regenerative medicine therapies and cell-based diagnostics.

Host Reaction to Biomaterials and Their Evaluation

CHAPTER II.2.1 INTRODUCTION: "BIOLOGICAL RESPONSES TO BIOMATERIALS"

Frederick J. Schoen
Professor of Pathology and Health Sciences (HST), Harvard Medical School, Executive Vice Chairman, Department of Pathology, Brigham and Women's Hospital, Boston, MA, USA

Biomaterials are now commonly used as implants and other tissue-contacting medical devices over a wide range of applications, including, for example, as *prostheses* in cardiovascular, orthopedic, dental, ophthalmological, and reconstructive surgery, in minimally invasive interventions such as stent placement in the biliary tree or in the blood vessels, and in extracorporeal devices as hemodialysis membranes, in surgical sutures or bioadhesives, and as controlled drug-release devices. Most implants serve their recipients well for extended periods by alleviating the conditions for which they were implanted. However, some implants and extracorporeal devices ultimately develop complications – adverse interactions of the patient with the device or *vice versa* – which constitute device failure, and thereby may cause harm to or death of the patient. Complications are costly, both to patient outcomes (mortality and morbidity) and to the healthcare budget.

Complications of biomaterials and medical devices result largely as a consequence of biomaterial–tissue interactions, which all implants have with the environment into which they are placed. Effects of both the implant on the host tissues and the host on the implant are important in mediating complications and device failure (Figure II.2.1.1). Moreover, these processes can be related (Anderson et al., 2008). The chapters in Section II.2 contain overview discussions of the most important host reactions to biomaterials and their evaluation, including non-specific inflammation and specific immunological reactions, systemic effects, blood–materials interactions, tumor formation, and infection. To a great extent, these interactions arise from alterations of physiological (normal) processes (e.g., immunity, inflammation, blood coagulation) comprising host defense mechanisms that function to protect an organism from deleterious external threats (such as bacteria and other

microbiologic organisms, injury, and foreign materials). The chapters in Section II.2 address degradation mechanisms in biomaterials (i.e., the effect of the host on biomaterials). Several key concepts of biomaterials–tissue interactions are emphasized below, in an effort to guide the reader and facilitate the use of this section.

THE INFLAMMATORY REACTION TO BIOMATERIALS

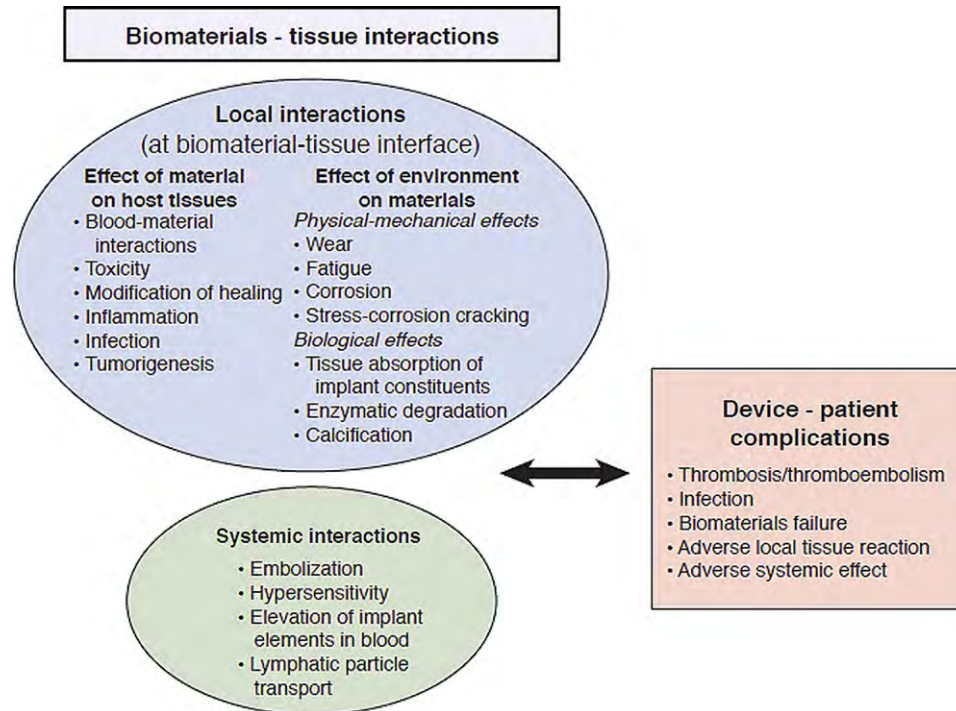
In their respective chapters, Anderson (II.2.2), Mitchell (II.2.3), and Johnson (II.2.4) describe the inflammatory and potential immunological interactions that occur with biomaterials. Most biomaterials of potential clinical interest typically elicit the *foreign-body reaction* (FBR), a special form of non-specific inflammation (see Chapter II.2.2 of this book). The most prominent cells in the FBR are macrophages, which attempt to phagocytose the material and are variably successful, but complete engulfment and degradation are often difficult. The macrophages, activated in the process of interacting with a biomaterial, may elaborate cytokines which stimulate inflammation or fibrosis. Macrophages are also the first line of defense against pathogens, and the mode of their activation will determine the success or failure of the host response to pathogens (Mège et al., 2011). Based on limited numbers of markers, activated macrophages can be classified along a phenotypic spectrum as classically activated (M1) macrophages that support microbicidal activity, are proinflammatory, and elicit dense connective tissue and/or scarring, or alternatively activated (M2) macrophages that are not competent to eliminate pathogens that are regulatory/homeostatic. Thus, a more constructive remodeling outcome may be due to the recruitment and survival of M2 cell populations to the sites of remodeling associated with materials (Brown et al., 2012). Multinucleated *giant cells* in the vicinity of a foreign-body are generally considered evidence of a more severe FBR (Brodbeck and Anderson, 2009). The more "biocompatible" the implant, the more quiescent (less inflammation) is the ultimate response. When the implant is a source of particles not easily controlled, such as wear debris from articulating joint surfaces (Pandit et al., 2008; Catelas et al., 2011), the inability of inflammatory cells to adhere


FIGURE II.2.1.1 Biomaterials–tissue interactions. (Reproduced from Schoen, F. J. (2002). Prosthetic-materials: Past, present and future. In: *Advances in Cardiovascular Medicine* (Harvey 1602–2002 Symposium, on the 4th Centenary of William Harvey's Graduation at the University of Padua), Thiene, G., & Pessina, A. C. (Eds.), Universita degli Studi di Padova, pp. 289–307 and Schoen, F. J. & Padera, R. (2012). Cardiovascular Pathology. In: *Cardiac Surgery in the Adult*, 4th edn., Cohn, L. H. & Edmunds, L. H. (Eds.). McGraw–Hill, pp. 95–148.)

to but not phagocytose particles larger than a critical size ("frustrated phagocytosis") can lead to release of enzymes (exocytosis) and chemical mediators (e.g., prostaglandin, tumor necrosis factor-alpha, and interleukin-1, etc.), and cause harm to the extracellular environment. Thus, inflammatory cell products that are critical in killing microorganisms in typical inflammation can damage tissue adjacent to foreign-bodies.

In contrast to living organ transplants, biomaterials are not generally "rejected." The process of tissue or whole organ rejection denotes an inflammatory process that results from a specific immune response (i.e., a response to specific antigens having certain characteristics that are described by Mitchell in Chapter II.2.3), and which synthetic biomaterials typically do not generate. Indeed, the usual response to biomaterials comprises a form of non-specific inflammation known as the "foreign body response" (see Chapter II.2.2).

However, as summarized by Mitchell (2001), tissue-derived biomaterials (such as bioprosthetic heart valves) may express foreign histocompatibility antigens, and be antigenic and capable of eliciting an immune response mediated by antibodies and antigen-specific T cells. Nevertheless, as explained in more detail below, it is important to understand that:

(1) the capacity for tissue immunogenicity does not necessarily induce immunologically mediated device dysfunction;

(2) specific immunological responses can be either a cause of or result from device failure;

(3) although mononuclear inflammatory cell infiltrates (containing macrophages and lymphocytes) are characteristically in organ/tissue rejection on histological examination, mononuclear inflammatory infiltrates are themselves non-specific, and comprise a largely stereotyped and generic response to tissue injury. Therefore, the presence of mononuclear cells does not necessarily denote a rejection pathogenesis.

In order to invoke an immunological reaction to a biomaterial as the cause of a device failure, an immunological variant of the classical Koch's Postulates that are the objective criteria for concluding that a disease is infectious and caused by a specific microbiologic agent would be appropriate. The classic Koch's Postulates state that (Inglis, 2007):

(1) a suspected infectious agent should be recoverable from the pathologic lesions of the human host;

(2) the agent should cause the pathologic lesions when inoculated into an animal host;

(3) the agent should then be recoverable from the pathologic lesions in the animal.

Mitchell (2001) describes an immunological variant of Koch's Postulates to test an immunological hypothesis for biomaterials failure, as exemplified by the widely quoted but non-proven immunological calcific and

non-calcific bioprosthetic valve failure (Mitchell, 2001; Schoen and Levy, 2005) as follows:

(1) antigen-specific elements (antibodies or cells) should be directly associated with failing valves. Moreover, control experiments should be performed to demonstrate that any antibodies or cells on implanted valves are not simply present because of surgical manipulation or aberrant flow conditions;

(2) antibodies or cells from experimental animals that have dysfunctional implanted valves transferred into an appropriate second host (immunologically-matched to the original valve donor) should cause valve failure;

(3) adoptively transferred cells or antibodies should be detectable on a failed valve in the second recipient.

Although some evidence for these criteria can be obtained in humans, carefully designed animal investigations provide the only rigorous way to satisfy them. With respect to tissue heart valves, although some investigators have demonstrated that such tissues can be immunogenic, *there exists no evidence that clinical valve destruction or loss-of-function is mediated by immune elements or that blockade of immune mechanisms by immunosuppression prevents that outcome.*

The nature of the reaction is largely dependent on the chemical and physical characteristics of the implant. For most inert biomaterials, the late tissue reaction is *encapsulation* by a fibrous tissue capsule (composed of collagen and fibroblasts). Tissue interactions can be modified by changing the chemistry of the surface (e.g., by adding specific chemical groupings to stimulate adhesion or bone formation in orthopedic implants), inducing roughness or porosity to enhance physical binding to the surrounding tissues, incorporating a surface–active agent to chemically bond the tissue, using a bioresorbable component to allow slow replacement by tissue to simulate natural healing properties, or by systemic or localized administration of corticosteroid drugs.

SYSTEMIC AND REMOTE EFFECTS

Hensten and Jacobsen (Chapter II.2.5) summarize biomaterials-related systemic toxicity and hypersensitivity reaction (through lymphatics and the bloodstream) in animals and patients with either stainless steel or cobalt–based orthopedic total joint replacement components, where elevations of metallic content occur in tissue (at both local and remote sites) and in serum and urine. Transport of particulates over large distances by macrophages to regional lymph nodes and to the lungs and liver has been considered a systemic and remote effect. As consequence, an enlarged, hard axillary lymph node in a woman who received a silicone-gel breast prosthesis for reconstruction following mastectomy for a carcinoma can be misdiagnosed as tumor (Hausner et al., 1978) and

prosthetic hip joint failure may present as liver problems (Peoc'h, 1996).

"Metal allergy" is well–recognized and is frequently associated in women with the use of cheap, high–nickel alloy costume jewelry or earrings, and can also occur in association with metallic implants (Hallab et al., 2001). By themselves, metal ions lack the structural complexity required to challenge the immune system. However, when combined with proteins, such as those available in the skin, connective tissues, and blood, a wide variety of metals induce immune responses, and this can have clinical effects. Cobalt, chromium, and nickel are included in this category, with nickel perhaps the most potent; at least 10% of a normal population will be sensitive by skin test to one or more of these metals, at some threshold level.

THROMBOEMBOLIC COMPLICATIONS

Hanson and Tucker (Chapter II.2.6) emphasize that exposure of blood to an artificial surface can induce thrombosis, embolization, and consumption of platelets and plasma coagulation factors, as well as the systemic effects of activated coagulation and complement products, and platelet activation. It is clear that no synthetic or modified biological surface generated by man is as resistant to thrombosis (*thromboresistant*) as normal unperturbed endothelium (the cellular lining of the circulatory system). However, it is important to understand that under some circumstances endothelial cells can be "dysfunctional," and although physically intact can express prothrombotic molecules that can induce thrombosis (Bonetti et al., 2003).

Thromboembolic complications are a major cause of mortality and morbidity with cardiovascular devices. Both fibrin (red) thrombus and platelet (white) thrombus form in association with valves and other cardiovascular devices. As in the cardiovascular system in general, Virchow's triad (surface thrombogenicity, hypercoagulability, and locally static blood flow) largely predicts the relative propensity toward thrombus formation and location of thrombotic deposits with cardiovascular prostheses (Bennett et al., 2009). However, despite over a quarter century of intense research, the physical and chemical characteristics of materials that control the outcome of blood–surface interaction are incompletely understood.

Considerable evidence implicates a primary regulatory role for blood platelets in the thrombogenic response to artificial surfaces (see Chapter II.2.6). Platelet adhesion to artificial surfaces strongly resembles that of adhesion to the vascular subendothelium that has been exposed by injury. Nevertheless, the major clinical approach to controlling thrombosis in cardiovascular devices is the use of systemic anticoagulants, particularly Coumadin® (warfarin), which inhibits thrombin formation but does not inhibit platelet–mediated thrombosis.

TUMORIGENESIS

Schoen (Chapter II.2.7) emphasizes that although animals frequently have sarcomas at the site of an experimental biomaterial implant, neoplasms occurring at the site of clinically implanted medical devices are rare, despite the large numbers of implants used clinically in humans over an extended duration. Moreover, a neoplasm at an implant site does not prove that the implant had a causal role. Cancers associated with foreign-bodies can appear at any postoperative interval, but tend to occur many years postoperatively. The pathogenesis of implant–induced tumors is not well understood; most experimental data indicate that the physical rather than chemical characteristics of the foreign-body primarily determine tumorigenicity. The possibility that implants may be causal to tumor formation is an ever present problem, with contemporary questions related to metal-on-metal hip joints and breast prostheses (see Chapter II.2.7).

INFECTION

As emphasized by Stoodley et al. (Chapter II.2.8), infection occurs in as many as 5–10% of patients with implanted prosthetic devices, and is a major source of morbidity and mortality (Tanner, 1997; Vlessis, 1997; Schierholz, 2001). *Infections associated with medical devices are often resistant to antibiotics and host defenses, often persisting until the devices are removed.* Early implant infections (less than approximately 1–2 months postoperatively) are most likely due to intraoperative contamination from airborne sources or nonsterile surgical technique, or to early postoperative complications such as wound infection. In contrast, late infections likely occur by a hematogenous (blood-borne) route, and are often initiated by bacteremia induced by therapeutic dental or genitourinary procedures. Perioperative prophylactic antibiotics and periodic antibiotic prophylaxis given shortly before diagnostic and therapeutic procedures protect against implant infection. Infections associated with foreign bodies are characterized microbiologically by a high prevalence of *Staphylococcus epidermidis* and other staphylococci, especially *S. aureus*. Ordinarily, *S. epidermidis* is an organism with low virulence, and is thus an infrequent cause of non–prosthesis–associated deep infections. This emphasizes the unique environment in the vicinity of a foreign-body.

The presence of a foreign-body per se *potentiates infection*. A classic experiment indicated that the staphylococcal bacterial inoculum required to cause infection in the presence of a foreign implant was 10,000 less than that when no foreign-body was present (Elek and Conen, 1957). Devices could facilitate infection in several ways. Microorganisms are provided access to the circulation and to deeper tissue by damage to natural barriers against infection during implantation or subsequent function of a prosthetic device. Moreover, an implanted foreign-body could: (1) limit phagocyte migration into infected tissue or (2) interfere with inflammatory cell phagocytic mechanisms, through release of soluble implant components or surface–mediated interactions, thus allowing bacteria to survive adjacent to the implant. As Stoodley et al. emphasize, adhesion of bacteria to the prosthetic surface and the formation of microcolonies within an adherent biofilm are fundamental steps in the pathogenesis of clinical and experimental infections associated with foreign bodies.

CHAPTER II.2.2 INFLAMMATION, WOUND HEALING, AND THE FOREIGN-BODY RESPONSE

James M. Anderson
Department of Pathology, Case Western Reserve University, Cleveland, OH, USA

Inflammation, wound healing, and foreign-body reaction are generally considered as parts of the tissue or cellular host responses to injury. Table II.2.2.1 lists the sequence/continuum of these events following injury. Overlap and simultaneous occurrence of these events should be considered; e.g., the foreign-body reaction at the implant interface may be initiated with the onset of acute and chronic inflammation. From a biomaterials perspective, placing a biomaterial in the *in vivo* environment requires injection, insertion or surgical implantation, all of which injure the tissues or organs involved.

Biocompatibility and Implantation

Implantation of a biomaterial, medical device, or prosthesis results in tissue injury that initiates host defense systems, e.g., inflammatory, wound healing, and foreign-body responses. The extent and time-dependent nature of these responses, in the context of the characteristics and properties of the biomaterial, form the basis for determining the biocompatibility or safety of the biomaterial. In addition to defining the biocompatibility of a biomaterial, a fundamental understanding of these responses permits their use as biological design criteria.

The placement procedure initiates a response to injury by the tissue, organ or body, and mechanisms are activated to maintain homeostasis. The degrees to which the homeostatic mechanisms are perturbed, and the extent to which pathophysiologic conditions are created and undergo resolution, are a measure of the host reactions to the biomaterial and may ultimately determine its biocompatibility. Although it is convenient to separate homeostatic mechanisms into blood–material or tissue–material interactions, it must be remembered that the various components or mechanisms involved in homeostasis are present in both blood and tissue, and are a part of the physiologic continuum. Furthermore, it must be noted that host reactions may be tissue-dependent, organ-dependent, and species-dependent. Obviously, the extent of injury varies with the implantation procedure.

OVERVIEW

Inflammation is generally defined as the reaction of vascularized living tissue to local injury. Inflammation serves to contain, neutralize, dilute, or wall off the injurious agent or process. In addition, it sets in motion a series of events that may heal and reconstitute the implant site through replacement of the injured tissue by regeneration of native parenchymal cells, formation of fibroblastic scar tissue, or a combination of these two processes.

Immediately following injury, there are changes in vascular flow, caliber, and permeability. Fluid, proteins, and blood cells escape from the vascular system into the injured tissue in a process called exudation. Following changes in the vascular system, which also include changes induced in blood and its components, cellular events occur and characterize the inflammatory response. The effect of the injury and/or biomaterial *in situ* on plasma or cells can produce chemical factors that mediate many of the vascular and cellular responses of inflammation.

Blood–material interactions and the inflammatory response are intimately linked, and in fact early responses to injury involve mainly blood and vasculature. Regardless of the tissue or organ into which a biomaterial is implanted, the initial inflammatory response is activated by injury to vascularized connective tissue (Table II.2.2.2). Since blood and its components are involved in the initial inflammatory responses, blood clot formation and/or thrombosis also occur. Blood coagulation and thrombosis are generally considered humoral responses that may be influenced by other homeostatic mechanisms, such as the extrinsic and intrinsic coagulation systems, the complement system, the fibrinolytic system, the kinin-generating system, and platelets. Thrombus or blood clot formation on the surface of a biomaterial is related to the well-known Vroman effect (see Chapter II.3.2),

in which a hierarchical and dynamic series of collision, absorption, and exchange processes, determined by protein mobility and concentration, regulate early time-dependent changes in blood protein adsorption. From a wound-healing perspective, blood protein deposition on a biomaterial surface is described as provisional matrix formation. Blood interactions with biomaterials are generally considered under the category of hematocompatibility and are discussed elsewhere in this book.

Injury to vascularized tissue in the implantation procedure leads to immediate development of the provisional matrix at the implant site. This provisional matrix consists of fibrin, produced by activation of the coagulation and thrombosis systems, and inflammatory products released by the complement system, activated platelets, inflammatory cells, and endothelial cells. These events occur early,

within minutes to hours following implantation of a medical device. Components within or released from the provisional matrix, i.e., fibrin network (thrombosis or clot), initiate the resolution, reorganization, and repair processes such as inflammatory cell and fibroblast recruitment. The provisional matrix appears to provide both structural and biochemical components to the process of wound healing. The complex three-dimensional structure of the fibrin network with attached adhesive proteins provides a substrate for cell adhesion and migration. The presence of mitogens, chemoattractants, cytokines, and growth factors within the provisional matrix provides for a rich milieu of activating and inhibiting substances for various cellular proliferative and synthetic processes. The provisional matrix may be viewed as a naturally derived, biodegradable, sustained release system in which mitogens, chemoattractants, cytokines, and growth factors are released to control subsequent wound-healing processes. In spite of the increase in our knowledge of the provisional matrix and its capabilities, our knowledge of the control of the formation of the provisional matrix and its effect on subsequent wound healing events is poor. In part, this lack of knowledge is due to the fact that much of our knowledge regarding the provisional matrix has been derived from *in vitro* studies, and there is a paucity of *in vivo* studies that provide for a more complex perspective. Little is known regarding the provisional matrix which forms at biomaterial and medical device interfaces *in vivo*, although attractive hypotheses have been presented regarding the presumed ability of materials and protein adsorbed materials to modulate cellular interactions through their interactions with adhesive molecules and cells.

The predominant cell type present in the inflammatory response varies with the age of the inflammatory injury (Figure II.2.2.1). In general, neutrophils predominate during the first several days following injury and then are replaced by monocytes as the predominant cell type. Three factors account for this change in cell type: neutrophils are short lived and disintegrate and disappear after

FIGURE II.2.2.1 The temporal variation in the acute inflammatory response, chronic inflammatory response, granulation tissue development, and foreign-body reaction to implanted biomaterials. The intensity and time variables are dependent upon the extent of injury created in the implantation and the size, shape, topography, and chemical and physical properties of the biomaterial.

24–48 hours; neutrophil emigration from the vasculature to the tissues is of short duration; and chemotactic factors for neutrophil migration are activated early in the inflammatory response. Following emigration from the vasculature, monocytes differentiate into macrophages and these cells are very long-lived (up to months). Monocyte emigration may continue for days to weeks, depending on the injury and implanted biomaterial, and chemotactic factors for monocytes are activated over longer periods of time. In short-term (24 hour) implants in humans, administration of both H1 and H2 histamine receptor antagonists greatly reduced the recruitment of macrophages/monocytes and neutrophils on polyethylene terephthalate surfaces. These studies also demonstrated that plasma-coated implants accumulated significantly more phagocytes than did serum-coated implants.

The temporal sequence of events following implantation of a biomaterial is illustrated in Figure II.2.2.1. The size, shape, and chemical and physical properties of the biomaterial may be responsible for variations in the intensity and duration of the inflammatory or wound-healing process. Thus, intensity and/or time duration of the inflammatory reaction may characterize the biocompatibility of a biomaterial.

While injury initiates the inflammatory response, the chemicals released from plasma, cells or injured tissue mediate the inflammatory response. Important classes of chemical mediators of inflammation are presented in Table II.2.2.3. Several points must be noted in order to understand the inflammatory response and how it relates to biomaterials. First, although chemical mediators are classified on a structural or functional basis, different mediator systems interact and provide a system of checks and balances regarding their respective activities and functions. Second, chemical mediators are quickly inactivated or destroyed, suggesting that their action is predominantly local (i.e., at the implant site). Third, generally the lysosomal proteases and the oxygen-derived free radicals produce the most significant damage or injury. These chemical mediators are also important in the degradation of biomaterials.

ACUTE INFLAMMATION

Acute inflammation is of relatively short duration, lasting for minutes to hours to days, depending on the extent of injury. Its main characteristics are the exudation of fluid and plasma proteins (edema) and the emigration of leukocytes (predominantly neutrophils). Neutrophils (polymorphonuclear leukocytes, PMNs) and other motile white cells emigrate or move from the blood vessels to the perivascular tissues and the injury (implant) site. Leukocyte emigration is assisted by "adhesion molecules" present on leukocyte and endothelial surfaces. The surface expression of these adhesion molecules can be induced, enhanced or altered by inflammatory agents and chemical mediators. White cell emigration is controlled, in part, by chemotaxis, which is the unidirectional migration of cells along a chemical gradient. A wide variety of exogenous and endogenous substances have been identified as chemotactic agents. Specific receptors for chemotactic agents on the cell membranes of leukocytes are important in the emigration or movement of leukocytes. These and other receptors also play a role in the transmigration of white cells across the endothelial lining of vessels, and the activation of leukocytes. Following localization of leukocytes at the injury (implant) site, phagocytosis and the release of enzymes occur following activation of neutrophils and macrophages. The major role of the neutrophil in acute inflammation is to phagocytose microorganisms and foreign materials. Phagocytosis is seen as a three-step process in which the injurious agent undergoes recognition and neutrophil attachment, engulfment, and killing or degradation. In regard to biomaterials, engulfment and degradation may or may not occur, depending on the properties of the biomaterial.

Although biomaterials are not generally phagocytosed by neutrophils or macrophages because of the disparity in size (i.e., the surface of the biomaterial is greater than the size of the cell), certain events in phagocytosis may occur. The process of recognition and attachment is expedited when the injurious agent is coated by naturally occurring serum factors called "opsonins." The two major opsonins are immunoglobulin G (IgG) and the complement-activated fragment, C3b. Both of

TABLE II.2.2.3	Important Chemical Mediators of Inflammation Derived from Plasma, Cells or Injured Tissue
Mediators	**Examples**
Vasoactive Agents	Histamines, serotonin, adenosine, endothelial-derived relaxing factor (EDRF), prostacyclin, endothelin, thromboxane α_2
Plasma Proteases	
Kinin system	Bradykinin, kallikrein
Complement system	C3a, C5a, C3b, C5b–C9
Coagulation/fibrinolytic system	Fibrin degradation products, activated Hageman factor (FXIIA), tissue plasminogen activator (tPA)
Leukotrienes	Leukotriene B_4 (LTB$_4$), hydroxyeicosatetranoic acid (HETE)
Lysosomal proteases	Collagenase, elastase
Oxygen-derived free radicals	H_2O_2, superoxide anion
Platelet activating factors	Cell membrane lipids
Cytokines	Interleukin 1 (IL-1), tumor necrosis factor (TNF)
Growth factors	Platelet-derived growth factor (PDGF), fibroblast growth factor (FGF), transforming growth factor TGF-α or (TGF-β), epithelial growth factor (EGF)

these plasma-derived proteins are known to adsorb to biomaterials, and neutrophils and macrophages have corresponding cell-membrane receptors for these opsonization proteins. These receptors may also play a role in the activation of the attached neutrophil or macrophage. Other blood proteins such as fibrinogen, fibronectin, and vitronectin may also facilitate cell adhesion to biomaterial surfaces. Owing to the disparity in size between the biomaterial surface and the attached cell, frustrated phagocytosis may occur. This process does not involve engulfment of the biomaterial, but does cause the extracellular release of leukocyte products in an attempt to degrade the biomaterial.

Henson (1971) has shown that neutrophils adherent to complement-coated and immunoglobulin-coated nonphagocytosable surfaces may release enzymes by direct extrusion or exocytosis from the cell. The amount of enzyme released during this process depends on the size of the polymer particle, with larger particles inducing greater amounts of enzyme release. This suggests that the specific mode of cell activation in the inflammatory response in tissue depends upon the size of the implant, and that a material in a phagocytosable form (i.e., powder, particulate or nanomaterial) may provoke a different degree of inflammatory response than the same material in a nonphagocytosable form (i.e., film). In general, materials greater than 5 microns are not phagocytosed, while materials less than 5 microns, i.e., nanomaterials, can be phagocytosed by inflammatory cells.

Acute inflammation normally resolves quickly, usually less than 1 week, depending on the extent of injury at the implant site. However, the presence of acute inflammation (i.e., PMNs) at the tissue/implant interface at time periods beyond 1 week (i.e., weeks, months, or years) suggests the presence of an infection (Figure II.2.2.2).
FIGURE II.2.2.2 Acute inflammation, secondary to infection, of an ePTFE (expanded poly tetrafluoroethylene) vascular graft. A focal zone of polymorphonuclear leukocytes is present at the lumenal surface of the vascular graft, surrounded by a fibrin cap, on the blood-contacting surface of the ePTFE vascular graft. Hematoxylin and eosin stain. Original magnification 4 ×.

CHRONIC INFLAMMATION

Chronic inflammation is less uniform histologically than acute inflammation. In general, chronic inflammation is characterized by the presence of macrophages, monocytes, and lymphocytes, with the proliferation of blood vessels and connective tissue. Many factors can modify the course and histologic appearance of chronic inflammation.

Persistent inflammatory stimuli lead to chronic inflammation. While the chemical and physical properties of the biomaterial in themselves may lead to chronic inflammation, motion in the implant site by the biomaterial or infection may also produce chronic inflammation. The chronic inflammatory response to biomaterials is usually of short duration, and is confined to the implant site. The presence of mononuclear cells, including lymphocytes and plasma cells, is considered chronic inflammation, whereas the foreign-body reaction with the development of granulation tissue is considered the normal wound healing response to implanted biomaterials (i.e., the normal foreign-body reaction). Chronic inflammation with the presence of collections of lymphocytes and monocytes at extended implant times (weeks, months, years) may also suggest the presence of a long-standing infection (Figures II.2.2.3A and II.2.2.3B). The prolonged presence of acute and/or chronic inflammation also may be due to toxic leachables from a biomaterial.

Lymphocytes and plasma cells are involved principally in immune reactions, and are key mediators of antibody production and delayed hypersensitivity responses. Although they may be present in nonimmunologic injuries and inflammation, their roles in such circumstances are largely unknown. Little is known regarding humoral immune responses and cell-mediated immunity to synthetic biomaterials. The role of macrophages must be considered in the possible development of immune responses to synthetic biomaterials. Macrophages and dendritic cells process and present the antigen to immunocompetent cells, and thus are key mediators in the development of immune reactions.

Monocytes and macrophages belong to the mononuclear phagocytic system (MPS), also known as the reticuloendothelial system (RES). These systems consist of cells in the bone marrow, peripheral blood, and specialized tissues. Table II.2.2.4 lists the tissues that contain cells belonging to the MPS or RES. The specialized cells in these tissues may be responsible for systemic effects in organs or tissues secondary to the release of components or products from implants through various tissue–material interactions (e.g., corrosion products, wear debris, degradation products) or the presence of implants (e.g., microcapsule or nanoparticle drug-delivery systems).

The macrophage is probably the most important cell in chronic inflammation, because of the great number of biologically active products it can produce. Important

classes of products produced and secreted by macrophages include neutral proteases, chemotactic factors, arachidonic acid metabolites, reactive oxygen metabolites, complement components, coagulation factors, growth-promoting factors, and cytokines.

Growth factors such as platelet-derived growth factor (PDGF), fibroblast growth factor (FGF), transforming growth factor-β (TGF-β), TGF-α/epidermal growth factor (EGF), and interleukin-1 (IL-1) or tumor necrosis factor (TNF-α) are important to the growth of fibroblasts and blood vessels, and the regeneration of epithelial cells. Growth factors released by activated cells can stimulate production of a wide variety of cells; initiate cell migration, differentiation, and tissue remodeling; and may be involved in various stages of wound healing.

GRANULATION TISSUE

Within one day following implantation of a biomaterial (i.e., injury), the healing response is initiated by the action of monocytes and macrophages. Fibroblasts and vascular endothelial cells in the implant site proliferate and begin to form granulation tissue, which is the specialized type of tissue that is the hallmark of healing inflammation. Granulation tissue derives its name from the pink, soft granular appearance on the surface of healing wounds, and its characteristic histologic features include the proliferation of new small blood vessels and fibroblasts (Figure II.2.2.4). Depending on the extent of injury, granulation tissue may be seen as early as 3–5 days following implantation of a biomaterial.

The new small blood vessels are formed by budding or sprouting of pre-existing vessels in a process known as neovascularization or angiogenesis. This process involves proliferation, maturation, and organization of endothelial cells into capillary vessels. Fibroblasts also proliferate in developing granulation tissue, and are active in synthesizing collagen and proteoglycans. In the early stages of granulation tissue development, proteoglycans predominate but later collagen, especially type III collagen, predominates and forms the fibrous capsule. Some fibroblasts in developing granulation tissue may have the features of smooth muscle cells, i.e., actin microfilaments. These cells are called myofibroblasts, and are considered to be responsible for the wound contraction seen during the development of granulation tissue. Macrophages are almost always present in granulation tissue. Other cells may also be present if chemotactic stimuli are generated.

The wound-healing response is generally dependent on the extent or degree of injury or defect created by the implantation procedure. Wound healing by primary union or first intention is the healing of clean, surgical incisions in which the wound edges have been approximated by surgical sutures. Healing under these conditions occurs without significant bacterial contamination, and with a minimal loss of tissue. Wound healing by secondary union or second intention occurs when there is a large tissue defect that must be filled or there is extensive loss of cells and tissue. In wound healing by secondary intention, regeneration of parenchymal cells cannot completely reconstitute the original architecture, and much larger amounts of granulation tissue are formed that result in larger areas of fibrosis or scar formation. Under these conditions, different regions of tissue may show different stages of the wound-healing process simultaneously.

Granulation tissue is distinctly different from granulomas, which are small collections of modified macrophages called epithelioid cells. Langhans' or foreign-body-type giant cells may surround nonphagocytosable particulate materials in granulomas. Foreign-body giant cells (FBGCs) are formed by the fusion of monocytes and macrophages in an attempt to phagocytose the material (Figure II.2.2.5).

Original magnification 4 ×.

FOREIGN-BODY REACTION

The foreign-body reaction to biomaterials is composed of foreign-body giant cells and the components of granulation tissue (e.g., macrophages, fibroblasts, and capillaries in varying amounts), depending upon the form and topography of the implanted material (Figure II.2.2.6). Relatively flat and smooth surfaces such as those found on breast prostheses have a foreign-body reaction that is composed of a layer of macrophages one-to-two cells in thickness. Relatively rough surfaces such as those found on the outer surfaces of expanded poly tetrafluoroethylene (ePTFE) or Dacron vascular prostheses have a foreign-body reaction composed of macrophages and foreign-body giant cells at the surface. Fabric materials generally have a surface response composed of macrophages and foreign-body giant cells, with varying degrees of granulation tissue subjacent to the surface response (Figure II.2.2.7).

As previously discussed, the form and topography of the surface of the biomaterial determine the composition of the foreign-body reaction. With biocompatible materials, the composition of the foreign-body reaction in the implant site may be controlled by the surface properties of the biomaterial, the form of the implant, and the relationship between the surface area of the biomaterial and the volume of the implant. For example, high surface-to-volume implants, such as fabrics, porous materials, particulate or microspheres will have higher ratios of macrophages and foreign-body giant cells in the implant site than smooth-surface implants, which will have fibrosis as a significant component of the implant site.

The foreign-body reaction consisting mainly of macrophages and/or foreign-body giant cells may persist at the tissue–implant interface for the lifetime of the implant (Figure II.2.2.1). Generally, fibrosis (i.e., fibrous encapsulation) surrounds the biomaterial or implant with its interfacial foreign-body reaction, isolating the implant and foreign-body reaction from the local tissue environment. Early in the inflammatory and wound-healing response, the macrophages are activated upon adherence to the material surface.
FIGURE II.2.2.5 *In vivo* transition from blood-borne monocyte to biomaterial adherent monocyte/macrophage to foreign-body giant cell at the tissue–biomaterial interface. Little is known regarding the indicated biological responses, which are considered to play important roles in the transition to FBGC development.
FIGURE II.2.6 (A) Focal foreign-body reaction to polyethylene wear particulate from a total knee prosthesis. Macrophages and foreign-body giant cells are identified within the tissue and lining the apparent void spaces indicative of polyethylene particulate. Hematoxylin and eosin stain. Original magnification 20 ×. (B) Partial polarized light view. Polyethylene particulate is identified within the void spaces commonly seen under normal light microscopy. Hematoxylin and eosin stain. Original magnification 20 ×.
FIGURE II.2.7 Foreign-body reaction with multinucleated foreign body giant cells and macrophages at the periadventitial (outer) surface of a Dacron vascular graft. Fibers from the Dacron vascular graft are identified as clear oval voids. Hematoxylin and eosin stain. Original magnification 20 ×.

Although it is generally considered that the chemical and physical properties of the biomaterial are responsible for macrophage activation, the subsequent events regarding the activity of macrophages at the surface are not clear. Tissue macrophages, derived from circulating blood monocytes, may coalesce to form multinucleated foreign-body giant cells. It is not uncommon to see very large foreign-body giant cells containing large numbers of nuclei on the surface of biomaterials. While these foreign-body giant cells may persist for the lifetime of the implant, it is not known if they remain activated, releasing their lysosomal constituents, or become quiescent.

Figure II.2.2.5 demonstrates the progression from circulating blood monocyte, to tissue macrophage, to foreign-body giant cell development that is most commonly observed. Indicated in the figure are important biological responses that are considered to play an important role in FBGC development. Material surface chemistry may control adherent macrophage apoptosis (i.e., programmed cell death) (see Chapter II.3.3) that renders potentially harmful macrophages

nonfunctional, while the surrounding environment of the implant remains unaffected. The level of adherent macrophage apoptosis appears to be inversely related to the surface's ability to promote fusion of macrophages into FBGCs, suggesting a mechanism for macrophages to escape apoptosis.

Figure II.2.2.8 demonstrates the sequence of events involved in inflammation and wound healing when medical devices are implanted. In general, the PMN predominant acute inflammatory response and the lymphocyte/monocyte predominant chronic inflammatory response resolve quickly (i.e., within 2 weeks) depending on the type and location of the implant. Studies using IL-4 or IL-13, respectively, demonstrate the role for Th2 helper lymphocytes and/or mast cells in the development of the foreign-body reaction at the tissue/material interface. Integrin receptors of IL-4-induced FBGC are characterized by the early constitutive expression of $\alpha V\beta1$, and the later induced expression of $\alpha5\beta1$ and $\alpha X\beta2$, which indicate potential interactions with adsorbed complement C3, fibrin(ogen), fibronectin, Factor X, and vitronectin. Interactions through indirect (paracrine) cytokine and chemokine signaling have shown a significant effect in enhancing adherent macrophage/FBGC activation at early times, whereas interactions via direct (juxtacrine) cell–cell mechanisms dominate at later times. Th2 helper lymphocytes have been described as "anti-inflammatory" based on their cytokine profile, of which IL-4 is a significant component.

FIBROSIS/FIBROUS ENCAPSULATION

The end-stage healing response to biomaterials is generally fibrosis or fibrous encapsulation (Figure II.2.2.9). However, there may be exceptions to this general statement (e.g., porous materials inoculated with parenchymal cells or porous materials implanted into bone) (Figure II.2.2.10). As previously stated, the tissue response to implants is, in part, dependent upon the extent of injury or defect created in the implantation procedure and the amount of provisional matrix.

Injury and Repair at Implant Sites

The ultimate goal of tissue engineering and regenerative medicine is replacement of injured tissue by cells that reconstitute normal tissue and organ structures. Numerous approaches, including stem cells, scaffolds, growth factors, etc., are currently being investigated. However, the relatively rapid responses of inflammation, wound healing, and the foreign-body reaction, as well as other significant factors in tissue regeneration, present major challenges to the successful achievement of this goal.

Repair of implant sites can involve two distinct processes: regeneration, which is the replacement of injured tissue by parenchymal cells of the same type or replacement by connective tissue that constitutes the fibrous capsule. These processes are generally controlled by either: (1) the proliferative capacity of the cells in the tissue or organ receiving the implant and the extent of injury as it relates to the destruction; or (2) persistence of the tissue framework of the implant site. See Chapter II.3.4 for a more complete discussion of the types of cells present in the organ parenchyma and stroma, respectively.

The regenerative capacity of cells allows them to be classified into three groups: labile; stable (or expanding); and permanent (or static) cells (see Chapter II.3.3). Labile cells continue to proliferate throughout life; stable cells retain this capacity but do not normally replicate; and permanent cells cannot reproduce themselves after birth. Perfect repair with restitution of normal structure can theoretically occur only in tissues consisting of stable and labile cells, whereas all injuries to tissues composed of permanent cells may give rise to fibrosis and fibrous capsule formation with very little restitution of the normal tissue or organ structure. Tissues composed of permanent cells (e.g., nerve cells and cardiac muscle cells) most commonly undergo an organization of the inflammatory exudate, leading to fibrosis. Tissues of stable cells (e.g., parenchymal cells of the liver, kidney, and pancreas); mesenchymal cells (e.g., fibroblasts, smooth muscle cells, osteoblasts, and chondroblasts); and vascular endothelial and labile cells (e.g., epithelial cells, lymphoid and hematopoietic cells) may also follow this pathway to fibrosis or may undergo resolution of the inflammatory exudate, leading to restitution of the normal tissue structure.

The condition of the underlying framework or supporting stroma of the parenchymal cells following an injury plays an important role in the restoration of normal tissue structure. Retention of the framework with injury may lead to restitution of the normal tissue structure, whereas destruction of the framework most commonly leads to fibrosis. It is important to consider the species-dependent nature of the regenerative capacity of cells. For example, cells from the same organ or tissue, but from different species, may exhibit different regenerative capacities and/or connective tissue repair.

Following injury, cells may undergo adaptations of growth and differentiation. Important cellular adaptations are atrophy (decrease in cell size or function), hypertrophy (increase in cell size), hyperplasia (increase in cell number), and metaplasia (change in cell type). Other adaptations include a change by cells from producing one family of proteins to another (phenotypic change) or marked overproduction of protein. This may be the case in cells producing various types of collagens and extracellular matrix proteins in chronic inflammation and fibrosis. Causes of atrophy may include decreased workload (e.g., stress-shielding by implants), diminished blood supply, and inadequate nutrition (e.g., fibrous capsules surrounding implants).

Local and systemic factors may play a role in the wound-healing response to biomaterials or implants. Local factors include the site (tissue or organ) of implantation, the adequacy of blood supply, and the potential for infection. Systemic factors may include nutrition, hematologic derangements, glucocortical steroids, and pre-existing diseases such as atherosclerosis, diabetes, and infection.

Finally, the implantation of biomaterials or medical devices may be best viewed at present from the perspective that the implant provides an impediment or hindrance to appropriate tissue or organ regeneration and healing. Given our current inability to control the sequence of events following injury in the implantation procedure, restitution of normal tissue structures with function is rare. Current studies directed toward developing a better understanding of the modification of the inflammatory response, stimuli providing for appropriate proliferation of permanent and stable cells, and the appropriate application of growth factors may provide keys to the control of inflammation, wound healing, and fibrous encapsulation of biomaterials.

Case Study | **Implant Toxicity**

In vivo implantation studies were carried out subcutaneously in rats and rabbits with naltrexone sustained release preparations that included placebo (polymer only) beads and naltrexone containing beads. Histopathological tissue reactions utilizing standard procedures and light microscopic evaluation to the respective preparations were determined at days 3, 7, 14, 21, and 28. The only significant histological finding in both rats and rabbits at any time period was the inflammation that occurred focally around the naltrexone containing beads. The focal inflammatory cell density in both rats and rabbits was higher for the naltrexone beads than for the placebo beads at days 14, 21, and 28, respectively. This difference in inflammatory response between naltrexone beads and placebo beads increased with increasing time of implantation. Considering the resolution of the inflammatory response for the placebo beads with implantation time in both rats and rabbits, it is suggested that the naltrexone drug itself is identified as the causative agent of the focal inflammation present surrounding the naltrexone beads in the implant sites (Yamaguchi & Anderson, 1992).

The important lesson from this case study is the necessary use of appropriate control materials. If no negative control, i.e., placebo polymer-only material, had been used, the polymer in the naltrexone containing beads also would have been considered as a causative agent of the extended inflammatory response. Similar inflammatory responses have been identified with drugs, polymer plasticizers and other additives, fabrication and manufacturing aids, and sterilization residuals. Each case presents its own unique factors in a risk assessment process necessary for determining safety (biocompatibility) and benefit versus risk in clinical application.

CHAPTER II.2.3 INNATE AND ADAPTIVE IMMUNITY: THE IMMUNE RESPONSE TO FOREIGN MATERIALS

Richard N. Mitchell

Department of Pathology, Brigham and Women's Hospital and Harvard Medical School, Boston, MA, USA

The goal of this chapter is to understand the general organization of the immune system (both specific and non-specific components), how the multiple different elements recognize apparent "invaders," and what effector responses are generated to eliminate perceived threats. "Immunology," as this subject is called, typically encompasses an entire course (with its own introductory text). Thus, an overview chapter can only paint with very broad brushstrokes what is a beautifully complex and intricate canvas of concepts regarding *innate* and *adaptive* immunity. The intent here is to provide a fundamental understanding of the body's response to the insertion of a foreign device, so that the reader can anticipate the issues that arise at the biomaterials–tissue interface. More extensive discussion of any aspect of the immune system

can be found in a number of excellent basic immunology texts (Coico et al., 2003; Abbas et al., 2007; Murphy et al., 2007), and from there to the primary literature (citations sprinkled throughout).

OVERVIEW

The immune system exists primarily to *defend the host against infectious organisms*. The general strategy begins with distinguishing "self" from "non-self." Once the immune system determines that something does not belong, the responding population proliferates, recruits additional cells, and generates mediators to neutralize and destroy the invader. In most cases, the immune response is so exquisitely specific that "self" is not perceived as foreign, and so well-regulated that host tissues do not sustain any "innocent bystander" injury in the process.

Unfortunately, this is not always the case. *Autoimmunity* (inappropriate immune responses to self) can be the source of chronic, debilitating, and life-threatening disease. Moreover, infections can occasionally lead to substantially greater tissue injury, and even death, occurring as a direct consequence of host immune responses. Finally, one of the most powerful triggers of the immune system is tissue injury. This makes good functional sense, since evolutionarily most cases of injury are either caused by microbial agents, or tissues damaged by another cause often becoming secondarily infected. Thus, although the system evolved primarily to identify and eliminate infectious agents, *noninfectious foreign materials* (including biomaterials in medical devices or the process by which they are implanted) can also elicit immune responses. Occasionally, these can result – even if uninfected – in severe tissue damage.

Consequently, a more inclusive definition of **immunity** is the body's *reaction to any substance* (microbes, proteins, polysaccharides, self, silastic implants, etc.) *regardless of the pathologic consequences*. In this chapter, we will initially focus on the physiologic pathways of immune activation in response to infectious agents, and describe the subsequent effector responses. We will then show how these same pathways can have pathologic outcomes, with special emphasis being given to the mechanisms underlying a response to a foreign biomaterial and/or implant.

An abbreviated glossary of terms is provided here to help the reader navigate the subsequent pages; other terms will be explained as they arise:

Adaptive immunity: Immune responses conferred by T lymphocytes or antibodies. The complete repertoire of T cells and antibodies in any given host has the capacity to bind uniquely to a huge number of antigens or distinct molecular configurations (a feature called *specificity*). Subsequent exposure to the same molecular configuration leads to more robust, faster responses (a feature called *memory*).

Allogeneic: Different than oneself, usually referring to the same molecule that has different configurations in different members of the same species (such as Major Histocompatibility Complex (MHC) molecules).

Allograft: Transplanted tissue or organ from a different donor, usually of the same species. A heart transplant from one human to another is called an *allograft*.

Antigen: A molecular configuration that is recognizable by the adaptive immune system. This molecular configuration can be a linear sequence of amino acids or a folded three-dimensional conformation; it can also be sugars, nucleotides or small molecules, or modified versions of any of these. Thus, a phosphorylated tyrosine in a short peptide can be *antigenic*. It is important to understand that antigens need not necessarily be foreign and can also be self-molecules. Moreover, just because a molecule is *antigenic* does not necessarily mean that it will elicit an immune response; issues related to the mode of antigen presentation, access, recognition, and tolerance induction all impact on host reactivity.

Autograft: Transplanted tissue or organ from the same individual. Thus explanted skin that is expanded in culture *ex vivo* and returned to the same donor is an *autograft*.

Immunogenic: Capable of eliciting a specific (adaptive) immune response.

Innate immunity: Immune responses conferred by macrophages and neutrophils, as well as complement and other proteins that recognize a discrete set of fixed motifs. There is a limited repertoire of *pathogen recognition receptors*, and responding cells have the same response with each contact (i.e., there is no *memory*).

Isograft: Transplanted tissue or organ from a different individual with identical genetic make-up. This is more typical in experimental situations involving *inbred animal strains*, but can occur in the setting of identical human twin donor and recipient pairs.

Syngeneic: The same as oneself, usually referring to genetic make-up, and more specifically in transplantation, identity for Major Histocompatibility Complex (MHC) molecule expression.

Xenogeneic: Differences across species. Thus, a porcine renal transplant into a baboon is a *xenograft*.

INNATE AND ADAPTIVE IMMUNITY

Defense against microbes is a two-stage process, beginning with a relatively non-specific *innate* response to "injury," followed by a targeted *adaptive* response more uniquely focused on the specific causal agent (Figure II.2.3.1; Table II.2.3.1).

COMPONENTS OF INNATE IMMUNITY

Also called "natural" or "native" immunity, this is the initial, rapid (hours) response to infection or injury; it is mediated by both cellular and protein constituents
FIGURE II.2.3.1 Innate and adaptive immunity. Although with a limited ability to recognize invading organisms, the relatively primitive (evolutionarily-speaking) components of innate immunity provide a very effective first line of defense against the vast majority of microbial infections. Adaptive immunity, with exquisite specificity to any particular infectious agent, develops sometime later after innate components have responded. Notably, the elements of innate immunity not only respond first, but direct subsequent adaptive immunity; in turn, elements of the adaptive immune responses orchestrate a more efficient and vigorous response by the components of innate immunity. The specific kinetics of the responses shown are approximations, and will vary depending on the inciting agent. (Figure reprinted with permission from Abbas et al. (2007), *Cellular and Molecular Immunology,* 6th ed.)

TABLE II.2.3.1	Components of Innate and Adaptive Immunity	
	Innate	**Adaptive**
Cellular and chemical barriers	Skin, mucosal epithelium, antimicrobial proteins (e.g., defensins, cathelicidins)	Lymphocytes in epithelia, secreted antibodies
Blood proteins	Complement, mannose-binding protein, C-reactive protein	Antibodies
Cells	Phagocytes (macrophages, neutrophils) natural killer cells	Lymphocytes

Adapted from Abbas et al., 2007.

(Figure II.2.3.2; Table II.2.3.2) (Medzhitov and Janeway, 2000; Medzhitov, 2007):

- physical and chemical barriers such as epithelia and anti-microbial proteins (e.g., *defensins*)
- phagocytic cells (neutrophils and macrophages) that ingest (*phagocytize*) and destroy microbes (see later)
- natural killer (NK) cells that kill virally-infected cells
- circulating proteins (complement, coagulation factors, C-reactive protein, etc.) that either directly insert pore-forming proteins in microbes that lead to cell death (e.g., complement, see below and also Chapter II.2.4), or that *opsonize* microbes (rendering them more "attractive" and readily phagocytized)
- cytokines: proteins secreted by cells of innate or adaptive immunity that regulate and coordinate the cellular response.

There is a bewildering plethora of cytokines with a wide array of activities influencing everything from endothelial cell function, to fibroblast synthetic activity, to lymphocyte differentiation (and more). Different cells will make different cohorts of cytokines, and any given cytokine can affect target cells differently. Multiple cytokines are in play in a particular location at any given time and can have synergistic or antagonistic effects on one another. Clearly, this is a fairly complex topic that warrants its own extensive treatment; for the purposes of this chapter, only selected cytokines will be discussed fleetingly, and the interested reader is encouraged to at least look at more comprehensive texts (Coico et al., 2003; Abbas et al., 2007; Murphy et al., 2007).

Innate immunity is an evolutionarily primitive system found even in invertebrates, and to some extent in plants (Litman et al., 2005); in most cases it can quite capably dispatch infections without the benefit of the lymphocytes or antibodies of adaptive immunity. Nevertheless, in cases where additional (and more specific) ammunition is required, the components of innate immunity are critical in mobilizing the subsequent lymphocyte and antibody effectors to clear invading microorganisms (see later).

RECOGNITION IN INNATE IMMUNITY

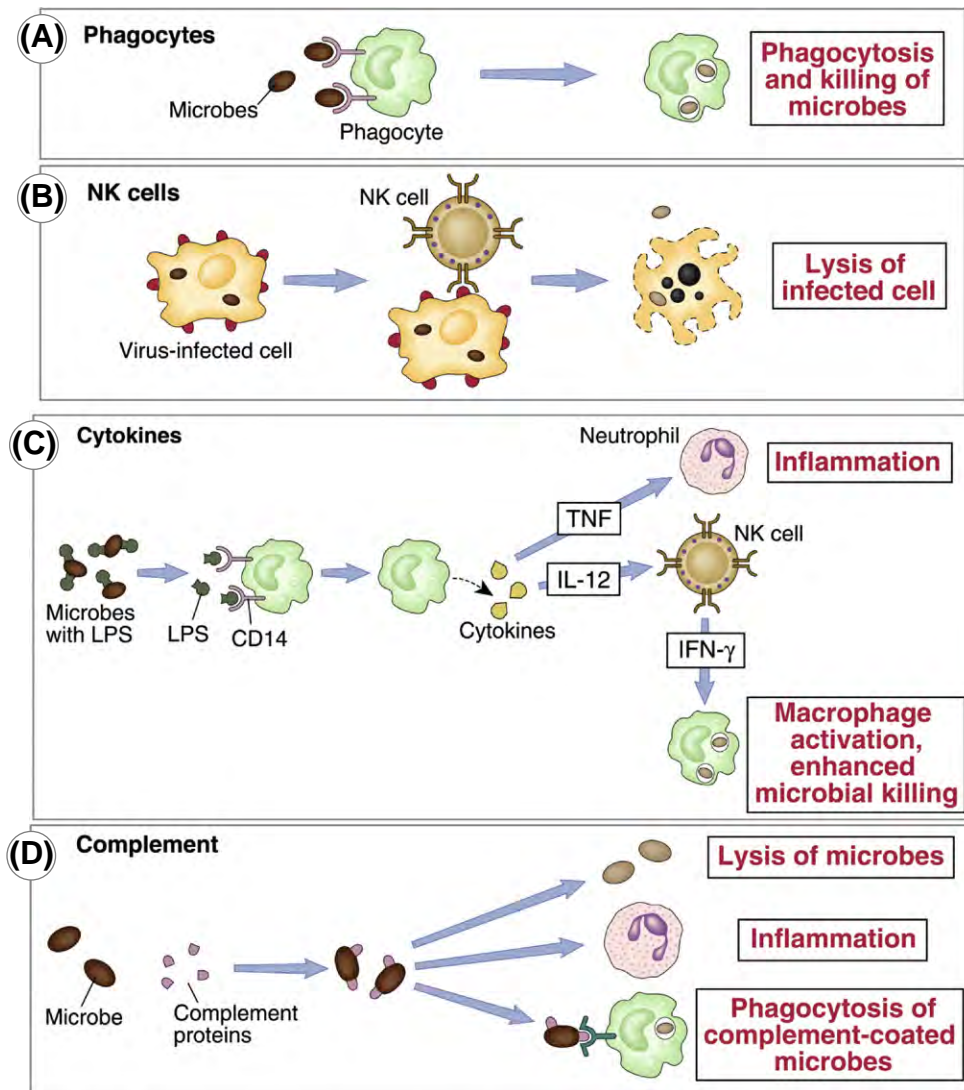
Innate immunity is triggered by molecular structures – called *pathogen-associated molecular patterns* (PAMPs) – that are common to groups of related microbes (Akira et al., 2006; Meylan et al., 2006; Palm and Medzhitov, 2009). These structures are characteristic of microbial pathogens and are not present on mammalian tissues;


FIGURE II.2.3.2 Basic mechanisms of innate immunity. The principal cellular components of innate immunity in defense against microbial infection include phagocytes and natural killer (NK) cells; the principal protein constituents are cytokines and complement (a proteolytic cascade of related proteins, see also Chapter II.2.4). (A) Phagocytes (*neutrophils* and *macrophages*) will directly bind, ingest, and intracellularly degrade various microbes; in addition, macrophages can secrete *cytokines* to recruit and activate additional inflammatory cell types (e.g., *neutrophils*) to sites of infection, and will help drive the activation of the T lymphocytes of the adaptive immune response. Note that macrophages may also require the production of cytokines (e.g., interferon-γ) by other cell types in order to be most active. (B) *Natural killer* (NK) cells directly lyse virally-infected cells, as well as cells coated with bound antibody; in addition, they are a source of cytokines (e.g., interferon-γ) that can activate macrophages and T lymphocytes. (C) *Cytokines* are proteins produced by cells of innate and adaptive immunity that locally and systemically affect inflammation. In the figure, macrophages have been activated by lipopolysaccharide (LPS, a constituent of bacterial cell walls) to secrete tumor necrosis factor (TNF) and interleukin-12 (IL-12). TNF results (among other activities) in the production, recruitment, and activation of neutrophils. IL-12 drives NK cell activation, resulting in the production of interferon-γ that in turn activates macrophages. (D) *Complement* proteins form pores in the membranes of microbes to cause direct cell lysis; in addition, complement components will incite inflammatory cell recruitment, and augment phagocytosis (*opsonize* microbes). (Figure reprinted with permission from Abbas et al. (2000), *Cellular and Molecular Immunology,* 4th ed.)

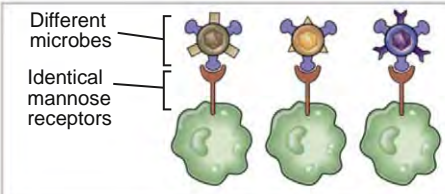
consequently, recognition via this pathway will distinguish self and non-self. Moreover, because the microbial products that are recognized are usually essential for the survival of the microorganism, they cannot be discarded or mutated. The *pattern recognition receptors* for pathogen-associated structures have a fairly limited diversity (numbering about 20 different types of molecules), and have no capacity to make fine distinctions between

different substances; each cell of the innate system also expresses essentially the same cohort of receptors (Figure II.2.3.3). The components of innate immunity have no functional memory; they react in essentially the same way each time they encounter the same infectious agent, so that there is no mechanism to allow more rapid or specific responses upon a second encounter with the same agent.


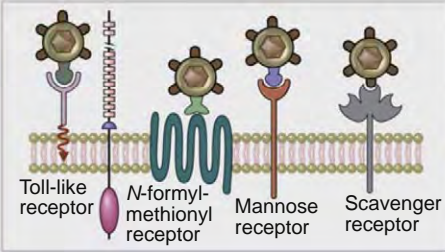


TABLE II.2.3.2	Components and Functions of Innate Immunity
Component	**Function**
Barriers	
Epithelium	Prevent microbial entry
Defensins, cathelicidins	Microbial killing
Intraepithelial leukocytes	Microbial killing
Circulating proteins	
Complement	Microbial killing, opsonization, leukocyte recruitment and activation
Mannose-binding protein	Opsonization, complement activation
C-reactive protein	Opsonization, complement activation
Coagulation factors	Thrombosis, leukocyte activation
Circulating cells	
Neutrophils	Early phagocytosis and killing
Macrophages	Subsequent, definitive phagocytosis and killing, cytokine production
Natural killer (NK) cells	Killing of infected cells, macrophage activation
Cytokines	
Chemokines	Leukocyte recruitment and activation
Interleukin-1 (IL-1) and tumor necrosis factor (TNF)	Leukocyte recruitment and activation, systemic inflammatory responses, endothelial activation, fibroblast activation
Interferon-α and -β	Anti-viral activity
Interferon-γ	Macrophage activation
Interleukin-12 (IL-12)	NK cell activation
Transforming growth factor-β (TGF-β)	Modulation of inflammation

Adapted from Abbas et al., 2000.

The PAMPs include:

- Double-stranded RNA found in cells containing replicating viruses. This induces cytokine production by infected cells leading to the destruction of the intracellular virus.
- Unmethylated CpG DNA sequences characteristic of bacterial infections. These induce autocrine macrophage activation and more effective intracellular killing of phagocytosed organisms.
- N-formylmethionine peptides from bacterial protein synthesis. Binding to receptors on neutrophils and macrophages causes *chemotaxis* (movement up a concentration gradient) and activation. Similar chemotaxis can be engendered by protein fragments released during complement activation, lipid mediators of inflammation, and chemokine proteins released by "stressed" cells.
- Mannose-rich oligosaccharides from bacterial or fungal cell walls. Engagement of receptors on macrophages induces phagocytosis; soluble mannose-binding protein in the plasma *opsonizes* or enhances phagocytosis of microbes bearing mannose.
- Bacterial or fungal wall oligosaccharides directly activate complement and induce either direct microbial

Innate immunity	
Specificity	For structures shared by classes of microbes ("pathogen-associated molecular patterns")
Receptors	Encoded in germline; limited diversity ("pattern recognition receptors")
Distribution of receptors	Nonclonal: identical receptors on all cells of the same lineage
Discrimination between self and nonself	Yes; host cells are not recognized or they may express molecules that prevent innate immune reactions

FIGURE II.2.3.3 Pattern recognition receptors. Cells of innate immunity have a limited repertoire of receptors for foreign molecular structures; the same receptors are present in all cells, and they can be on the cell surface (e.g., the mannose receptor or scavenger receptor) or cytosolic (e.g., Nod-like receptors). Circulating molecules such as C-reactive protein and mannose-binding protein are also pattern recognition receptors; their binding to microbes can trigger subsequent complement activation or phagocytosis. Because the number of different receptors is relatively small, they are all encoded in the germline. In comparison, the recognition of antigens by the adaptive immune system is specific and unique for each potential antigen (see Figure II.2.3.10); to achieve the potential diversity of roughly 10^{10} different specificities requires somatic recombination of different gene segments. (Figure reprinted with permission from Abbas et al. (2007), *Cellular and Molecular Immunology,* 6th ed.)

lysis or microbial coating with complement that markedly enhances phagocytosis.
- Phosphorylcholine in bacterial cell walls binds to circulating *C-reactive protein* (CRP; also called *pentraxin*); CRP induces opsonization and also activates complement.
- *Lipopolysaccharide* (LPS) from bacterial cell walls binds to circulating LPS-binding protein which in turn binds to CD14 surface molecules on macrophages, activating it through an associated *toll-like receptor* (TLR). The macrophages respond by producing a host of cytokines including tumor necrosis factor (TNF) and interleukin-12 that recruit and activate neutrophils and NK cells, respectively. By similar

pathways, LPS induces severe systemic responses that can culminate in *septic shock* (Hotchkiss and Karl, 2003).

Components of the innate system also recognize sites of injury, anticipating either that these may be primarily caused by infection or may be subject to subsequent infection. Heat shock proteins, altered membrane phospholipids, and urates released from the degradation of nucleic acids are among the danger signals released by necrotic tissues that can lead to macrophage activation (Kono and Rock, 2008). Moreover, components of the coagulation cascade, denatured connective tissue elements (such as might occur at sites of trauma), or denatured circulating proteins can also bind to macrophage cell surface receptors and induce activation. In particular, denatured proteins expressing previously cryptic RGD (arginine-glycine-aspartic acid) motifs that bind to cells via integrins can participate in the recruitment and activation of the cells of innate immunity. These become especially important in the context of the implantation of foreign bodies where otherwise minor trauma, and the presence of denatured proteins non-specifically adhering to "inert" surfaces, leads to macrophage activation (Tang and Eaton, 1999; Anderson et al., 2008).

EFFECTOR MECHANISMS OF INNATE IMMUNITY

As we will discuss in greater detail with the effector functions of adaptive immunity, the immune system needs to deal with pathogens lurking in two general environments – those that live in the extracellular space, and those that are intracellular. Extracellular pathogens are dispatched by a combination of direct killing (NK cells and complement) and ingestion (macrophages and neutrophils). Intracellular microbes (e.g., viruses) require either that the infected cell marshal its own defense mechanisms (such as interferon-α to reduce viral replication), or – failing that – be killed by NK cells (presumably taking down the virus at the same time), or even commit cellular suicide (*apoptosis*, see Chapter II.2.4).

Although the cells and proteins of innate immunity are primarily intended to clear infections, inappropriate, over-exuberant or poorly controlled effector activity can also result in host tissue injury. Once set into motion, activated proteases, macrophages and neutrophils, cytokines and other mediators will execute their functions somewhat blindly, and without regard to whether the "victim" is a microbe or self. This will continue until the initial stimulus abates or regulatory mechanisms supervene. Even business-as-usual for innate immunity can cause host cell death (i.e., the action of NK cells killing virally-infected cells), or loss of normal function (i.e., scarring of a tissue).

COMPLEMENT

Complement is an important protein constituent of the recognition and effector arms of innate immunity (Roozendaal and Carroll, 2006), as well as an important mediator of adaptive immune function (Carroll, 2004) (see also Chapter II.2.4). It is comprised of a number of related proteins (called C1–C9, plus other co-factors B, D, and properdin) that form a self-amplifying proteolytic cascade – in other words, complement components earlier in the cascade enzymatically cleave and activate subsequent components. Late products in the cascade have the ability to form pores in cell membranes and cause cell lysis (a complex of C5b, C6, C7, C8, and C9 called the membrane attack complex or MAC), while many of the proteolytic fragments generated along the way (e.g., C3b, C5a, C5b) have additional useful activities (Figure II.2.3.4 and below) (Walport, 2001a,b). Complement in the circulation is synthesized by the liver; in tissues, macrophages constitute the major source. The complement cascade can be activated (albeit somewhat inefficiently) by binding directly to microbial surfaces or it can be activated by circulating proteins of the innate system (e.g., mannose binding protein) that bind to microbial PAMPs. However, it can be efficiently activated (10^3–10^4 better than direct activation) by antibody first binding to a particular antigen (discussed later).

The complement cascade can induce microbial death and/or cellular injury by:

- direct *cytolysis* via C5b–9, the membrane-attack complex (MAC) punching holes in a cell's plasma membrane
- *opsonization* (via the C3b fragment), enhancing phagocytosis by macrophages and neutrophils
- C3a and C5a (so-called *anaphylotoxins*) mediate *increased vascular permeability* and smooth muscle relaxation (*vasodilation*), mainly by inducing mast cells to degranulate, releasing histamine from mast cells
- C5a also activates the lipoxygenase pathway in arachidonic acid catabolism, resulting in *increased leukotriene synthesis*
- C5a mediates *chemotaxis* of polymorphonuclear cells (PMN; neutrophils) and monocytes.

NEUTROPHILS AND MACROPHAGES: CELLS OF INNATE IMMUNITY

The primary function of all the various recruiting and activating factors is to attract phagocytes (literally, *eating cells*) into a site of infection to ingest and destroy microbes (Figure II.2.3.5). The primary responding cell in the earliest stages of injury or infection is the *neutrophil*, a short-lived (hours) phagocytic cell capable of ingesting and destroying microbes, as well as releasing a

FIGURE II.2.3.4 The major functions of complement. (A) Complement fragment C3b on the surface of microbes (or other cells) promotes phagocytosis (also called *opsonization*). (B) C3a and C5a proteolytic fragments increase vascular permeability and cause vasodilation by releasing histamine from mast cells; C5a is also chemotactic and enhances leukocyte binding to endothelium (shown here is a neutrophil), while stimulating leukotriene synthesis and the production of reactive oxygen species. (C) The C5b–C9 complex forms a membrane attack complex (MAC) that punches holes in microbes (and other cells) leading to osmotic rupture. (Figure reprinted with permission from Abbas et al. (2007), *Cellular and Molecular Immunology,* 6th ed.)

variety of potent proteases. Neutrophils are the characteristic cellular feature of *acute inflammation*; these cells are typically first on the scene following injury (within 6–12 hours), and this phase of the host response to damage lasts for roughly 24–48 hours. Thereafter, the host response enters a phase of *chronic inflammation*, characterized by *macrophage* infiltration. Macrophages generally constitute the second wave of inflammatory cells recruited to sites of injury; they are substantially longer-lived and can persist at sites of inflammation, making them the dominant effector cell type in late stage innate immunity.

Both neutrophils and macrophages are recruited to sites of injury by changes in *adhesion molecule* expression on endothelial cells in the vicinity, and by *chemotactic signals* (acting e.g., through G-protein coupled receptors on neutrophils) delivered by injured cells (i.e., chemokines), by complement components (generated during complement activation), and by microorganisms themselves. The successive waves of inflammatory cell recruitment (neutrophils followed by macrophages) are regulated by distinct subsets of adhesion molecules and chemokines with different specificities. The recruited phagocytic cells clear *opsonized* microorganisms, kill them with *reactive oxygen intermediates* (superoxide, oxyhalide molecules, nitric oxide, and hydrogen peroxide), and degrade them with proteases (Figure II.2.3.5) (Segal, 2005). However, release of such cytotoxic and degradative molecules into

the neighboring environment will also cause local tissue injury. Severe local injury due to excessive neutrophil activation results in an *abscess* with total destruction of parenchyma and stroma. C3b opsonization can also lead *indirectly* to tissue injury; large, non-ingestible cells or tissue can result in "frustrated phagocytosis" by neutrophils or macrophages. The attempted intracellular lysis results instead in the extracellular release of proteases and toxic oxygen metabolites (neutrophils), and/or cytokines (macrophages).

In addition, activated macrophages (and neutrophils to a more limited extent) release a variety of cytokines and other factors that can have both local and systemic effects (Figure II.2.3.6):

- *tumor necrosis factor* (TNF) recruits and activates neutrophils
- *interleukin-12* (IL-12) activates T cells and NK cells
- activates coagulation pathways (*tissue factor* elaboration)
- secretes angiogenic factors (new blood vessel formation)
- fibroblast activating factors (e.g., *platelet-derived growth factor*; PDGF) that induce fibroblast proliferation
- *transforming growth factor-β* (TGF-β) expression increases extracellular matrix (ECM) synthesis and down-regulates many aspects of inflammation
- matrix metalloproteinases that remodel the ECM.
FIGURE II.2.3.5 Phagocytosis and intracellular destruction of microorganisms. Surface receptors on phagocytes can either bind microbes directly, or may bind opsonized microbes (for example, Mac-1 integrin binds microorganisms after they have been coated with complement proteins). After binding to one (or more) of the variety of surface receptors, microbes are internalized into phagosomes, which subsequently fuse with intracellular lysosomes to form *phagolysosomes*. Following fusion, *reactive oxygen species* (ROS, e.g., superoxide and hydrogen peroxide) and *nitric oxide* (NO) are selectively generated within the phagolysosomes; these reactive oxygen species kill the microbes largely via free radical injury; the lysosomes also contain a wealth of catabolic enzymes that digest the microbes. (Figure reprinted with permission from Abbas et al. (2007), *Cellular and Molecular Immunology,* 6th ed.)

Thus (as can be inferred from the preceding descriptions), in the setting of prolonged activation, innate immunity ultimately drives tissue fibrosis and scarring (Figure II.2.3.6) (Henry and Garner, 2003; Martin and Leibovich, 2005). This clearly has ramifications in the setting of inserted foreign bodies intended to persist for many years.

ADAPTIVE IMMUNITY

Adaptive immunity (also called "specific" or "acquired" immunity) is comprised of cellular (*lymphocyte*) and humoral circulating protein (*antibody*) mediators; temporally, these will follow innate immunity in recognizing and resolving infections.

Adaptive immunity is more evolutionarily advanced than its innate counterpart, and is first seen in phylogenic development with the jawed vertebrates. Lymphocytes have the cardinal features of: (1) exquisite *specificity* for distinct macromolecules; and (2) *memory*, the latter being the ability to respond more vigorously to subsequent exposures to the same microorganism. The substances that induce specific immune responses are called *antigens*. These can be proteins, carbohydrates, lipids or other small molecules; they can also be self or non-self, microbial or non-infectious. The cells and antibodies of adaptive immunity each have the theoretical capacity to

recognize 10^9–10^{11} distinct antigenic determinants. Since each cell of the adaptive immune system can only recognize and respond to a single antigenic determinant, the impressive diversity of the system requires an equally large number of different cells. Given that the human body only has 10^{13}–10^{14} cells in *total*, there obviously cannot be more than a few tens to hundreds of cells of any one specificity at baseline. This has important ramifications in eliminating an infection; the small numbers of cells that can initially recognize an invader will not be up to the task on their own. Rather, following recognition of a pathogen, the responding cell(s) must clonally expand, as well as recruit an additional army of additional effectors (see later).

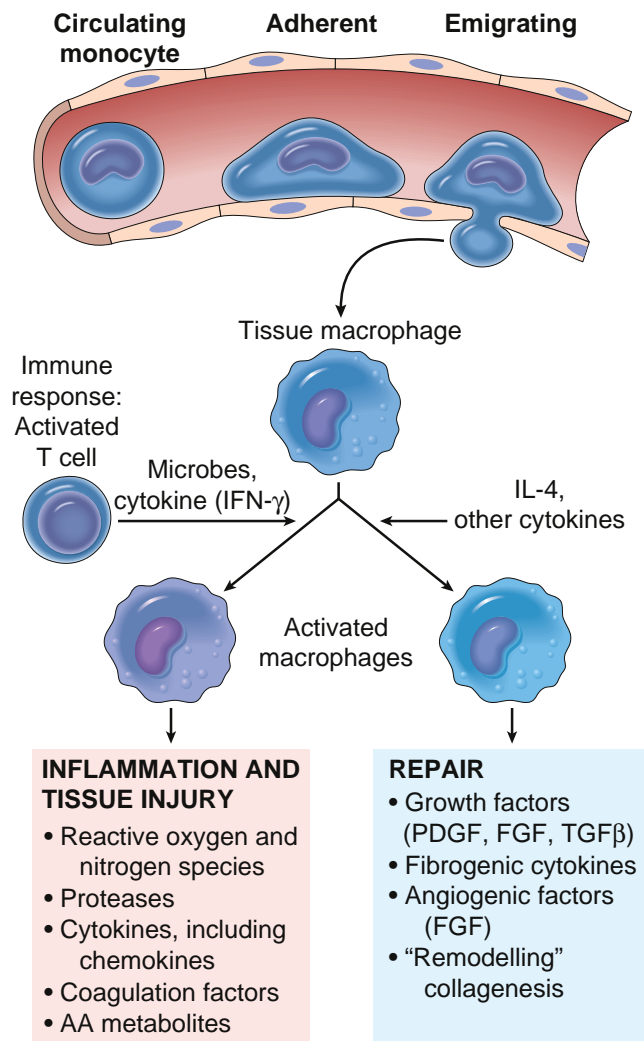
The other important concept is that the elements of adaptive immunity (like innate immunity) need to be able to respond to two basic infectious challenges – pathogens that are extracellular and those that reside within cells. As we will see when we look at effector mechanisms, the humoral and cellular elements complement each other in this enterprise – and also take advantage of the innate immune system. Thus, not only does the initial innate response influence the strength and nature of adaptive immune responses (e.g., whether antibodies or cellular mediators are produced), but the same effectors of innate immunity are also conscripted by adaptive immunity to clear infectious agents.


FIGURE II.2.3.6 Macrophage recruitment and local tissue effects after activation. Circulating monocytes are recruited to sites of tissue injury by changes in adhesion molecule expression on endothelial cells in the vicinity of the injury, as well as by *chemotactic signals* (chemokines) delivered by injured cells or neutrophils, by complement components (generated during complement activation), and by microorganisms themselves. Once monocytes emigrate from the vasculature, they become tissue *macrophages*. Macrophages are activated by interferon-γ (IFN-γ) from various sources – including activated NK cells or T cells – or by non-immunologic stimuli such as endotoxin. Activated macrophages aggressively phagocytize microorganisms and necrotic debris, and also secrete a number of eicosanoids (arachadonic acid or AA metabolites such as prostglandins and leukotrienes), reactive oxygen intermediates, and proteases that can sterilize the local environment, but will also incite tissue injury. Overall, the cytokine mediators produced by activated macrophages will tend to induce fibrosis (scar). (Figure reprinted with permission from Kumar et al. (2007), *Robbins Basic Pathology,* 8th ed.)

COMPONENTS OF ADAPTIVE IMMUNITY

The principal components of adaptive immunity are:

- *B lymphocytes* (also called B cells), responsible for making antibodies
- Antibodies: proteins secreted by B lymphocytes with specificity for a specific antigen

- *T lymphocytes* (also called T cells) are functionally divided into *helper T cells* (*Th cells*) that produce *cytokines* to orchestrate the activity of other cell types, and *cytotoxic T cells* (*Tc cells*) that kill selected target cells. Th cells express a cell surface protein designated CD4 ("CD" stands for "cluster of differentiation;" there are over 300 different CD molecules marking various cell types), and are therefore also generically referred to as CD4+ ("CD4-positive") cells. Tc cells express CD8 and may be referred to as CD8+ cells. All T cells also express CD3 (actually a complex of γ, δ, and ε protein chains) that is involved in T cell activation.
- Cytokines: many of the cytokines produced by T cells are also secreted by cells of innate immunity; several, however, are relatively T-cell specific, and are involved in modulating immune responses or in effector cell differentiation. Although typically synthesized by Th cells, Tc cells and even B cells can be sources of these protein mediators.

Not all the possible adaptive responses are elicited concurrently in response to a particular pathogen. In some cases, it may be more advantageous to induce primarily a B cell antibody-mediated response; in other circumstances, a cytotoxic T cell response may be most warranted. Moreover, the adaptive immune response needs to be tightly regulated to prevent ongoing tissue injury, and therefore a negative-regulatory feedback must exist. The regulation of which of these potential outcomes occurs derives from the helper T cells, and more specifically the nature of the cytokines that they produce.

ANTIBODIES

The generic antibody (also called an immunoglobulin or Ig) is a vaguely "Y"-shaped structure composed of four disulfide-linked proteins – two smaller (25 kD) light chains and two larger (50 kD) heavy chains (Figure II.2.3.7); for any given Ig the light chains on each arm of the "Y" are identical, as are the heavy chains. The N-termini of both chains have genetically (germline and somatic) variable domains (designated V_L and V_H in Figure II.2.3.7) that are the source of the tremendous antigen-binding diversity of the total antibody repertoire. The C-termini of each chain are genetically homogeneous for any given Ig, and are designated as constant domains (C_L or C_H). The two "arms" of the Ig are each composed of heavy and light chains, and are called the Fab or antigen-binding *fragment* of the molecule; the "body" of the Ig is composed of paired heavy chain constant regions, and is called the Fc portion of the molecule (for historical reasons, the "c" stands for "crystallizable" but "constant" is equally applicable).

Once antigen is bound to the Fab portion of an Ig (more on this recognition step later), the protein undergoes a conformational change in the Fc region that allows the antibody to activate complement, or to attach to one

Secreted IgG
FIGURE II.2.3.7 Generic antibody structure. Antibodies typically adopt a "Y"-shaped structure composed of two light chains and two heavy chains. The N-termini are the antigen binding fragments (Fab) and contain variable regions that allow the necessary diversity. The C-termini are constant for any particular immunoglobulin isotype (called Fc fragment). Antigen binding to the Fab area causes a conformational change in the Fc region that allows the antibody to activate complement, or to attach to Fc receptors. (Figure reprinted with permission from Abbas et al. (2007), *Cellular and Molecular Immunology,* 6th ed.)

of a variety of surface-bound Fc receptors on different cell types (e.g., macrophages, neutrophils, B cells, NK cells, etc.). Based on the structure of the heavy chain constant regions, antibodies occur as five major isotypes, IgA, IgD, IgE, IgG, and IgM; IgA has two subtypes and IgG has four. IgG is the most common of the antibody isotypes. All except IgD (which is only found in the membrane-bound form on naïve B cells) exist as circulating *and* B cell membrane-bound forms; the membrane-bound form of Ig is the antigen receptor for B cells and engagement drives B cell activation and differentiation. The different antibody isotypes are specialized to activate specific effector mechanisms (e.g., phagocytosis, complement activation or NK cell killing); we will also specifically revisit one (IgE) in detail later when we discuss allergy.

T LYMPHOCYTES

As we will see, T cells can participate in the adaptive immune response and elimination of extracellular pathogens. However, they are also the main mechanism by which *intracellular pathogens* (e.g., viruses and certain bacteria) – not accessible to phagocytes and circulating antibodies – can be targeted (see later).

In broad strokes, the helper *versus* cytotoxic T cell dichotomy addresses the requirements of defending against extracellular (Th) and intracellular (Tc) pathogens;

having said that, Th cells are also involved in immunity to intracellular microbes, and help drive the Tc response.

Th CELLS

CD4+ T helper cells achieve their function by secreting specific cytokines to stimulate the proliferation and differentiation of other cells. Two basic subsets of Th cells are classically described, called Th1 and Th2; each produce a handful of specific cytokines that will induce a different general immunologic response (Moss et al., 2004; Pulendran, 2004). Once a Th1- or a Th2-specific reaction is established against a particular pathogen, the responding population tends to maintain that pattern of differentiation. This is accomplished because Th1 cell cytokines promotes further Th1 differentiation and inhibits Th2 cells, and *vice versa*.

Generally speaking, Th1 cells are induced by intracellular pathogens that infect or activate macrophages and NK cells. The Th1 cytokines include interferon-γ (IFN-γ, the signature cytokine of Th1 cells), lymphotoxin, and tumor necrosis factor (TNF); these promote phagocyte-mediated defenses, especially against intracellular microbes (Figure II.2.3.8).

Th2 cells are induced by extracellular pathogens (especially worms) and certain polymeric antigens (*allergens*). The cardinal cytokines of this subset include interleukin (IL)-4, -5, and -10; these promote IgE and mast cell/eosinophil activation (and inhibit macrophage activation); these pathways putatively evolved to deal with helminthic infections that are not effectively eradicated by macrophages and NK cells (Figure II.2.3.9); however, Th2 differentiation also underlies many allergic responses.

More recently, a unique third Th subset has been described, generated in the context of TGF-β and IL-6 or IL-1 cytokine production; IFNγ and IL-4 actually inhibit the expansion of this subset. These are called Th17 cells because they characteristically produce IL-17, a cytokine that, in association with IL-22 and other mediators, induces neutrophil-rich inflammatory responses (Korn et al., 2007, 2009). Since Th17 cells can potentially significantly contribute to tissue damage in the setting of local inflammation (due to the neutrophil-rich infiltrates), and because they are lineage-related to *anti-inflammatory regulatory T cells*, the pathways controlling their differentiation and activation are a focus of intense research.

Tc CELLS

CD8+ cytotoxic T lymphocytes (also called CTL) are effector cells that function to eliminate intracellular infections. The strategy is similar to NK cells, in that infected cells are induced to undergo apoptotic cell death. However, there is greater specificity of these cells *versus* NK cells, and CD8+ T cells also have the attribute of memory – subsequent exposure to the same antigen results in a faster, more robust secondary response.

FIGURE II.2.3.8 Th1 cell functions. Differentiation of CD4+ T cells into Th1 cells results in the production of interferon-γ (IFN-γ), lymphotoxin (LT), and tumor necrosis factor (TNF). IFN-γ drives macrophage activation increasing their capacity to kill intracellular microbes; IFN-γ also induces the differentiation of B cells to produce antibodies that are better at opsonization and complement activation (e.g., IgG). LT and TNF function to recruit and activate additional inflammatory cells at a site of injury; shown here is a neutrophil, but macrophages are also involved. The net result of the Th1 cytokines is the enhancement of phagocyte-mediated defenses against infection; this involves both extracellular pathogens and those that can persist within non-activated macrophages. (Figure reprinted with permission from Abbas et al. (2007), *Cellular and Molecular Immunology,* 6th ed.)
FIGURE II.2.3.9 Th2 cell functions. Differentiation of CD4+ T cells into Th2 cells results in the production of interleukin (IL)-4, IL-5, and Il-10. IL-4 drives the differentiation of B cells to produce antibody isotypes that either bind well to mast cell Fc receptors (IgE) or bind antigen but do not activate complement or induce opsonization (e.g., IgG4); IL-4 (along with IL-10) also modulates macrophage activation status, antagonizing the actions of IFN-γ. IL-5 is involved in the recruitment and activation of eosinophils that are potent mediators, particularly against helminths. The net effect is to augment responses that will be effective against large extracellular pathogens such as worms. (Figure reprinted with permission from Abbas et al. (2007), *Cellular and Molecular Immunology,* 6th ed.)
RECOGNITION IN ADAPTIVE IMMUNITY

B cells, antibodies, and T cells can potentially recognize 10^{11} different antigenic specificities; this is achieved by somatic mutation and rearrangement of limited numbers of germline sequences, but the genetic details are beyond the scope of this discussion. However, *what* these different components of adaptive immunity recognize *is* important. Thus, B cell receptor and secretory Ig binds to *intact* antigens, although the antigen need not necessarily be in its native conformation (Figure II.2.3.10). In comparison, T cells cannot recognize antigens until they have been degraded into smaller fragments and associated with self *histocompatibility molecules* on antigen presenting cells (Figure II.2.3.11). The following sections will elaborate on these basic tenets.

B CELL AND ANTIBODY RECOGNITION

As shown in Figure II.2.3.10, antibodies can bind to conformations that depend on some combination of primary, secondary, and tertiary structure. Antigens can be linear sequences of amino acids or sugars, or can be composed of elements that are juxtaposed by virtue of
FIGURE II.2.3.10 Antigen–antibody binding. (A) Antibodies can bind to three-dimensional conformations of proteins with determinants (or epitopes) comprised of multiple amino acids (or other small molecules) from different loops; denaturation of the protein will result in loss of antibody binding to this particular kind of antigen. (B) Antibodies can bind to primary sequences of amino acids (or other small molecules) that can be present in the native molecule or be occult – that is, hidden within the folded tertiary structure. Denaturation of the protein will not affect antibody binding to this antigenic structure, and indeed, may expose previous inaccessible determinants. (C) Antibodies can bind to determinants that are only exposed or created by proteolytic degradation. (Figure reprinted with permission from Abbas et al. (2007), *Cellular and Molecular Immunology,* 6th ed.)

three-dimensional folding; the same molecule can have multiple different potential antigenic *epitopes* (also called *determinants*). The nature of the epitopes is significant because in native, intact molecules, certain determinants may be internally folded and inaccessible to antibody. However, denaturation or proteolytic cleavage (e.g., at sites of tissue injury) can conceivably expose previously occult epitopes, and allow antibody binding and subsequent effector activity.

T CELL RECOGNITION

T cells have surface receptors that cannot "see" intact antigens, but rather only recognize proteolytically digested antigen fragments ("processed antigen") presented on the surface of certain host cells in association with *major histocompatibility complex* molecules (Figure II.2.3.11). For Th cells, these accessory or *antigen-presenting cells* (APC) include macrophages, one of the major cell types of the innate immune response; in this manner, the innate system can influence adaptive immune responses.

Histocompatibility molecules are grouped together on chromosomes into clusters generically called *Major Histocompatibility Complexes* or MHC. Proteins of this complex are denoted as "histocompatibility" molecules because they were first recognized as the major determining element in tissue ("histo") compatibility in organ transplantation. When inbred strains of animals shared the same MHC determinants, tissue grafts could be transplanted with relative impunity; if the donor

and host were MHC-disparate, grafts were said to be histo-incompatible, and the organs ultimately failed by a process called *rejection*. This is due to the host "interpreting" foreign MHC as a potential pathogen, and then engaging the full fury of the various immune effectors. Tissue incompatibility clearly has ramifications in the assembly and implantation of devices prepared from non-autologous (*autologous* = self) viable human cells; in most cases, these cells will express host-incompatible MHC and trigger specific immune responses (see discussion at the end of this chapter).

In humans, this MHC cluster occurs on chromosome 6, and the molecules are called *Human Leukocyte Antigens* or HLA. There are two general categories of MHC molecules, called *class I* and *class II*. In humans, MHC class I (MHC I) molecules are called HLA-A, -B, and -C; MHC class II (MHC II) molecules are called HLA-DP, -DQ, and -DR. In the general population, each type of HLA molecule (e.g., HLA-A, HLA-B, etc.) has hundreds of possible different alleles. Thus, outside of haplo-identical twins, it is virtually impossible to have a perfect match among all the possible class I and class II MHC combinations.

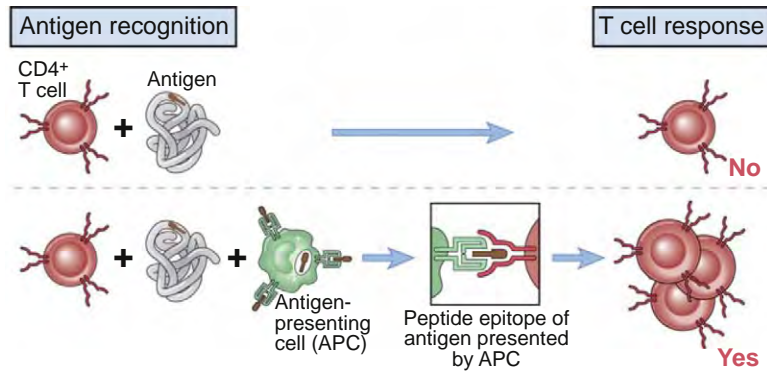
The MHC class I molecules present peptide fragments derived from intracellular antigens to CD8+ Tc cells; in this manner, intracellular infections can be detected and the infected cell can be killed. In comparison, MHC class II molecules present peptide fragments from extracellular antigens to CD4+ Th cells. In this pathway, the APC is not killed; rather, extracellular infections are detected by the Th cells that subsequently release cytokines to recruit


FIGURE II.2.3.11 T cells cannot recognize unprocessed antigen. Intact protein antigens will not bind the T cell receptor (TCR). Instead, the TCR can only bind to smaller (10–15 amino acids in length) polypeptides, and then only when complexed to self major histocompatibility (MHC) molecules. Thus, exogenous antigen must be taken up by antigen presenting cells (APC), delivered to intracellular endosomes for proteolytic processing, and the resulting fragments joined to newly synthesized MHC before being displayed on the cell surface. (Figure reprinted with permission from Abbas et al. (2007), *Cellular and Molecular Immunology,* 6th ed.)
FIGURE II.2.3.12 Presentation of extracellular versus intracellular antigens to cytotoxic versus helper T cells. (A) Extracellular antigens (e.g., from extracellular bacteria) are ingested and degraded by macrophages or other antigen presenting cells (APC, including B cells as shown, and dendritic cells), and are then presented in association with MHC II surface molecules to CD4+ helper T cells. Helper T cells activated in this manner lead to macrophage and/or B cell activation that will generate effector functions to more proficiently eliminate the extracellular microbe. (B) Intracellular antigens (e.g., from intracellular viruses) are degraded and presented in association with MHC I surface molecules to CD8+ cytotoxic T cells. Killer T cells activated in this manner then lyse (kill) the cell that originally harbored the intracellular pathogen. (Figure reprinted with permission from Abbas et al. (2007), *Cellular and Molecular Immunology,* 6th ed.)

additional effectors (Figure II.2.3.12) (Klein and Sato, 2000a,b).

T cell recognition of antigen fragments bound to MHC molecules results in *T cell activation*. This recognition step is accomplished by T cell receptors (*TCR*) on the surface of T lymphocytes interacting with the CD3 complex and additional molecules to transduce a signal to the nucleus, resulting in selected gene transcription (Kuhns et al., 2006). Complete activation of T cells also requires additional interplay between other molecules (called *co-stimulator molecules*) on the surface of T cells and antigen presenting cells of the innate immune system. *Incomplete activation* of T cells (i.e., without the co-stimulators) may result in *anergy* (no response) to the antigen (Peter and Warnatz, 2005) (Figure II.2.3.13).

EFFECTOR PATHWAYS IN ADAPTIVE IMMUNITY

Depending on the nature of the inciting pathogen and the preceding innate response, different elements of adaptive immunity will be engaged; as a result, different effector functions will also obviously be involved.

Figure II.2.3.14 depicts schematically how antibodies can be marshaled to defend against pathogens. Binding to microbial surface receptor molecules can prevent access to target cells; similarly, binding to circulating toxins can serve to block their activity. Antibody opsonization will increase the phagocytosis (and intracellular destruction) of pathogens, as well as facilitate NK cell killing; both of these happen through the interaction
FIGURE II.2.3.13 Role of co-stimulation in T cell activation. (A) Antigen presenting cells (APC) that are not activated will express few or no co-stimulator molecules. In that setting, even though the APC display processed antigen in the appropriate MHC context, the T cells will fail to respond. Indeed, such co-stimulator-poor APC presentation may result in a long-term *anergy* (inability to respond) to particular antigens. (B) Microbes and cytokines produced during innate immune responses activate APC to make co-stimulator molecules (such as B7, shown here) that will result in "complete" activation of the T cells. Activated APC also produce additional cytokines such as interleukin-12 (IL-12) that also participate in stimulating T cell activation and differentiation. (Figure reprinted with permission from Abbas et al. (2007), *Cellular and Molecular Immunology,* 6th ed.)
FIGURE II.2.3.14 Effector functions of antibodies. From top to bottom, antibodies can: bind pathogens (or their toxins) and neutralize them (i.e., prevent their attachment or entrance into host cells); bind to microbes and induce opsonization (ingestion by Fc-receptor-bearing phagocytes); bind to microbes and direct natural killer (NK) cell cytolysis; and activate complement to cause direct lysis, opsonization, or additional inflammatory cell recruitment. (Figure reprinted with permission from Abbas et al. (2007), *Cellular and Molecular Immunology,* 6th ed.)

of bound Ig and cells bearing specific Fc receptors. Finally, antibody binding also efficiently activates complement with subsequent MAC formation, additional opsonization, and the augmented recruitment and activation of innate inflammatory cells. The downside to these activities occurs when antibody is bound – either specifically or non-specifically – to self tissues: the full array of antibody-mediated effector functions are then brought to bear and can cause substantial injury (see later).

FIGURE II.2.3.15 Effector functions of T lymphocytes. (A) When CD4+ T cells encounter antigenic fragments presented appropriately by antigen presenting cells (APC) they respond by the production of cytokines that will drive subsequent effector cell recruitment and activation (see also Figures II.2.3.8 and II.2.3.9); shown here is the response of a Th1 cell producing cytokines that increase macrophage activation and inflammatory cell recruitment. CD8+ T cells can also be a source of cytokines that affect the local inflammatory response. (B) Recognition of processed antigen on target cells by CD8+ cytotoxic T lymphocytes (CTL) typically results in the directed CTL killing of the target. (Figure reprinted with permission from Abbas et al. (2007), *Cellular and Molecular Immunology,* 6th ed.)
In comparison, Figure II.2.3.15 shows the general effector mechanism of cell-mediated immunity. Recognition of infected cells by CD8+ CTL leads to their cytolysis. Antigen recognition by CD4+ Th cells leads to cytokine production that recruits and activates additional effector cells to more efficiently carry out their microbicidal activities. The down-side to CTL is that inappropriate targeting of host cells (*autoimmunity*) will cause their destruction; even the appropriate targeting of infected cells can wreak substantial havoc if the infection is widespread. If Th activity is not well-regulated or if Th cells begin recognizing self-antigens, then exuberant innate immunity activation will also cause significant tissue damage and scarring (see also below).

OVERVIEW: IMMUNITY TO PATHOGENS

Recall that following pathogen recognition – and depending on the location of the invader – effector functions need to be appropriately coordinated to neutralize and/or destroy either intracellular or extracellular microbes.

Extracellular pathogens: Innate immunity deals with an extracellular challenge largely through the activation of complement and phagocytosis, as well as by being effective at recruiting additional cells that can do more of the same. Antibodies are the major components of adaptive immunity that contribute to the battle against extracellular pathogens; they do so by binding and neutralizing microbes or their toxins, and by highly effectively inducing complement activation and phagocytosis. Th cells can also participate by secreting cytokines that recruit neutrophils, and by recruiting and activating macrophages, augmenting their phagocytic capacity to kill.

Intracellular pathogens: Intracellular pathogens trigger the involvement of innate immunity through interferon-α and -β production, by the activation of macrophages to more effectively kill ingested pathogens, and by the

activation of NK cells to kill infected cells. On the adaptive immune side, CTL kill virally infected cells, and Th cells mediate highly effective macrophage activation. As it turns out, the most important immune response to intracellular bacteria – as well as large extracellular pathogens such as fungi – involves T cell-driven activation of macrophages to more avidly ingest microbes, and produce more reactive oxygen species (ROS) and nitric oxide. If these activities fail to completely eliminate the inciting pathogens, ongoing recruitment and activation of macrophages leads to the formation of a *granuloma*, a collection of activated macrophages that effectively form a vigilant ring of inflammation to wall off the invader (Figure II.2.3.16). A potentially negative outcome of persistent granulomatous inflammation is tissue injury due to compression atrophy by the expanding sphere of activated macrophages, and by the surrounding fibrosis these activated cells will engender.

PATHOLOGY ASSOCIATED WITH IMMUNE RESPONSES

The chapter began with the assertion that innate and adaptive immune systems exist primarily to defend the human body against infection. Unfortunately, immune activation leads not only to the activation of host defenses and production of protective Ig and T cells, but also occasionally to the development of responses that may potentially damage host tissues.

Both innate and adaptive immune responses are implicated in causing disease states. As described above, in the setting of prolonged activation, macrophages will ultimately mediate tissue fibrosis and scarring. Indeed, the response to foreign materials – causing much of the local pathology associated with implants – is attributable to such persistent macrophage activation. Moreover, certain bacterial toxins (e.g., LPS) non-specifically stimulate macrophages (as well as other cell types), and

(A)
(B)
FIGURE II.2.3.16 Granulomatous inflammation. Schematic illustration of the events that lead to granuloma formation in response to large or persistent antigens. Antigen-presenting cells (APC) of the innate immune system process antigen and subsequently present it to CD4+ helper Th1 cells; the APC also provide interleukin-12 (IL-12) and other cytokines to drive T cell activation. Activated T cells, in turn, elaborate cytokines such as tumor necrosis factor (TNF) that will recruit inflammatory cells, and interferon-γ (IFN-γ) that will induce the activation of the recruited cells, in particular macrophages (large, activated macrophages are also called "epithelioid cells"). These cytokines can also induce macrophage fusion to generate multinucleated "giant cells." If the antigen is not effectively eliminated, the constant cycle of T cell and macrophage activation leads to the accumulation of an aggregate of activated cells. Activated macrophages will also elaborate mediators that result in tissue injury, as well as cytokines resulting in fibroblast activation and tissue fibrosis (see also Figure II.2.3.6). The end-result is loss of tissue function and scar formation. In the case of "inert" foreign bodies, absorption of host proteins onto the foreign body surface with subsequent denaturation and modification can lead to direct macrophage activation via the receptors involved in innate immunity. (Figure reprinted with permission from Kumar et al. (2005), *Robbins and Cotran Pathologic Basis of Disease,* 7th ed.)

result in systemic pathology from excessive cytokine elaboration.

By having increased specificity, adaptive immunity might be expected to lead overall to less secondary damage. Normally, an exquisite system of checks and balances optimizes the antigen-specific eradication of infecting organisms with only trivial innocent bystander injury. However, certain types of infection (e.g., virus) may require destroying host tissues to eliminate the disease (see Figure II.2.3.15B). Still other types of infections (e.g., tuberculosis) may only be controlled by a granulomatous response that walls off the offending agent with activated macrophages and scar, often at the expense of adjacent normal parenchyma (similar to foreign body responses).

Even when the host response to an infectious agent is a specific antibody, the antibody may occasionally cross-react with self-antigens (e.g., anti-cardiac antibodies following certain streptococcal infections, causing rheumatic heart disease). Immune complexes composed of specific antibody and circulating antigens can also precipitate at inappropriate sites (see below) and cause injury by activation of the complement cascade or by facilitating binding of neutrophils and macrophages (e.g., in a disease such as post-streptococcal glomerulonephritis). If the antibody made in response to a particular antigen is IgE, any subsequent response to that antigen will be immediate hypersensitivity (*allergy*), potentially culminating in *anaphylaxis*. Finally, not all antigens that attract the attention of lymphocytes are exogenous and infectious. The immune system occasionally (but fortunately, rarely), loses tolerance for endogenous self-antigens, which results in *autoimmune disease*.

All of these forms of immune-mediated injury are collectively denoted as **hypersensitivity reactions**. As discussed below and in Chapter II.2.4, they are traditionally subdivided into four types; three are variations on antibody (Ig)-mediated injury, while the fourth is T cell-mediated:

- IgE-mediated "immediate-type hypersensitivity" (allergy and anaphylaxis)
- antibody against circulating or tissue antigens
- antigen–antibody (immune complex)-mediated
- T cell-mediated (CTL and "delayed-type hypersensitivity" (DTH)).

PATHOGENESIS OF ANTIBODY-MEDIATED DISEASE

Antibodies involved in immune-mediated diseases can bind to antigenic determinants that are *intrinsic* to a particular tissue or cell, or which are *exogenous* and have been passively adsorbed (e.g., certain antibiotics or foreign proteins). Regardless of what they recognize or how they got there, antibodies bound to the surfaces of cells or to extracellular matrix cause injury by certain basic mechanisms.

IgE-Mediated (Immediate) Hypersensitivity (Kay, 2001a,b)

Mast cells and *basophils* express surface *Fc-receptors* that can bind the Fc constant region of immunoglobulin E (IgE). When circulating IgE binds to the Fc-receptors on these cells and is then cross-linked by specific *allergen* (typically a polyvalent antigen), this induces mast cell or basophil *degranulation* with release of preformed mediators, as well as synthesis of other potent effectors (Figure II.2.3.17):

- **pre-formed mediators**: amines such as histamine and serotonin (cause vasodilation and increased vascular permeability)
- **arachidonate, lipid, and cytokine mediators synthesized *de novo***:
  - prostaglandins (e.g., PGD_2) that can affect vessel and airway contraction, and vascular permeability
  - leukotrienes (e.g., LTC_4, LTD_4, and LTE_4) that are exceptional vasoconstrictors and bronchoconstrictors
  - platelet activating factor (PAF), a rapidly catabolized phospholipid derivative that increases vascular permeability and diminishes vascular smooth muscle tone; it also causes bronchoconstriction
  - cytokines, in particular TNF (recruits sequential waves of neutrophils and monocytes), and IL-4 (interleukin 4, induces local epithelial and macrophage expression of chemokines like eotaxin, and also increases endothelial adhesion molecule expression: the combined effect will be to recruit *eosinophils*).

In most vascular beds, the overall result is vasodilation and increased vascular permeability, with a variable infiltrate classically predominated by *eosinophils*. Eosinophils are an inflammatory cell type classically associated with parasitic infections (especially worms), as well as with allergies; they contain specific granules with potent cytotoxic activity for a variety of cell types. In the respiratory tree, the net result of an allergic stimulus is increased mucus secretion and bronchoconstriction.

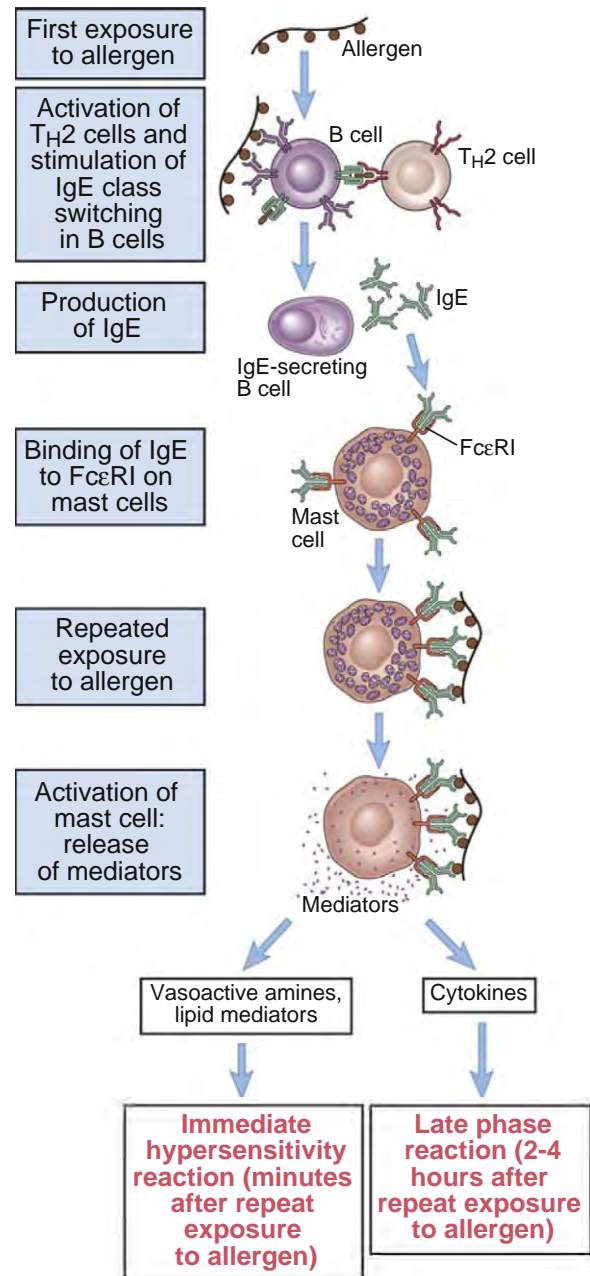
The nature of the symptoms in any particular instance will depend on the portal of antigen entry, e.g., cutaneous (hives and rash, although these can also occur with inhaled or ingested allergen), inhaled (wheezing, airway congestion), ingested (diarrhea, cramping) or systemic (hypotension). The associated diseases range from the merely annoying (seasonal rhinitis or "hay fever") to debilitating (asthma) to life-threatening (*anaphylaxis*). In the last case, systemic vasodilation leads to hypotension (low blood pressure), increased vascular permeability leads to increased tissue edema – most problematic around the larynx – and bronchoconstriction narrows the airways and impedes airflow; the combination can culminate in fatal anaphylactic shock.


FIGURE II.2.3.17 Events in immediate-type hypersensitivity (allergy). Immediate hypersensitivity is initiated following contact with a specific *allergen* (typically a polyvalent antigen). For unclear reasons, allergens induce in a susceptible host a predominant Th2 response that ultimately promotes an IgE antibody response. IgE binds to mast cells in tissues (and *basophils* in the circulation, not shown) via specific IgE Fc receptors. Subsequent encounter with the relevant allergen results in IgE-Fc receptor cross-linking that activates the mast cells and basophils. Once activated, the cells release granules containing pre-formed mediators (e.g., histamine) causing the characteristic immediate response (vasodilation and increased vascular permeability, with bronchoconstriction). Over the next few hours (up to 24 hours), these activated cells will also synthesize and release additional mediators (prostaglandins, leukotrienes, platelet activating factor, and cytokines; see text). (Figure reprinted with permission from Abbas et al. (2007), *Cellular and Molecular Immunology*, 6th ed.)

Antibody Bound to Cell Surfaces or Fixed Tissue Antigens

Antibodies bound to either intrinsic or extrinsic tissue antigens can induce tissue injury by promoting complement activation, inducing opsonization, or by interacting with important cell surface molecules (Figure II.2.3.18):

- **Complement**: Recall that complement may induce injury either by direct cytolysis via the C5b–9 membrane-attack complex (MAC) punching holes in a cell's plasma membrane, or by opsonization (via the C3b fragment), enhancing phagocytosis by macrophages and neutrophils. In addition to direct cell killing, local activation of the complement cascade will result in the generation of complement fragments such as C3a and C5a that alter vascular tone and permeability (Figure II.2.3.4 and Chapter II.2.4).
- **Opsonization**: Antibody on the surface of cells will promote phagocytosis by cells bearing Fc receptors.

- On *circulating blood cells*, bound complement may directly mediate cell lysis; in addition, bound antibody and opsonizing complement fragments induce efficient uptake and destruction by cells of the splenic and hepatic mononuclear phagocyte system.
- Antibody binding in conjunction with C3b opsonization can also lead *indirectly* to tissue injury. Large, non-phagocytosable cells or tissue may promote "frustrated phagocytosis" by neutrophils or macrophages; the attempted intracellular lysis results instead in the extracellular release of proteases and toxic oxygen metabolites (Figures II.2.3.18B and II.2.3.19A).
- **Antibody binding to cell receptors**: Binding of antibodies to certain receptors can induce pathology even without causing tissue injury. For example, in the case of *Grave's disease*, antibodies bind to the thyroid stimulating hormone (TSH) receptor on thyroid epithelial cells and mimic authentic TSH ligand interaction; the result is autonomous stimulation of

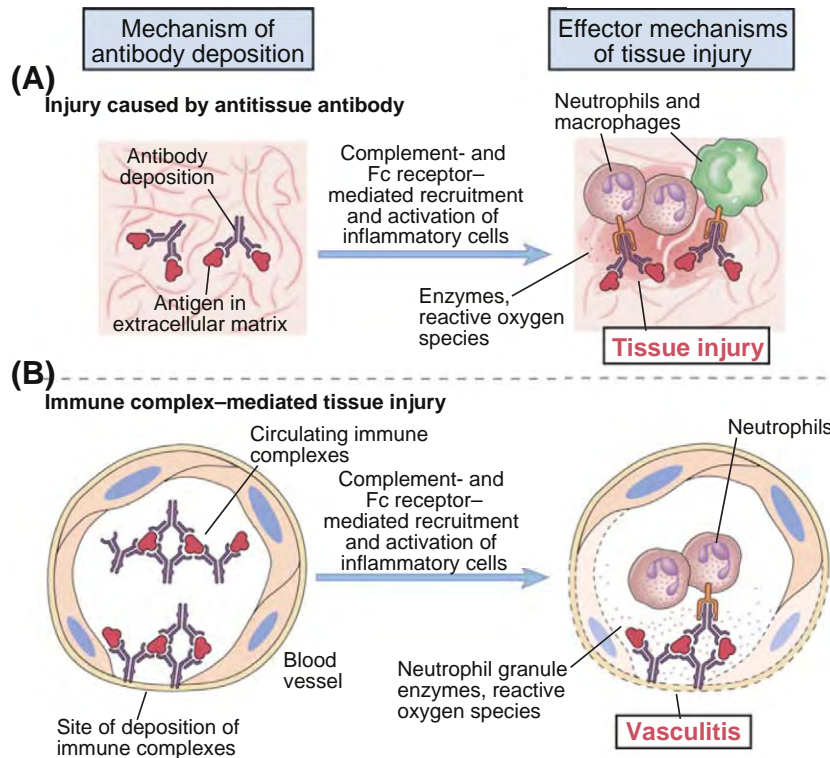
FIGURE II.2.3.18 Effector mechanisms in antibody-mediated disease. (A) Antibodies, with or without complement activation, will opsonize cells leading to phagocytosis and destruction. (B) Antibodies, and secondarily-generated complement fragments bound to large non-phagocytosable cells or tissues will recruit inflammatory cells such as neutrophils and macrophages. If these inflammatory cells cannot completely ingest the target, *frustrated phagocytosis* will result in the release of lysosomal contents and reactive oxygen intermediates into the tissues with subsequent cellular and matrix damage. (C) Antibodies can also elicit pathology without causing tissue damage. In the panel on the left, antibodies to the thyroid stimulating hormone (TSH) receptor can mimic authentic TSH to cause hyperstimulation of the thyroid (*Grave's disease*). In the panel on the right, antibodies to the acetylcholine (ACh) receptor at the neuromuscular junction can block normal ACh stimulation of muscle contraction leading to weakness (*myasthenia gravis*). (Figure reprinted with permission from Abbas et al. (2007), *Cellular and Molecular Immunology,* 6th ed.)


FIGURE II.2.3.19 Antibody-mediated pathology. (A) Direct binding of antibodies to tissue antigens will cause tissue injury by recruiting inflammatory cells and activating complement. (B) Circulating antigen–antibody complexes (also called *immune complexes*) can deposit in vessels and tissues also leading to inflammatory cell recruitment and complement activation. The classic vascular lesion in the setting of immune complex deposition is called *vasculitis*; such vessel inflammation will typically lead to thrombosis and tissue ischemia. (Figure reprinted with permission from Abbas et al. (2007), *Cellular and Molecular Immunology,* 6th ed.)

the gland with hyperthyroidism. Alternatively, antibodies that bind to the acetylcholine receptor at the nerve–muscle synapse can block binding of acetylcholine and result in the weakness seen in the disease *myasthenia gravis* (Figure II.2.3.18C).

Immune Complex (IC)-Mediated Injury

In many circumstances, circulating antigen and antibody combine to form insoluble aggregates called immune complexes (IC). These are usually efficiently cleared by macrophages in the spleen and liver, but can occasionally deposit in certain vascular beds. Once IC are deposited, the mechanism of injury is basically the same, regardless of where or for what reason IC have accumulated; the major sources of pathology are *complement activation* (see above) and *interactions with cells bearing Fc receptors* (e.g., neutrophils and macrophages) (Figure II.2.3.19B).

PATHOGENESIS OF T CELL-MEDIATED DISEASE

T cell-mediated responses are of two general types (Figure II.2.3.20):

T cell-mediated cytolysis: In CTL-mediated reactions, CD8+ T lymphocytes recognize specific antigen in association with class I MHC and induce direct cytolysis.

CTL-mediated cytolysis is *highly specific*, without significant "innocent bystander" injury.

Delayed-type hypersensitivity (DTH): In the case of cell-mediated immunity, CD4+ helper T cells recognize specific antigen in the context of class II MHC, and respond by producing a variety of soluble *antigen-nonspecific* cytokines. These soluble mediators induce further T lymphocyte recruitment and proliferation, and attract and activate *antigen non-specific* macrophages and other inflammatory cells; at the site of a CD4+ T cell-mediated response, the vast majority (greater than 90%) of newly recruited cells is not specific for the original inciting antigen. Although tightly regulated, the relatively non-specific effector components of cell-mediated immunity (cytokines and activated macrophages) are largely responsible for the injury seen in *delayed-type hypersensitivity* (DTH).

In comparison to CTL, cytokine-mediated immunity may ultimately develop an antigen non-specific component; that is, after the initial antigen-specific T cell response, the recruited antigen non-specific T cells and macrophages can cause significant bystander injury. Macrophages, in particular, are an important component of the recruited inflammatory cells in DTH, and mediate much of the subsequent immune effector responses. By virtue of the release of reactive oxygen intermediates, prostaglandins, lysosomal enzymes, and cytokines such as TNF (which, in turn, have potent effects, e.g., on the

(B)

T cell-mediated cytolysis
FIGURE II.2.3.20 Mechanisms of T cell-mediated disease. (A) In *delayed-type hypersensitivity* responses, T cells (typically CD4+ helper T cells) respond to tissue or cellular antigens by secreting cytokines that stimulate inflammation, and ultimately promote tissue injury (APC, antigen-presenting cell). (B) In some diseases, CD8+ cytotoxic T cells directly kill tissue cells. (Figure reprinted with permission from Abbas et al. (2007), *Cellular and Molecular Immunology,* 6th ed.)

synthetic function of fibroblasts, lymphocytes, and endothelium), activated macrophages can potentially wreak significant havoc.

Recall also that *granulomas* (nodules of granulomatous inflammation) are the characteristic response of the immune system to large, persistent, and/or non-degradable antigens. Besides antigenic stimulation, direct macrophage activation can also occur by binding to denatured or modified host proteins that have adsorbed on the surfaces of the foreign materials via the receptors used for innate immunity (Tang and Eaton, 1999; Anderson et al., 2008). Thus, foreign objects (such as implanted devices) can frequently elicit a granulomatous response that becomes a significant impediment to local tissue integrity and normal function. With persistent stimulation, for example, chronic macrophage activation leads to cytokines that culminate in a surrounding fibrosis. Injury associated with granulomas is also due to displacement, compression, and necrosis of adjacent healthy tissue. Granulomas associated with a variety of "autoimmune disorders" such as *temporal arteritis*, *Crohn's disease*, and *Wegener's granulomatosis* presumably reflect diseases with persistent antigen stimulation or a heightened DTH response to specific self-antigens.

IMMUNE RESPONSES TO TRANSPLANTED TISSUES, BIOMATERIALS, AND SYNTHETIC SUBSTANCES

When foreign cells or organs are transplanted into a new host, the histocompatibility proteins on the cell surfaces of the graft are recognized by the components of adaptive immunity as being non-self. Note that, except for minor genetic polymorphisms, most of the structural proteins

and other molecular components in a graft are nearly identical to those that the host will also express (e.g., the contractile proteins in heart muscle, the collagenous extracellular matrix, the usual housekeeping proteins, etc.). The MHC molecules, however, are distinctly different between most humans (except identical twins) and will elicit helper and cytotoxic T cell activation, as well as B cell antibody production. Clearly, once these pathways have been activated, the usual physiologic effector mechanisms (direct cell killing, complement activation, phagocytosis, cytokine elaboration, etc.) will be brought to bear on the graft, and can effect its destruction. Besides direct killing of parenchymal cells (e.g., myocytes in a heart, hepatocytes in the liver, tubular epithelial cells in the kidney), the adaptive immune system and its various effectors also attack the graft vasculature, and can cause graft failure by vessel thrombosis and ischemia. Even in the absence of infarction or direct killing, cytokines and other inflammatory mediators such as prostaglandins and reactive oxygen species can cause significant graft dysfunction (i.e., a loss of myocardial contractility) that may be as clinically deleterious as frank injury.

Again, although components of innate immunity are recruited and activated in the process of graft damage, the initial recognition step and the driving force for *transplant rejection* is via the cells of adaptive immunity (you are also referred to the basic immunology texts for excellent overviews of the rejection phenomenon: Coico et al., 2003; Abbas et al., 2007; Murphy et al., 2007). To prevent or reverse such rejection requires a substantial armamentarium of immunosuppressive agents (e.g., cytotoxic drugs or agents such as *cyclosporine*), which put the recipient at risk of infections and malignancies.

The point is emphasized here because in the *immunologic* sense, synthetic devices are *not* rejected; moreover,

if *non-cellular* biomaterials are derived from the same species (or sufficiently-related species so that there are no major antigenic differences in, e.g., collagen proteins), such engineered devices are also *not rejected*. Such devices do not elicit specific (adaptive) immune responses, and therefore will not have antibodies or lymphocytes that recognize the materials and cannot therefore drive the overall response. As a corollary statement, simply finding inflammatory cells (and even T cells and antibodies) does not in any way prove that the response is "rejection;" such elements will accrue at any site of injury in a non-specific way. For example, recall that some 90% of T cells in a DTH response are not antigen-specific, but are non-specifically recruited to the site of injury.

This is much more than a semantic point, in that synthetic or biomaterial device functions or longevity are not likely to benefit from specific immunosuppression. Of course, if a device incorporates viable cells in its manufacture (e.g., endothelial cells lining a vascular conduit), those *cells* will express MHC proteins, and will elicit adaptive immune responses that materially contribute to device failure. In that instance, it will either be necessary to engineer such devices using cells derived from the individual who will eventually receive the implant (making them an *autograft*), or to rely on long-term immunosuppression as is routinely required for organ transplants.

It should also be emphasized that although synthetic and biomaterials are *not* rejected in the immunologic sense, components of the immune system (particularly innate immunity) *can* contribute to device dysfunction and failure. In particular, and as described above, non-specific activation of macrophages and complement will lead to local tissue damage via proteolysis, accumulation of other inflammatory cells, and/or cytokine elaboration; in most cases, with an ongoing, persistent innate response to a device that cannot be eliminated, fibrous scar tissue will also occur in and around the implant (Anderson et al., 2008).

Thus, synthetic materials and biomaterials can have failure modes that are attributable to activation of the immune system (particularly innate immunity). An "inert" silastic-clad breast prosthesis, for example, can accumulate dense scar tissue around it (secondary to persistent macrophage activation) that is not aesthetically ideal. Similarly a titanium hip prosthesis can induce ongoing macrophage activation that in the bone will lead to cytokine production that ultimately drives bone resorption and prosthesis loosening. In some individuals, idiosyncratic IL-4 or IL-10 cytokine responses to stent grafts may underlie local aneurysm formation and "stent creep" associated with intravascular stenting (Levisay et al., 2008). Heavy metal hypersensitivities (e.g., to nickel) occur because the metal complexes with host proteins, creating a modified version of "self;" when these modified proteins are then processed and presented as part of normal immune surveillance, Th-mediated DTH responses can occur with associated inflammation

and swelling. Notably, heavy metal hypersensitivities are localized to the immediate vicinity of the implant. While administration of steroids in any of these settings may have some beneficial effect by limiting macrophage activation, they may also induce complications since steroids (among other side-effects) also inhibit healing and increase susceptibility to infections.

Finally, there is a body of controversial work suggesting that denatured host proteins non-specifically adhering on device surfaces or complexing with fragmented and circulating implant materials can potentially break host self-tolerance for these molecules. In this hypothetical model, novel previously occult antigenic determinants become exposed (see Figure II.2.3.10). These can then elicit antibodies that can bind to damaged (or even normal) versions of the same or cross-reactive proteins, and cause local tissue damage or subsequent immune complex formation and deposition. Although the experiments that purport to support this are problematic, and the evidence for such a pathologic pathway is weak, such models are frequently invoked to explain new onset autoimmune disease following device implantation (or following infection, vaccine, or other external trigger) (Molina and Shoenfeld, 2005; Wolfram et al., 2008).

In deciding whether a particular response to biomaterials is driven by immune mechanisms, it may be well to consider applying an immunologic variant of Koch's Postulates. In the late 19th century, a microbiologist named Robert Koch proposed a set of objective criteria to be used in demonstrating that a particular organism was responsible for a particular disease (actually used the first time in proving the pathogenic basis of anthrax!). Koch's Postulates basically state that the presumed microbe should be routinely recovered from the pathologic lesions of the human host; should be culturable in a pure form and cause the same disease when injected into a new host; and should be recoverable again in a pure form from the secondary host.

Thus, Koch's *Immunologic* Postulates would provide a more rigorous basis for implicating host immunity in biomaterial failures or subsequent host pathology:

- antigen-specific elements (antibodies or cells) should be directly associated with the pathology of interest
- antibodies or cells from affected hosts should cause the same pathology by transfer into an appropriate secondary host
- adoptively transferred antibodies or cells should be recoverable (or at least demonstrable) in the pathology of the secondary host.

CHAPTER II.2.4 THE COMPLEMENT SYSTEM

Richard J. Johnson
Baxter Healthcare Corporation, Round Lake, IL, USA

As discussed in the previous chapter, the immune system acts to protect each of us from the constant exposure to pathogenic agents such as bacteria, fungi, viruses, and cancerous cells that pose a threat to our lives. The sheer multitude of structures that the immune system must recognize, differentiate from "self," and mount an effective response against, has driven the evolution of this system into a complex network of proteins, cells, and distinct organs. An immune response to any foreign element involves all of these components, acting in concert, to defend the host from intrusion. Historically, the immune system has been viewed from two perspectives: cellular or humoral. This is a somewhat subjective distinction, since most humoral components (such as antibodies, complement components, and cytokines) are made by the various cells of the immune system and, in turn, often function to regulate the activity of the multiple types of immune cells. The focus of this chapter will be on the basic biochemistry and pathobiology of the complement system, a critical element of the innate immune response, and its relevance to biomaterials research and development.

INTRODUCTION

Complement is a term devised by Paul Ehrlich to refer to plasma components that were known to be necessary for antibody-mediated bactericidal activity (Ross, 1986). We now know that the complement system is composed of more than 30 distinct plasma- and membrane-bound proteins involving three separate pathways: classical; alternative; and the lectin pathway. The complement system directly and indirectly contributes to both innate inflammatory reactions, as well as cellular (i.e., adaptive) immune responses. This array of effector functions is due

TABLE II.2.4.1	Complement Activities
Activity	**Complement Protein**
Identification/opsonization of pathogens	C3, C4
Recruitment/activation of inflammatory cells	C3a, C5a
Lysis of pathogens/ cytotoxicity	C5b-9 (MAC)
Clearing immune complexes and apoptotic cells	C1q, C3b, C4b
Augment cellular immune responses (T and B cells)	C3, C4, C3a, C5a, DAF(CD55)

TABLE II.2.4.2	Proteins of the Classical Pathway of Complement		
Protein	**Molecular Weight**	**Subunits**	**Plasma Concentration (ug/ml)**
C1q	410,000	6A, 6B, 6C	70
C1r	85,000	1	35
C1s	85,000	1	35
C2	102,000	1	25
C4	200,000	α, β, γ	600

C4bp	570,000	8	230

to the activity of a number of complement components and their receptors on various cells. These activities are summarized in Table II.2.4.1, along with the responsible complement protein(s). One of the principal functions of complement is to serve as a primative self–non-self discriminatory defense system. This is accomplished by coating a foreign material with complement fragments and recruiting phagocytic cells that attempt to destroy and digest the "intruder." Although the system evolved to protect the host from the invasion of adventitious pathogens, the nonspecific and spontaneous nature of the alternative pathway permits activation by various biomaterial surfaces. Because complement activation can follow three distinct but interacting pathways, the various ways of activating the cascade will be outlined separately below.

> One of the principal functions of complement is to serve as a primative self–non-self discriminatory defense system. This is accomplished by coating a foreign material with complement fragments and recruiting phagocytic cells that attempt to destroy and digest the "intruder." Although the system evolved to protect the host from the invasion of adventitious pathogens, the nonspecific and spontaneous nature of the alternative pathway permits activation by various biomaterial surfaces.

CLASSICAL PATHWAY

The classical pathway (CP) is activated primarily by immune complexes (ICs) composed of antigen and specific antibody, although other proteins, such as C-Reactive Protein, Serum Amyloid Protein, and amyloid fibrils, as well as apoptotic bodies can also activate the CP (Bohlson et al., 2007; Cooper, 1985). The proteins of this pathway are C1, C2, C4, C1 inhibitor (C1-Inh), and C4 binding protein (C4bp). Some of their basic characteristics are summarized in Table II.2.4.2.

Complement activation by the CP is illustrated in Figure II.2.4.1. This system is an example of an enzyme cascade in which each step in the series, from initiation to the final product, involves enzymatic reactions (in this case, proteolytic cleavage reactions) that result in some degree of amplification. Research with knock-out mice

FIGURE II.2.4.1 Complement activation by the classical pathway (CP). Upon binding to the Fc region of an immune complex, C1 is activated and cleaves C4, exposing its thioester, which permits covalent attachment of C4b to the activating surface. C2 is cleaved, producing C2b, which binds to C4b to form the CP C3 convertase. C2b is a serine protease that specifically acts on C3 to generate C3b and C3a. The lectin pathway is also illustrated. MBL recognizes certain sugar residues (mannose, N-Acetylglucosamine) on the surface of an activator (bacteria). MASP-1 appears to activate MASP-2, which then cleaves both C4 and C2 of the CP, generating the CP C3 convertase.

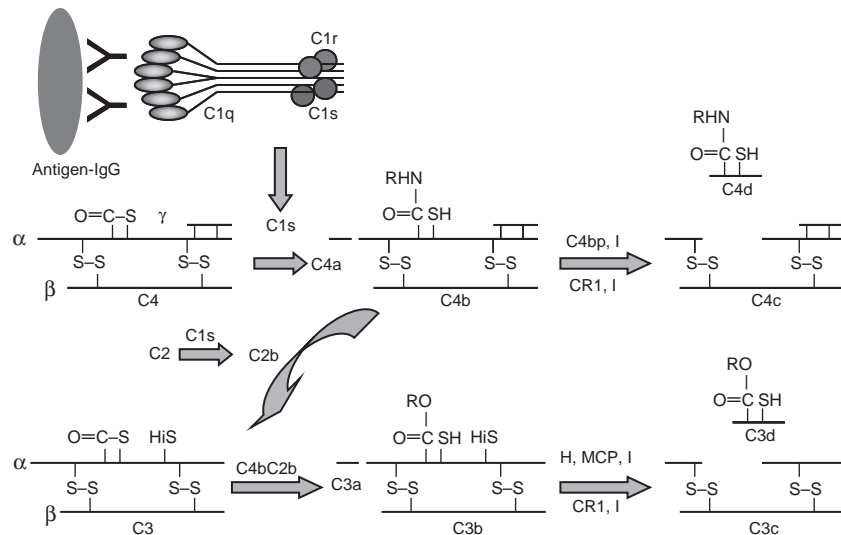
(mice deficient in C1q, C2, C4 or IgG) has shown that the CP is in a state of continuous low level activation, essentially primed to react vigorously in the presence of an IC (Manderson et al., 2001). When an IC forms, the cascade is initiated when C1 binds to the Fc portion of an antigen–antibody complex. The C1 protein is composed of three different types of subunits called C1q, C1r, and C1s (Figure II.2.4.2). One end of C1q binds to an IC formed between an antigen and one molecule of (pentameric) immunoglobulin (Ig) M or several closely spaced IgG molecules. This interaction is believed to produce a conformational change in the C1q that results in activation (i.e., autocatalytic proteolysis) of the two C1r and then the two C1s subunits bound to the other end of the C1q protein. Both C1r and C1s are zymogen serine proteases that are bound to the C1q in a calcium-dependent manner that is inhibited by calcium chelators such as citrate or EDTA. The proteolysis of C1s completes the


FIGURE II.2.4.2 Schematic illustration of C4 and C3 protein structures. O=C–S represents the reactive thioester bond that permits covalent attachment to surface nucleophiles (hydroxyl or amino groups). The pattern of proteolytic degradation and the resulting fragments are also shown. Although factor I is the relevant *in vivo* protease, some of these same fragments can be generated with trypsin, plasmin, and thrombin.

activation of C1, which then proceeds to act on the next proteins in the cascade, C4 and C2.

C4 is composed of three separate chains, α, β, and γ (Figure II.2.4.2), bound together by disulfide bonds. Activated C1s cleaves C4 near the amino terminus of the αchain, yielding a 77-amino acid polypeptide called C4a and a much larger (190,000 Da) C4b fragment. The C4 protein contains a unique structural element called a thioester (Figure II.2.4.2), that has only been detected in two other plasma proteins, α 2-macroglobulin and C3. Upon cleavage of C4, the buried thioester becomes exposed and available to react with a surface containing amino or hydroxyl moieties. About 5% of the C4b molecules produced react through the thioester, and become covalently attached to the surface. This represents the first amplification step in the pathway, since each molecule of C1 produces a number of surface-bound C4b sites.

The C4b protein, attached to the surface, acts as a receptor for C2. After binding to C4b, C2 becomes a substrate for C1s. Cleavage of C2 yields two fragments; a smaller C2a portion diffuses into the plasma, while the larger C2b remains bound to the C4b. The C2b protein is another serine protease that, in association with C4b, represents the classical pathway C3/C5 convertase.

As the name implies, the function of the C4b•C2b complex is to bind and cleave C3. The C3 protein sits at the juncture of the classical and alternative pathways, and represents one of the critical control points. Cleavage of C3 by C2b yields a 9000 Da C3a fragment and a 175,000 Dalton C3b fragment that is very similar to C4b in both structure and function. Cleavage of C3 produces a conformational change in the C3b protein that results in exposure of its thioester group (Figure II.2.4.2). Condensation with surface nucleophiles (such as carbohydrates) results in covalent attachment of 10–15% of the C3b to the surface of the activator. This is the second amplification step in the sequence, since as many as 200 molecules of C3b can become attached to the surface surrounding every C4b•C2b complex. Eventually one of the C3b molecules reacts with a site on the C4b protein, creating a C3b–C4b•C2b complex that acts as a C5 convertase (Figure II.2.4.3). Recent investigations have demonstrated that the C4b•C2b complex can also cleave C5 at very low rates, but that the addition of C3b to the complex increases the affinity for (and thus the turnover of) C5 by approximately 1000-fold (Rawal et al., 2008).

In contrast to C3, which can be cleaved in the fluid phase (see later discussion), proteolytic activation of C5 occurs only after it is bound to the C3b portion of the C5 convertase on the surface of an activator (e.g., the immune complex). Like C3, C5 is also cleaved by C2b to produce fragments designated C5a (16,000 Da) and C5b (170,000 Da). The C5b molecule combines with the proteins of the terminal components to form the membrane attack complex described later. C5a is a potent inflammatory mediator, and is responsible for many of the adverse reactions normally attributed to complement activation in various clinical settings.

LECTIN PATHWAY

In the 1990s, investigators working with a protein called mannose binding lectin (MBL) discovered a third pathway that leads to complement activation (Matsushita, 1996). This scheme is called the lectin pathway, and is composed of lectins like MBL and three MBL-associated serine proteases or MASPs (Table II.2.4.3). MBL is an acute phase protein, so its concentration in plasma increases substantially during an infection. MBL binds to terminal mannose, N-acetyl-glucosamine, and N-acetyl-mannosamine residues in complex carbohydrate structures. MBL has long been recognized as an opsonin, i.e., a protein that
FIGURE II.2.4.3 Conversion of C5 produces C5a and C5b, the latter leads to formation of the membrane attack complex (MAC). C5a binds to receptors on a variety of cells and results in numerous activities. C5b, formed by the CP, lectin or the AP, binds C6 and C7 to form a complex that associates with the plasma membrane. This C5b67 multimer then binds C8, which results in the formation of a small hole in the lipid bilayer that allows small molecules to pass through. Association of multiple C9 proteins enlarges the pore, leading to loss of membrane integrity and cell death.

TABLE II.2.4.3	Proteins of the Lectin Pathway of Complement		
Protein	**Molecular Weight**	**Subunits**	**Plasma Concentration (ug/ml)**
MBL	270–650,000	18	1–3
MASP-1	93,000	2 (H,L)	6
MASP-2	76,000	2 (H,L)	0.4
MASP-3	110,000	2 (H,L)	

facilitates phagocytosis of bacteria. Low concentrations of MBL in children are associated with recurrent bacterial infections. MBL is similar in structure to C1q, having an amino terminal domain with a collagen-like structure that binds the MASP proteins, followed by a globular carbohydrate recognition domain (CDR) that binds to sugar residues. There are three MASP proteins, called MASP-1, MASP-2, and MASP-3, which are very similar in structure to C1r and C1s (Wong et al., 1999). MASP-2 can cleave both C4 and C2, forming a CP C3 convertase (Figure II.2.4.1), while MASP-1 can target C2 and MASP-2 to help accelerate convertase formation (Takahashi et al., 2008).

ALTERNATIVE PATHWAY

The alternative pathway (AP) was originally discovered in the early 1950s by Pillemer et al. (1954). Pillemer's group studied the ability of a yeast cell wall preparation, called zymosan, to consume C3 without affecting the amount of C1, C2 or C4. A new protein, called properdin, was

isolated and implicated in initiating C3 activation independent of the CP. This new scheme was called the properdin pathway. However, this work fell into disrepute when it was realized that plasma contains natural antibodies against zymosan, which implied CP involvement in Pillemer's experiments. The pathway was rediscovered in the late 1960s with the study of complement activation by bacterial lipopolysaccharide, and with the discovery of a C4-deficient guinea pig. The 1970s witnessed the isolation and characterization of each of the proteins of this pathway until it was possible to completely reconstruct the entire AP by recombining each of the purified proteins (Schreiber et al., 1978). Most biomaterials activate complement through the alternative pathway (AP), although there is evidence that the classical pathway (CP) can also contribute (presumably subsequent to IgG binding (Andersson et al., 2005)).

> Most biomaterials activate complement through the alternative pathway (AP), although there is evidence that the classical pathway (CP) can also contribute (presumably subsequent to IgG binding (Andersson et al., 2005)).

The proteins of this pathway are described in Table II.2.4.4. Their actions can be conceptually divided into three phases: initiation; amplification; and regulation (Figures II.2.4.4 and II.2.4.5). Initiation is a spontaneous process that is responsible for the nonselective nature of complement. During this stage, a small portion of the C3 molecules in plasma undergo a conformational change that results in hydrolysis of the thioester group,

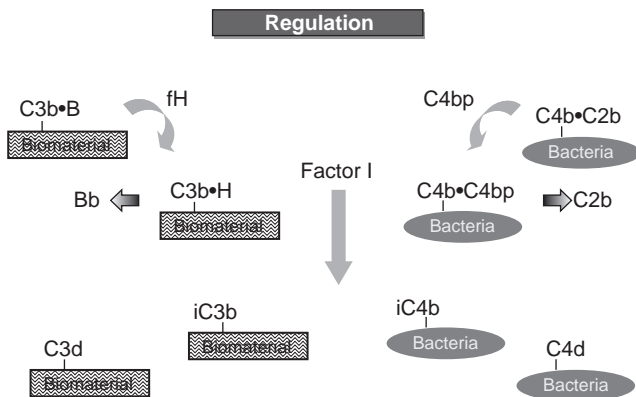
TABLE II.2.4.4	Proteins of the Alternative Pathway of Complement		
Protein	Molecular Weight	Subunits	Plasma Concentration (ug/ml)
C3	185,000	α, β	1300
B	93,000	1	210
D	24,000	1	1
H	150,000	1	500
I	88,000	α, β	34
P	106–212,000	2–4	20
FIGURE II.2.4.4 Complement activation by the alternative pathway (AP). The spontaneous conversion of C3 to C3(H$_2$O) permits the continuous production of C3b from C3, a process called C3 tickover. In the presence of an activating surface, the C3b is covalently bound and becomes the focal point for subsequent interactions. The bound C3b is recognized by factor B, which is then cleaved by factor D to produce a surface-bound C3 convertase (C3b•Bb). This results in amplification of the original signal to produce more convertase.


FIGURE II.2.4.5 Control of complement activation by factors H, I, and C4 binding protein. The extent to which complement activation occurs on different surfaces is dependent on the ability of fH or C4BP to recognize C3b or C4b on the surface. Degradation by factor I results in irreversible inactivation and the production of C3 and C4 fragments recognized by various complement receptors on white blood cell (WBC).

producing an activated form of C3 called C3(H$_2$O) ("C3-water"), that will bind to factor B. The C3(H$_2$O)•B complex is a substrate for factor D (another serine protease), which cleaves the B protein to form a solution phase alternative pathway C3 convertase: C3(H$_2$O)•Bb. Analogous to C2b in the CP, Bb is a serine protease that (in association with C3(H$_2$O)) will cleave more C3 to form C3b. Under normal physiological conditions, most of the C3b produced is hydrolyzed and inactivated, a process that has been termed "C3 tickover." C3 tickover is a continuous process that ensures a constant supply of reactive C3b molecules to deposit on foreign surfaces, such as cellulosic- or nylon-based biomaterials. Recognition of the C3b by factor B, cleavage by factor D, and generation of more C3 convertase leads to the amplification phase (Figure II.2.4.4). During this stage, many more C3b molecules are produced, bind to the surface, and in turn lead to additional C3b•Bb sites. Eventually, a C3b molecule attaches to one of the C3 convertase sites by direct attachment to the C3b protein component of the enzyme. This C3b–C3b•Bb complex is the alternative pathway C5 convertase and, in a manner reminiscent of the CP C5 convertase, converts C5 to C5b and C5a (Figure II.2.4.3).

Recent work with purified proteins and techniques to measure direct interactions with polymer surfaces has revealed an additional potential mechanism for alternative pathway activation (Andersson et al., 2002). Both C3b and C3 will adsorb to (not react with) polystyrene. A portion (about 10%) of the bound C3 or C3b binds factor B. This complex is recognized by factor D, which then catalyzes the formation of an AP C3 convertase. This process is facilitated by properdin, which increases the amount of convertase formed under these conditions. Interestingly, while the C3b•Bb convertase is controlled by factors H and I (see below), the surface bound C3•Bb convertase is not. The adsorption of C3 does not occur if the polystyrene surface is pre-coated with fibrinogen, so the extent to which this occurs in whole blood, where many other proteins can compete with C3 for binding to a biomaterial surface, has not been demonstrated.

MEMBRANE ATTACK COMPLEX

All three pathways lead to a common point: cleavage of C5 to produce C5b and C5a. C5a is a potent inflammatory mediator and is discussed later in the context of receptor-mediated white blood cell activation. The production of C5b initiates the formation of a macromolecular complex of proteins called the membrane attack complex (MAC) that disrupts the cellular lipid bilayer, leading to cell death (Table II.2.4.5). The sequence of events in MAC formation is outlined in Figure II.2.4.3.

Following cleavage of C5 by C5 convertase, the C5b remains weakly bound to C3b in an activated state in which it can bind C6 to form a stable complex called C5b6. This complex binds to C7 to form C5b67, which

TABLE II.2.4.5	Proteins of the Membrane Attack Complex		
Protein	**Molecular Weight**	**Subunits**	**Plasma Concentration (ug/ml)**
C5	190,000	α, β	70
C6	120,000	1	60
C7	105,000	1	60
C8	150,000	α, β	55
C9	75,000	1	55
S-Protein	80,000	1	500

has ampiphilic properties that allow it to bind to, and partially insert into, lipid bilayers. The C5b67 complex then binds C8 and inserts itself into the lipid bilayer. The C5b678 complex disrupts the plasma membrane and produces small pores (r ~ 1 nm) that permit leakage of small molecules. The final step occurs when multiple copies of C9 bind to the C5b678 complex and insert into the membrane. This enlarges the pore to about 10 nm, and can lead to lysis and cell death. Even at sublytic levels, formation of MAC on host cells results in a number of activation responses (elevated Ca^{+2}, arachadonic acid metabolism, cytokine production).

In addition to the usual means of generating C5b (i.e., through C5 convertase activity), several groups (Vogt, 1996; Vogt et al., 1992) have shown that C5 can be modified by a variety of oxidizing agents (H_2O_2, superoxide anion, and others) to convert C5 into a C5b-like structure that will bind C6. The oxidized C5•C6 complex can bind C7, C8, and C9 to form lytic MAC. This mechanism of MAC formation may be relevant at sites where neutrophils and macrophages attempt to phagocytize a biomaterial, producing a variety of reactive oxygen species, or in hypoxia/reperfusion settings (angioplasty, CPB, etc.).

CONTROL MECHANISMS

Various types of control mechanisms have evolved to regulate the activity of the complement system at numerous points in the cascade (Liszewski et al., 1996). These mechanisms are shown in Figure II.2.4.6 and include: (1) decay (dissociation) of converatase complexes; (2) proteolytic degradation of active components that is facilitated by several cofactors; (3) protease inhibitors; and (4) association of control proteins with terminal components that interfere with MAC formation. Without these important control elements, unregulated activation of the cascade results in overt inflammatory damage to various tissues, and has been demonstrated to contribute to the pathology of many diseases (discussed below).

Starting at the top of the cascade, control of the classical and lectin pathway activation is mediated by a protein called C1 esterase inhibitor (C1-Inh). C1-Inh acts by binding to activated C1r and C1s subunits in C1, as
FIGURE II.2.4.6 Control of complement activation occurs by various mechanisms, and is facilitated by a number of different proteins in the plasma (fH, fI, C1 Inh, C4BP, sCPN, S protein, and clusterin) or on cell surfaces (CR1, DAF, MCP, and CD59). Decay acceleration refers to the increased rate of displacement of either C2b or fBb from CP or AP convertases. Cofactor activity refers to the increase rate of factor I-mediated proteolysis facilitated by some proteins.

well as MASP proteases bound to MBL. C1-Inh actually forms a covalent bond with these proteases, thus irreversibly inactivating these proteins. The effectiveness of this interaction is illustrated by the short half-life of C1s under physiological conditions (13 sec). The classical/lectin pathway C3/C5 convertase (C4b•C2b complex) spontaneously "decays" by dissociation of the C2b catalytic subunit. The rate of dissociation is increased by C4 binding protein (C4bp), which competes with C2 for a binding site on C4b. C4bp also acts as a cofactor for another control protein called factor I, which destroys the C4b by proteolytic degradation (Figures II.2.4.2 and II.2.4.6).

The alternative pathway is also highly regulated by mechanisms that are very similar to the CP. The intrinsic instability of the C3b thioester bond (half-life = 60 microseconds) ensures that most of the C3b (80–90%) is inactivated in the fluid phase. Once formed, the C3 convertase (C3b•Bb complex) also spontaneously dissociates, and the rate of "decay" is increased by factor H. Aside from accelerating the decay of C3 convertase activity, factor H also promotes the proteolytic degradation of C3b by factor I (Figures II.2.4.2 and II.2.4.6). Factors H and I also combine to limit the amount of active $C3(H_2O)$ produced in the fluid phase.

In addition to factor H, there are several cell membrane-bound proteins that have similar activities and structures (Figure II.2.4.7). These proteins act to limit complement-mediated damage to autologous, bystander cells. Decay-accelerating factor, or DAF, displaces Bb from the C3 convertase and thus destroys the enzyme activity. DAF is found on all cells in the blood (bound to the plasma membrane through a unique lipid group), but is absent in a disease called proximal nocturnal hemoglobinuria (PNH), which manifests a high spontaneous rate of red blood cell lysis. In addition to DAF, there are two other cell-bound control proteins: membrane cofactor protein (MCP); and complement receptor 1 (CR1; see later discussion). MCP is found on all blood cells except

erythrocytes, while CR1 is expressed on most blood cells as well as cells in tissues such as the kidney. Both of these proteins display cofactor activity for the factor I-mediated cleavage of C3b. CR1 also acts like factor H and DAF to displace Bb from the C3 convertase. A soluble recombinant form of CR1 (sCR1) was originally described by Weisman et al. (1990), and later produced commercially (Avant Immunotherapeutics). A number of investigations have used sCR1 to limit complement activation in various disease models (Couser et al., 1995; Larsson et al., 1997).

In contrast to the inhibitory proteins discussed above, properdin, the protein originally discovered by Pillemer, functions by binding to surface-bound C3b and stabilizing the C3 and C5 convertase enzymes. Recent work from several labs has shown that properdin binds to a number of AP activators (Rabbit Erythrocytes, Zymosan, LPS, apoptotic and necrotic cells) independent of C3b. This has lead to an alternative model for AP activation on some surfaces, where properdin plays the initial role in surface recognition, binds C3b, facilitates Factor B binding, and helps drive AP activation

FIGURE II.2.4.7 Structure–activity relationships for complement control proteins. Each circle represents one Short Consensus Repeat (SCR) domain, made up of about 60 amino acids. These SCR domains are strung together to create the different structures shown.

(Spitzer et al., 2007; Kimura et al., 2008). A genetic deficiency of this protein in humans has been associated with an increased susceptibility to meningococcal infections, an observation corroborated in properdin knock-out mice.

As with the other stages of the cascade, there are several control mechanisms that operate to limit MAC formation and the potential for random lysis of "bystander" cells. The short half-life of the activated C5b (2 min), and the propensity of the C5b67 complex to self-aggregate into a nonlytic form, helps limit MAC formation. In addition, a MAC inhibitor, originally called S protein and subsequently shown to be identical to vitronectin, binds to C5b67 (also C5b678 and C5b6789) and prevents cell lysis. Another way to control MAC is through homologous restriction factors (HRF). HRFs control assembly of the MAC on autologous cells (i.e., human MAC on human cells), but do not stop heterologous interactions (e.g., guinea pig MAC on sheep red blood cells). One well-characterized member of this group is called CD59. It is widely distributed, found on erythrocytes, white blood cells, endothelial cells, epithelial cells, and hepatocytes. CD59 functions by interacting with C8 and C9, preventing functional expression of MAC complexes on autologous cells. Finally, cells are also able to form outward vesicles or exosomes, releasing a portion of their plasma membrane. These microvesicles have been shown to contain MAC, and MAC has been shown to stimulate vesicle formation, leading to the suggestion that this may be a mechanism used by cells to physically remove MAC from the plasma membrane.

COMPLEMENT RECEPTORS

Except for the cytotoxic action of the MAC, most of the biological responses elicited by complement proteins result from ligand–receptor-mediated cellular activation (Sengelov, 1995). These ligands are listed in Table II.2.4.6 and are discussed briefly here.

TABLE II.2.4.6	Receptors for Complement Proteins	
Receptor Name/Ligand	**Structure**	**Cellular Distribution/Response**
CR1/C3b, C4b	200,000 Da single chain	RBC, PMN, monocytes, B, and T cells/clearance of immune complexes, phagocytosis, facilitates cleavage of C3b to C3dg by Factor I
CR2/C3dg	140,000 Da single chain	B cells/regulate B cell proliferation
CR4	150,000 Da α chain 95,000 Da β chain	PMN, platelets, B cells/leukocyte-endothelial cell interaction
CR3/ iC3b, ICAM-1, βglucan zfibrinogen, factor Xa	185,000 Da α chain 95,000 Da β chain	PMN, monocyte/phagocytosis of microorganisms, respiratory burst activity
C5a/C5a$_{des Arg}$	40,000 Da	PMN, monocytes, Mast cells, T cells, epithelial and endothelial cells, hepatocytes, CNS, fibroblasts/chemotaxis, degranulation, hyperadherence, respiratory burst, cytokine production (IL-6,IL-8)
C3a/C3a$_{des Arg}$	65,000 Da	Mast cells, eosinophils (various tissues)/histamine release, IL-6 production
C1q/C1q	70,000 Da	PMN, monocytes, B cells/respiratory burst activity
H/H	50,000 Da (3 chains)	B cells, monocytes/secretion of factor I, respiratory burst activity

The ability of complement to function in the opsonization of foreign elements is accomplished in large part by a set of receptors that recognize various C3 and C4 fragments bound to these foreign surfaces. These receptors are called Complement Receptor 1, 2, 3 or 4 (CR1, CR2, etc). CR1 is found on a variety of cells including RBCs, neutrophils, monocytes, B cells, and some T cells, and recognizes a site within the C3c region of C3b (Figure II.2.4.2). On neutrophils and monocytes, activated CR1 will facilitate the phagocytosis of C3b- and C4b-coated particles. On RBCs, CR1 acts to transport C3b-immune complexes to the liver for metabolism. As discussed above, CR1 is also a complement regulatory protein. CR2 is structurally similar to CR1 (with 16 SCR domains; see Figure II.2.4.7), but recognizes the C3d fragment of C3b that is bound to antigen. CR2 is expressed on antigen-presenting cells, such as follicular dendritic cells and B cells, where it facilitates the process of antigen-immune complex-driven B cell proliferation, providing a link between innate and adaptive immunity. CR3 represents another complement receptor that binds to iC3b and β-glucan structures found on zymosan (yeast cell wall). Also, on activated monocytes, CR3 has been shown to bind fibrinogen and factor Xa (of the coagulation cascade). CR3 is a member of the β2-integrin family of cell adhesion proteins that includes leukocyte functional antigen-1 (LFA-1) and CR4. LFA-1, CR3, and CR4 are routinely referred to as CD11a, CD11b, and CD11c respectively. Each of these proteins associates with a molecule of CD18 to form an α-β heterodimer that is then transported and expressed on the cell surface. These proteins help mediate the cell–cell interactions necessary for activities such as chemotaxis and cytotoxic killing. A genetic deficiency in CR3/LFA proteins leads to recurrent life-threatening infections. CR4 is found on neutrophils and platelets, and binds C3d and iC3b. CR4 may facilitate the accumulation of neutrophils and platelets at sites of immune complex deposition.

In contrast to the ligands discussed earlier, which remain attached to activating surfaces, C3a, C4a, and C5a are small cationic polypeptides that diffuse into the surrounding medium to activate specific cells. These peptides are called anaphylatoxins because they stimulate histamine release from mast cells and cause smooth muscle contraction, which can produce increased vascular permeability and lead to a fatal form of shock called anaphylactic shock. These activities are lost when the peptides are converted to their des Arg analogs (i.e., with the loss of their carboxyl terminal arginine residue, referred to as $C3a_{des\ Arg}$, $C5a_{des\ Arg}$, etc.). This occurs rapidly *in vivo*, and is catalyzed by serum carboxypeptidase N (Mueller-Ortiz et al., 2009).

In addition to its anaphylatoxic properties, C5a and $C5a_{des\ Arg}$ bind to specific receptors originally found on neutrophils and monocytes. The receptors for both C5a and C3a have been cloned and sequenced. C5aR (CD88)

has been shown to be expressed on endothelial cells (EC), hepatocytes, epithelial cells (lung and kidney tubules), T cells, and cells in the CNS, as well as on the myeloid cell lines (Monk et al., 2007). In addition, expression levels of C5aRs are increased on EC and hepatocytes by exposure to LPS and IL-6. In myeloid cells (neutrophils and monocytes), the C5a-receptor interaction leads to a variety of responses, including chemotaxis of these cells into an inflammatory locus; activation of the cells to release the contents of several types of secretory vesicles and produce reactive oxygen species that mediate cell killing; increased expression of CR1, CR3, and LFA-1, resulting in cellular hyperadherence; and the production of other mediators such as various arachidonic acid metabolites and cytokines, e.g., IL-1, -6, and -8. Many of the adverse reactions seen during extracorporeal therapies, such as hemodialysis, are directly attributable to C5a production. C3aRs are expressed on a variety of cell types including eosinophils, neutrophils, monocytes, mast cells, and astrocytes (in the CNS), as well as γ-IFN-activated T cells. In eosinophils, C3a elicits responses similar to C5a, including intracellular calcium elevation, increases endothelial cell adhesion, and the generation of reactive oxygen intermediates.

CLINICAL CORRELATES

The normal function of complement is to mediate a localized inflammatory response to a foreign material. The complement system can become clinically relevant in situations where it either fails to function or where it is activated inappropriately; some of these settings are shown in Table II.2.4.7 (Markiewski and Lambris, 2007; Unsworth, 2008). In the first instance, a lack of activity due to a genetic deficiency in one or more complement proteins has been associated with increased incidence of recurrent infections (MBL deficiency in children), autoimmune disease (over 90% of C1 deficient patients develop SLE), and other pathologies (for example, a deficiency of C1 inhibitor is known to result in hereditary angioedema, where various soft tissues

become extremely swollen due to over-production of various vasoactive mediators). A recent genomic analysis has linked a mutation in Factor H (where a tyrosine at position 402 is replaced with a histidine residue) to various diseases. The strongest association has been made with the development of an eye disease called adult macular degeneration (AMD; Klein et al., 2005). The mutation has been shown to decrease the interaction of Factor H with cell surface sugars, linking this loss in cell surface control of complement to the development of AMD and other diseases (Schmidt et al., 2008). This is also an example of inappropriate activation, which can occur in a variety of circumstances. It is now recognized that endothelial cells exposed to hypoxic conditions (ischemia due to angioplasty or a blocked artery due to atherosclerosis) activate complement following reperfusion of the blocked vessel. This results in further damage to the vessel wall, and eventually to the surrounding tissue. Activation of the classical pathway by immune complexes occurs in various autoimmune diseases, such as systemic lupus erythematosus and rheumatoid arthritis. Glomerular deposition of immune complexes results in local inflammation that can contribute to a type of kidney damage called glomerulonephritis (GN). Quite a bit of experimental and clinical data has accumulated demonstrating that complement directly contributes to the initiation and/or progression of GN (Table II.2.4.8), resulting in the development of end stage renal disease, and the necessity of hemodialysis therapy.

One of the major settings where complement has been implicated in adverse clinical reactions is during extracorporeal therapies such as hemodialysis, cardiopulmonary bypass, and apheresis therapy. The same nonspecific mechanism, which permits the alternative pathway to recognize microbes, results in complement activation by the various biomaterials found in different medical devices. The following discussion summarizes the clinical experience with hemodialysis and cardiopulmonary bypass, but many of the observations concerning complement activation and WBC activation are relevant to other medical biomaterial applications.

One of the major settings where complement has been implicated in adverse clinical reactions is during extracorporeal therapies such as hemodialysis, cardiopulmonary bypass, and apheresis therapy. The same nonspecific mechanism, which permits the alternative pathway to recognize microbes, results in complement activation by the various biomaterials found in different medical devices.

One of the most investigated materials (from the perspective of complement activation) is the cellulosic Cuprophan membrane used extensively for hemodialysis. Some of the adverse reactions that occur during clinical use of a Cuprophan dialyzer are listed in Table II.2.4.9. In 1977, Craddock et al. showed that some of these same manifestations (neutropenia, leukosequestration, and pulmonary hypertension) could be reproduced in rabbits and sheep when the animals were infused with autologous plasma that had been incubated *in vitro* with either Cuprophan or zymosan. This effect could be abrogated by treatment of the plasma to inhibit complement activation (heating to 56°C or addition of EDTA), thus linking these effects with complement. The development and use of specific radioimmunoassays (RIAs) to measure C3a and C5a by Dennis Chenoweth (1984) led to the identification of these complement components in the plasma of patients during dialysis therapy. A typical patient response to a Cuprophan membrane is shown schematically in Figure II.2.4.8. The C3a (and C5a) levels rise during the first 5–15 minutes, peaking between 10–20 minutes. For a Cuprophan membrane, typical peak C3a levels range from 4000 to 6000 ng/ml. During this period the white blood cells become hyperadherent and are trapped in the lung, resulting in a peripheral loss of these cells (neutropenia). As complement activation is controlled (e.g., by factor H), the C3a and C5a levels decrease to baseline levels, and the WBC returns to the peripheral circulation, now in a more activated (primed) state. This is a very consistent response, and many authors have noted a direct correlation between the extent of complement activation and the degree of

TABLE II.2.4.9	Clinical Symptoms Associated with Cuprophan-Induced Biocompatibility Reactions
Cardiopulmonary:	Pulmonary hypertension Hypoxemia Respiratory distress (dyspnea) Neutropenia (pulmonary leukosequestration) Tachycardia Angina pectoris Cardiac arrest
Other:	Nausea, vomiting, diarrhea Fever, chills, malaise Urticaria, pruritus Headache

Typical Response of Hemodialysis
FIGURE II.2.4.8 A typical response pattern to dialysis with a complement-activating hemodialysis membrane. Many investigators have noted that the extent of C3a production is directly proportional to the degree of neutropenia at the same time points.

neutropenia (as well as other responses such as CR3 expression) seen with various dialysis membranes.

Based on our understanding of the biochemistry of complement and its biological actions, the following scenario can be drawn (Figure II.2.4.9). Contact by blood with the membrane results in initial protein deposition, including IgG, C3, and especially C3b, eventually leading to the formation of C3 and C5 convertase enzymes. Conversion of C5 results in C5a production, which leads to receptor-mediated neutrophil and monocyte activation. Production of C5b leads to MAC formation, which binds to bystander cells and results in subsequent activation of these cells through calcium-dependent mechanisms. Recognition of biomaterial-bound C3 and C4 fragments by WBC results in cell adherence and further activation of these cells. These various responses account for much of the pathophysiology seen clinically. The critical role of C5a in mediating many of these adverse reactions was confirmed in experiments employing purified sheep C5a. Infusion of this isolated peptide into sheep, in a manner that would simulate exposure to this molecule during hemodialysis, produced dose-dependent responses identical to those seen when the sheep are subjected to dialysis (Johnson et al., 1996). In addition, numerous *in vivo* and *in vitro* studies have documented the relationship between complement activation by biomaterials, the extent of WBC activation, and the resulting inflammatory response illustrated in Figure II.2.4.9 (Lewis and Van Epps, 1987; Gemmell et al., 1996; Larsson et al., 1997; Tang et al., 1998).

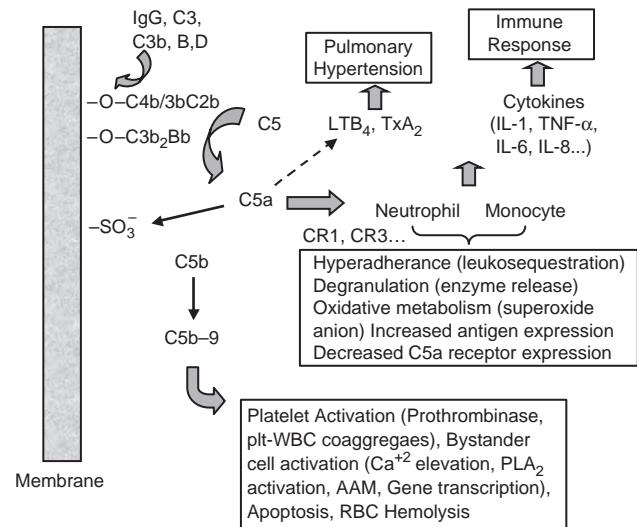
In the same time frame that clinicians were linking complement with leukopenia in the hemodialysis setting, a number of cardiovascular scientists were demonstrating complement activation by the materials used to make cardiopulmonary bypass circuits. Typical levels of C3a produced in these procedures ranged from 300 to 2400 ng/ml. These investigations soon associated C3a and C5a production with a group of symptoms


FIGURE II.2.4.9 The biochemical basis for complement-mediated adverse reactions during extracorporeal therapy. Production of C5a leads to receptor-dependent white blood cell activation. This results in profound neutropenia, increased concentrations of degradative enzymes, and reactive oxygen species that ultimately may lead to tissue damage and dysfunction of these important immune cells. Generation of secondary mediators, such as arachidonic acid metabolites (TxA2, LTB4) and cytokines can have profound consequences on whole organ systems. Finally, formation of the MAC (C5b-9) has been linked with increased hemolysis during cardiopulmonary bypass, formation of microparticles, and has been shown to increase platelet prothrombinase activity *in vitro*. This last observation suggests that surfaces that activate complement aggressively may be more thrombogenic.

TABLE II.2.4.10	Post-Perfusion or Post-Pump Syndrome

known as "post-perfusion" or "post-pump" syndrome (Table II.2.4.10). Further analysis showed that complement was activated by the materials in the circuit (such as the polypropylene membranes and the nylon filters), but was also activated during neutralization of the heparin anticoagulant with the protamine sulfate that was given to each patient at the end of the operation. This was further exacerbated by complement activation that occurred in the ischemic vascular bed upon reperfusion of the tissue that also occurred at the end of the procedure. The importance of complement activation, and C5 conversion in particular, to the clinical outcome of Cardiopulmonary Bypass (CPB) patients was clearly demonstrated in a study by Fitch et al. (1999). These investigators showed, using a single chain anti-C5 antibody fragment that inhibited C5a and MAC generation during the procedure, that this antibody fragment lowered WBC activation, blood loss, cognitive deficits, and

myocardial injury. Subsequent studies demonstrated that this complement inhibitor significantly reduced mortality in higher risk cardiac surgical patients (Haverich, 2006). These results are consistent with other studies (Velthuis et al., 1996; Hsu, 2001) using heparin-coated CPB circuits that demonstrate lower inflammatory indices (complement, cytokine, and elastase levels) that are associated with improved clinical outcomes (blood loss, shorter ICU stays, and morbidity).

The CPB experience with heparin-coated devices demonstrates that modification of device materials (or the blood-contacting surfaces of those materials) can dramatically limit complement activation and the subsequent inflammatory response. Based in part on this and similar observations, hemodialyzer/membrane manufacturers began developing new membranes to produce more biocompatible (i.e., less complement-activating) devices. These new membranes tend to fall into two groups: moderately activating modified cellulosics (such as cellulose acetate (CA), hemophane, and cellulose triacetate (CT)); and low activating synthetics (such as polyacrylonitrile (AN69), polymethylmethacrylate (PMMA), and polysulfone (PS)). Moderately activating modified cellulosics produce C3a levels and neutropenic responses that are about 50% of Cuprophan levels, while the synthetic materials display 0–20% activation compared to Cuprophan. Based on the known properties of complement, and the structures of these membranes, the reasons for the improved biocompatibility can be rationalized as follows. Most of these materials have a diminished level of surface nucleophiles. In theory, this should result in lower deposition of C3b, and in fact this has been verified experimentally. The diminished capacity to bind C3b results in lower levels of C3 and C5 convertase activity, and consequently a reduced production of C3a and C5a. Patient exposure to C5a is reduced even further by materials that allow for transport through the membrane to the dialysate (for example, high flux membranes such as polysulfone will do this) or by absorbing the peptide back onto the surface (the negatively charged AN69 has been shown to have a high capacity for binding cationic C5a). Thus, limiting C3b deposition and C5a exposure are two proven mechanisms of avoiding the clinical consequences of complement activation.

The same result can also be accomplished by facilitating the normal control of C3 convertase by factor H. Kazatchkine et al. (1979) have shown that heparin, coupled to either zymosan or Sepharose, limits the normal complement activation that occurs on these surfaces by augmenting C3b inactivation through factors H and I. Presumably, this accounts for the improved biocompatibility of heparin-coated circuits used in CPB described above. Mauzac et al. (1985) have prepared heparin-like dextran derivatives that are extensively modified with carboxymethyl and benzylamine sulfonate groups. These researchers have shown that these modifications

diminish complement activation by the dextran substrate. A simple modification of cellulose membranes (Cuprophan) with maleic anhydride has been shown to limit the complement-activating potential of these materials by over 90% (Johnson et al., 1990). Again, increased binding of factor H to surface-bound C3b appears to account for the improved biocompatibility of maleated cellulose. Thus, materials that limit complement activation through normal regulatory mechanisms are on hand, and may prove to be the next generation of complement-compatible materials. In addition, pharmaceutical control of complement is now possible with agents that are FDA approved (Alexion's Solaris®) or now in clinical development.

> Thus, materials that limit complement activation through normal regulatory mechanisms are on hand, and may prove to be the next generation of complement-compatible materials. In addition, pharmaceutical control of complement is now possible with agents that are FDA approved (Alexion's Solaris®) or now in clinical development.

SUMMARY AND FUTURE DIRECTIONS

The immune response to a biomaterial involves both humoral and cellular components. Activation of the complement cascade by either classical, lectin or alternative pathways leads to the deposition of C4b and C3b proteins. Recognition of these molecules by receptors on granulocytes can cause activation of these cells, leading to the production of degradative enzymes and destructive oxygen metabolites. Recognition of C4b or C3b by other proteins in the cascade leads to enzyme formation (C3 and C5 convertases), which amplifies the response and can lead to the production of a potent inflammatory mediator, C5a. C5a binds to specific receptors found on PMNs and monocytes. The interaction of C5a with these cells elicits a variety of responses, including hyperadherence, degranulation, superoxide production, chemotaxis, and cytokine production. Systemic exposure to C5a during extracorporeal therapies has been associated with neutropenia and cardiopulmonary manifestations (Tables II.2.4.9 and II.2.4.10) that can have pathologic consequences. The other portion of the C5 protein, C5b, leads to formation of a membrane attack complex that activates cells at sublytic levels and has cytotoxic potential if produced in large amounts. The control of these processes is understood well enough to begin designing materials that are more biocompatible. Limiting C3b deposition (nucleophilicity), adsorbing C5a to negatively charged surface groups, and facilitating the role of factors H and I are three approaches that have been shown to be effective. Translating the last mechanism into commercial materials is one of the major challenges facing the development of truly complement-compatible membranes.

CHAPTER II.2.5 SYSTEMIC TOXICITY AND HYPERSENSITIVITY

Arne Hensten[1] and Nils Jacobsen[2]
[1]Department of Clinical Densitry, University of Tromsø, Tromsø, Norway

[2]Nordic Institute of Dental Materials Sognsveien, Ullevål Stadion, Oslo, Norway

Artificial implant devices comprise a variety of metallic alloys, polymers, ceramics, hydrogels or composites for a large number of purposes and with widely different properties. With the exception of drug delivery systems, sutures, and other degradable biomaterial systems (Chapter II.2.5), the implant devices are intended to resist chemical and biochemical degradation, and to have minimal leaching of structural components or additives. However, synthetic devices are influenced by chemical, and in some cases enzymatic, processes resulting in the release of biomaterials-associated components. Since there are no natural repair mechanisms parallel to natural tissues, degradation (biodegradation) is a "one-way" process that brings about microscopic and macroscopic surface and bulk changes of the devices, sometimes enhanced by the biomechanical and bioelectrical conditions that the devices are intended to resist. With the exception of pathologic calcification of certain polymer implants, the surface changes may not be significant for the mechanical strength of the implant, whereas in contrast the released substances very often have biological effects on the surrounding tissues or, possibly, at other remote locations. Inflammatory, foreign body, or other local host reactions, and tumorigenesis are discussed in Chapters II.4.1, II.4.2, and II.4.6. The following discussion is concerned with the possibility of systemic toxic reactions and/or hypersensitive reactions caused by biomaterials-derived xenobiotics.

KINETICS AND THE NATURE OF BIOMATERIALS COMPONENTS

Xenobiotic components derived from *in vivo* medical devices have parenteral contact with connective tissue or other specialized tissues such as bone, dentin, vascular or ocular tissue, whereas leachables from skin and mucosa contacting devices have to pass the epithelial lining of the oral mucosa, the skin, the gastrointestinal tract, or – for volatiles – the lung alveoli to get "inside" the body. In any of these cases, further distribution of foreign substances to other tissues and organs is dependent on membrane diffusion into blood capillaries and lymph vessels. The transport may be facilitated by reversible binding to plasma proteins, globulins (metal, metal compounds), and chylomicrons (lipophilic substances). Storage – and later release – may take place for certain components in tissues such as fat and bone.

In addition to particulate matter, the released components consist of chemical substances of different atomic and molecular size, solubility, and other chemical characteristics, depending on the mother material. Examples are metal ions from orthopedic implants or prosthodontic materials, or residual monomers, chemical initiators, inhibitors, plasticizers, antioxidants, etc., from polymer implants and dental materials. Other degradation products from inorganic, organic, and composite devices also "rub off" to the surrounding tissues. The kinetic mechanisms for biomaterials components are in part the same as those of xenobiotics introduced by food or environmental exposure, i.e., the released components are subject to oxidation, reduction, and hydrolysis, followed by conjugation mechanisms. All metabolic changes are, by their nature, intended to eliminate them by way of the urine, bile, lungs, and to a certain degree in salivary-, sweat-, and mammary glands, and hair (deBruin, 1981).

A key question is, do the released components or their metabolites have any systemic toxic effect on the host, and/or could they induce unwanted immunological reactions?

TOXICO-DYNAMIC CONSIDERATIONS

Systemic toxicity depends on toxic substances hitting a target organ with high sensitivity to a specific toxicant. Target organs are the central nervous system, the circulatory system, the hematopoietic system, and visceral organs such as liver, kidney, and lungs, in that order. The toxicity is based on interference with key cell functions, and depends on the dose, and the duration, of the exposure. Serious effects may be incompatible with continued life, but most effects cause local and reversible cell damage. However, some sublethal effects may include somatic cell mutation expressed as carcinogenesis, or germinal cell mutation, resulting in reproductive toxicity.

The key word in the evaluation of general toxicity is the *dose*, defined as the amount of substance an organism is exposed to, usually expressed as mg per kg

bodyweight. Adverse effects of foreign substances are often the result of repeated, chronic exposure to small doses that, over a prolonged period of time, may have deleterious effects similar to one large, short-term exposure, provided that the repeated doses exceed a certain threshold level. This level is determined by the capacity for metabolism and elimination. Another important factor is the possibility of synergistic potentiating effects when several toxicants are present simultanously. Whatever mechanism is involved, the principle of systemic toxicity presupposes a dose-dependent reaction that may be measured and described, and that may be explained by specific reactions at distinct molecular sites (Eaton and Gilbert, 2008).

The components derived from biomaterials represent a large series of widely different foreign substances with few characteristics in common, and with a largely unknown concentration. Most of them have to be characterized as toxic *per se*, with large variations as regards their place on a ranking list of potential toxicity. This statement is relevant for metal ions and salts, as well as for polymeric components derived from biomaterials devices. Local inflammatory and other host reactions towards biomaterial implants are well known (Chapter II.4.2), whereas the significance of individual implant components is difficult to assess.

METALLIC MATERIALS

However, many studies have provided information on the presence of wear and corrosion debris from metallic orthopedic implants, often initiated by the aseptic loosening of total hip replacements. Oxides or hydroxides of cobalt, titanium, aluminium, iron, nickel, and chromium are found in the periprosthetic tissues, depending on the alloys used. Post-mortem data also indicate accumulation in regional lymph nodes and liver. Further vascular distribution of ions and extremely small particles has made it possible to estimate concentration of some of these components in whole blood. Such findings open up the possibility of evaluating the potential effect on different organs. Information in this area is growing by sophisticated cytotoxicity research, by experimental animal studies, and by extrapolation of occupational and environmental data. So far, the risk of systemic toxicity caused by metallic implant components is considered to be negligible, although it is recommended that the orthopedic research community pay attention to the basic functions of kidneys, reproductive organs, and the central nervous system among arthroplastic patients (Keegan et al., 2007).

Metallic dental material is another source of exposure. *In vitro* experiments have shown that chromium and nickel are released from base metal orthodontic appliances, although the amounts are not comparable with the amounts calculated in food intake (Park and Shearer, 1983). As witnessed by hypersensitive reactions,

uptake of metal components by mucosa from fillings and prosthodontic devices does take place, but on a scale too low to be of interest in the systemic toxicity context.

An exception is the release and pulmonary uptake of volatile metallic mercury from dental amalgam fillings. Many studies have been able to quantify the concentration of mercury in plasma and urine depending on the burden of dental amalgam (Mackert and Berglund, 1997), and occupational studies have demonstrated that mercury accumulates in tissues belonging to the central nervous system (Nylander et al., 1989). Reproductive toxicity has been of specific concern for dental personnel.

However, similar to other metals such as chromium and nickel, mercury exposure also takes place in food and respiratory air. Careful scrutiny by national and international scientific committees of the large amount of (partly controversial) data has not resulted in a consensus conclusion that the application of mercury dental amalgam should be discontinued, although the environmental concern of mercury is recognized. The European Commission (2008), by its Scientific Committee of Emerging and Newly Identified Health Risks (SCENIHR), has recently investigated possible adverse effects of mercury dental amalgam on urinary, neurological, immunological, psychological, reproductive, and other systems, and concludes that there is little epidemiological evidence to show that mercury released by dental amalgam fillings contributes to the etiology of systemic diseases.

NON-METALLIC BIOMATERIALS

Non-metallic dental materials comprise numerous composite polymeric materials based on a variety of methacrylate monomers polymerized by specific chemical additives. Numerous elution experiments have demonstrated the release of monomers and additives, particularly during the first hours after polymerization (Michelsen et al., 2007). Degradation and erosion of the dental filling and prosthodontic materials over time is another source of released components. Most released substances have proven to be cytotoxic *in vitro* (Geurtsen et al., 1998). Some components have been of specific interest for their toxicity to the reproductive system. Examples are the UV-absorber oxybenzone, Bisphenol A, and phtalates, all released from different polymeric materials. Oxybenzone has an estrogenic potential, Bisphenol A binds estrogen receptors *in vitro* with the potential of impairing the reproductive system, and phtalates have antiandrogenic characteristics as judged by environmental research. Since Bisphenol A is released from fissure sealants, mainly applied in children, this issue has been of specific interest in the toxicological discussion of dental materials. However, current literature does not support any risk associated with these materials (Azarpazhooh and Main, 2008).

Minute quantities of phtalates and degradation products of chemical additives derived from freshly made

(poly)methylmethacrylate dental prostheses have been demonstrated in saliva (Lygre et al., 1993). Larger amounts of plastiziser phtalates are released from temporary biomaterials such as PVC tubing; therefore the risk of deleterious effects on specific patient groups such as dialysis patients or premature neonatates has been discussed (Calafat et al., 2004). Another point in this context is the observation that (poly)methylmethacrylate monomer from setting bone cement may cause transient cardiovascular reactions. The dose applied in hip arthroplasty is large enough to cause hypotension, whereas the smaller dose associated with percutaneous vertebroplasty is not (Kaufmann et al., 2002).

Other clinically relevant data on the systemic toxicity of degradation products from dental polymeric materials and non-metallic implants are scarce. On this background a fair conclusion would be that there is no data indicating long-standing systemic toxicity caused by biomaterials-derived xenobiotics. However, current cytotoxic and animal research may reveal toxic mechanisms on the intracellular level that may prove relevant for released biomaterials components. In addition, the biomaterials field is characterized by the increasing number of synthetic materials on the market. Despite the premarketing testing programs, it is difficult to predict single or synergistic toxic effects of leachable components and degradation products in the future.

ADVERSE EFFECTS OF DEFENSE MECHANISMS

The low probability of direct systemic adverse effects on target organs caused by biomaterials products does not rule out deleterious effects by other mechanisms requiring only minute amounts of the foreign material. All substances not recognized as natural components of the tissues are subject to possible clearance by several mechanisms, e.g., phagocytic cells such as polymorphonuclear leucocytes, macrophages, and monocytes attempting to degrade and export the components. Larger foreign components are subject to more aggressive reactions by giant cells causing an inflammatory foreign-body reaction. Enzymes and other bioactive molecules associated with phagocytosis and foreign-body reaction may cause severe local tissue damage. In addition, phagocytic cell contact, and contact with the circulatory system of lymph and blood, opens up another way of neutralizing foreign substances by way of the immune system, introducing a biologic memory of previously encountered foreign substances, and an enhancement system for their neutralization.

HYPERSENSITIVITY AND IMMUNOTOXICITY

The immune system is an indispensable biological mechanism to fight potentially adverse invaders, most commonly of microbial origin. However, the immune system occasionally strikes invading molecules – adverse or not – with an intensity that stands in contrast to their modest concentration, and with the ability to cause host tissue damage. This phenomenon is called hypersensitivity. The resulting injury is part of a group of adverse reactions classified as immunotoxic.

In principle, immunologic hypersensitivity comprises two different mechanisms: allergy and intolerance. Allergy is an acquired condition resulting in an overreaction upon contact with a foreign substance, provided there is a genetic disposition and previous exposure to the substance. Allergic reactions may include asthma, rhinitis, urticaria, intraoral and systemic symptoms, and eczema. Intolerance is an inherited reaction that resembles allergy and has common mediators and potentiating factors, such as complement activation, histamine release, etc., but is not dependent on a previous sensitization process. Intolerance reactions have been associated with drugs such as acetyl-salicylic acid, whereas intolerance to leachable biomaterial components such as benzoic acid is conceivable but not known.

ALLERGY AND BIOMATERIALS

A foreign substance able to induce an allergic reaction is called an allergen. There is no acceptable way of predicting whether a substance or a compound is potentially allergenic on the basis of its chemical composition and/or structure alone. However, experimental evidence, and years of empirical results after testing substances causing allergic reactions, has given some leads, e.g., large foreign molecules such as proteins and nucleoproteins are strong allergens, whereas lipids are not. However, the strongest chemical allergens associated with biomaterials are often chemically active substances of low molecular weight, often less than 500 Da, such as lipid-soluble organic substances derived from polymer materials or metal ions and metal salts. These are called haptens, i.e., they become full allergens only after reaction or combination with proteins that may be present in macrophages and Langerhans cells of the host.

TYPES OF ALLERGIES

Allergies are most often categorized into four main groups (Type I–IV) according to the reaction mechanisms. Types I to III are associated with humoral antibodies initiated by B-lymphocytes that develop into immunoglobulin-producing plasma cells. The immunoglobulins are classified into five different classes, IgE, A, D, G, and M, according to their basic structure and size. A variable portion of the immmunoglobulin is specific for the antigen that induced its production. The Type IV reaction is a cell-mediated reaction caused by T lymphocytes.

Types II and III allergies comprise antigen–antibody encounters including complement activation, cell lysis,

release of vasoactive substances, inflammatory reaction, and tissue damage. Necrosis of peri-implant tissue with histologic appearance and serum complement analyses consistent with Type III hypersensitivity has been observed in cases of atypical loosening of total hip prostheses (Hensten-Pettersen, 1993). However, according to the appropriate ISO and FDA documents for immunotoxicological testing of medical devices (ISO 10993-20, 2006, and FDA Immunotoxicity Testing Guidance, 1999) Type II and III reactions are omitted because they are relatively rare, and are less likely to occur with medical devices/materials, leaving Types I and IV relevant in the present context.

TYPE I HYPERSENSITIVITY

The Type I reaction is based on an interaction between an intruding allergen and IgE immunoglobulins located in mast cells, basophils, eosinophils, and platelets, resulting in release of active mediators such as histamine and other vasoactive substances. The results are local or systemic reactions seen within a short time (minutes). The symptoms depend on the tissue or organ subject to sensitization, e.g., inhaled allergens such as pollen, residual proteins associated with surgical latex gloves or other natural latex products may result in asthmatic seizures, swelling of the mucosa of the throat or worse: decreased blood pressure and anaphylactic shock. Food allergies may also give systemic symptoms. This type of host reaction is usually associated with full antigens. Since the potential allergens associated with biomaterials are small molecular haptens, the probablility of IgE-based allergic reactions is low, although IgE antibodies to chromium and nickel have been reported (Hensten-Pettersen, 1993). Reports on adverse reactions to orthopedic devices describe patients with urticarial reactions. Contact urticaria is a wheal and flare response to compounds applied on intact skin. The role of immunological contact urticaria in relation to medical devices is not clear.

TYPE IV HYPERSENSITIVITY

Cell-mediated hypersensitivity is referred to as "delayed," because it takes more than 12 hours to develop, often 24–72 hours. The T lymphocytes producing the response have been sensitized by a previous encounter with an allergen, and act in concert with other lymphocytes and mononuclear phagocytes to create three histologically different types, characterized by skin-related tissue reactions. The reactions are elicited by interaction of cells and mediators which comprise: (1) induration (the granulomatous type); (2) swelling and induration, and possibly fever (the tuberculin type); and (3) eczema (the contact type) (Britton, 2001).

Prolonged challenges of macrophage-resistant allergens, usually of microbial origin, may result in persistant immunological granuloma formation. Such reactions

have been associated with occupational beryllium and zirconium exposure, but the main form of delayed hypersensitivity in relation to biomaterials is the contact form.

Allergic contact dermatitis is acquired through previous sensitization with a foreign substance. The hapten is absorbed by the skin or mucosa, and binds to certain proteins associated with the Langerhans cells, forming a complete antigen. The antigen stimulates the formation of activated, specialized T cells. Upon new exposure, the allergen–T cell encounter releases inflammatory mediators resulting in further production and attraction of T cells, causing tissue damage. The reactions are not necessarily limited to the exposure site.

The presence of allergic contact dermatitis is evaluated by epidermal or intradermal skin tests. A vast amount of information on the allergenic characteristics of biomaterials-related substances has been obtained in this way, especially as regards dental materials (Kanerva et al., 1995). However, many biomaterials employed in dentistry, such as metal alloys and resin-based materials, have medical counterparts which are encountered in everyday life. The sensitization process, therefore, often has taken place before the biomaterials contact.

ATOPY

Atopic individuals have a constitutional predisposition for IgE-based hypersensitive reactions caused by environmental and food allergens. The reaction includes histamine-mediated hay fever, asthma, gastrointestinal symptoms or skin rashes, and is more pronounced at an early age. Atopics have an increased risk of acquiring irritant contact dermatitis to external biomaterial devices, such as orthodontic appliances. The relation to allergic contact dermatitis is unclear (Lindsten and Kurol, 1997), so also is the relationship between atopy and allergens or haptens from biomaterials exposed parenterally.

IMMUNOLOGIC TOXICITY OF BIOMATERIALS

Biomaterial immunology includes reactions associated with oral rehabilitation, as well as medical devices. Of these, dental materials are by far the most common, and represent a large variety of metallic and polymer products. With the exception of some extraoral orthodontic equipment and latex utensils, the exposure site of these materials is oral tissues. The local immunological reactions include gingivitis or gingival lichenoids, mucosal inflammation and blistering or perioral dermal reactions, all of the delayed contact reaction type. In addition, dermal reactions may occur at remote locations. Occasionally IgE-based immediate reactions, such as angioedema, contact urticaria or anaphylaxis are seen, mostly related to temporary biomaterials, such as natural rubber latex.

Considering the vast number of dental patients, the incidence of immunotoxicity reactions is extremely low.

In contrast to medical implants, such reactions are easily observed in the dental clinic, but determination of the eliciting allergen is not easy. In Table II.2.5.1 some allergenic components associated with dental biomaterials are listed on the basis of empirical findings by epidermal patch tests. Some of these items have their counterparts in orthopedic implants or other medical devices.

Information on immunological adverse effects in dental medicine has been obtained by case reports, questionnaire studies, and reports from adverse reaction registry units and dermatological units. In some cases the cause–effect relationship has been assessed by clinical experience only. For these and other reasons, there are no reliable epidemiological statistics on adverse effects in terms of incidence data. The prevalence in published reports varies from 1:100 to 1:10,000 (Schedle et al., 2007), and comprises both local and remote hypersensitivity reactions. However, all reports indicate salts of nickel, gold, cobalt, palladium, mercury, and chromium as the main metallic allergens. Of the polymer alternatives, the monomers of HEMA, EGDMA, TEGDMA, and MMA, together with polymerization chemicals, such as benzoyl peroxide and dimethylparatoluidin, are prevalent. It is argued that the sensitization may have taken place by exposure to parallell allergens in everyday life, and that the oral encounter elicits the reaction. It is also accepted that, for anatomical reasons, oral tissues develop hypersensitive reactions less easily than dermal tissues.

IMPLANT ALLERGY

The exact progress of hypersensitivity reactions associated with implants is not clear. It might include both the sensitization and the elicitation process, or just the latter. Reactions of this type are difficult to recognize unless they have dermal or systemic expressions, such as eczemas or fistulas. In addition, such reactions may be part of local atoxic and/or mechanically induced inflammation using similar mediators for tissue response. Because of a lack of more distinct descriptions, such reactions have been referred to as "deep tissue" reactions of Type IV hypersensitivity. Immunological toxicity to surface medical devices and external communicating devices (dialyzers, laparoscopes, etc.) may represent mechanisms of sensitization and hypersensitivity reactions similar to those of orally exposed biomaterials.

A vast battery of *in vitro* and *in vivo* experimental studies have been performed to study potential adverse effects of biomaterial devices, such as artificial joints, heart valves, and breast prostheses (Rodgers et al., 1997). Aseptic loosening of metallic hip prostheses has been associated with "biologic" causes, in addition to biomechanical factors and wear debris. However, it is unclear whether metal sensitivity is a contributing factor to implant failure (Hallab et al., 2001). In fact, it is argued that the loosening process enhances immunological sensitization, indicating that the cause–effect relation may be the reverse (Milavec-Puretic et al., 1998). German orthopedists and immunologists, discussing the complicated relationship between potential allergens and the presence of implant failures, fistulas, and dermal reactions, underline the value of an allergological anamnesis (Thomas et al., 2008). However, similar to dental medicine, there is no strict contraindication for using a biomaterial containing a known allergen for a particular patient. Such decisions have to be taken on the basis of individual evaluation. What is clear, however, is that local and general eczematous reactions have been observed following the insertion of metallic implants in patients subsequently shown to be allergic to cobalt, chromium, and nickel.

Many case reports also describe the immediate healing of dermal reactions after the removal of metal implants (Al-Saffar and Revell, 1999). In addition, metal allergy has been discussed as a contributing factor in the development of in-stent coronary restenosis, although there is little evidence for this effect (Hillen et al., 2002). However, established metal allergy in a patient does not as a rule seem to be accompanied by clinical reactions to implant alloys containing the metal. If this statement is true, it is in line with clinical observations made in

TABLE II.2.5.1	Some Allergens in Dental Materials Based on Epicutaneous Testing
Metals	**Monomers and Cross-Linking Agents**
Nickel*	Methylmethacrylate (MMA)*
Cobalt*	Triethyleneglycol dimethacrylate (TEGDMA)
Chromium*	Urethane dimethacrylate (UEDMA)
Gold	Ethyleneglycoldimethacrylate (EGDMA)
Mercury	Bisphenol A diglycidyl dimethacrylate (BIS-GMA)
Copper*	1,4-Butanediol methacrylate (BUDMA)
Palladium	Bisphenol A methacrylate (BIS-MA)
Titanium*	2-hydroxyethylmethacrylate (HEMA)*
Aluminum	
Tin	
Beryllium	
Silver	
Platinum	
Zirconium	
Polymerization Chemicals and Additives	
Methylhydroquinone (stabilizer)*	
Camphoroquinone (initiator)	
Dibenzoylperoxide (initiator)*	
N,N-Dimethyl-4-paratoluidine (activator)*	
N,N-Dimethylaminoethyl methacrylate (activator)*	
4-Tolyldiethanolamine (activator)	
Tinuvin P (UV stabilizer)	
2-Hydroxy-4-methoxy benzophenone (UV stabilizer)	

*Sensitizers in orthopedic surgery. Other orthopedic metals are manganese, vanadium, molybdenum, aluminum, and zirconium, all with undecided allergen characteristics (Thomas et al., 2008; Geier et al., 2008). In addition, protein in natural rubber latex is a Type I allergen in dental and general medicine.

surveys on the use of metallic alloys in prosthodontics and orthodontics. Inhomogeneiety or a mixture of alloys appears to determine the efflux of potentially hypersensitive metal ions, and hence increases the possibility of eliciting a hypersensitive reaction (Grimsdottir et al., 1992).

Methyl-methacrylate bone cement is another potential allergenic factor in orthopedic surgery, as is their counterpart in dentistry and cosmetic dentistry (Kaplan et al., 2002). As indicated in Table II.2.5.1, prime elicitors are monomers of MMA and HEMA, and additives such as benzoyl peroxide, N,N-dimethyl-p-toluidine, and hydroquinone (Thomas et al., 2006).

An extensive literature reflects clinical surveys and research activities related to natural latex used as a barrier material by the health professions. It is accepted that residual latex proteins and chemicals associated with the production process may cause immediate and delayed reactions in patients and health personnel (Turjanmaa et al., 1996).

OTHER INTERACTIONS

The FDA testing guidance referred to above (FDA, 1999) also lists other interactions of medical devices, extracts of medical devices or adjuvants with the immune system, such as impairment of the normal immunologic protective mechanisms (immunosuppression), and long-term immmunological activity (immunostimulation) that may lead to harmful autoimmune responses. The autoimmune reaction is explained by the biomaterial-associated agent acting as an adjuvant that is stimulating to antibody–complement-based tissue damage by cross-reactions with human protein. Chronic inflammatory, immune-related granuloma may take part in the development of autoimmune reactions.

CONCLUDING REMARKS

Biocompatibility issues related to medical devices form a multidimensional crossroads of technology and biology. One component is the various classes of biomaterials, such as plastics and other polymers, metals, ceramics, glasses, etc., depending on expert design to obtain maximal mechanical properties and minimal chemical dissolution. Another is the mode of application, ranging from skin and mucosal contact to totally submerged implants, with external communicating devices in-between. A third dimension is the duration of contact, ranging from minutes to the expected lifetime, and the fourth, and decisive component, is the biological reactions that can be expected. These circumstances prevent general statements on biomaterials. The present overview is aimed at students, and limited to a focus on collective mechanisms determining systemic toxicity and discussion of hypersensitivity reactions documented by clinical reports.

CHAPTER II.2.6 BLOOD COAGULATION AND BLOOD–MATERIALS INTERACTIONS

Stephen R. Hanson and Erik I. Tucker
Division of Biomedical Engineering, School of Medicine,
Oregon Health & Science University, Portland, Oregon, USA

The hemostatic mechanism is designed to arrest bleeding from injured blood vessels. The same process may produce adverse consequences when artificial surfaces are placed in contact with blood. These events involve a complex set of interdependent reactions between: (1) the surface; (2) platelets; and (3) coagulation proteins, resulting in the formation of a clot or thrombus which may subsequently undergo removal by; (4) fibrinolysis. The process is localized at the surface by opposing activation and inhibition systems, which ensure that the fluidity of blood in the circulation is maintained. In this chapter, a brief overview of the hemostatic mechanism is presented. Although a great deal is known about blood responses to injured arteries and blood-contacting devices, important relationships remain to be defined in many instances. More detailed discussions of hemostasis and thrombosis have been provided elsewhere (Forbes and Courtney, 1987; Stamatoyannopoulos et al., 1994; Gresle et al., 2002; Esmon 2003; Colman et al., 2005).

PLATELETS

Platelets ("little plates") are non-nucleated, disk-shaped cells having a diameter of 3–4 μm, and an average volume of 10×10^{-9} mm^3. Platelets are produced in the bone marrow, circulate at an average concentration of about 250,000 cells per microliter of whole blood, and occupy approximately 0.3% of the total blood volume. In contrast, red cells typically circulate at 5×10^6 cells per microliter, and may comprise 40–50% of the total blood volume. As discussed below, platelet functions are designed to: (1) initially arrest bleeding through formation of platelet plugs; and (2) stabilize the initial platelet plugs by catalyzing coagulation reactions leading to the formation of fibrin.

Platelet structure provides a basis for understanding platelet function. In the normal (nonstimulated) state, the platelet discoid shape is maintained by a circumferential bundle (cytoskeleton) of microtubules (Figure II.2.6.1). The external surface coat of the platelet contains membrane-bound receptors (e.g., glycoproteins Ib, and IIb/IIIa) that mediate the contact reactions of adhesion (platelet–surface interactions) and aggregation (platelet–platelet interactions). The membrane also provides a phospholipid surface which accelerates important coagulation reactions (see below), and forms a spongy, canal-like (canalicular) open network which represents an expanded reactive surface to which plasma factors are
FIGURE II.2.6.1 Platelet structure.
FIGURE II.2.6.2 Platelet reactions to artificial surfaces. Following protein adsorption to surfaces, platelets adhere and release α-granule contents, including platelet factor 4 (PF4) and β-thromboglobulin (β-TG), and dense granule contents, including ADP. Thrombin is generated locally through coagulation reactions catalyzed by procoagulant platelet surface phospholipids. Thromboxane A_2 (TxA_2) is synthesized. ADP, TxA_2, and thrombin recruit additional circulating platelets into an enlarging platelet aggregate. Thrombin-generated fibrin stabilizes the platelet mass.

selectively adsorbed. Platelets contain substantial quantities of muscle protein (e.g., actin, myosin) which allow for internal contraction when platelets are activated. Platelets also contain three types of cytoplasmic storage granules: (1) α-granules, which are numerous and contain the platelet-specific proteins platelet factor 4 (PF-4) and β-thromboglobulin (β-TG), and proteins found in plasma (including fibrinogen, albumin, fibronectin, coagulation factors V and VIII); (2) dense granules which contain adenosine diphosphate (ADP), calcium ions (Ca^{2+}), and serotonin; and (3) lysosomal granules containing enzymes (acid hydrolases).

Platelets are extremely sensitive cells that may respond to minimal stimulation. Activation causes platelets to become sticky and change in shape to irregular spheres with spiny pseudopods. Activation is accompanied by internal contraction and extrusion of the storage granule contents into the extracellular environment. Secreted platelet products such as ADP stimulate other platelets, leading to irreversible platelet aggregation and the formation of a fused platelet thrombus (Figure II.2.6.2).

Platelet Adhesion

Platelets adhere to artificial surfaces and injured blood vessels. At sites of vessel injury, the adhesion process involves the interaction of platelet glycoprotein Ib (GP Ib) and connective tissue elements, which become exposed (e.g., collagen) and require plasma von Willebrand factor (vWF) as an essential cofactor. GP Ib (about 25,000 molecules per platelet) acts as the surface receptor for vWF (Colman et al., 2005). The hereditary absence of GP Ib or vWF results in defective platelet adhesion and serious abnormal bleeding.

Platelet adhesion to artificial surfaces may also be mediated through platelet glycoprotein IIb/IIIa (integrin $\alpha_{IIb}\beta_3$), as well as through the GP Ib–vWF interaction. GP IIb/IIIa (about 80,000 copies per resting platelet) is the platelet receptor for adhesive plasma proteins which support cell attachment, including fibrinogen, vWF, fibronectin, and vitronectin (Gresle et al., 2002). Resting platelets do not bind these adhesive glycoproteins, an event which normally occurs only after platelet activation causes a conformational change in GP IIb/IIIa. Platelets which have become activated near artificial surfaces (for example, by exposure to factors released from already adherent cells) could adhere directly to surfaces through this mechanism (e.g., via GP IIb/IIIa binding to surface-adsorbed fibrinogen). Also, normally unactivated GP IIb/IIIa receptors could react with surface proteins which have undergone conformational changes as a result of the adsorption process (Chapter II.3.2). The enhanced adhesiveness of platelets toward surfaces preadsorbed with fibrinogen supports this view. Following adhesion, activation, and release reactions, the expression of functionally competent GP IIb/IIIa receptors may also support tight binding and platelet spreading through multiple focal contacts with fibrinogen and other surface-adsorbed adhesive proteins.

Platelet Aggregation

Following platelet adhesion, a complex series of reactions is initiated involving: (1) the release of dense granule ADP; (2) the formation of small amounts of thrombin (see below); and (3) the activation of platelet biochemical processes leading to the generation of thromboxane A_2. The release of ADP, thrombin formation, and generation of thromboxanes all act in concert to recruit platelets into the growing platelet aggregate (Figure II.2.6.2). Platelet stimulation by these agonists causes the expression on the platelet surface of activated GP IIb/IIIa, which then binds plasma proteins that support platelet aggregation. In normal blood, fibrinogen, owing to its relatively high concentration (Table II.2.6.1), is the most important protein supporting platelet aggregation. The platelet–platelet interaction involves Ca^{2+}-dependent bridging of adjacent platelets by fibrinogen molecules (platelets will not aggregate in the absence of fibrinogen, GP IIb/IIIa or Ca^{2+}). Thrombin binds directly to platelet thrombin receptors, and plays a key role in platelet aggregate formation by: (1) activating platelets which then catalyze the production of more thrombin; (2) stimulating ADP release and thromboxane A_2 formation; and (3) stimulating the formation of fibrin, which stabilizes the platelet thrombus.

Platelet Release Reaction

The release reaction is the secretory process by which substances stored in platelet granules are extruded from

TABLE II.2.6.1	Properties of Human Clotting Factors		
Clotting Factor	Apparent Molecular Weight (Number of Chains)	Approximate Normal Plasma Concentration (μG/Ml)	Active Form
INTRINSIC CLOTTING SYSTEM			
Prekallikrein	86,000 (1)	50	Serine protease
High molecular weight kininogen	120,000 (1)	70–90	Cofactor
Factor XII	80,000 (1)	30–40	Serine protease
Factor XI	160,000 (2)	3–6	Serine protease
Factor IX	55,000 (1)	3–5	Serine protease
Factor VIII[a]	330,000 (1)	0.1–0.2	Cofactor
Von Willebrand factor[a]	250,000 (1)	10	Cofactor for platelet adhesion
EXTRINSIC CLOTTING SYSTEM			
Tissue factor	47,000 (1)	0[b]	Cofactor
Factor VII	50,000 (1)	0.5	Serine protease
COMMON PATHWAY			
Factor X	59,000 (2)	8–10	Serine protease
Factor V	330,000 (1)	5–12	Cofactor
Prothrombin	72,000 (1)	100–150	Serine protease
Fibrinogen	340,000 (6)	1500–4500	Fibrin polymer
Factor XIII	320,000 (4)	10	Transglutaminase

[a]In plasma, factor VIII is complexed with von Willebrand factor, which circulates as a series of multimers ranging in molecular weight from about 600,000 to 2×10^7.
[b]The tissue factor concentration in cell-free plasma is absent or minimal since tissue factor is an integral cell membrane-associated protein expressed by vascular and inflammatory cells.

the platelet. ADP, collagen, epinephrine, and thrombin are physiologically important release-inducing agents, and interact with the platelet through specific receptors on the platelet surface. Alpha-granule contents (PF-4, β-TG, and other proteins) are readily released by relatively weak agonists such as ADP. Release of the dense granule contents (ADP, Ca^{2+}, and serotonin) requires platelet stimulation by a stronger agonist, such as thrombin. Agonist binding to platelets also initiates the formation of intermediates that cause activation of the contractile–secretory apparatus, production of thromboxane A_2, and mobilization of calcium from intracellular storage sites. Elevated cytoplasmic calcium is probably the final mediator of platelet aggregation and release. As noted, substances which are released (ADP), synthesized (TxA_2), and generated (thrombin), as a result of platelet stimulation and release, affect other platelets and actively promote their incorporation into growing platelet aggregates. *In vivo*, measurements of plasma levels of platelet-specific proteins (PF-4, β-TG) have been widely used as indirect measures of platelet activation and release.

Platelet Coagulant Activity

When platelets aggregate, platelet coagulant activity is initiated, including expression of negatively charged membrane phospholipids (phosphatidyl serine) which accelerate two critical steps of the blood coagulation sequence: factor X activation; and the conversion of prothrombin to thrombin (see below). Platelets may also promote the proteolytic activation of factors XII and XI.

The surface of the aggregated platelet mass thus serves as a site where thrombin can form rapidly in excess of the neutralizing capacity of blood anticoagulant mechanisms. Thrombin also activates platelets directly, and generates polymerizing fibrin which adheres to the surface of the platelet thrombus.

Platelet Consumption

In humans, platelets labeled with radioisotopes are cleared from circulating blood in an approximately linear fashion over time, with an apparent lifespan of approximately 10 days. Platelet lifespan in experimental animals may be somewhat shorter. With ongoing or chronic thrombosis that may be produced by cardiovascular devices, platelets may be removed from circulating blood at a more rapid rate. Thus steady-state elevations in the rate of platelet destruction, as reflected in a shortening of platelet lifespan, have been used as a measure of the thrombogenicity of artificial surfaces and prosthetic devices (Hanson et al., 1980, 1990).

COAGULATION

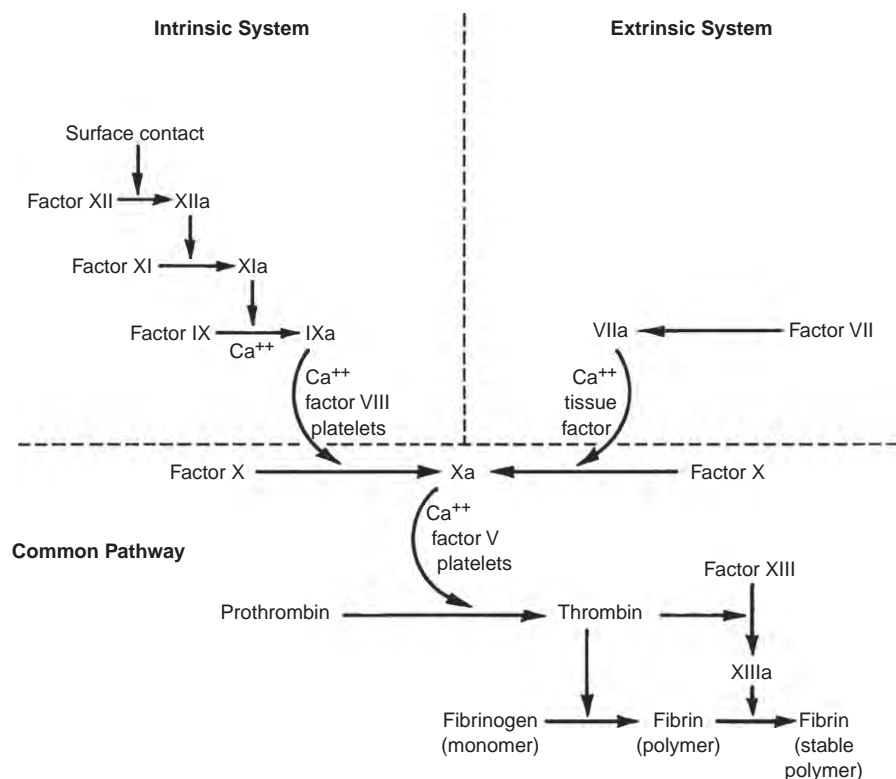
In the test tube, at least 12 plasma proteins interact in a series of reactions leading to blood clotting. Their designation as Roman numerals was made in order of discovery, often before their role in the clotting scheme was fully appreciated. Their biochemical properties are summarized in Table II.2.6.1. Initiation of clotting occurs either intrinsically by surface-mediated reactions or extrinsically through factors derived from


FIGURE II.2.6.3 Mechanisms of clotting factor interactions. Clotting factors (proenzymes), identified by Roman numerals, interact in a sequential series of enzymatic activation reactions (coagulation cascade) leading to the amplified production of the enzyme thrombin, which in turn cleaves fibrinogen to form a fibrin polymer that stabilizes the clot or thrombus. Clotting is initiated by either an intrinsic or extrinsic pathway with subsequent factor interactions which converge upon a final, common path. The underlined factors are all activatable by the enzyme thrombin. The dotted line highlights the importance of feedback activation of FXI by thrombin, which results in increased thrombin production.

tissues. The two systems converge upon a final common pathway which leads to the formation of thrombin and an insoluble fibrin gel when thrombin acts on fibrinogen.

Coagulation proceeds through a "cascade" of reactions by which normally inactive factors (e.g., factor XII) become enzymatically active following surface contact, or after proteolytic cleavage by other enzymes (e.g., surface contact activates factor XII to factor XIIa). The newly activated enzymes in turn activate other normally inactive precursor molecules (e.g., factor XIIa converts factor XI to factor XIa). Because this sequence involves a series of steps, and because one enzyme molecule can activate many substrate molecules, the reactions are quickly amplified so that significant amounts of thrombin are produced, resulting in platelet activation, fibrin formation, and the arrest of bleeding. The process is localized (i.e., widespread clotting does not occur) owing to dilution of activated factors by blood flow, the actions of inhibitors which are present or are generated in clotting blood, and because several reaction steps proceed at an effective rate only when catalyzed on the surface of activated platelets or at sites of tissue injury.

Figure II.2.6.3 presents a scheme of the clotting factor interactions involved in both the intrinsic and extrinsic systems, and their common path. Except for the contact phase, calcium is required for most reactions and is the reason why chelators of calcium (e.g., citrate) are effective anticoagulants. It is also clear that the *in vitro* interactions of clotting factors, i.e., clotting, is not identical with coagulation *in vivo*, which may be triggered by artificial surfaces and by exposure of the cell-associated protein, tissue factor. There are also interrelationships between the intrinsic and extrinsic systems, such that under some conditions "crossover" or reciprocal activation reactions may be important (Bennett et al., 1987; Colman et al., 2005).

MECHANISMS OF COAGULATION

In the intrinsic clotting system, contact activation refers to reactions following adsorption of contact factors onto a negatively charged surface. Involved are factors XII, XI, prekallikrein, and high molecular weight kininogen (HMWK) (Figure II.2.6.4). All contact reactions take place in the absence of calcium. Kallikrein also participates in fibrinolytic system reactions and inflammation (Bennett et al., 1987). Although these reactions are well-understood *in vitro*, their pathologic significance remains uncertain. For example, in hereditary disorders, factor XII deficiency is not associated with an increased bleeding tendency, and only a marked deficiency of factor XI produces abnormal bleeding.
FIGURE II.2.6.4 Contact activation. The initial event *in vitro* is the adsorption of factor XII to a negatively charged surface (hatched, horizontal ovoid) where it is activated to form factor XIIa. Factor XIIa converts prekallikrein to kallikrein. Additional factor XIIa and kallikrein are then generated by reciprocal activation. Factor XIIa also activates factor XIa. Both prekallikrein and factor XI bind to a cofactor, high molecular weight kininogen (HMWK), which anchors them to the charged surface. Kallikrein is also responsible for the liberation of the vasoactive peptide bradykinin for HMWK, linking coagulation and inflammation.

A middle phase of intrinsic clotting begins with the first calcium-dependent step, the activation of factor IX by factor XIa. Factor IXa subsequently activates factor X. Factor VIII is an essential cofactor in the intrinsic activation of factor X, and factor VIII first requires modification by an enzyme, such as thrombin, to exert its cofactor activity. In the presence of calcium, factors IXa and VIIIa form a complex (the "tenase" complex) on phospholipid surfaces (expressed on the surface of activated platelets) to activate factor X. This reaction proceeds slowly in the absence of an appropriate phospholipid surface, and serves to localize the clotting reactions to the surface (versus bulk fluid) phase. The extrinsic system is initiated by the activation of factor VII. When factor VII interacts with tissue factor, a cell membrane protein which may also circulate in a soluble form, factor VIIa becomes an active enzyme which is the extrinsic factor X activator. Tissue factor is present in many body tissues; is expressed by stimulated white cells and endothelial cells, and becomes available when underlying vascular structures are exposed to flowing blood upon vessel injury.

The common path begins when factor X is activated by either factor VIIa-tissue factor by or the factor IXa–VIIIa complex. After formation of factor Xa, the next step involves factor V, a cofactor which (like factor VIII) has activity after modification by another enzyme, such as thrombin. Factor Xa–Va, in the presence of calcium and platelet phospholipids, forms a complex ("prothrombinase" complex) which converts prothrombin (factor II) to thrombin. Like the conversion of factor X, prothrombin activation is effectively surface catalyzed. The higher plasma concentration of

prothrombin (Table II.2.6.1), as well as the biological amplification of the clotting system, allows a few molecules of activated initiator to generate a large burst of thrombin activity. Thrombin, in addition to its ability to modify factors V and VIII and activate platelets, acts on two substrates: fibrinogen and factor XIII. The action of thrombin on fibrinogen releases small peptides from fibrinogen (e.g., fibrinopeptide A) which can be assayed in plasma as evidence of thrombin activity. The fibrin monomers so formed polymerize to become a gel. Factor XIII is either trapped within the clot or provided by platelets, and is activated directly by thrombin. A tough, insoluble fibrin polymer is formed by interaction of the fibrin polymer with factor XIIIa.

CONTROL MECHANISMS

Obviously, the blood and vasculature must have mechanisms for avoiding massive thrombus formation once coagulation is initiated. At least four types of mechanisms may be considered. First, blood flow may reduce the localized concentration of precursors and remove activated materials by dilution into a larger volume, with subsequent removal from the circulation following passage through the liver. Second, the rate of several clotting reactions is fast only when the reaction is catalyzed by a surface. These reactions include the contact reactions, the activation of factor X by factor VII tissue factor at sites of tissue injury, and reactions which are accelerated by locally deposited platelet masses (activation of factor X and prothrombin). Third, there are naturally occurring inhibitors of coagulation enzymes, such as antithrombin III, which are potent inhibitors of thrombin and other coagulation enzymes (plasma levels of thrombin–antithrombin III complex can also be assayed as a measure of thrombin production *in vivo*). Another example of a naturally occuring inhibitor is tissue factor pathway inhibitor (TFPI), a protein that, in association with factor Xa, inhibits the tissue factor–factor VII complex. Fourth, during the process of coagulation, enzymes are generated which not only activate coagulation factors, but also degrade cofactors. For example, the fibrinolytic enzyme plasmin (see below) degrades fibrinogen and fibrin monomers, and can inactivate cofactors V and VIII. Thrombin is also removed when it binds to thrombomodulin, a protein found on the surface of blood vessel endothelial cells. The thrombin–thrombomodulin complex then converts another plasma protein, protein C, to an active form which can also degrade factors V and VIII. *In vivo*, the protein C pathway is a key physiologic anticoagulant mechanism (Esmon, 2003; Colman et al., 2005).

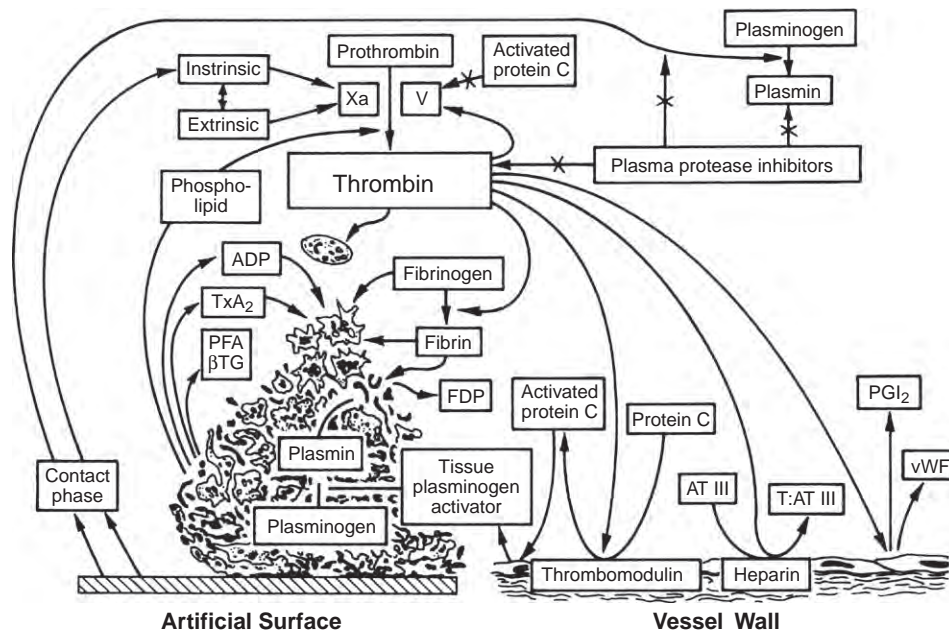
In summary, the platelet, coagulation, and endothelial systems interact in a number of ways which promote localized hemostasis while preventing generalized thrombosis. Figure II.2.6.5 depicts some of the relationships and inhibitory pathways which apply to blood


FIGURE II.2.6.5 Integrated hemostatic reactions between a foreign surface and platelets, coagulation factors, the vessel endothelium, and the fibrinolytic system.

reactions following contact with both natural and artificial surfaces.

Fibrinolysis

The fibrinolytic system removes unwanted fibrin deposits to improve blood flow following thrombus formation, and to facilitate the healing process after injury and inflammation. It is a multicomponent system composed of precursors, activators, cofactors, and inhibitors, and has been studied extensively (Forbes and Courtney, 1987; Colman et al., 2005). The fibrinolytic system also interacts with the coagulation system at the level of contact activation (Bennett et al., 1987). A simplified scheme of the fibrinolytic pathway is shown in Figure II.2.6.6.

The most well-studied fibrinolytic enzyme is plasmin, which circulates in an inactive form as the protein plasminogen. Plasminogen adheres to a fibrin clot, being incorporated into the mesh during polymerization. Plasminogen is activated to plasmin by the actions of plasminogen activators which may be present in blood or released from tissues, or which may be administered therapeutically. Important plasminogen activators occurring naturally in humans include tissue plasminogen activator (tPA) and urokinase. Following activation, plasmin digests the fibrin clot, releasing soluble fibrin-fibrinogen digestion products (FDP) into circulating blood, which may be assayed as markers of *in vivo* fibrinolysis (e.g., the fibrin D-D dimer fragment). Fibrinolysis is inhibited by plasminogen activator inhibitors (PAIs), and by a thrombin-activated fibrinolysis inhibitor (TAFI), which promotes the stabilization of fibrin and fibrin clots (Colman et al., 2005).
FIGURE II.2.6.6 Fibrinolytic sequence. Plasminogen activators, such as tissue plasminogen activator (tPA) or urokinase, activate plasminogen to form plasmin. Plasmin enzymatically cleaves insoluble fibrin polymers into soluble degradation products (FDP), thereby effecting the removal of unnecessary fibrin clot.

Complement

The complement system is primarily designed to effect a biological response to antigen–antibody reactions. Like the coagulation and fibrinolytic systems, complement proteins are activated enzymatically through a complex series of reaction steps (Bennett et al., 1987). Several proteins in the complement cascade function as inflammatory mediators. The end result of these activation steps is the generation of an enzymatic complex which causes irreversible damage (by lytic mechanisms) to the membrane of the antigen-carrying cell (e.g., bacteria).

Since there are a number of interactions between the complement, coagulation, and fibrinolytic systems, there has been considerable interest in the problem of complement activation by artificial surfaces, prompted in part by observations that devices having large surface areas (e.g., hemodialyzers) may cause: (1) reciprocal activation reactions between complement enzymes and white cells; and (2) complement activation which may mediate both white cell and platelet adhesion to artificial surfaces.

Further observations regarding the complement activation pathways involved in blood–materials interactions are likely to be of interest.

Red Cells

Red cells are usually considered as passive participants in processes of hemostasis and thrombosis, although under some conditions (low shear or venous flows) red cells may comprise a large proportion of the total thrombus mass. The concentration and motion of red cells have important mechanical effects on the diffusive transport of blood elements. For example, in flowing blood, red cell motions may increase the effective diffusivity of platelets by several orders of magnitude. Under some conditions, red cells may also contribute chemical factors that influence platelet reactivity (Turitto and Weiss, 1980). The process of direct attachment of red cells to artificial surfaces has been considered to be of minor importance, and has therefore received little attention in studies of blood–materials interactions.

White Cells

The various classes of white cells perform many functions in inflammation, infection, wound healing, and the blood response to foreign materials. White cell interactions with artificial surfaces may proceed through as yet poorly-defined mechanisms related to activation of the complement, coagulation, fibrinolytic, and other enzyme systems, resulting in the expression by white cells of procoagulant, fibrinolytic, and inflammatory activities. For example, stimulated monocytes express tissue factor, which can initiate extrinsic coagulation. Neutrophils may contribute to clot dissolution by releasing potent fibrinolytic enzymes (e.g., neutrophil elastase). White cell interactions with devices having large surface areas may be extensive (especially with surfaces that activate complement), resulting in their marked depletion from circulating blood. Activated white cells, through their enzymatic and other activities, may produce organ dysfunction in other parts of the body. In general, the role of white cell mechanisms of thrombosis and thrombolysis, in relation to other pathways, remains an area of considerable interest.

CONCLUSIONS

Interrelated blood systems respond to tissue injury in order to rapidly minimize blood loss, and later to remove unneeded deposits after healing has occurred. When artificial surfaces are exposed, an imbalance between the processes of activation and inhibition of these systems can lead to excessive thrombus formation, and an exaggerated inflammatory response. While many of the key blood cells, proteins, and reaction steps have been identified, their reactions in association with artificial surfaces have not been well-defined in many instances. Therefore, blood reactions which might cause thrombosis continue to limit the potential usefulness of many cardiovascular devices for applications in humans. Consequently, these devices commonly require the use of systemic anticoagulants, which present an inherent bleeding risk.

CHAPTER II.2.7 TUMORS ASSOCIATED WITH BIOMATERIALS AND IMPLANTS

Frederick J. Schoen
Professor of Pathology and Health Sciences and Technology (HST),
Hardvard Medical School, Executive Chairman, Department of
Pathology, Brigham and Women's Hospital, Boston, MA, USA

Biomaterials have been shown to be potentially tumorigenic in laboratory animals, and malignancies have occurred rarely in association with metallic and other implants in pets and humans. Thus, the possibility that implant materials could cause tumors or promote tumor growth has long been a concern of clinicians and biomaterials researchers. This chapter describes general concepts in neoplasia (i.e., the process of tumor formation), the association of tumors with implants in humans and animals, the pathobiology of tumor formation adjacent to (and potentially stimulated by) biomaterials, and other pathophysiologic interactions of biomaterials with tissues that may simulate tumor formation.

GENERAL CONCEPTS

Neoplasia, which literally means "new growth," is the process of excessive and uncontrolled cell proliferation (Kumar et al., 2010). The new growth is called a *neoplasm* or *tumor* (i.e., a swelling, since most neoplasms are expansile, solid masses of abnormal tissue). Tumors are either *benign* (when their pathologic characteristics and clinical behavior are relatively innocent) or *malignant* (meaning harmful, often deadly). Malignant tumors are collectively referred to as *cancers* (derived from the Latin word for crab, to emphasize their obstinate ability to adhere to adjacent structures and spread in many directions simultaneously). The characteristics of benign and malignant tumors are summarized in Table. II.2.7.1. Types of malignant tumors are shown in Figure. II.2.7.1. Benign tumors do not penetrate (invade) adjacent tissues, nor do they spread to distant sites. They remain localized and, thus, surgical excision can be curative in many cases. In contrast, malignant tumors have a propensity to invade contiguous tissues. Moreover, owing to their ability to gain entrance into blood and lymph vessels, cells from a malignant neoplasm can be transported to distant sites, where subpopulations of malignant cells take up residence, grow, and again invade as satellite tumors (called *metastases*).

The primary descriptor of any tumor is its cell or tissue of origin. Benign tumors are identified by the suffix "oma," which is preceded by a reference to the cell or tissue of origin (e.g., adenoma – from an endocrine gland; chondroma – from cartilage). The malignant counterparts of benign tumors carry similar names, except that the suffix *carcinoma* is applied to cancers derived from epithelium (e.g., squamous- or adeno-carcinoma, from protective and glandular epithelia, respectively), and *sarcoma* (e.g., osteo- or chondro-sarcoma, producing bone and cartilage, respectively) is applied to those of mesenchymal (i.e., connective tissue or vascular) origin. Malignant neoplasms of the hematopoietic (i.e., blood cell producing) system, in which the cancerous cells circulate in blood, are called *leukemias*; solid tumors of lymphoid tissue are called *lymphomas*.

Cancer cells express varying degrees of resemblance to the normal precursor cells from which they derive. Thus, neoplastic growth entails both abnormal cellular proliferation, and modification of the structural and functional characteristics of the cell types involved. Malignant cells are generally less differentiated than their original normal counterparts. The structural similarity of cancer cells to those of the tissue of origin enables specific *diagnosis* (of both source organ and cell type); moreover, the degree of resemblance to the corresponding normal tissue usually predicts *prognosis* of the patient (i.e., expected outcome based on biologic behavior of the cancer surmised from its pathologic characteristics). Therefore, poorly differentiated tumors are generally more aggressive (i.e., display more malignant behavior) than those that are better differentiated. The degree to which a tumor mimics a normal cell or tissue type is called its *grade* of differentiation. The extent of spread and other effects on the patient determine its *stage*.

Neoplastic growth is unregulated. Neoplastic cell proliferation is therefore unrelated to the physiological requirements of the tissue, and is unaffected by removal of the stimulus which initially caused it. Thus, its growth is autonomous. These characteristics differentiate neoplasms from: (1) normal proliferations of cells during fetal development or postnatal growth; (2) normal

TABLE II.2.7.1	Characteristics of Benign and Malignant Tumors	
Characteristics	**Benign**	**Malignant**
Differentiation	Well defined; structure may be typical of tissue of origin	Less differentiated, with bizarre (anaplastic) cells; often atypical structure
Rate of growth	Usually progressive and slow; may come to a standstill or regress; cells in mitosis are rare	Erratic, and may be slow to rapid; mitoses may be absent to numerous and abnormal
Local invasion	Usually cohesive, expansile, well-demarcated masses that neither invade nor infiltrate the surrounding normal tissues	Locally invasive, infiltrating adjacent normal tissues
Metastasis	Absent	Often present at distant sites; larger and more undifferentiated primary tumors more likely to metastasize
FIGURE II.2.7.1 Types of malignant tumors. (A) Carcinoma, exemplified by an adenocarcinoma (gland formation noted by asterisk). (B) Sarcoma (composed of spindle cells). (C) Lymphoma (composed of an aggregation of malignant lymphocytes). All stained with hematoxylin and eosin. (A, B and C courtesy of Robert F. Padera, M.D., Ph.D., Department of Pathology, Brigham and Women's Hospital, Boston, USA.)

wound healing following an injury; and (3) hyperplastic growth which adapts to a physiological need, but which ceases when the stimulus is removed.

Analogous to normal tissues (see Chapter II.1.5), benign and malignant tumors have two basic components: (1) proliferating neoplastic cells that constitute their *parenchyma*; and (2) supportive *stroma* made up of connective tissue and blood vessels. The parenchyma of neoplasms is characteristic of the specific cells of origin. Tumor growth and evolution are critically dependent on the non-specific stroma, which is usually composed of blood vessels, connective tissue, and inflammatory cells.

> Neoplasms occurring at the site of implanted medical devices are rare, despite the large numbers of implants used clinically over an extended period of time. Nevertheless, both human and veterinary implant-associated tumors have been reported, most as case reports or small series.

ASSOCIATION OF IMPLANTS WITH HUMAN AND ANIMAL TUMORS

Neoplasms occurring at the site of implanted medical devices are rare, despite the large numbers of implants used clinically over an extended period of time. Nevertheless, both human and veterinary implant-associated tumors have been reported, most as case reports or small series (Pedley et al., 1981; Schoen, 1987; Black, 1988; Jennings et al., 1988; Keel et al., 2001; Visuri et al., 2006a,b; Balzer and Weiss, 2009). In all, approximately 100 cases

of tumors associated with orthopedic and other surgical implants have been reported, and tumors related to other foreign materials (e.g., bullets, shrapnel, other metal fragments, sutures, bone wax, and surgical sponge) are also known. One review cites 46 cases of reported malignant tumors at the site of total hip arthroplasty from 1974 to 2002 (Visuri et al., 2006a). Tumors are also well-known to occur with environmental exposure and consequent pulmonary ingestion of foreign materials, especially asbestos, which has a cause-and-effect relationship with a special type of tumor called *mesothelioma* (Robinson et al., 2005).

The vast majority of malignant neoplasms associated with clinical fracture fixation devices, total joint replacements, vascular grafts, breast implants, and experimental foreign-bodies in both animals and humans are sarcomas (i.e., mesenchymal tumors). They comprise various histologic subtypes, including fibrosarcoma, osteosarcoma (osteogenic sarcoma), chondrosarcoma, malignant fibrous histiocytoma, angiosarcoma, etc., and are characterized by rapid and locally infiltrative growth. Therapeutic implant-related tumors have been reported both short- and long-term following implantation. In a more recent case series and review confined to orthopedic implant sarcomas (Keel et al., 2001), most presented less than 15 years following surgery; implant associated tumors presented as early as 0.5 years and as late as 30 years. An osteosarcoma has been reported forming adjacent to a clinical titanium total hip replacement for osteoarthritis three years following insertion in a 68-year-old man (illustrated in Figure. II.2.7.2) (Keel et al., 2001). Diagnosis was delayed, since the initial
FIGURE II.2.7.2 Orthopedic implant-related osteosarcoma in a 68-year-old man three years following total hip replacement. (A) Radiograph demonstrating the osteoblastic (i.e., bone-making) tumor surrounding the implant. (B) Photo of the tumor, showing its relationship to the implant and partially destroyed proximal femur. (C) Photomicrograph of tumor, demonstrating high-grade osteosarcoma. The cytologically malignant cells surround coarse lace-like neoplastic bone. (Courtesy of Andrew E. Rosenberg, M.D., Department of Pathology, University of Miami, Miami, FL, USA. symptoms of the tumor were attributed to the original orthopedic problem. Carcinomas, reported in association with foreign-bodies far less frequently, have usually been restricted to situations where an implant has been placed in the lumen of an epithelium-lined organ. Illustrative reported cases are noted in Table. II.2.7.2; descriptions of others are available (Jennings, et al., 1988; Goodfellow, 1992; Jacobs, et al., 1992; Keel et al., 2001; Balzer and Weiss 2009, Mallick et al. 2009). Lymphomas have also been reported in association with the capsules surrounding breast implants (Keech and Creech, 1997; Gaudet et al., 2002; Sahoo et al., 2003; Visuri et al., 2006a; Mallick et al., 2009). A non-implant-related primary tumor (gastric cancer) with a metastasis to a total knee replacement also has been reported (Kolstad and Hgstorp, 1990).

> Whether there is a casual role for implanted medical devices in local or distant malignancy in general or in specific cases remains controversial. In an individual case, caution is necessary in implicating the implant in the formation of a neoplasm; clearly, demonstration of a tumor occurring adjacent to an implant does not necessarily prove that the implant caused the tumor.

Whether there is a causal role for implanted medical devices in local or distant malignancy in general or in specific cases remains controversial. In an individual case, caution is necessary in implicating the implant in the formation of a neoplasm; clearly, demonstration of a tumor occurring adjacent to an implant does not necessarily prove that the implant caused the tumor (Morgan

and Elcock, 1995). Large-scale epidemiological studies and reviews of available data have concluded that there is no evidence in humans for tumorgenicity of non-metallic and metallic surgical implants (McGregor et al., 2000). Indeed, the risk in populations must be low, as exemplified by the recent cohorts of patients with both total hip replacement and breast implants that show no detectable increases in tumors at the implant site (Deapen and Brody, 1991; Berkel et al., 1992; Mathiesen et al., 1995; Brinton and Brown, 1997; Visuri, 2006b). Although cancers at most other (systemic) sites seem not to be increased, some studies suggest that there may be a slightly increased risk of the hematopoietic cancers (i.e., leukemias and lymphomas). Such cancers occur in organs where exogenous elements and particles may accumulate (e.g., lymph nodes); in this regard, one study suggests enhanced surveillance in total hip recipients with metal-on-metal articulations, in which the number of metallic particles is estimated to be much higher than with metal-on-plastic bearings (Visuri, 2006b), and the size of the particles smaller, with a correspondingly high reactive surface area. One clinical and experimental study suggested that the incidence of breast carcinoma may actually be decreased in women with breast implants (Su et al., 1995). Importantly, the presence of a breast implant does not impair the diagnosis of breast cancer (Brinton and Brown, 1997).

Moreover, neoplasms are common in both humans and animals, and can occur naturally at sites where biomaterials are implanted. Spontaneous human sarcomas in musculoskeletal sites are not unusual. Most clinical veterinary cases have been observed in dogs, a species

[a]Materials: D: Dacron; PMMA: poly(methacrylate) bone cement; SS: stainless steel; Ti: titanium; UHMWPE: ultra-high molecular weight polyethylene; V: Vitallium.
[b]Tumor types: AS: angiosarcoma; ES: epithelioid sarcoma; L: lymphoma; MFH: malignant fibrous histiocytoma; OS: osteosarcoma; RS: rhapdomyosarcoma; SS: synovial sarcoma; STS: soft tissue sarcoma.

with a relatively high natural frequency of osteosarcoma, and other tumors at sites where orthopedic devices are implanted. However, since sarcomas arising in the aorta and other large arteries are particularly rare, the association of primary vascular malignancies with clinical polymeric grafts may be stronger than that with orthopedic devices (Weinberg and Maini, 1980).

A possible association between anaplastic large cell lymphoma (ALCL) and breast implants, which has received recent attention from the FDA (Center for Devices and Radiological Health, FDA, 2011), exemplifies the difficulties in assessing cause-effect relationships with implant-associated tumors. Firstly, it is not possible to confirm with statistical certainty that breast implants cause ALCL. ALCL is extremely rare, and women with breast implants may have a very small but increased risk of developing this disease in the scar capsule adjacent to the implant (and not in other sites within the breast tissue). No association of risk with type of implant (silicone versus saline) or a reason for implant (reconstruction versus augmentation) has been established. ALCL has been identified most frequently in patients undergoing implant revision operations for late onset, persistent peri-implant fluid collection (seroma), with implant durations reported to vary from 3 to 23 years. Some researchers have suggested that breast implant-associated ALCL may represent a new clinical entity with less-aggressive (indolent) behavior than ALCL not associated with implants (Miranda et al., 2009).

Benign but exuberant foreign-body reactions may simulate neoplasms. A fibrous lesion caused by a foreign-body reaction which masquerades as neoplasm is often called *pseudotumor*. For example, fibrohistiocytic lesions resembling malignant tumors may occur as a reaction to silica, previously injected as a soft tissue sclerosing agent (Weiss et al., 1978), and exuberant fibrohistiocytic lesions have been reported in associated with the capsules forming around breast implants (Balzer and Weiss, 2009) and a polytetraethylene sleeve used in association with a lung cancer resection (Fernandez et al., 2008). Moreover, regional lymphadenopathy (i.e., enlargement of lymph nodes) may result from an exuberant foreign-body reaction to material which has migrated from a prosthesis through lymphatic vessels. This has been documented in cases of silicone emanating from both finger joints (Christie et al., 1977) and breast prostheses (Hausner et al., 1978), as well as in association with polymeric replacements of the temporomandibular joint, and with conventional metallic, ceramic, and polymeric total replacements of large joints (Jacobs et al., 1995).

Exuberant fibro-inflammatory lesions have been reported recently with breast implants, metal-on-metal hip replacements, and other implants. For example, such lesions have been reported in associated with the capsules forming around breast implants (Blazer, 2009) and a polytetraethylene sleeve used in association with a lung cancer resection (Fernandez, 2008). Moreover, locally-destructive pseudotumors have been reported recently in association with failed metal-on-metal hip resurfacing arthroplasty and may occur in as many as 1% of patients who have had metal-on-metal resurfacings (Kwon et al, 2010; Ebramzadeh et al, 2011; Guyer et al, 2011). The

cause is presently unknown, but a toxic and/or hypersensivity reaction to a high rate of particulate wear debris is considered to be a central feature.

PATHOBIOLOGY OF FOREIGN-BODY TUMORIGENESIS

Considerable progress has been made over the last several decades toward understanding the molecular basis of cancer (Kumar et al., 2010). Four principles are fundamental and well-accepted: (1) neoplasia is associated with, and often results from, non-lethal genetic damage (or mutation), either inherited or acquired by the action of environmental agents such as physical effects (e.g., radiation, fibers or foreign bodies; Fry, 1989), chemicals or viruses; (2) the principal targets of the genetic damage are cellular regulatory genes (normally present and necessary for physiologic cell function, inducing cellular replication, growth, and repair of damaged DNA); (3) the tumor mass evolves from the clonal expansion of a single progenitor cell which has incurred the genetic damage; (4) tumorigenesis is a multistep process, generally owing to accumulation of successive genetic lesions. After a tumor has been initiated, the most important factors in its growth are the kinetics (i.e., balance of replication or loss) of cell number change and its blood supply. The formation of new vessels (called *angiogenesis*) is essential for enlargement of tumors, and for their access to the vasculature, and hence, metastasis.

> The pathogenesis of implant-induced tumors is not well-understood, yet most experimental data indicated that physical effects rather than the chemical characteristics of the foreign-body are the principal determinants of tumorigenicity.

The pathogenesis of implant-induced tumors is not well-understood, yet most experimental data indicate that physical effects rather than the chemical characteristics of the foreign-body are the principal determinants of tumorigenicity (Brand et al., 1975). Tumors are induced experimentally by a wide array of materials of diverse composition, including those that could be considered essentially nonreactive, such as certain glasses, gold or platinum, and other relatively pure metals and polymers. Indeed, one surgeon performed a much-maligned experiment in which coins inserted in rats yielded a rate of 60% sarcomas in 16 months (prompting the suggestion that probably all metallic coins were carcinogenic and should be discontinued!) (Moore and Palmer, 1997). Solid materials implanted in a configuration with high surface area are most tumorigenic. Materials lose their tumorigenicity when implanted in pulverized, finely shredded or woven form, or when surface continuity is interrupted by multiple perforations. This trend is often called the *Oppenheimer effect*. Thus, foreign-body neoplasia is generally considered to be a transformation process mediated by the physical state of implants; it is largely independent of the composition of the materials, unless specific carcinogens are present. However, recent evidence suggests that tumor formation induced by nanoparticles is dependent on both the physical and chemical properties in a particle-dependent preneoplasia-neoplasia model (Hansen et al., 2006). Clearly, more detailed studies regarding the physical and chemical particle–tissue interactions are of vital interest for our understanding of the use of nanoparticles in medicine.

Solid-state tumorigenesis depends on the development of a fibrous capsule around the implant, a process that involves myofibroblasts (Hinz et al., 2007), mesenchymal cells which could be involved in tumor formation. Tumorigenicity corresponds directly to the extent and maturity of tissue encapsulation of a foreign-body, and inversely with the degree of active cellular inflammation. Thus, an active, persistent inflammatory response inhibits tumor formation in experimental systems. Host (especially genetic) factors also affect the propensity to form tumors as a response to foreign-bodies. Humans are less susceptible to foreign-body tumorigenesis than rodents, the usual experimental model. In rodent systems, tumor frequency and latency depend on species, strain, sex, and age. Concern has been raised over the possibility that foreign-body neoplasia can be induced by the release of wear debris or needle-like elements from composites in a mechanism that is analogous to that of asbestos-related mesothelioma (Brown et al., 1990; Jurand, 1991). However, animal experiments suggest only particles with very high length-to-diameter ratios (>100) produce this effect. Particles with this high aspect ratio are highly unlikely to arise as wear debris from orthopedic implants.

Nevertheless, cancer at foreign-body sites may be mechanistically related to that which occurs in diseases in which tissue fibrosis is a prominent characteristic, including asbestosis (i.e., lung damage caused by chronic inhalation of asbestos), lung or liver scarring, or chronic bone infections (Brand, 1982; Robinson et al., 2005). However, in contrast to the mesenchymal origin of most implant-related tumors, other cancers associated with scarring are generally derived from adjacent epithelial structures (e.g., mesothelioma with asbestos).

Chemical induction effects are also possible. With orthopedic implants, the stimulus for tumorigenesis could be metal particulates released by wear of the implant (Harris, 1994). Indeed, implants of chromium, nickel, cobalt, and some of their compounds, either as foils or debris, are carcinogenic in rodents (Swierenza et al., 1987), and the clearly demonstrated widespread dissemination of metal debris from implants (to lymph nodes, bone marrow, liver and spleen, particularly in subjects with loose, worn joint prostheses) could not only cause damage to distant organs, but also could be associated with the induction of neoplasia (Case et al., 1994). Although unequivocal cases of metal particles or elemental metals provoking the formation of malignant tumors are not available, continued vigilance and further

study of the problem in animal models is warranted (Lewis and Sunderman, 1996).

"Nonbiodegradable" and "inert" implants have been shown to contain and/or release trace amounts of substances such as remnant monomers, catalysts, plasticizers, and antioxidants. Nevertheless, such substances injected in experimental animals at appropriate test sites (without implants) in quantities comparable to those found adjacent to implants, are generally not tumorigenic. Moreover, chemical carcinogens, such as nitrosamines or those contained in tobacco smoke, may potentiate scar-associated cancers.

A chemical effect has been considered in the potential carcinogenicity of polyurethane biomaterials (Pinchuk, 1994). Under certain conditions (i.e., high temperatures in the presence of strong bases), diamines called 2,4-toluene diamine (TDA) and 4,4′-methylene dianiline (MDA) can be produced from the aromatic isocyanates used in the synthesis of polyurethanes. TDA and MDA are carcinogenic in rodents. However, it is uncertain whether: (1) TDA and MDA are formed *in vivo*; and (2) these compounds are indeed carcinogenic in humans, especially in the low dose rate provided by medical devices. Although attention has been focused on polyurethane foam-coated silicone gel-filled breast implants, one type of which contained the precursor to TDA, the risk is considered zero to negligible (Expert Panel, 1991).

Foreign-body tumorigenesis is characterized by a long latent period, during which the presence of the implant is required for tumor formation. Available data suggest the following sequence of essential developmental stages in foreign-body tumorigenesis: (1) cellular proliferation in conjunction with tissue inflammation associated with the foreign-body reaction (specific susceptible preneoplastic cells may be present at this stage); (2) progressive formation of a well-demarcated fibrotic tissue capsule surrounding the implant; (3) quiescence of the tissue reaction (i.e., dormancy and phagocytic inactivity of macrophages attached to the foreign body), but direct contact of clonal preneoplastic cells with the foreign-body surface; (4) final maturation of preneoplastic cells; and (5) sarcomatous proliferation. Support for this multistep hypothesis for foreign-body tumorigenesis comes from an experimental study by Kirkpatrick et al. (2000), in which premalignant lesions were frequently found in implant capsules. A spectrum of lesions was observed, from proliferative lesions without atypical calls, to atypical proliferation, to incipient sarcoma.

The essential hypothesis is that initial acquisition of neoplastic potential and the determination of specific tumor characteristics do not depend on direct physical or chemical interaction between susceptible cells and the foreign-body and, thus, the foreign-body *per se* probably does not initiate the tumor. However, although the critical initial event occurs early during the foreign-body reaction, the final step to neoplastic autonomy (presumably a genetic event) is accomplished only when preneoplastic cells attach themselves to the foreign-body surface. Subsequently, there is proliferation of abnormal mesenchymal cells in this relatively quiescent microenvironment, a situation not permitted with the prolonged active inflammation associated with less inert implants. Interestingly, a study, using a model of biomaterial-induced sarcoma formation in which preneoplastic changes in both tumors and the foreign-body-induced fibrous capsule can be studied by contemporary histologic and molecular techniques (Kirkpatrick et al., 2000), suggested that biomaterials-associated tumorigenesis does not occur by a specific genetic insult, and thereby is different from spontaneous tumorigenesis (Weber et al., 2009). The significance of this observation is not yet apparent.

Thus, the critical factors in sarcomas induced by foreign-bodies include implant configuration, fibrous capsule development and remodeling, and a period of latency long enough to allow progression to neoplasia in a susceptible host. The major role of the foreign-body itself seems to be that of stimulating the formation of a fibrous capsule conducive to neoplastic cell maturation and proliferation, by yet poorly-understood mechanisms. The rarity of human foreign-body-associated tumors suggests that cancer-prone cells are infrequent in the foreign-body reactions to implanted medical devices in humans.

> A new set of considerations related to tumorigenesis has arisen with the use of stem cells in tissue engineering and regenerative therapeutics.

A new set of considerations related to tumorigenesis has arisen with the use of stem cells in tissue engineering and regenerative therapeutics. It is well known that similar mechanisms underly developmemtal processes, would healing and tumor formation (Friedl and Gilmour, 2009). The possibility of tumor stimulation by autologous stem cells is probably minimal or absent (Brittberg et al., 1994), but embryonic stem cells (ESC) isolated from the mouse and human are pleuripotent, and have robust tumorigenicity as each readily forms teratomas when transplanted *in vivo* (Blum and Benvenisty, 2008). Human-induced pleuripotent stem cells (IPSC) are predicted to have a tumorigenic potential at least as great as ESCs (Knoeppler, 2009). This issue is certain to generate considerable research and controversy over the next several years.

CONCLUSIONS

Neoplasms associated with therapeutic clinical implants in humans are rare, and causality is difficult to demonstrate in any individual case. Experimental implant-related tumors are induced by a large spectrum of materials and biomaterials, dependent primarily on the physical, and not the chemical, configuration of the implant. The mechanism of experimental tumor formation remains incompletely understood. The potential for tumors associated with therapeutic applications of stem cells must be considered.

INTRODUCTION

The chapter "History of Biomaterials" at the start of this book documents the development and design of indwelling materials for medical and dental purposes. The initial design criteria in the choice of materials were pragmatic, and based on the necessary mechanical properties required to fashion a functional device. Orthopedic implants require strong materials for weight-bearing, and articulating surfaces such as joints require durability and resistance to wear. Stents and shunts require flexibility and patency, and sutures require a high tensile strength yet also must be flexible enough for intricate manipulation. As the devices became more sophisticated and developments in materials science provided more options for manufacture, implants are being used more frequently and with longer anticipated lifetimes. Concurrently, the design process increasingly incorporated biocompatibility and comfort into the design criteria. However, with longer lifetimes, the more frequent use of invasive surgical procedures involving indwelling devices and biologically-friendly materials, there has been a rise in the number of

incidences of device-related infection. Urinary catheters have been estimated to account for 30% of all nosocomial infections (Gould et al., 2010). Between 66 and 88% of these occur after urinary catheterization (Wong, 1983). It is also reported that almost 100% of catheterized patients develop an infection in an openly draining indwelling catheter which has been in place for four days or more (Wong, 1983). For some procedures, such as orthopedic joint arthroplasties, the diagnosed surgical site infection rates are relatively low (between 1% and 2%; Hsieh et al., 2009); however, the increasing number of patients undergoing joint-replacement surgery translates to large numbers of patients afflicted with the consequences of complicating infections per year. Furthermore, infection of artificial joints can be devastating, since oral or IV antibiotic therapy frequently fails to resolve the infection, with the only remaining course of action being surgical debridement or partial or total revision. These two examples, the first with very high numbers of patients but of lesser severity in terms of impact to the individual, and the second, low numbers but severe patient impact, reflect the incentive to pursue a third design criteria – that of infection resistance – into materials and devices (Maki and Tambyah, 2001). In the following sections we will discuss the role of bacterial biofilms in infection, and the growing literature highlighting biofilms as an important cause of device-related infection.

BACTERIAL BIOFILMS

What Are Biofilms, Where Are They Found, and Why Are They Problematic?

Bacterial biofilms are communities of bacteria which attach and subsequently grow on surfaces of abiotic materials, as well as host tissues (Stoodley et al., 2002; Hall-Stoodley and Stoodley, 2009) (Figure II.2.8.1). The bacteria embed themselves in a highly hydrated protective matrix termed "extracellular polymeric substance" (or sometimes slime) (EPS) (Donlan and Costerton, 2002). Biofilm development is an ancient adaptation of prokaryotes which is believed to have facilitated survival in hostile environments, and allowing colonization of new niches by active dispersal mechanisms (Hall-Stoodley and Stoodley, 2005; Purevdorj-Gage et al., 2005; Barraud et al., 2009; Davies and Marques, 2009; Kaplan, 2010).

Bacteria in biofilms also demonstrate coordinated behavior that culminates in the development of complex three-dimensional structures comprised of functionally heterogeneous bacterial communities on virtually all surfaces. Phenotypic heterogeneity and localized specialization in biofilms can be seen by differential expression of pili, fimbriae, flagella (Barken et al., 2008), carbohydrate (Vuong et al., 2004), adhesins (Hendrickx et al., 2009; Vergara-Irigaray et al., 2009), and genes associated with dormancy (Stewart and Franklin, 2008; Perez-Osorio et al., 2010) and antibiotic resistance
FIGURE II.2.8.1 Key processes in biofilm development based on the conceptual model described by Stoodley et al. (2002). For illustrative purposes this schematic shows a mixed biofilm consisting of rods capable of swimming motility (i.e., *P. aeruginosa* shown in red) and two types of non-motile cocci (i.e., *S. aureus* and *S. epidermidis* shown in green and yellow). The EPS slime matrix surrounding the cells is shown in green. (1) Initial attachment of single cells and clumps of detached biofilm bacteria. (2) Production of EPS to more firmly adhere cells to the surface. (3) Early development of biofilm clusters by clonal expansion (can be mixed or single species colonies). (4) Mature biofilm when the biofilm is in (pseudo) steady-state. (5) Dispersion of single cells by motility-driven swarming dispersion (*P. aeruginosa*) and the sloughing of biofilms clusters containing cells and EPS.

(Bagge et al., 2004). Biofilm bacteria coordinate their behavior by cell–cell communication using secreted chemical signals which allow the bacteria to sense and respond to their environment by assessing cell density or environmental cues, resulting in modification of gene expression. This ability to adapt to and modify microniches at a surface interface allows bacteria in biofilms to facilitate survival at a population level.

Adaptation of Biofilm Structure for Survival in Changing Environments

Biofilms growing in highly varied environments from hot springs to urinary catheters appear to utilize similar strategies to attach and grow on surfaces, and can also show remarkable structural similarity suggesting a selective advantage that surface association offers. This suggests that structural specialization in different environments reflects an important survival strategy. For example, biofilm growth under high fluid shear often exhibits filamentous streamers, while biofilms grown in low shear environments form towers or mound-like structures which vary according to different nutrient conditions or mass transfer-determined localized growth patterns. These observations suggest that bacteria in biofilms can rapidly adapt to their local environment, to an extent not possible with multicellular eukaryotic organisms (Donlan and Costerton, 2002; Hall-Stoodley et al., 2004).

Resistance of Bacteria in Biofilms

Numerous studies document that bacteria in biofilms are more resistant to environmental stresses, such as dehydration, metals toxicity, and UV light exposure,

than free floating or planktonic, bacteria. These strategies which have evolved for survival in the natural environment appear to be readily adapted to facilitate survival against human attempts to eradicate them with modern materials, antibiotics, and antimicrobials. The exact nature of the resistance is not fully understood, but the most commonly considered mechanisms are: (1) bacteria in the interior of the biofilm enter a dormant-like state (Klapper et al., 2007), possibly induced by nutrient depletion caused by consumption by bacteria on the periphery of the biofilm cell clusters (Fux et al., 2004); (2) reaction of the antimicrobial agent with the extracellular polymeric slime (EPS) matrix (binding and/or degradation) (Anderl et al., 2000); and (3) the development of resistant populations, such as slow growing small colony variants or "persister" cells which occur at greater frequency and in higher numbers in biofilm populations than in planktonic populations (Lewis, 2005).

The first and second mechanisms have been referred to as "tolerance" rather than "resistance," the latter of which is usually associated with a genetic basis (Harrison et al., 2007). In addition to providing a nidus for bacterial biofilm formation, foreign materials also suppress the efficacy of phagocytic clearance. The EPS matrix of carbohydrates, proteins, and extracellular bacterial DNA (eDNA) provides structural integrity, as well as protecting the bacterial cells within from phagocytic attack (Leid et al., 2002; Jesaitis et al., 2003; Bjarnsholt et al., 2005); although *in vitro* experiments suggest that the degree of protection also depends on the species and age of the biofilm (Guenther et al., 2009). The EPS also reduces the ability of IgG human antibodies to penetrate the biofilm (deBeer et al., 1997; Bryers and Drummond, 1998). Therefore, biofilm formation also appears to be a mechanism which helps bacteria to evade host immunity. Indeed, many diseases associated with biofilms (infection of the cystic fibrosis (CF) lung, otitis media, gingivitis) are also associated with chronic inflammation. Mounting evidence suggests that the "inappropriate" inflammatory response to biofilms often fails to eradicate the biofilm, and may in fact contribute to the pathology pathogenesis by degrading host tissue, which in turn provides nutrients to the bacteria.

BIOFILM MICROBIOLOGY AND INFECTIOUS DISEASE

Many of the concepts and techniques that have served microbiologists well in the understanding, diagnosis, and treatment of many acute epidemic bacterial diseases, are being re-evaluated with respect to device-related and other biofilm-associated infections. This section on biofilm microbiology will focus on how biofilm bacteria differ from their planktonic counterparts, and the importance of using appropriate biofilm *in vitro* assays to assess the potential bacterial colonization of biomaterials *in vivo*.

Bacterial Adhesion to Surfaces

Derjaguin, Landau, Verwey, and Overbeek (DLVO) theory is often applied to the study of bacterial adhesion to surfaces (van Loosdrecht et al., 1990). This classic concept of colloid behavior characterizes a planktonic bacterial cell as a smooth particle that interacts with a surface in a manner based on the charges on both surfaces, which overcome the basic repulsion of individual particles. However, direct observations of the surfaces of planktonic bacteria using electron microscopy have demonstrated that these surfaces are not smooth (Fux et al., 2005). In addition to protein appendages (i.e., flagella and pili) projecting as much as 2–6 μm from the cell, the entire surface of bacterial planktonic cells is covered by a structured matrix of hydrophobic exopolysaccharide (EPS) fibers and protein. The external glycocalyx of planktonic cells is anchored to the polysaccharide O antigen fibers that project from the lipopolysaccharide (LPS) of the outer membrane of gram-negative cells, and to the polysaccharide teichoic acid fibers that project from the cell wall of gram-positive cells. Elegant freeze-substitution microscopy preparations have shown that the actual surface of planktonic bacterial cells capable of interacting with a surface to be colonized consists of a 0.2–0.4 μm thick layer of protein and polysaccharide fibers. Thus, the planktonic bacterial cell is not a smooth-surfaced colloid particle, and the actual interaction of these cells with surfaces is based on the bridging of bacterial fibers with fibers adsorbed to the surface being colonized. Therefore, DLVO theory has a limited application in the study of bacterial adhesion.

Moreover, the reliance on bacteria isolated from the system of interest, but subcultured repeatedly in rich media, also does not serve us well in biofilm studies relevant to medical devices. This method, which dates from the 19th century, may select for strains of bacteria that exhibit rapid planktonic growth on rich media, since slow-growing strains might not be cultured or overgrown, and strongly adherent bacteria may not be readily transferred. Such strains may lack many surface structures that would be necessary for their survival in the real world on a surface where they are challenged by antibacterial agents, nutrient limitation, competing bacteria or host defenses. However, these laboratory-adapted strains used in studies of bacterial adhesion to biomaterials may be physically closer to the smooth-surfaced colloidal particles suggested in DLVO theory, potentially confounding data designed to further the understanding of device-related infections (Fux et al., 2005). This may help to explain why many novel biomaterials perform less successfully *in vitro* when tested with clinical isolates, and further highlights the necessity of using clinical strains in biomaterials testing. However, there are also challenges with using clinical isolates. Techniques such as rapid genomic sequencing (Hiller et al., 2007) and multi-locus strain typing (MLST) (Jefferies et al., 2004) have revealed an enormous amount

of genomic and phenotypic diversity between strains of the same species, and indeed biofilms appear to accelerate the generation of variants (Webb et al., 2004; Starkey et al., 2009). Thus, data generated from any one clinical isolate might, like reference strains, also not be generalizable. Thus, ideally, anti-biofilm assays should be conducted with reference strains to allow benchmark comparisons between studies in different laboratories, as well as at least two or three low-passage clinical isolates.

Many researchers in the biomaterials field have intuitively speculated that a few key surface characteristics can inhibit (or favor) bacterial adhesion, and surfaces engineered with various combinations of these characteristics have been tried in the search for colonization-resistant biomaterials. Bacteria adhere equally well to very hydrophobic (e.g., Teflon™) and to very hydrophilic (e.g., PVC) surfaces, can colonize smooth surfaces as well as rough surfaces (Marrie et al., 1982; Sottile et al., 1986), and can colonize surfaces in relatively high physiologically-relevant shear flows (Leid et al., 2002). Indeed, Bos et al. have reported that hydrophobicity had little correlation with initial attachment of various bacterial strains to surfaces, but was correlated with attachment strength (Bos et al., 1999). Thus, currently, while there is no perfect biocompatible biomaterial surface which also inherently resists bacterial colonization, more sophisticated non-fouling surfaces which incorporate designer antimicrobial peptides to target and kill bacteria (Loose et al., 2006) or zwitterionic surfaces which are generally resistant to protein adhesion (Cheng et al., 2007) show potential for this application.

Processes of Biofilm Formation

When planktonic cells adhere to a surface, they exhibit behaviors that have been divided into "reversible" and "irreversible" patterns (Marshall et al., 1971). Motile organisms (e.g., *P. aeruginosa*) may use their flagella for initial attachment, followed by type IV pili for twitching motility that allow them to form elaborate structures (Barken et al., 2008). However, surface appendages and motility are not required for biofilm formation, staphylococci and streptococci are both capable of forming biofilms *in vitro* and *in vivo*, although in these cases it is assumed that biofilm structures develop from clonal growth. Movies showing the attachment of various biofilm bacteria are available on the Center for Biofilm Engineering (CBE) web site (www.erc.montana.edu). Such movies show that many cells that adhere to surfaces may also quickly detach, before they make the phenotypic switch to initiate irreversible attachment and subsequent biofilm formation.

When a bacterial cell colonizes a surface, the pattern of gene expression is profoundly different from the previous planktonic phenotype, resulting in a distinct biofilm phenotype that may differ by as much as 70% in the proteins expressed (Sauer and Camper, 2001). Among the first genes that are upregulated in adherent cells are those involved in the production of molecules associated with the EPS that forms the biofilm matrix and anchors the cell irreversibly to the surface. In mucoid *P. aeruginosa*, the upregulation of *algC*, which is a part of the alginate synthesis pathway, occurs within 18 minutes of initial cell adhesion (Davies and Geesey, 1995), and there is a secretion of bacterial biofilm matrix material by these cells within 30 minutes. Once attached, cells which have triggered the conversion to the biofilm phenotype and the formation of a multicellular community on the colonized surface begin to accrete larger numbers of cells through growth. As they increase in numbers and produce more EPS matrix material, the attached cells form microcolonies which constitute approximately 10% of the volume, with the EPS matrix occupying approximately 90% of the biofilm. Recent data suggest that the structure of the EPS is much more sophisticated than previously thought, with confocal and SEM (scanning electron microscope) images showing features such as "honeycombs" and 3D networks in *P. aeruginosa* and staphylococcal biofilms grown *in vitro* (Schaudinn et al., 2007). Borlee et al. (2010) have found evidence for secreted proteins which specifically cross-link extracellular polysaccharides, suggesting a possible mechanism for extracellular remodeling of the EPS.

The microcolonies can assume tower-like, frond, and mushroom-like structures in many natural and cultured biofilms, but other morphologies may be dictated by individual species characteristics, and by nutrient availability. As the biofilm matures and undergoes more phenotypic changes, the processes of growth and recruitment are balanced by detachment of planktonic cells from the sessile community and sloughing of larger pieces of biofilm. *In vitro* studies suggest that biofilms reach a mature thickness and a stable community structure within a week or two of their initiation of colonization (Stoodley et al., 2002). Numerous *in vitro* studies show that both gram-negative and gram-positive pathogens are clearly capable of forming extensive biofilms on commonly used medical materials, including devices themselves, such as surgical sutures and meshes (Engelsman et al., 2007), and orthopedic implants and catheters (Jacobsen et al., 2008; Machado et al., 2009).

DEVICE-RELATED INFECTION

Although biofilm formation may be an ancient adaptation of prokaryotic life, the full impact of biofilms on human health is only now being realized, through one of the fastest technologically advancing fields – the development of medical devices, which are all susceptible to colonization with microorganisms growing in biofilms.

Medical and surgical practices rely on an increasing array of biomedical implants, and tens of millions are implanted each year. Intravenous catheters, prosthetic heart valves, joint prostheses, peritoneal dialysis catheters, cardiac

pacemakers, cerebrospinal fluid shunts, and endotracheal tubes certainly save millions of lives, but all carry the risk of surface-associated infections. Device-related infections were among the first clinical problems to be identified as having a bacterial biofilm etiology. Biofilms associated with medical devices were first noted in the literature in the early 1980s, although Bayston and Penny published a report in 1972 that correlated *Staphylococcus mucoidy* as a possible factor in the colonization of Holter shunts (Bayston and Penny, 1972). Electron microscopy revealed bacteria deposited on the surface of indwelling devices such as intravenous catheters and a cardiac pacemaker lead (Marrie et al., 1982). However, the relationship between medical devices and infection is arguably best established for catheters (O'Grady et al., 2002). Many types of catheters and fluid management devices, such as central venous catheters, dialysis catheters, ventilators, neurosurgical shunts, and drains are also commonly associated with infection (Rolighed, 2010).

Implant infections are common occurrences, with rates estimated between 4–5% for orthopedic implants and 7% for cardiovascular implants (Campoccia et al., 2006; Hetrick and Schoenfisch, 2006). Due to the increasing use of these interventions, infections affect millions of patients per year, making device related infections a serious clinical problem that is being addressed from many perspectives.

There is a clear correlation between implanted devices and risk of infection, which may not be surprising since any time the protective skin barrier is breached, the possibility for introduction of bacteria to normally sterile sites exists. A 1979 study by Fitzgerald (Fitzgerald, 1979), and discussed in Subbiahdoss et al. (2009), reported that during surgery a wound was exposed to approximately 270 bacterial-carrying particles per cm^2 per hour. No doubt with improved operating room (OR) facilities, such as laminar flow air handling and the implementation of more rigorous practices aimed at reducing the rates of nosocomial infections, this rate will have decreased. Nevertheless, the study illustrates that possible airborne contamination can occur within the "sterile field." Possibly of greater concern is the introduction of skin pathogens during the procedure. Higher rates of infection associated with more heavily microbially-colonized anatomical sites (such as the groin or armpit), suggest that transmission from the skin, despite disinfection of the skin, is an important route of transmission. Even devices which are not transdermal or surgically implanted, such as urinary catheters, are associated with a high risk for infection, in part due to the fact that these devices are placed in patients who are already immunocompromized, and it is likely that many catheters are being placed in an already infected site.

In the controlled condition of a hospital the device be implanted is sterile immediately out of the packaging. However, once it is exposed there is potential for the implant to be contaminated with bacteria that might also have inadvertently enter the wound during surgery. The probability of infection has been related to the relative time taken to colonize the artificial surface by host cells or infectious microorganisms. This was termed "The race to the surface" by Gristina et al. (1988), who hypothesized that if a surface was colonized with host cells before a biofilm could become established, the probability of subsequent infection was low, even if bacteria were introduced during the procedure. Subbiahdoss et al. (2009) experimentally demonstrated the importance of the "race to the surface" by showing that the successful colonization of a glass substratum by osteosarcoma cells was negatively influenced by preseeded *S. epidermidis* cells on the surface. Whether this observation is generalizable to the *in vivo* situation remains to be verified.

Although device-related infections are initially localized to the site where the device is inserted, these infections are often chronic in nature and can be a source of periodic acute sepsis. The direct link between the presence of a foreign body and bacterial sepsis in hemodialysis catheters is illustrated in a study by Feely (Feely et al., 2007). In a group of hemodialysis patients with a history of recurrent bacteremia, the rate of catheter-related bacteremia went down from 9.13 per 1000 catheter days to 1.04 after catheter-lock solutions (CLS) were instigated. When CLS was discontinued, the rate rose back up to 7.94 per 1000. Catheter lock is a technique whereby a controlled volume of antibiotic solution is introduced into a catheter so as to fill the catheter, but is not allowed to enter the bloodstream. Thus, much higher concentrations of antibiotics can be applied directly to the catheter than would otherwise be tolerated systemically. This study clearly implicates the foreign body as harboring the source of infection.

The organisms most frequently observed with medical devices are the staphylococci, both the coagulase negative staphylococci (particularly *Staphylococcus epidermidis*) and *S. aureus* followed by *P. aeruginosa* and other opportunistic bacteria that survive in the environment. Biofilm formation on medical implants, most notably by *S. epidermidis*, has led to the characterization of a new infectious disease: "chronic polymer-associated infection" (von Eiff et al., 1999; Gotz, 2002). *S. epidermidis*, a common colonizer of the skin, is therefore frequently found in wounds and implants. It was not considered even an opportunistic pathogen until device-related infections became problematic (Otto, 2009). Biofilm formation therefore can be considered a virulence factor in the context of device-related infections – a bacterial strategy that contributes to its ability to cause and maintain an infection.

Biofilm Formation by Staphylococci

Staphylococci are particularly problematic in biofilm-associated infections with surgical site infection of deep tissue implants. This is partly due to the propensity of these organisms to form biofilms, and the increasing spread of multi drug-resistant methicillin-resistant *S. aureus* (MRSA) and *S. epidermidis* (MRSE). Biofilm

formation is characterized by two stages with staphylococci: (1) adhesion to a solid surface; and (2) growth-dependent cell accumulation resulting in multiple cell layers in microcolonies. In *S. epidermidis*, the cell–cell layer aggregation is specifically linked with a β-1,6-linked glycosaminoglycan polysaccharide complex know as polysaccharide intercellular adhesin (PIA) (Mack et al., 1996). Proteins involved in the synthesis of this matrix polysaccharide are regulated by the *ica* gene locus in *S. epidermidis* (Heilmann et al., 1997; Chang et al., 2010) which is conserved among phyologenetically related staphylococci. However, PIA and *ica* are not absolutely required for biofilm formation, since mutants lacking the *ica* locus have been isolated which can still form biofilms, suggesting complex, redundant mechanisms for biofilm development. For example, an *S. epidermidis* transposon mutant, unable to form biofilms on polystyrene, formed biofilms on glass, suggesting that bacterial adhesion mechanisms vary according to the substratum (Heilmann et al., 1997).

A further level of complexity comes from the numerous environmental factors that can affect biofilm formation. For example, biofilm formation in *S. epidermidis* is strongly influenced by sugar substrate, oleic acid, antibiotic treatment, oxygen levels, iron, osmolarity, temperature, and ethanol stress (Gotz, 2002). Also, the initial adhesion stage alone is multifactorial, depending on the physio-chemical properties of the biomedical polymer material, and the nature of the bacterial cell surface. Bacterial surface proteins contribute significantly to adhesion, and several key proteins have been identified that play a role in staphylococcal biofilm formation. In *S. aureus*, teichoic acid lacking D-alanine (dltA) resulted in a change in surface charge that affected several characteristics, including biofilm formation (Gross et al., 2001). Interestingly, dltA mutants were defective in the ability to attach to polystyrene and glass. While consistent with charge equilibrium of surface interactions, the biofilm defect was re-established by the addition of magnesium ions. Other researchers found that *S. epidermidis* biofilm formation was enhanced by Mg^{2+} and inhibited by EDTA (Dunne and Burd, 1992). Another surface protein in *S. aureus*, the biofilm-associated protein or bap, was shown to contribute to biofilm formation on microtiter plates, but more importantly showed increased pathogenesis in a mouse foreign-body infection model (Cucarella et al., 2002).

Detecting Device-Related Infections

Biofilm-associated infections are often difficult to detect using conventional culturing methods (Parsek and Singh, 2003), and many of the clinical studies which conclude that biofilms were present on a medical device rely on indirect evidence such as the recovery of bacteria removed using sonication (Tunney et al., 1998; Trampuz and Widmer, 2006; Bjerkan et al., 2009) or the culture of strains positive for slime production or biofilm formation (Arciola et al., 2006). Arguably, at the present time

microscopic examination of the devices and associated tissue themselves, are still the only way to definitively demonstrate the presence of biofilm (Hall-Stoodley and Stoodley, 2009; Marrie et al., 1982). Confocal microscopy has an advantage over electron microscopy, in that it can be performed on fully hydrated specimens using water immersion objectives, which, in itself, demonstrates firm attachment of the bacteria to the surface, and is also compatible with a wide range of specific fluorescent staining techniques, including antibody labeling and fluorescent *in situ* hybridization (FISH), to identify bacterial species, or membrane integrity-based nucleic acid viability staining methods to detect live and dead bacteria. Figure II.2.8.2 shows an example of predominantly staphylococcal biofilm growing on a surgical screw.

Bacteria can also be identified through the detection of their DNA. First, a specimen or swab is digested to release any bacterial DNA. Next the polymerase chain reaction (PCR) is used to amplify specifically targeted fragments of DNA. In some cases the targets are specifically designed for a certain species, genus or strain. In other cases sections of universal genes, such as 16s ribosomal DNA (rDNA), are amplified using primers to highly conserved regions while the sequencing of the variable region between the primers can identify the bacteria.

While PCR-based 16S rDNA detection methods appear to be much more accurate than conventional clinical culture, which has increasingly been shown to produce high levels of false negatives in chronic biofilm-associated infections, PCR for targeted genes does not differentiate between biofilm and planktonic infections. PCR has also been criticized for being too sensitive, and producing false positives from contaminants which are not clinically relevant. However, the visual demonstration of clusters of bacteria firmly attached to devices demonstrates a "growth-in-place" process, which is unlikely to have resulted from contamination during the relatively short period of the surgery. Therefore, confocal microscopy, PCR, and reverse transcriptase PCR (RT-PCR) have been used in combination to provide strong evidence for the presence of active bacterial biofilms on various implant materials (Nucci et al., 2005; Stoodley et al., 2008, 2010, 2011) as well as host tissue (Hall-Stoodley et al., 2006; James et al., 2008; Schlafer et al., 2008; Bjarnsholt et al., 2009). However, a drawback of confocal microscopy-based diagnosis of biofilm is that it requires highly specialized equipment and training, along with laborious searching for clusters of bacteria with dimensions as low as 10s to 100s of microns on implants that might have large areas with convoluted surfaces.

While confocal microscopy might be useful to validate more rapid methods which are conducive to standardization in the setting of a clinical laboratory, it will require refinement of the existing technology before it can be used as a routine diagnostic tool. Ideally, the diagnosis of a biofilm infection would be made prior to surgery. One approach is to devise enzyme-linked immunosorbent
FIGURE II.2.8.2 Biofilm attached to orthopedic screws from a non-union fracture case. The surface of the screw and associated invested tissue are blue and imaged by reflected confocal microscopy. Staphylococci were stained red by fluorescence *in situ* hybridization (FISH) using the Sau probe. General bacteria were stained green with the Eub338 probe. The overlay (bottom left) shows that the biofilm consisted primarily of staphylococci with occasional other types of cocci. Scale bar = 25 μm.

array (ELISA) type assays to detect biofilm specific proteins through a simple blood test (Brady et al., 2007). Another approach is to develop medical imaging techniques, such as X-ray computed tomography (CT) scan or magnetic resonance imaging (MRI) scans, so that biofilms can be visualized in place. However, the small size of the biofilm, and the lack of contrast between biofilm and host tissue, makes imaging a challenge. In diagnostic imaging for cancer detection contrast agents are used which help distinguish the malignant cells from the healthy tissue. The importance of more effectively treating cancer through early detection has led to much research and development in the imaging of ever smaller tumors, and it is possible that techniques developed in oncology could be utilized for detection of biofilms. Imaging is not only useful for diagnostics, but also has the added advantage in that it can be invaluable in monitoring and planning surgical intervention.

Nucleic Acid-Based Detection Methods

PCR-based detection techniques generally fall into one of two categories. One approach is targeted PCR in which genus, species or strain-specific primers or combinations of primers are used to detect pathogens of interest. However, this approach does not provide any information regarding the presence or absence of non-targeted bacteria. A second approach is a "finger-printing method," by which primers are used to amplify universal DNA sequences (16S rDNA is commonly used). The amplicon is separated out as bands on a gel by techniques such as denaturing gel gradient electrophoresis (DGGE) (Li et al., 2005) or, after digestion using restriction enzymes, by restriction fragment length polymorphism (RFLP) (Dempsey et al., 2007). The separation patterns can be used to identify specific species. However, in polymicrobial infections the many overlapping and complex patterns of bands can be difficult to resolve.

A more specific approach is to sequence the various 16S amplimers from individual bacterial colonies in a clone library or directly by high-throughput sequencing techniques, such as 454 pyrosequencing (Hamady et al., 2008; McKenna et al., 2008). Individual species can be identified by comparing the cloned sequences with database sequences, using tools such as the Basic Local Alignment Search Tool (BLAST). The drawback of these approaches is that they are relatively time consuming, either in the preparation of the library or the data analysis, and are not yet conducive for utility where a rapid diagnosis is needed. An alternative approach is the combination of PCR with ion spray mass spectroscopy to precisely weigh each complementary strand of the amplimer. Bacterial species can be identified by mass due to differences in the nucleotide ratios. Multiple sets of primers are used to amplify sequences from genes which are universal to bacteria (i.e., 16S and 23S rDNA), and genes or alleles specific to certain species or strain (Ecker et al., 2008). More targeted primer sets can be designed to identify site-specific pathogens or the presence of the bacterial virulence genes, such as *mecA* which is responsible for methicillin resistance in *S. aureus* (MRSA) (Costerton et al., 2010; Stoodley et al., 2011). Primer sets could be designed to detect genes associated with biofilm formation, such as the *ica* operon which regulates EPS production in staphylococci.

CLINICAL EXAMPLES OF BIOFILM INFECTIONS

Infection Related to Surgical Repair Materials

Surgical repair materials, such as staples, sutures, and meshes, have also been identified as possible foci of infection in such diverse anatomic sites and procedures as abdominal wall repair and ocular and dental procedures (Nucci et al., 2005; Otten et al., 2005; Edmiston et al., 2006; Engelsman et al., 2007). The implication of the foreign body as a causative factor of infection is supported in a study by Wissing et al. (1987), who reported that the late post-operative incidence of suture sinus development associated with fascia repair after midline laparotomy was significantly greater with nonabsorbable sutures (nylon) than with absorbable sutures (polyglactin or polydioxanone). There was a direct relationship between material absorption time and incidence of sinus formation, which was 3–4% for polyglactin, which is fully absorbed after 70 days, 11% for polydioxanone, which is fully absorbed after 180 days, and 23% for nylon, which is permanent. This study nicely illustrates the compromise that has to be made between functionality of the material and the risk of infection, since there was an inverse relationship between the incident rate of incisional herniation and suture absorption time caused by the loss of tensile strength during the absorption process.

Bacterial Biofilms on Sutures

Bacterial adherence to, and colonization of, suture material has been of interest to the surgical community for decades. Thirty years ago Osterberg and Blomstedt observed that multifilament "capillary" suture material recovered from *S. aureus*-inoculated tissues in a rat model harbored substantially greater quantities of bacteria than "non-capillary" suture (Osterberg and Blomstedt, 1979). Their conclusion was that: "in the case of the capillary suture material, the bacteria would tend to be protected through their enclosure in the interstices of the material." In a subsequent study, Osterberg further commented that "bacteria which are enclosed in the interstices of multifilament suture material, and protected from the phagocytic activity of leukocytes, can sustain and prolong an infection" (Osterberg, 1983). These prescient early observations concur well with our present understanding of bacterial biofilm formation and persistence, but suture material as a host for pathogenic biofilm in patients has thus far been only occasionally examined (principally in the ophthalmologic literature). We have reported several cases where biofilm was documented on clinical specimens of explanted permanent suture material, with resolution of the infection on removal of the offending suture substratum (Kathju et al., 2009, 2010) (Figure II.2.8.3). Multiple studies have noted that "suture sinuses" are associated with nonabsorbable suture materials, presumably due to resident biofilm, although direct evidence was lacking (Hodgson et al., 2000; van't Riet et al., 2002).

Prevention of infectious complications by modifying the suture material itself has recently become an area of intense interest. A number of studies have focused on suture materials coated with the antimicrobial agent triclosan. *In vitro* and *in vivo* animal experiments have shown that coated polyglactin 910 suture (braided) can significantly decrease the number of viable bacteria recovered from inoculated suture material versus a non-coated control (Edmiston et al., 2006; Storch et al., 2004). Similar antimicrobial activity has also been reported with the addition of triclosan to poliglecaprone 25 (Ming et al., 2007) and polidioxanone (Ming et al., 2008) suture. Early clinical experience has also been promising: use of triclosan-coated polyglactin 910 suture versus uncoated polidioxanone suture in 2088 patients undergoing midline laparotomy resulted in a significantly reduced reported incidence of wound infection (Justinger et al., 2009).

Bacterial Biofilms on Surgical Mesh

Surgical mesh implants are routinely used to address the clinical problem of hernia. These implants typically restore structural domain to the abdominal/pelvic wall and prevent extrusion of visceral contents. Multiple complications have been associated with the use of surgical mesh, including infection, extrusion, and erosion into subjacent structures (i.e., development of
FIGURE II.2.8.3 Biofilm infected sutures. (A) Ti-cron braided polyester suture used for hernia repair following open gastric bypass surgery removed from a chronic draining wound was found to have a biofilm formed from live cocci (stained green with the BacLight™ LIVE/DEAD® kit). Diffuse green staining (arrow) is suggestive of eDNA in the biofilm slime matrix. The individual filaments of the suture are shown by autofluorescence (blue). Biofilm was particularly noted in the crevices formed from the braiding. Scale bar = 4 μm. (B) The same suture as in "A" but at a location a few mm away. In this location there were many inflammatory cells indicated by nuclear morphology (nuclei stained yellow and red). Scale bar = 20 μm. (C) *In vitro* biofilm grown on braided sutures from a clinical MRSA (stained green with the LIVE/DEAD® kit) isolated from a patient with an infected surgical repair mesh. Similar to the *ex vivo* image the biofilm preferentially grew in the protected crevices between individual filaments in the braid. Scale bar = 50 μm. (D) Higher magnification confocal image of the suture at a different location. Scale bar = 20 μm.

enterocutaneous fistula). Not infrequently, surgical mesh implants must be removed, often due to infectious complications, and recently an entirely new "current procedural terminology" code (11008) describing the explantation of abdominal wall mesh due to chronic and necrotizing infection has been recognized.

Multiple studies have examined the morphological and surface characteristics of various available meshes, and have documented the ability of both gram-negative and gram-positive organisms to form biofilms on these materials (Engelsman et al., 2008; Aydinuraz et al., 2009). The hydrophobicity of the mesh surface, as well as the presence of numerous niches (or pockets) in multifilament mesh configurations, appear to correlate with the extent of biofilm formation *in vitro* (Engelsman et al., 2008). We have been able to demonstrate biofilms present on clinical specimens of explanted mesh from patients with a variety of clinical presentations (Stoodley et al., manuscript in preparation).

A similar approach to modifying mesh materials (as has been done with suture) may prove beneficial to reducing the infectious complications noted with surgical mesh, but these studies are in their infancy. Monofilament polypropylene mesh modified with a coating to release nitric oxide in bactericidal quantities was found to significantly inhibit biofilm from multiple organisms *in vitro*, but had little effect in an *in vivo* animal model (Engelsman et al., 2009). Clinically, acellular dermal grafts composed entirely of organic materials and therefore presumably less susceptible to the establishment of persistent biofilms, have recently gained popularity as alternatives to mesh reconstruction in abdominal wall surgery.

Bacterial Biofilms in Orthopedic Prosthetic Joint Infection

Orthopedic implant infections differ clinically from the previous infections described, for several reasons. First,

although they are chronic and persistent like all biofilm infections, they often develop months or years after the implant. Second, these infections are often difficult to detect in orthopedic implants via routine examination or culturing, thereby delaying diagnosis and treatment. Third, unlike the catheter lock solution treatment, there is no easy way to deliver high doses of antibiotics to the site. Therefore, orthopedic infections often require repeated antibiotic applications to resolve the infection, which increases the risk of the development of antibiotic resistance. Finally, treatment of chronic infections that fail to resolve with conventional antibiotic treatment may require sustained high dose antibiotic therapy, removal of the implant, and replacement of the orthopedic implant, resulting in pain and discomfort, immobility, and excessive costs to the patient and healthcare facility. The failure of antibiotics to effectively and fully treat these infections suggests that other strategies are necessary; approaches to resolve these problems range from enhancing hospital sterility protocols to the investigation of active release (Campoccia et al., 2006), nonadhesive or bactericidal coatings (Senaratne et al., 2005; Khoo et al., 2009; Zhao et al., 2009). Despite researchers' best efforts, often the only treatment for intractable implant infections is revision surgery, requiring removal of the infected implant and placement of a new one. However, secondary (revisional) total hip replacements have a higher infection rate (3.2%), and secondary total knee replacements exhibit a remarkable 5.6% re-infection rate. To compound the problem, in revision surgery a larger implant must be used, since bone is destroyed during the original implantation and subsequent explantation. This process may require splintering the surrounding bone, along with substantial soft tissue resection and debridement. The patient is then confined to absolute bed rest and continuous intravenous antibiotic therapy for several weeks. If the revisional surgery fails, limb amputation may occur. The number of total hip and knee replacements within the United States surpassed 1,000,000 in 2009 (http://www.cdc.gov/nchs/fastats/insurg.htm), and is expected to increase dramatically over the next several decades due to specific risk factors within the US population that include obesity, sports injuries, and longer lifespan. In addition to the physical and emotional costs, the financial cost of revisions is high, with explant surgery, post-procedural medical treatment, and re-implantational surgery exceeding $500,000 per patient. Conservative estimates put the current costs of revisional therapy in excess of two billion dollars annually.

Addressing this objective, the 2004 Association of Bone and Joint Surgeons Musculoskeletal Infection Workshop (Hanssen et al., 2005) suggested that orthopedic materials designed to prevent bacterial biofilm formation would be a relevant clinical strategy for reducing orthopedic device infections. Therefore, the investigation of antimicrobial surfaces that inhibit or retard biofilm development represents a significant new direction in the antimicrobial arsenal against bacterial biofilm formation and implant infections. These antimicrobial surfaces fall into two broad categories: (1) those surfaces that are made of materials that resist bacterial attachment; and (2) those materials that are impregnated or coated with antimicrobial compounds, which upon diffusion from the surface inhibit or abrogate bacterial growth at the implant site. This direction of research is at an early stage, and represents an important part of the unmet need of the pharmaceutical therapeutic market, but most saliently, the proven effectiveness of orthopedic materials specifically designed to resist bacterial colonization and biofilm formation would result in a significant advance in patient care.

Total joint replacement (TJR) is one of the most common and successful surgical procedures in orthopedics. The majority of patients undergoing TJR benefit from marked improvements in their pain, functional status, and overall quality of life (NIH statement 2003). Infection following primary TJR is uncommon, occurring with a prevalence of ~1–3%, but it can be a debilitating complication of TJR surgery. Infection following revision arthroplasty is significantly higher, approaching 10% (Cui et al., 2007). In the US, revisions are usually in two stages with a period of time between removal of the old hardware and replacement of the new which allows resolution of the infection. However, the fact that infection rates in revised cases are higher than for primary surgeries suggests that, although the symptoms might have resolved, the bacterial source of the underlying infection might not have been fully eradicated. The treatment of an infected joint prosthesis is both complicated and expensive. Diagnosis can itself be problematic, and the necessary intervention may vary depending on the clinical picture; e.g., acute postoperative infections may be initially managed with operative debridement, intravenous antibiotics, and retention of the implant, whereas late chronic infections will likely ultimately require more extensive surgery, typically in multiple stages. Even with aggressive measures there is a ~10% rate of failure to eradicate the infection, and the patient may proceed to resection of the arthroplasty, arthrodesis, or even amputation, in each case with significantly greater morbidity (Cui et al., 2007).

Although the concept of biofilm as a relevant physiological factor in prosthetic joint infections has gained some currency, there are actually few examples of experimentally imaged bacteria in biofilm configuration from any orthopedic implanted material. Gristina and Costerton first found bacteria in biofilms on orthopedic explants by scanning electron micrography (Gristina and Costerton, 1985). Confocal microscopy has visualized biofilm on the surface of an explanted hip prosthesis, and the microscopic identification of clusters of bacteria consistent with biofilms were present in sonicate from infected explanted prostheses, where the sonication was used to

dislodge any extant attached biofilm (Neut et al., 2003). We have documented bacterial biofilm in the aspirate, on tissue, and on bone cement originally impregnated with gentamicin in a patient with a chronic infection after total elbow arthroplasty (Stoodley et al., 2008). The majority of reports imputing biofilms on orthopedic prostheses and surfaces, however, have been in *in vitro* systems, and a major argument for biofilm involvement in chronic orthopedic prosthetic joint infections remains the highly suggestive clinical features demonstrated by such infections, supported by our general understanding of the bacterial propensity to occupy available abiotic surfaces.

Netherless, surgeons and investigators have become increasingly interested in adjuvant techniques and technologies that minimize the risk of prosthetic joint infection, possibly by preventing adherence to and colonization of the implant in the first place. Orthopedic surgeons already routinely use antibiotic-loaded bone cement in surgery, and the use of other antibiotic-supplemented materials is under active investigation. Direct covalent attachment of an antibiotic moiety (vancomycin) to a titanium surface has been shown to inhibit both *S. aureus* and *S. epidermidis* colonization of the modified implant material *in vitro*, despite repeated challenges and over prolonged incubation times (Antoci et al., 2007a). The use of vancomycin-modified titanium implants in a rat model similarly showed evidence of reduced bacterial adherence (Antoci et al., 2007b). An alternative approach to direct modification that would still provide high local concentrations of antibiosis to an implant surface is the deployment of antibiotic-loaded conforming films or sheaths for orthopedic prostheses (Aviv et al., 2007).

PREVENTION AND TREATMENT

Biofilm-Resistant Biomaterials

In previous sections we have discussed biofilm-related complications associated with considerable morbidity and mortality. Here we will discuss some of the new agents and strategies that may give more effective control over the colonization of biomaterials, and the incidence of device-related infections. Finally, we will discuss new methods for the release/delivery of these agents at the surfaces of biomaterials. But first we discuss the evaluation of novel surfaces for resistance to bacterial adhesion, and the formation of bacterial biofilms.

Testing for Antibacterial and Antibiofilm Properties of Biomaterials

There are serious concerns with the utility and information content of some of the methods used to assess the biofilm resistance of biomaterials; namely, if a biomaterial gives a positive zone of inhibition test, what does this mean? Fundamentally, this widely-used test indicates that the biomaterial contained an antibacterial agent, which was released in the moist environment of the surface of an agar plate, was still active, and the agent could prevent the planktonic bacteria deposited on the agar from growing. The major parameter operative in the test is the diffusion of the antibacterial agent through the agar or in the fluid on the agar surface, as well as the effectiveness of the agent. A very potent agent may produce a small or no zone of inhibition, if it is not released or moves slowly through agar, and a less potent agent may produce a large zone if it diffuse rapidly through agar. Shake flask test such as the ASTM E2149-10 tests, in which candidate biomaterials are suspended in a growth medium that is simultaneously inoculated with planktonic bacteria, are equally naïve. If the biomaterials release enough of an antibacterial agent in the first few minutes of the test, all of the planktonic cells in the inoculum will be killed, resulting in a situation where there are no organisms left to colonize the biomaterial. So, an antibiotic-releasing biomaterial that releases all of its antibacterial agents in a few minutes may emerge from this test as a favorable candidate, although this may not reflect a physiologically relevant timescale over which the biomaterial is expected to perform. Generally, tests are conducted over a few hours in rich medium, in an essentially "closed" system, while *in vitro* the biomaterials might be expected to perform over days, or even years, in open systems where leached active agents can diffuse away. Therefore, such conventional tests are largely inappropriate, and may lead to the development of biomaterials that fail in biofilm resistance in animal and clinical trials.

More appropriate tests are ones that mimic the conditions in the systems in which the biomaterial is targeted for use. If the biomaterial will be subjected to flow or fluid exchange, the test should include these parameters. If the biomaterial will be used in a body fluid, such as blood or urine, an accurate simulation of that fluid should be used in the test, and the bacteria supplying the challenge should be adapted to the fluid. One of the pitfalls of laboratory testing is to base a culture medium on the relevant physiological chemistry, but then to add rich components, such as yeast or amino acid extracts, to stimulate growth to allow for rapid testing, typically over a 24-hour period or less. The concept is valid, that is, to accelerate natural processes; however, as discussed earlier, a rich medium and much higher concentrations of bacteria than might be physiologically relevant might also unintentionally interfere with surface chemistry and product efficacy.

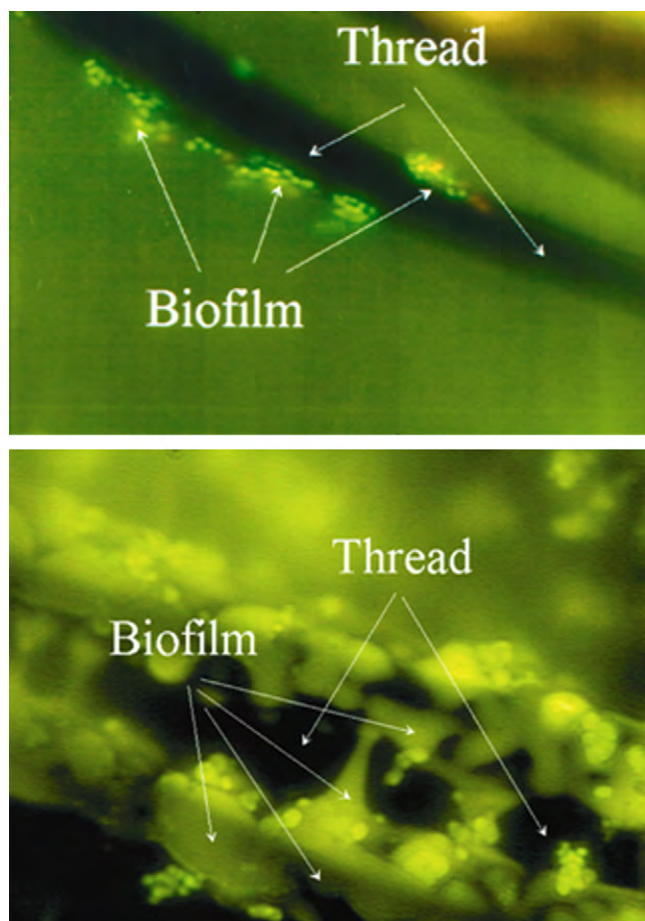
Flow cells are useful for quantifying the rates of bacterial attachment and biofilm formation under a defined fluid shear stress, because they allow direct observation of the surface which can be monitored continuously. Confocal microscopy is particularly suited for biofilm assays since it allows the examination of living hydrated preparations, microbial cells that adhere to the biomaterial surface can be easily visualized (Figure II.2.8.4).


FIGURE II.2.8.4 Confocal microscope images of unfixed biofilms formed on individual fibers of the cloth-like material used to form the sewing cuffs of mechanical heart valves. The biofilms formed when fibers of a silver-coated medical device were exposed to planktonic cells of *Staphylococcus epidermidis*, in a flow cell (Cook et al., 2000) after 24 (top panel) and 48 hours (bottom panel). Staining with the LIVE/DEAD® BacLight™ probe showed that many cells were live (green) in marked contrast to dead cells (red). After 48 hours distinct biofilm cell clusters had formed on the fibers. Diffuse staining between and around the individual cells with the green nucleic acid stain Syto9 is associated with staining of the eDNA in the EPS slime matrix.

If the adherent cells survive, they will initiate biofilm formation, and the adherent cells will gradually form matrix-enclosed structured biofilm cell clusters (Figure II.2.8.4, bottom panel), within which the cells will be separated by EPS. The formation of biofilms requires that the adherent cells must be alive, so the observation of live biofilm on surfaces that make antibacterial and antibiofilm claims could have unfortunate clinical consequences (Cook et al., 2000).

Optimally the preference is for biomaterials which inherently resist attachment or kill colonizing bacteria, and do not retain these dead cells on the surface, i.e., prevention rather than treatment. For this reason, one of several available live/dead probes to ascertain the viability of adherent bacterial cells on biomaterials can be used. The Molecular Probes® BacLight™ LIVE/DEAD® kit has become a standard research method for distinguishing live cells on the basis of membrane integrity; live cells stain green while dead cells stain red. In practical terms, biomaterials set up in flow cells can be exposed to realistic fluid shear containing potentially pathogenic bacteria, and the colonization of its surface can be monitored by confocal microscopy.

Although direct observation is still the "gold standard" to test the resistance of biomaterials to bacterial colonization, confocal microscopes are complex and relatively expensive. Alternatively, sessile biofilm bacteria can be removed from colonized surfaces and enumerated by standard microbiological techniques; commonly referred to as "scraping and plating." The theory behind the technique is that it first removes all biofilm from a surface, then completely breaks up the clumps of bacteria into single unassociated cells, and finally spreads various dilutions of the cells on the surface of an agar plate so that each cell gives rise to one colony when the plate is incubated. Although this technique can drastically underestimate the actual surface cell concentration (usually expressed as colony forming units/cm^2, CFU/cm^2), microscopy can be used to validate the removal and homogenization steps which can be major sources of error. First, some cells may be left on the surface by the removal method, whether it is physical scraping, sonication or another method. Second, the removed biofilm must be completely homogenized to break up clumps of bacteria to ensure that each living bacterium gives rise to one colony on the agar plate. This step is usually achieved by vortexing, sonicating or use of a homogenizer. Sonication may kill some cells, so it is therefore important to calibrate the sonication time for each type of biofilm until microscopy shows that the resultant suspension is mostly single cells, and most of these cells are alive.

When scraping and plating are used without such validation, this method can yield data that are up to 4 logs lower than the bacterial numbers seen by direct microscopy. However, the scrape and plate method can yield accurate and consistent *in vitro* data when it is properly calibrated by microscopy, and the first biofilm method using this enumeration technique was ASTM Method E 2196-02. Darla Goeres and Marty Hamilton at the Center for Biofilm Engineering were instrumental in developing this method, and have been actively involved in developing other statistically robust experimental methods for biofilm evaluation which undoubtedly will form the basis for standard testing and claims substantiation in the anti-infective biomaterials industry. More rapid approaches include the development of conventional multi-well plates or biofilm-specific devices, used in combination with a plate reader to estimate biofilm biomass by general stains such as crystal violet staining or live/dead ratios.

Potential Agents for the Control of Microbial Colonization of Biomaterials

The strategy most commonly used in current antibacterial biomaterials is the incorporation of conventional antibiotics into the material, with the objective of killing incoming planktonic cells before they can adhere and initiate biofilm formation at the implant site (Campoccia et al., 2006). The release strategy has been used for years to infuse bone cements with gentamicin, and is actively pursued with researchers showing that release of NO, antibiotics, antibodies, and silver ion (Ag⁺) from polymers and hydroxapatite materials reduce bacterial growth on plates in culture (Nablo et al., 2005; Hetrick et al., 2009; Zhao et al., 2009). This approach shows promise, and is being actively pursued. However, one problem is that these coatings are not synthetically flexible or covalently adhered to the surface, leading to bursts of antimicrobial activity and localized toxicity stemming from the introduction of non-resorbable coatings into the body (Zhao et al., 2009).

The quandary of balancing antimicrobial efficacy against the danger of promoting bacterial resistance does not affect the large cohort of bacterial manipulation molecules that is currently moving briskly toward the biomaterials market. Some of these biofilm control molecules are specifically targeted to interfere with the bacteria's own developmental signaling pathways to affect both biofilm formation and detachment. The theory is that by influencing natural signaling processes, bacteria can be manipulated not to form biofilms or to detach by triggering a dispersal event, thus reducing the likelihood of inducing defense responses or the generation of resistant mutants. Natural antibiofilm strategies developed by marine seaweeds, which use furanones to interfere with natural biofilm signaling pathways show promise since these defense strategies have been presumably developed over millions of years of coevolution, yet still remain effective (de Nys et al., 2006). The pivotal concept is that bacteria in contact with a biomaterial would be prevented from forming a biofilm on its surface, would be "locked" in the planktonic phenotype, and would be subsequently killed by host defenses (antibodies and activated leukocytes) and any antibiotics that might be present. The best described signal pathways are the acetyl homoserine lactone (AHL) systems of some gram-negative species (Davies et al., 1998), and the autoinducer two (AI2) signaling peptides in both gram-negative and gram-positive species (Camilli and Bassler, 2006). Of relevance to the design of biomaterials which utilize signal blocking is the finding that the effect of AI2 on biofilm is concentration dependent (Rickard et al., 2006), and while very low, µM concentrations added exogenously inhibited biofilm formation, higher concentrations showed no effect or actually stimulated biofilm formation.

A third class of signaling molecule which controls biofilm formation in staphylococci is RNAIII-inhibiting peptide (RIP) which targets the RNAIII-activating protein (RAP), and has been shown to prevent infection on implant materials in rats (Kiran et al., 2008). When specific antibiotics were administered to these test animals, while the challenging bacteria were locked in the planktonic phenotype, no live cells could be recovered from the biomaterial surfaces of the surrounding tissues. More recently, attention has been focused on the secondary messenger cyclic-di-GMP, which is not secreted into the surrounding medium but is intracellular (Hengge, 2009). Cyclic di-GMP is influenced by nitric oxide, but as with AI2, concentration is important. At higher concentrations, NO is toxic to the cells, but at nM levels appears to act as a dispersal signal (Barraud et al., 2009), thus highlighting the importance of precisely controlling the concentration to achieve the desired effect, perhaps a difficult challenge in an *in vivo* setting. Another potential biofilm dispersal signal is the fatty acid signal *cis*-2-decenoic acid, which is produced by *P. aeruginosa* (and possibly other species) and has been shown to be active *in vitro* against a broad range of organisms, over a wide range of concentrations (Davies and Marques, 2009). Such a signal makes a good candidate for antibiofilm biomaterials. However, while existence of a "universal" biofilm prevention or dispersal signal is attractive, the reality might be elusive. From an evolutionary perspective it seems unlikely that a diverse multitude of bacteria would so easily give up control of their biofilm development to a single molecule produced by competing species (Salta et al., 2010).

Delivery of Biofilm Control Agents at Biomaterial Surfaces

Killing the planktonic bacteria before they have time to initiate biofilm formation is the objective of many research programs, and this can be accomplished by three general strategies:

1. Systemic antibiotic therapy that produces bactericidal concentrations in the body fluids in the operative field;
2. Release of antibiotics and other bacterial manipulation molecules from the biomaterials to produce sustained effective concentrations of the agent in the immediate vicinity of the device;
3. Irrigation and other techniques that deliver antibiotics to the biomaterial surface after the device is installed, but before the operative wound is closed.

Many surgeons use systemic antibiotic therapy in the perioperative timeframe, and most also use this strategy in subsequent operations (including dental procedures) if a device has recently been installed and might not be fully epithelialized. The simplest manifestation of the antibiotic-releasing biomaterial strategy is a class of materials that

can be "loaded," such as a sponge, by soaking them in a solution of the antibiotic in question immediately before the device is installed. In the case of filler or adhesive materials, such as poly-methylmethacrylate (PMMA), an active agent can be directly mixed prior to polymerization in the OR. Whenever a molecule is loaded into or onto a polymer there will be an immediate initial burst of diffusion in the early timeframe, followed by a tapering off over time as the concentration in this reservoir is depleted. These biomaterials are useful, but the low-level release of the agent for months or years after this effective timeframe cannot be controlled. This produces a prolonged period in which the agent is present at a sublethal concentration, near the device and sometimes in the whole body, and raises the specter of the development of acquired antibiotic resistance in many potentially dangerous bacterial species. Recently, several papers have even shown that sub-inhibitory concentrations of antibiotic may actually induce biofilm formation (Hoffman et al., 2005).

There is a similar problem with antibiotic impregnated coatings, since usually these coatings are not synthetically flexible or covalently adhered to the surface, leading to bursts of antimicrobial activity, and possibly localized toxicity stemming from the introduction of non-resorbable coatings into the body. The controlled release of active agents is one of the most problematic aspects of devices which rely on this technology for infection protection. One solution is to engineer surfaces to release active agents "on demand." Biomaterials can be coated with a molecular "skin," a self-assembled surface layer, that completely contains molecules loaded into an underlying plastic and can be temporarily deranged (by ultrasonic energy) to yield a controlled release (Kwok et al., 2001). Such a coating has been used to deliver insulin, as well as ciprofloxacin in controlled pulses in the laboratory (Norris et al., 2005). High concentrations of these agents could be released at the surfaces of medical devices perioperatively or at any preliminary signs of device-related infection.

The Bioelectric Effect as an Adjunct to Antibiotics

Coatings which release antibiotics at the site of potential infection have the advantage over systemically administered antibiotics, in that they can achieve much higher local concentrations and avoid toxicity effects, since the overall amount of antibiotic can be relatively small. However, due to difficulties with the controlled release and surfaces which are challenging to modify, it is desirable to be able to sensitize bacteria to conventional antibiotics. As discussed previously, one approach is to use signals in an attempt to induce a planktonic phenotype through cell signaling. Another promising area is to achieve planktonic-like antibiotic sensitivity by applying low voltage electrical fields (Khoury et al., 1992). The so called "bioelectric effect" has recently shown promise at treating *S. epidermidis* chronic foreign-body osteomyelitis in a rabbit model (Del Pozo et al., 2009a); however, the same group also reports that the efficacy is dependant on the pathogen and the class of antibiotic (Del Pozo et al., 2009b).

Biomaterials that Resist Bacterial Attachment and Biofilm Formation

An alternative approach to killing posited by the Association of Bone and Joint Surgeons Musculoskeletal Infection Workshop is to design coatings for implant surfaces that resist bacterial attachment. Most of the work in the literature has focused on the model systems of self-assembled monolayers (SAMs) on gold or polymeric coatings (Vaudaux et al., 1994; Sampedro and Patel, 2007). SAMs have many advantages as a flexible platform over macromolecules (Figure II.2.8.5). One major advantage of SAMs is their ease in engineering interfacial structures at the molecular level, due to the fact that they form defined structures on the surface and therefore present functional tail groups in a consistent, active manner (Laibinis et al., 1989; Hederos et al., 2005; Jiang et al., 2005). They are also synthetically flexible, which allows for the modification of the tail group for prevention of non-specific adsorption of cells. However, the SAM technology developed in model systems is not necessarily directly transferable to metal oxide systems used in biomaterials, and coating the surface with gold is not always practical. Alkanethiols form SAMs on gold and other noble metals, such as silver or copper, but not on oxide surfaces, such as those used in biomaterials (Ostuni et al., 2001). Functional groups can be immobilized through basic organic chemistry at the
FIGURE II.2.8.5 Self-assembled monolayers form spontaneously on a surface placed in a solution. They consist of organic monomers with reactive head groups and exposed tail groups. Tail groups can be designed to accomplish a task, such as cell resistance, or to participate in chemical reaction for further functionalization of the surface. SAMs on gold form defined structures in which all of the carbon–carbon bonds are oriented "trans" to one another (at an angle of 109.5°). These monolayers are considered ordered.

tail groups of the monolayer or by synthesizing molecules with functional tail groups and forming a mixed SAM that includes multiple functionalities. Delivering multiple, active groups in a single polymeric coating is synthetically challenging (Kang et al., 2009). Polymeric coatings that are peptidomimetic have been successful in the laboratory at resisting bacteria adhesion, and could also be used as platforms for further functionalization (Jiang et al., 2005; Statz et al., 2005; Khoo et al., 2009). As a result, new chemistry for non-specific bacterial resistance on metal oxide surfaces must be developed that is appropriate for orthopedic implant materials.

The underlying mechanism by which SAMs render surfaces inert is under study. Many tail groups have been employed to render gold surfaces inert to protein and non-specific cellular adhesion. While oligo-ethylene glycol has been the standard by which inert surfaces are measured, and is the only SAM system used to mitigate bacterial adhesion, other groups such as mannitol, maltose, taurin (Espeland and Wetzel, 2001), and tertiary amine oxides have rendered gold surfaces inert to protein and cellular adhesion. A survey of literature suggests that formation of an inert surface utilizing self-assembled monolayers is a combination of many parameters including substrate wettability, tail functionality, lateral packing density, conformational flexibility of the molecule, structure of water on the surface, and kosmotropicity (the degree to which solutes stabilize water-to-water interactions, and hence affect molecular interactions) (Espeland and Wetzel, 2001). The underlying reason for their inert effect on surfaces may be due to their ability to order surrounding water molecules, excluding them from the surface and rendering the surface inert to protein adsorption. However, the molecular basis for the resistance of some surfaces continues to be debated, in part due to conflicting data in the literature, with some favoring the hydrophobic effect as the driving force (Dibdin et al., 1996), while others disagree. Due to the large interdependent, complex interactions between cells and organically modified surfaces, the understanding and harnessing of the phenomenon of controlling adhesion on oxide surfaces has been difficult.

Biomimicry or bioinspiration is another approach used by engineers in the design of inherently non-fouling surfaces (Salta et al., 2010). Nano-textured patterns found on the skins of sharks have been found to resist initial bacterial attachment in laboratory experiments. It is thought that this approach, originally designed as a control for marine biofouling (Schumacher et al., 2007), might be utilized for medical devices (Chung et al., 2007), illustrating the importance of interdisciplinary collaboration and thinking in the area of biomaterials design. A similar approach was used in the development of the natural and synthetic furanone cell signal blockers, which were first discovered to play a role in the resistance of red algae to marine biofouling, and are now being developed for infection protection of medical devices (de Nys et al., 2006).

CONCLUSIONS

Undoubtedly, medical devices will be increasingly used in patient management, whether temporarily or intermittently for fluids exchange, as in the case of catheters, or as permanent implants to repair loss of function, as is the case for orthopedic joints and cardiovascular stents. What is also ensured is that as more devices are used bacteria will take advantage of an access site into the body and with the convenience of an abiotic surface to colonize the spread of antibiotic resistant strains may likely increase. For permanent implants, overall rates of infection may drop as data show that there is an inverse correlation with surgical-site infection and numbers of procedures performed per institution and surgeon. However, the overall number of patients with surgical-site infections will inevitably rise, as more and more people undergo such surgeries, whether out of absolute necessity or to improve quality of life. To a certain extent, infection associated with permanent implants can be minimized through the controlled environment of the OR and the ever-increasing experience of the surgeon. Infections associated with catheters might present a greater challenge, since they require frequent manipulations and are usually managed in less controlled environments.

A challenge to biomaterials engineers and surface scientists is to design and develop materials for the manufacture of devices which are functional, biocompatible, resistant to infection, and do not add to the development of resistant strains. While 100% biofilm-proof surfaces may be a long way off, we at least now know our enemy much more intimately than even less than a decade ago. Observational studies of biofilms have begun to reveal the true complexities and coordination that pathogenic bacteria are capable of, and molecular techniques are revealing the mechanisms of biofilm development and dispersal, as well as revealing the full extent of diversity of biofilm populations, including the genetic and phenotypic divergence that develops in biofilms formed from a single strain in only a matter of hours to days. The challenge is formidable, but the rewards are great, with the potential to improve the quality of life of millions of people. To quote from *The Art of War* written by Sun Tzu in the 6th century: "So it is said that if you know your enemies and know yourself, you can win a hundred battles without a single loss. If you only know yourself, but not your opponent, you may win or may lose. If you know neither yourself nor your enemy, you will always endanger yourself." With our current understanding of biofilms we are only just beginning to know the enemy with respect to device-related biofilm infections. Even if the "biofilm-proof" surface proves elusive, the challenge is to effectively utilize what we have learned about biofilm biology to engineer playing fields which tip the balance for the race to the surface in favor of ourselves and away from the bacteria.

Biological Testing of Biomaterials

CHAPTER II.3.1 HOW WELL WILL IT WORK? INTRODUCTION TO TESTING BIOMATERIALS

Buddy D. Ratner

Professor, Bioengineering and Chemical Engineering, Director of University of Washington Engineered Biomaterials (UWEB), Seattle, WA, USA

When an engineer designs a suspension bridge over a river, he or she will start with a precise engineering drawing and then, based on well-established mathematical models, assess the strength of materials and corrosion resistance needed to ensure the structure will stand for some anticipated lifetime, e.g., 100 years. The strength of materials and corrosion resistance are compiled in widely accepted handbooks containing data obtained through rigorous testing. The engineer can confidently design the bridge from computer models and handbook data. The bridge will stand and function appropriately for 100 years. Moreover, such a bridge manufactured according to a given set of design criteria and specifications should perform approximately the same whether it crosses a river in Seattle, Birmingham or Boston.

Now, consider an engineer who sets out to design a heart assist device or a hip prosthesis. This engineer will find the basic mechanical property data relevant to the materials used in handbooks, but little on specific bio-interactions, biodurability, and the implications of these biological reactions for the ultimate performance of the complex device. Because of the limited amounts of validated and qualified data on how a given material will perform in the challenging *in vivo* environment, biomaterials scientists devise tests to observe the performance of materials (and devices), and assess potential biointeractions. These tests are often (but not always) focused on the mechanics and biology relevant to the specific application (orthopedic, cardiovascular, urological, etc.), and they do not consider the potential for different circumstances and possibly different biomaterials–tissue interactions in different patients. This section of the textbook focuses on useful tools and ideas for testing biomaterials.

After this introduction, the section leads off with a chapter titled "The Concept and Assessment of Biocompatibility (Chapter II.3.2)." Biocompatibility is possibly the most central concept in understanding biomaterials; and you cannot test for biocompatibility until you understand what it is. Chapter II.3.3 (*In Vitro* Assessment of Cell and Tissue Compatibility,) and Chapter II.3.4 (*In Vivo* Assessment of Tissue Compatibility) provide fine overviews of thinking *circa* early 21st century on testing for biocompatibility, primarily focused on toxicology (*in vitro*) and the foreign-body reaction (*in vivo*), and parallel the thinking by most national regulatory agencies (for example, the US Food and Drugs Administration, FDA). So, why do we need a chapter on the concept of biocompatibility? There are new developments that will probably change the definition of biocompatibility. For example, Chapter II.3.2 discusses a material (with no toxic leachables) fabricated as a solid film that heals with the classic foreign-body reaction, and the same material fabricated as a precise, porous structure that heals in a vascularized, afibrotic manner. Today's definitions and regulatory climate are not structured to appreciate the significance of these differences. Furthermore, there are other strategies to shift the healing of today's "biocompatible" biomaterials to a more tissue-integrated, vascularized reconstruction. To prepare this third edition of the *Biomaterials Science* textbook for changes that will occur in the next few years, we introduce the issues and concerns stimulating new thinking on biocompatibility in Chapter II.3.2. Chapter II.2.2 (Inflammation, Wound Healing, and the Foreign-Body Response) provides essential background to understand the material in Chapters II.3.2, II.3.3, and II.3.4.

Chapter II.3.5, Evaluation of Blood–Materials Interactions, looks at another face of the biological reaction to synthetic materials. Millions of medical devices are interfaced with the bloodstream each year. The reaction of blood with biomaterials is strikingly different from the reactions seen in soft tissue and bone in both kinetics (rapid) and outcomes (clot). Although blood compatibility assessment goes back to the 1930s, to this day we have no widely accepted list of biomaterials that are blood-compatible. Indeed, there is little agreement about the structural/chemical/molecular characteristics of a material that engender blood compatibility. Why this lack of clarity and consensus? Chapter II.3.5 introduces the issues in blood compatibility assessment (the nature of blood, the impact of flow, and the nature of

the biomaterial), and illustrates how simple assessment schemes can lead to erroneous conclusions. Accepted blood compatibility tests are introduced but, more importantly, the chapter provides guidelines for drawing conclusions from the results of these tests. Some thoughts on which materials might be blood compatible are offered in this chapter.

Chapter II.3.6 and Chapter II.3.7 address the use of animals in biomaterials, and in medical device research. Animal implants (*in vivo* assessment) are usually required for preclinical testing of medical devices. Without animal testing, it is less likely that the research we perform will transition from laboratory bench to patient. The use of animals in testing is fraught with ethical issues – respect for the animal lives to be sacrificed and minimization of pain to the animal (see Chapter III.2.7). Also, a key issue is how significant are the results obtained in animals for understanding the performance of the medical device in humans? Humans are different genetically, biochemically, and biomechanically from animals. Also, humans are different genetically, biochemically, and biomechanically from each other, whereas animal models are genetically homogeneous. Can predictive models be developed? The answer is, in most cases, "yes," but not with some forethought and planning. Without careful consideration and understanding of specific animal models, animal lives will be sacrificed and research funds wasted, since the results obtained may not be useful for the human device. The biomechanics issue is particularly challenging. Almost any orthopedic device (spine, joints) will be subjected to different mechanical forces in the skeletal system of an animal walking on four legs versus an upright, bipedal human. Other considerations are: (1) should we go directly from *in vitro* testing to testing in human subjects (see Chapter III.2.7); and (2) what about developing devices for veterinary use (for example, about 5000 intraocular lenses are implanted in dogs each year)? Biomaterials researchers are largely dependent on animal models, and understanding them is essential – Chapters II.3.6 and II.3.7 provide a start in appreciating the complex issues surrounding animal models.

The section on testing concludes with a chapter on the basics of microscopy (Chapter II.3.8). Microscopic examination of tissues and implants is a key element in most biomaterials testing, *in vitro* and *in vivo*. To visually observe the cellular and tissue reactions at the interface between a biomaterial and a living system provides clues as to the functionality and prospects for success of a biomaterial or medical device. The range of microscopic techniques, and the resolution and information content of these methods, is now in a period of evolutionary development, so this chapter primarily addresses the basics for observing biomaterials and bioreactions at the micron scale and the nanoscale.

CHAPTER II.3.2 THE CONCEPT AND ASSESSMENT OF BIOCOMPATIBILITY

Buddy D. Ratner[1] and Frederick J. Schoen[2]
[1]Professor, Bioengineering and Chemical Engineering, Director of University of Washington Engineered Biomaterials (UWEB), Seattle, WA, USA

[2]Professor of Pathology and Health Sciences and Technology (HST), Harvard Medical School, Executive Vice Chairman, Department of Pathology, Brigham and Women's Hospital, Boston, MA, USA

What do we mean when we say a biomaterial is biocompatible?

- Is biocompatibility "yes" or "no," or is there a continuum of biocompatibilities ranging from "good" to "bad?"
- How can we measure biocompatibility?
- How do we improve or enhance the biocompatibility of a biomaterial?

The *idea* of biocompatibility is central to what makes a material a biomaterial. Also, new developments and concepts in cell biology are shifting thinking about biocompatibility, and this chapter offers an opportunity of a glimpse into the future of biocompatible biomaterials.

> Biocompatibility is so central to what makes a material a biomaterial, that a focused discussion of the subject is justified.

This chapter clarifies some of the issues in biocompatibility, and also raises questions that will likely impact the field in the coming years. In contrast to empirical approaches and practical considerations focused solely about the safety of implanted devices (for example, toxicology, the state of the art today), modern cell and molecular biology ideas may give us a useful "theory of biocompatibility" with quantifiable parameters, testable hypotheses, and validated engineering rules.

BIOCOMPATIBILITY TODAY

We start with an overview of the state of the art in biocompatibility today, i.e., in the first decade in the 21st century.

A definition for biocompatibility, widely used in the biomaterials/medical device community, has been presented previously in the textbook and is repeated here:

> *"the ability of a material to perform with an appropriate host response in a specific application"* (Williams, 1987).

This definition, though accurate and quite useful in the design, development, and application of biomaterials in medicine, nevertheless offers no insights into

the mechanisms of biocompatibility, how to test the biocompatibility of a material or how to optimize or enhance the biocompatibility of a material. This section of the textbook will expand the definition and explore the philosophical and scientific ideas surrounding biocompatibility.

Specific concepts impacting biocompatibility are elaborated upon in Chapters II.2.2 (Inflammation, Wound Healing, and the Foreign-Body Response), II.3.3 (*In Vitro* Assessment of Cell and Tissue Compatibility), II.3.4 (*In Vivo* Assessment of Tissue Compatibility), and III.2.3 (Voluntary Consensus Standards) (and other sections throughout this textbook). Biocompatibility can be assessed using *in vitro* and *in vivo* assays. Although a variety of direct chemical and physical interactions may also be important, measurement of the consequences of leachable or secreted substances from biomaterials to cells in culture is the primary goal of *in vitro* biocompatibility assays. For example, cell proliferation inhibition or cell death are negative outcomes in such assays, and would be characteristic of materials that are not biocompatible. The *in vivo* (implantation) response to a "biocompatible" biomaterial is generally described as a no more than mild inflammatory reaction, which, after some 2–3 weeks, resolves itself into a thin fibrous capsule (largely scar as a result of the tissue trauma of implantation). This is sometimes referred to as a low level, long-term, minimal inflammatory response (i.e., macrophages are present at the implant surface even years after implantation, but the reaction site is relatively quiescent, and there is otherwise no indication of adverse local or systemic response). The presence of foreign-body giant cells at the interface may suggest lesser "biocompatibility." The composite reaction is termed the "foreign-body reaction," or FBR.

Four factors impact that which we refer to as "biocompatibility." These are:

1. Toxicology (the measurement and study of the effects of material leaching from biomaterials) (II.3.3 *In Vitro* Assessment of Tissue Compatibility and III.2.2 Standards).
2. Reactions related to products from extrinsic microbiologic organisms colonizing the biomaterial (for example, endotoxin contamination; see Chapters II.2.8 and III.1.2).
3. Mechanical effects such as rubbing, irritation, compression, and modulus mismatch. Closely related are size-related effects, for example, if the implant is much larger than a macrophage, comparable in size to a macrophage, and capable of being phagocytosed, or much smaller than a macrophage, i.e., nano-size.
4. A broad range of interactions with surrounding proteins, and cells, inducing cell–biomaterials interactions (and tissue–biomaterials interactions) that might direct longer-term *in vivo* bioreaction.

> Four factors impact that which we refer to as "biocompatibility." These are:
>
> - toxicology
> - extrinsic organisms
> - mechanical effects
> - cell–biomaterial interactions.

Points 1, 2, and 3, above, are well-understood, and often applied in the design of biocompatible biomaterials – we understand the principles, have the ability to measure their impact, and we can design devices using clearly-defined principles to achieve good outcomes. Point 4 is less well-developed and concerns are expanded upon below.

TOXICOLOGY

Polymeric materials often contain extractable components, such as unreacted monomer, oligomers, initiator fragments, stabilizers, and other processing additives. Metals, glasses, and ceramics can release ions and other processing components. The type of reaction that will be considered from a toxicology standpoint is if these substances are released and negatively impact cells (*in vitro*) or adjacent tissues (*in vivo*), or if they affect an organism systemically. Biomaterials science, standards organizations, and allied fields have developed reliable methods to measure and identify leachates, and also sensitive and standardized methods to look at the reaction of tissues and cells to these leached substances. These methods are summarized in Chapter II.3.3. The ISO 10993 standards provide many specific, defined tests for toxicity associated with leachables.

THE PRODUCTS OF EXTRINSIC ORGANISMS COLONIZING THE BIOMATERIAL

Bacteria and their cell wall components are intense inflammatory activators. Fungi such as *Candida* are also inflammatory activators (Kojic and Darouiche, 2004). In the case of implants that are contaminated with fungi, bacteria or bacterial cell-wall endotoxin (lipopolysaccharide), an intense and usually long-term biological reaction is seen, characterized by large numbers of white cells (mostly neutrophils and macrophages, collectively called "pus") in the vicinity of the implant. In humans, this reaction would be described by the patient as producing pain, redness, and heat. This response to the contaminated implant can lead to exceptionally thick foreign-body capsules. High concentrations of extravascular white cells and thick, dense foreign-body capsules are characteristics of poor biocompatibility. Such extreme reactions to devices with contaminating organisms have been documented with breast implants (Pajkos et al., 2003), and with other implant devices. This is distinct from *infection*

with live microbiologic organisms, such as bacteria or fungi, in which the organisms may proliferate and cause ongoing local tissue destruction and potentially systemic effects. Although infection with live organisms shares some morphologic features with, and can occasionally look like, "poor biocompatibility," we generally refer to this not as a biocompatibility issue, but rather a sterilization issue (see Chapter III.1.2).

MECHANICAL EFFECTS

If an implant is rubbing, abrading or moving in contact with tissue, or has sharp corners, undesirable reactions that are superficially classified as "non-biocompatible" will be observed. Mechanical mismatch between a hard biomaterial and a soft tissue can lead to damage or irritation to the soft tissue. Cell responses to mechanical forces are well-known and usually quite significant (Stamenović and Ingber, 2009). An excellent example of the mechanical effect on *in vivo* bioreaction was seen in 1976, where scientists implanted in rat muscle medical grade "biocompatible" materials having circular, triangular, and pentagonal shapes (Matlaga et al., 1976). The degree of reaction increased in the order: circle (lowest reaction), pentagon, triangle. The effect was attributed to micromotion associated with the acute angle of the triangle leading to the greatest tissue irritation. In general, it is the role of the implant designer to ensure that the device does not excessively rub or irritate tissue (rounded edges are better than sharp edges, for example). It is the role of the surgeon to appropriately place and anchor the device in the implant site to minimize such rubbing and irritation.

CELL–BIOMATERIALS INTERACTIONS

This topic dominates the literature in biomaterials science (see Chapter II.1.3, Cells and Surfaces *In Vitro*, for a detailed elaboration). It has been clear for 100 years or more that living cells interact and attach to different materials in different ways, and the nature of that interaction may have immense influence on cell fate, including attachment, spreading, proliferation, differentiation, activation, secretion, and detachment. It is also well-established that the adsorbed protein film always preceding cell interaction with surfaces directs and modulates the cell response (see Chapter II.1.2). Since inflammatory cells, such as neutrophils and macrophages, "interrogate" implanted materials shortly after implantation, and since different surfaces interact in different ways with proteins and cells, we would expect the biomaterial to impact the cell-driven *in vivo* reaction. However, let's examine this conclusion. *In vitro*, profound differences are seen in cell interactions between different materials. For example, a poly(2-hydroxyethyl methacrylate)(polyHEMA) hydrogel will not permit macrophages to adhere in cell culture, while a tissue culture polystyrene (TCPS) surface readily

allows those same cells to adhere. Yet, if the polyHEMA and TCPS are implanted *in vivo*, both will heal similarly with an avascular, collagenous foreign-body capsule. In fact, all "biocompatible" materials, be they hydrophilic, hydrophobic, metallic, polymeric or ceramic, will heal similarly with a classic (and largely quiescent) foreign-body reaction (FBR) if there are: (1) no leachables; (2) no products from extrinsic organisms; and (3) no mechanical irritation. The explanation for this striking difference between *in vitro* bioreaction and *in vivo* bioreaction has yet to be identified, but does highlight the multi-cell complexity of the *in vivo* environment, in comparison to the relatively simple environment with one cell type *in vitro*.

The phenomena of: (1) frustrated phagocytosis; and (2) cytokine release are important to discuss here. Macrophages are programmed to engulf and digest foreign material. Phagocytosis occurs after the foreign-body has bound to molecules called "receptors" that are on the surface of the macrophage. The macrophage then stretches itself around the foreign-body and engulfs it. Once inside this phagocyte, the foreign particle is trapped in a compartment called a lysosome which has a battery of chemicals that attempt to degrade the foreign material. Frustrated phagocytosis is the term used to express the concept that the macrophage is incapable of "eating" a piece of biomaterial approximately larger than its size or certainly a macroscopic implant. In this situation the lysosomes (which may be in contact with the foreign material but open to the surroundings) may release their contents into the adjacent tissues. This may cause local tissue damage and inflammation. Moreover, to address the large surface, the macrophage might fuse with other macrophages and form multinucleated foreign-body giant cells, often used as a marker of a more severe FBR. Macrophages also release cytokines (diffusible signaling proteins) in response to biomaterials (Bonfield et al., 1992). Cytokines can be considered as proinflammatory (e.g., IL-1, TNF-a) or anti-inflammatory (e.g. IL-4, IL-10). A measurement of the cytokine shower from an implanted biomaterial may offer insights to biocompatibility.

SUMMARY OF IDEAS TO THIS POINT

Important points about biocompatibility as we understand it today are:

1. The biological reaction we call biocompatibility is negatively impacted by leachables, products of extrinsic organism surface contamination, and micromotion.
2. As long as leachables, extrinsic organism surface contamination, and micromotion are not impacting the reaction, all materials will give an approximately similar bioreaction *in vivo*, referred to as the normal FBR, composed of a thin fibrous capsule and minimal ongoing inflammation.
3. When the foreign body capsule is thin and the reaction site, after approximately one month, is relatively

quiescent, this is an acceptable FBR and we call the implant "biocompatible (or inert)."

4. Inert biomaterials lead to the reaction described in point 3 (above), and thus are called "biocompatible."

5. The favorable long-term interface between a biomaterial and the surrounding tissues in most medical devices is characterized by a thin, dense, collagenous capsule that isolates the biomaterial implant from the body.

NEW DEVELOPMENTS ARE CHANGING THE PARADIGM OF BIOCOMPATIBILITY

Although we implant millions of devices made of biocompatible biomaterials in humans every year, largely with much success, there are concerns with the way implants heal (the FBR), and new generations of materials are designed for applications in which something different than a quiescent FBR is desired.

For example, a dense fibrous capsule can inhibit diffusion of analytes to implanted sensors, interfere with release of drugs from implanted controlled drug release devices, and enhance the resistance of an electrical path, thereby blocking communication with tissues for implanted electrodes. Capsular contraction is a problem for some devices, such as breast implants, where the contraction of the fibrous capsule (i.e., all scars contract) distorts the soft implant, tending to make it spherical. Moreover, the lack of vascularity near the implant–tissue interface can slow the body's response to, and treatment of, bacterial invasion and related biofilm formation. Certainly, the capsule associated with the FBR can create surgical problems for device removal and revision. In many cases, a vascularized, integrated tissue reconstruction (more resembling normal tissue reconstruction) would be preferable to the avascular, dense capsule.

The potential for vascularized, non-fibrotic healing is now being realized. Such reconstructive healing can be achieved with extracellular matrix (ECM) components or with inert biomaterials with engineered porosity.

Decellularized ECM derived from a number of tissues, for example small intestinal submucosa (SIS), has been found to heal into the body with little or no fibrosis, excellent vascularity, and general tissue reconstruction (Badylak, 2007). SIS and other decellularized ECMs have been used in more than 1,000,000 human surgeries, largely with good results. Chapter II.6.16 elaborates on these decellularized tissues as biomaterials. If the SIS is cross-linked, it will heal in a proinflammatory manner, with a capsule and a classical FBR. The excellent healing of SIS is attributed to the ability of macrophages to degrade the ECM to bioactive peptides that actively promote healing. Importantly, the ECM structure is heavily infused with macrophages in the early stage of healing, and those macrophages have been shown to be in a phenotype (also referred to as a polarization) conducive to healing (M2), in contrast to the proinflammatory, fibrotic

M1 phenotype (Mantovani, 2006; Badylak et al., 2008). There are also suggestions that soluble ECMs derived from neonatal cell culture might be used as coating for implants to aid in healing and integration (Naughton and Kellar, 2008).

Certain porous synthetic biomaterials will also heal in a minimally fibrotic, angiogenic fashion. Observations on the special characteristics of the healing of porous structures in the body go back to the early 1970s (Karp et al., 1973; Klawitter et al., 1976). Many studies discussed this porosity effect, and an extensive study in 1992 clearly demonstrated the importance of pore size to healing (Brauker et al., 1995). The concern with all these studies was that the materials used had a broad distribution of pore sizes, making it difficult to ascertain the effect on healing of a specific pore size. A method was developed to make materials with a single, consistent pore size, based on using solvent-soluble microspheres as templates to create uniform, interconnected pores. When such materials were implanted subcutaneously, it was noted that when pores were in the size range 30–40 microns, vascularized healing and reconstruction with little fibrosis was observed (Marshall et al., 2004; Madden et al., 2010). Also, these materials were heavily infused with macrophages during healing, and more of the macrophages were in the M2 phenotype (Madden et al., 2010). These same materials with 30–40 micron pores healed well in skin percutaneous sites (with dermal and epidermal reconstruction) (Fukano et al., 2010), heart muscle, and other tissues. A further discussion of porous materials can be found in Chapter I.2.15.

With relevance to biocompatibility, consider differences engendered solely as a result of physical factors. A synthetic hydrogel is fabricated as a solid slab or as a porous structure with 30–40 micron interconnected pores. The chemical compositions of both are identical. Also, they have similar mechanical properties, no leachables, and no endotoxin or bacteria. Yet one heals in a capsule with the classic FBR, while the other heals in a vascularized, reconstructed manner with little fibrosis. It seems challenging to use the word "biocompatible" for both, given the sharp differences in *in vivo* biological reaction, despite identical chemistries.

> A "biocompatible" material is fabricated as a porous structure or a solid slab. The porous structure heals in an avascular, pro-angiogenic manner. The solid slab is encapsulated with the classic FBR. How can we use the word "biocompatible" for two such different bioreactions?

CONCLUSIONS

Since the introduction of "modern" biomaterials to medical practice in the late 1940s and early 1950s, we have seen an evolution in sophistication and

functionality (Williams, 2008). *First generation* biomaterials were simply inert (e.g., Titanium, Teflon™, Polyethylene). *Second generation* biomaterials (1970s, 1980s) interacted with and changed the biological environment in a controlled manner. Such materials might be engineered for biodegradability, poly(lactic acid) for example, or engineered to integrate into bone and induce bone healing, such as bioactive glasses, or to induce a controlled thrombotic deposit, such as a textured polymer surface on the internal surface of a left ventricular assist device. *Third generation* biomaterials (1990+) biospecifically orchestrate biological processes, and can direct regeneration and restore functionality, and/or respond to the environment in a proactive manner to favorably influence a tissue reaction. Examples include engineered extracellular matrices (Lutolf and Hubbell, 2005), sphere templated biomaterials (Madden et al., 2010), SIS (Badylak, 2007), and "smart" biomaterials (Reyes et al., 2007). Also, consider the published debate on the effectiveness of biomaterials guided by specific peptide signals (Williams, 2011). As biomaterials evolve, so too must the definition of biocompatibility.

Thus, the way we define biocompatibility may change over the next few years. Examples that challenge the present paradigm of biocompatibility are published, and materials that show unique healing are being applied in clinical medicine. Recent clarification on the diversity of macrophage phenotypes and understanding of resident tissue stem cell pools in the body may permit engineered "biocompatibility," with control of the extent, rate, and speed of integration. These new developments strengthen the science of biocompatibility, and bring biomaterials and tissue engineering closer together. Precision control of biocompatibility can lead to new biomaterials-based therapies with profound advantages for the patient.

For now, the medical device regulatory agencies subscribe almost exclusively to the definition of biocompatibility that we have been using since the first functionally successful implants in the 1950s. In learning the subject of biomaterials, it is important that one appreciates the accepted standards for biomaterials; standards that are used by the $300 billion plus medical device industry worldwide (estimated to reach $415 billion in 2016) and standards that impact millions of patients (see Chapters III.2.2 and III.2.3). Still, since we are on the cusp of a shift in thinking about this subject, it is useful for these newer ideas to be addressed and placed in the context of the word "biocompatibility."

> Understanding biocompatibility is central to understanding biomaterials.

INTRODUCTION

This chapter explains how *in vitro* methods may be used to assess the biocompatibility of medical device materials. While such methods unavoidably present a simplified view of the complex *in vivo* milieu, they are valuable because they provide insight to potential *in vivo* tissue and cellular responses. Many *in vitro* methods have been standardized through a global harmonization process. These standardized tests serve a key role in the biological safety evaluation of medical devices and materials. In the following pages, the scientific basis for each test is explored. Also presented are examples of *in vitro* techniques developed in response to a growing shift towards devices that combine drugs or biological agents to improve therapy. It should be noted that results of *in vitro* tests described in this chapter are often supported with additional *in vivo* testing (see Chapters II.5.3–II.5.5).

BACKGROUND CONCEPTS

At the cellular and molecular level, the presence of a biomaterial has potential to impart a perturbation in the local surroundings that may impact any number of proteins, genes, pathways, molecular modules and networks, and cells. The compatibility of such perturbations, that is the particular response of a cell or tissue to the material and *vice versa*, is then defined by the extent to which the response is deleterious to the microenvironment. Adding to this complexity is the wide range of tissue interfaces and potential materials used in today's medical device applications (see Table II.3.1).

Foreign materials or chemicals found inside the body are referred to as *xenobiotics*. Any chemical leaching or degrading from a device/material – or, in extreme circumstances, pieces of the material itself – falls under this definition. Thus, assessing the cellular and tissue compatibility of a device/material often involves examination of the potential xenobiotic chemicals that it may release. Whether these leachable chemicals trigger an unacceptable response in the host's biological microenvironment is key to determining the potential biocompatibility of the device/material.

> Foreign materials or chemicals found inside the body are referred to as xenobiotics. Any chemical leaching or degrading from a medical device or material – or, in extreme circumstances, pieces of the material itself – falls under this definition. Thus, assessing the cellular and tissue compatibility of a device/material often involves examination of the potential xenobiotic chemicals that it may release.

Chemicals that possess potentially harmful or adverse properties are referred to as *toxicants*.[1] The response to a toxicant from a device/material is greatly influenced not only by the material itself, but also by the type of exposure. Exposure characteristics include the *route*(s) and *site*(s) of exposure (e.g., brain tissue versus subcutaneous tissue), *duration of exposure* (e.g., several hours versus permanent implantation), and the potential *frequency of exposure* over the treatment period or lifetime of the host. (Contrast, for example, the exposure a patient with degenerative heart disease receives from a single prosthetic valve implant to the exposure a diabetic individual receives from insulin pump infusion lines replaced every 72 hours.) *Chemical reactivity* of a toxicant is an additional key factor that will impact the degree and type of response in the host (Casarett et al., 2003). A particular reaction may occur because of an agent's chemical reactivity, or it may be due to a more specific recognition or reactivity towards a molecular structure in the biological environment. The compatibility of a chemically-reactive agent depends on whether it elicits undesirable cell responses or damages cellular structures.

The *degree of response* in the host in relation to the *amount of material or toxicant* present defines its *dose–response relationship*. This relationship is extremely important in the characterization of toxicants, as it can often depict a threshold dose below which the probability of an adverse response occurring in the host is either very low (the lowest-observable adverse effect level, or LOAEL) or not measureable (the no-observable adverse effect level, or NOAEL). This threshold dose is of key interest when studying the dose–response effect of a device material and attempting to assess its compatibility with cells and tissues. A classic example of the latter is demonstrated in the case of porcine bioprosthetic heart valves treated with glutaraldehyde to increase biostability and durability. Here, low levels of residual glutaraldehyde may produce negative responses in *in vitro* tests. Nonetheless, the device itself has proven to be safe and enormously beneficial in patients with cardiac valve disease.

Assessing cell and tissue biocompatibility has historically been evaluated with the *in vitro* tests described

*Parts 1, 2, 7, 9, and 12 are general guidance documents on use of the standard, animal welfare, sterilization residuals, degradation products, and sample preparation, respectively; Parts 6, 10, 11, 16, and 20 are general guidance documents on in vivo testing relevant to local effects after implantation, irritation and delayed-type hypersensitivity, toxicokinetics study of degradation products and leachables, and principles of immunotoxicity testing, respectively. Part 8 was withdrawn and does not exist. CD refers to committee draft stage of the ISO standard development process.

in this chapter. Here, the focus has been on assays for DNA damage, cytotoxicity, cell proliferation, and quantification of specific proteins recognized to be an influential component or end product of a critical pathway or event.

USE OF MEDICAL DEVICE CHEMICAL COMPOSITION AND MATERIAL EXTRACTS FOR TOXICOLOGICAL RISK ASSESSMENT AND *IN VITRO* TESTING

Medical devices are primarily composed of polymers, metals, ceramics, and to a lesser extent, xenograft and allograft biological tissues and molecules. Assessing the *in vitro* cell and tissue compatibility of these solid multidimensional and multicompositional devices presents significant challenges. Not surprisingly, these challenges have lead to the development of an international standard on test material sample preparation (ISO 10993-12, 2007).

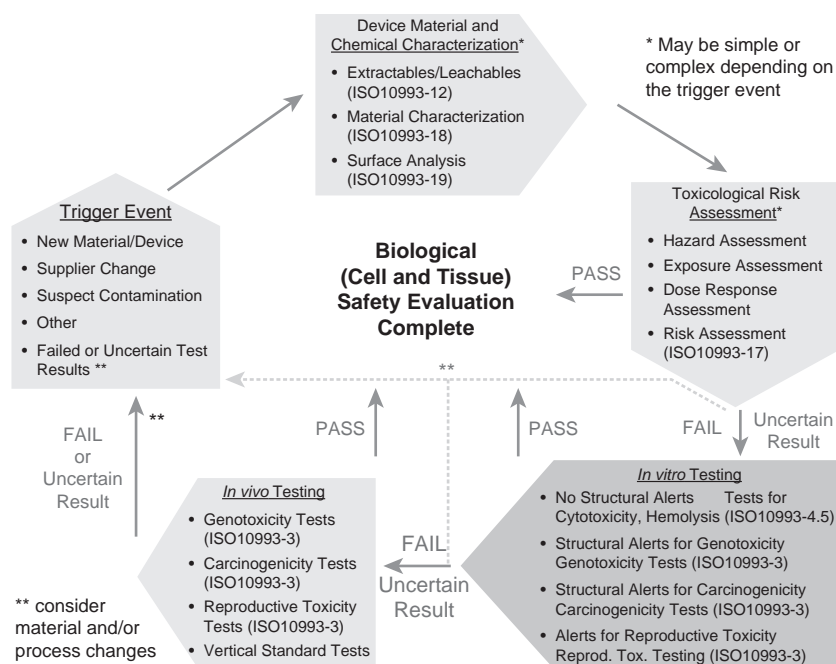
Challenges encountered in sample preparation include: (1) how to properly bring diverse material and device test samples into a standardized and appropriate level of contact with test systems; (2) how to treat composite materials and devices; (3) how to account for potential material interactions, given the frequency of composite devices; and (4) other confounding factors. Examples of the latter include device size, supplier variability, tissue contact differences, implant duration diversity, potential residues and contamination, and varying biological responses due to a patient's individual genetics, age, size, sex, and disease state. For *in vitro* testing, a simplifying premise is that compatibility is most readily verified by focusing on the impact of chemical constituents that may potentially be released from the device/material *in vivo*. For example, while most polymers used in medical devices are made from clinically proven, relatively inert, high molecular weight materials, it is their leachable components (i.e., residual monomers, oligomers, catalysts, processing aids,


FIGURE II.3.3.1 Schematic depicting the process that occurs to establish the preclinical biological safety of a medical device material. Material characterization and toxicological risk assessment precede *in vitro* testing for cell and tissue compatibility. *In vivo* testing may follow, but only if warranted based upon *in vitro* findings. Note: *structural alerts* refers to chemical structures of varying concern that may be linked to known toxicological mechanisms.

additives, and contaminants) that often present a concern. The presence and extent of such leachables depends on a host of factors, such as the source of the material, differing manufacturing processes, and the intended function of the additive(s). In addition, new chemical species may be formed during secondary manufacturing processes, such as heat treatments, irradiation, welding, and sterilization.

In devices composed of inorganic materials such as metals, alloys, and ceramics, the release of metal ions may also be a cause for concern. Once free, metal ions have the potential to form complexes with proteins and/ or DNA; these complexes may, in turn, disrupt a number of biological processes (ISO 10993-3, 2009).

The potential toxicity of a material is determined by a *toxicological risk assessment*. Such assessments involve: (1) identifying hazardous chemicals present in medical devices; (2) assessing the extent of a patient's potential exposure to these chemicals; (3) determining the chemical's dose–response relationship; and (4) combining this information to characterize the risk. Risk assessment calculations are based upon conservative worst-case exposure scenarios. Such scenarios often assume that all of a material's chemical constituents will be released into the patient during the first 24 hours. (In clinical practice this is unlikely to occur, but it is nevertheless a common conservative assumption designed to protect patients.) In these calculations, tolerable intakes (TI) for chemicals of concern are determined using safe exposure level values (NOAEL or LOAEL), and uncertainty factors (UF) to account for intraspecies variability among humans (UF_1), interspecies extrapolation from

animals to humans (UF_2), and quality and relevance of the experimental data (UF_3). A margin of safety is then calculated (TI divided by the worst-case exposure dose) to verify that exposure to the chemical of concern does not present a health risk (ISO 10993-17, 2008). Supporting toxicity information is frequently found on free government websites or in proprietary commercial databases.[2] ISO 10993-1, 2009 recommends that toxicological risk assessments be conducted as a precursor to biological evaluation testing (see Figure II.3.3.1). This is because well-thought-out and thorough risk assessments may negate the need for expensive and time-consuming *in vitro* and *in vivo* testing.

> The potential toxicity of a material is determined by a *toxicological risk assessment*. Such assessments involve: (1) identifying hazardous chemicals present in medical devices; (2) assessing the extent of a patient's potential exposure to these chemicals; (3) determining the chemical's dose–response relationship; and (4) combining this information to characterize the risk. A well-thought out and thorough risk assessment may negate the need for expensive and time-consuming *in vitro* and *in vivo* testing.

Detailed guidance for preparing *in vitro* testing samples is provided in ISO 10993 *Biological evaluation of*

TABLE II.3.3.2	In vitro tests under ISO 10993 Part 3: Tests for Genotoxicity, Carcinogenicity, and Reproductive Toxicity		
In vitro Test Category	**Test***	**Assay Basis**	**Information Gained**
Genotoxicity	Bacterial Reverse Mutation Assay	*Reverse mutation assay;* Small changes in prokaryotic DNA induced by a test material or extract thereof, result in a quantifiable change in phenotypic expression of a target gene	Determines if a device material** has potential to react with DNA and cause altered DNA expression. Caveat: has potential for false positives
Genotoxicity	In vitro Mouse Lymphoma tk Assay	*Forward mutation assay;* Same as above but assay utilizes a eukaryotic cell line	Same as above. Note: this test may be more predictive than tests using prokaryotic cell lines.
Genotoxicity	Chromosomal Aberration	*Chromosome morphology analysis;* quantification and categorization of mammalian cell chromosome aberrations	Determines if a device material** shows potential to interfere with normal DNA replication and/or division processes leading to changes in normal chromosome morphology.
Carcinogenicity	Syrian Hamster Embryo (SHE) Cell Transformation Assays*	*Morphological transformation* of normal-karotype primary cells; assay designed to mimic 2-stage carcinogenesis model (initiation and promotion)	Determines if a device material** has potential to transform normal cells to cells with morphologies and behavior consistent with tumorigenic cells.
Carcinogenicity	Balb/c 3T3 Focus Transformation Assay*	*Macroscopic and microscopic morphological categorization* of foci; assay uses immortalized aneuploid fibroblastic cell line; assay can mimic 2-stage carcinogenesis model	Determines if a device material** has potential to transform cells into cells with morphologies consistent with tumorigenic cells; Caveat: time consuming and mixed reproducibility.
Reproductive Toxicity	Embryonic Stem Cell (ESC)Test*	*Biostatistically-derived, prediction-model equations* utilizing values for: 50% inhibition of ESC differentiation, 50% inhibition of cell growth of ESC cells, and 50% inhibition of cell growth of BALB/c 3T3 cells	Determines if a device material** has potential to be embryotoxic (teratogenic); presumes (with its limitations) that demonstration of toxicity at this stage may be indicative of concern for impact at other stages of reproduction.

*See Website for assay details
**Device material extract/leachable chemical(s), or a metabolic derivative(s) thereof.

medical devices, Parts 1, 3, and 12 (ISO 10993-1, 2009; ISO 10993-12, 2007; ISO 10993-3, 2009 Annex D). Sample preparation for genotoxicity tests requires careful attention due to each test's volume and extractable percentage requirements. Extraction procedures should: (1) simulate or exaggerate the clinical conditions of use; (2) take into account the chemical characteristics of the test sample; (3) not cause significant changes in the physicochemical properties of the sample; (4) test the device or material in its intended clinical use state (e.g., identically sterilized); (5) consider use of both a polar and a non-polar extraction solvent (see Table II.3.3.2); (6) be performed in chemically inert sterile closed containers; (7) be conducted for appropriate duration; and (8) be carried out at a suitable temperature, particularly when using cell culture media as an extraction vehicle.

IN VITRO ASSAYS TO ASSESS CELL AND TISSUE COMPATIBILITY IN BIOMATERIAL/MEDICAL DEVICE EVALUATION FOR REGULATORY PURPOSES

The primary purpose of a preclinical biological safety evaluation of a material or device is to protect humans from potential biological risks arising from the use of the material or device (ISO 10993-1, 2009). Standardizing this process safeguards consumers, but also provides industry and governments with a common scientific basis for evaluating new medical technologies. The most widely recognized guidance documents for this purpose are the ISO 10993 series of standards[3] for the biological evaluation of medical devices developed by the International Organization for Standardization (ISO/TC 194, 2004; ISO, 2009 – see www.iso.org/iso/home.htm2009 for further information).

Three parts of the ISO 10993 standard describe certain considerations and particular methodologies for *in vitro* assessment of material/device compatibility with cells and tissues. These methods are discussed in further detail below. Table II.3.3.1 shows the various parts of the standard relevant to the specific *in vitro* assays prescribed as of 2009. As *in vitro* analytical tests focusing on the material characterization elements of the toxicological risk assessment (described earlier) are themselves

---

[3]Parts of the 10993 standard range from how to use the standard and how to prepare test samples (ISO 10993-1 and ISO 10993-12); understanding material stability (ISO 10993-9, -13, -14, and -15) (ISO/TC 194, 2004); establishment of allowable limits for leachable substances (ISO 10993-17, and -7) (ISO/TC 194, 2004); and, chemical characterization to support device material characterization and toxicological risk assessments (ISO 10993-18 and -19) (ISO/TC 194, 2004).

indirect tests for cell and tissue compatibility, these parts of the standard are included for reference. The *in vivo* approaches included in this standard, and the many device-specific *vertical standards*, are extremely important to proper cell and tissue compatibility testing. For further information on these topics the reader is referred to Chapters II.5.3, II.5.4, and II.5.5 of this book.

In Vitro Tests for Genotoxicity, Carcinogenicity, and Reproductive Toxicity: ISO 10993-3

Much of our understanding of cellular processes stems from the study of genetics and our ability to manipulate and characterize DNA and RNA (and the proteins they regulate). The ability to portray the impact of these manipulations has been crucial as well. Such information has increased our understanding of how genetic anomalies lead to human disease and defects, and has provided insight into the mechanisms of carcinogenesis. This awareness has also provided material providers, device manufacturers, and regulatory bodies with increasingly sophisticated tools and standards for screening materials and chemicals for potential health concerns.

In the context of biomaterial science, genotoxicity refers to the potential of the solid device material, and/or its constituent chemicals, biodegradation products, metabolites, leachables or contaminants to induce an undesirable effect on DNA itself, or on the genetic processes of a host cell or tissue (ISO 10993-3, 2009). To thoroughly screen the genotoxic *potential* of a new device or material, the standard relies on well-established *in vitro* tests from the Organization for Economic Cooperation and Development (OECD) guidelines for testing chemicals (OECD, 2009). These guidelines describe primary tests that look at gene mutations in prokaryote bacteria (OECD 471, 2007), cytogenetic evaluation of chromosomal damage in eukaryotic mammalian cells (i.e., chromosome aberration test; OECD 473, 1997; see Figure II.3.3.2), and gene mutation in mouse lymphoma cells (OECD 476, 1997). Taken together, when each is negative, these tests indicate a low potential for genotoxicity. Where one or more of these tests gives a positive result, the material or chemical is presumed to have a genotoxic potential. In the latter case, one or more *in vivo* assays are often considered to further evaluate the genotoxicity of the compound, material or device (OECD 474, 1997; OECD 475, 1997; ISO 10993-3, 2009). See website for details on the bacterial reverse mutation and chromosome aberration assays.

> In the context of biomaterials science, genotoxicity refers to the potential of the solid device material, and/or its constituent chemicals, biodegradation products, metabolites, leachables or contaminants to induce an undesirable effect on DNA itself, or on the genetic processes of a host cell or tissue (ISO 10993-3, 2009).

Along with tests for genotoxicity, carcinogenicity testing is also addressed in ISO 10993-3. Although materials indicating a genotoxic potential may be presumed to have a carcinogenic potential, a toxicological risk assessment focused on carcinogenic effects should occur before proceeding to carcinogenicity testing. This is based on the predictive potential of the *in vitro* assays, the need to abide by stipulations in ISO 10993-1, ISO 10993-2, and ISO 10993-6 (ISO/TC 194, 2004) to eliminate unnecessary use of animals, and on the known mechanisms of carcinogenesis. These mechanisms have clearly shown that not all genotoxins can also be classified as carcinogens. That is, some chemical carcinogens act through pathways that disrupt cellular metabolic processes (rather than DNA integrity) to induce uncontrolled cell division leading to tumor formation. Therefore, careful consideration must be given to a material's history of safe clinical use and chemical characterization *before* proceeding to carcinogenicity studies.

Given the complex processes involved in carcinogenesis, standard carcinogenicity testing (when called for) requires time-consuming and costly *in vivo* models. As a result, several non-OECD *in vitro* alternatives designed to mimic stages of the complex, multistep carcinogenic process have been developed for prescreening and are mentioned in the standard (Official Journal of the European Communities, 1988; LeBoeuf et al., 1999). The particular *in vitro* tests that have received the greatest attention are referred to as "cell transformation assays" (e.g., the Syrian Hamster Embryo (SHE) Cell Transformation Assay and the BALB/c 3T3 Focus Transformation Assay – see website for specific details). In these assays the transformed cells (resulting from exposure to test xenobiotics/test extracts) acquiring the characteristics of malignant cells have also demonstrated the ability to induce tumors in susceptible animals. Other cellular features indicative of transformation to a tumorigenic phenotype include alteration of individual cell morphology, development of anchorage-independent replication, and formation of disordered patterns of colony growth.

As in testing for carcinogenicity, safe history of clinical use and material/device chemical characterization requires careful consideration before proceeding to the final topic covered in this section, reproductive toxicity. Here, however, attention is directed at the potential exposure of the material/device, or any of its constituents, to the host reproductive tissues, an embryo/fetus or a potential nursing child. With sufficient and supportive toxicity data from absorption, distribution, metabolism, and excretion studies, there is often no need for reproductive toxicity testing (ISO 10993-3, 2009). This type of testing is furthermore not required where a toxicological risk assessment has established steps to appropriately mitigate situations of reproductive and developmental toxicity concern.

Current testing for reproductive and developmental toxicology relies heavily upon established *in vivo* models, given the complexity of the phenomena being investigated
FIGURE II.3.3.2 Some common chromosome aberrations seen after exposure of CHO cells to extracts from test materials and/or positive controls. (A) Normal spread; (B) chromosome break; (C) chromatid break and triradial; (D) double minute and ring; (E) complex rearrangements and many breaks; (F) complex rearrangements and triradial; (G) quadraradial; (H) quadraradials; (I) triradial; (J) quadraradial; (K) interstitial deletion; and (L) chromosomal interchange. Note: in this type of testing chromatid gaps, isochromatid gaps, and uncoiled chromosomes are identified but are not computed in the analysis. Arrows point to each type of aberration. See website for further details.

(OECD 415, 1983; OECD 421, 1995; OECD 414, 2001; OECD 416, 2001). However, a variety of alternatives to whole animal testing are becoming increasingly available. The purely *in vitro* Embryonic Stem Cell Test (EST) has received particular attention following its correlation to primary embryonic cells and whole embryos. Here, a validation study funded by the European Centre for the Validation of Alternative Methods (ECVAM) showed strong correlation of three *in vitro* embryotoxicity tests across a diverse group of chemicals presenting different embryotoxic potentials (Brown, 2002; Genschow et al., 2002, 2004; ECVAM, 2008, 2009). Details of the EST test can be found on the website.

In the area of medical devices and materials, relatively few applications require reproductive toxicity consideration. However, noteworthy applications are intrauterine devices (IUDs) and energy-depositing radioactive seeds used in oncology that may come into close or direct contact with reproductive tissues, an embryo or fetus.

As discussed earlier, with medical devices typically composed of solid materials, testing often necessitates the use of extracts, rather than actual solid materials or their raw components. This is done to mimic the extraction that may occur in the body. The resultant extracts are often complex chemical mixtures, which is a notable difference from the single chemical assessment upon which the tests were based. These complex mixtures then require a number of refined analytical chemistry methods to identify specific agents of concern. In addition, analyses are further complicated by the fact that metabolic activation often plays a central role in the toxic potential of a material or chemical. To account for this, testing may require inclusion of a parallel set of test extracts exposed to an *in vitro* metabolic activation system.[4] This is done to capture chemicals called *promutagens* (i.e., compounds that are not mutagenic by themselves, but may be activated into mutagens by metabolic processes). In the simple Bacterial Reverse Mutation Assay (OECD 471), for instance, the prokaryotic cell lines clearly lack the metabolic capacity of normal intact mammalian tissue. Likewise, in testing involving eukaryotic cells, cells may present a metabolic deficiency and/or lack normal metabolic enzymes. Tests for genotoxicity, carcinogenicity, and reproductive toxicity (and cyotoxicity–see below) must therefore include a metabolic activator in order to detect the presence of metabolically-activated promutagens and toxicants in the device extracts.

Table II.3.3.2 briefly summarizes the *in vitro* tests for genotoxicity, carcinogenicity, and reproductive toxicity

as mentioned in ISO 10993-3 (see website for further details on such methods). Recall that the *in vitro* methods described in Table II.3.3.2 are considered applicable *only* when the need to evaluate a medical device for potential genotoxicity, carcinogenicity, or reproductive toxicity has been established. This is determined through a toxicological risk assessment process and material characterization evaluation (see Figure II.3.3.1, and ISO 10993-1, -17, and -18 (ISO/TC 194, 2004)). When the risk assessment warrants *in vitro* testing, the limitations are that no single test is capable of detecting all relevant toxic agents, and that not all test methods are equally well-developed or validated for the testing of medical device materials. To effectively evaluate this category of material/device biological safety, the most objective assessment is often achieved by performing a battery of tests.

In Vitro Tests for Interactions with Blood: ISO 10993-4

A significant proportion of medical devices used today present a blood-contacting surface. These devices span a variety of limited, prolonged, and permanent contact applications, and the nature of the blood contact varies widely. Important factors at the blood interface include the material(s), blood flow, surface area(s), state of blood anticoagulation and dilution, and the presence of blood trauma and other tissues. Given the importance of this interface and the range of blood-contacting device applications, this area of testing is treated as a separate section within the ISO 10993 standard (ISO 10993-4). It is also given similar treatment in this book (see Chapters II.2.6 and II.3.5). Table II.3.3.3 identifies some of the most commonly applied *in vitro* tests by the key categories of concern in material/device interaction with blood. These assays focus on assessing the device or device material for potential to cause thrombosis, interact with platelets, bring about red blood cell damage and lysis, and stimulate alternative pathway immune reactions (i.e., complement pathway activation).

Just as there are a host of unique blood-contacting parameters associated with each device application, *in vitro* testing for blood interaction requires unique models and carefully designed and controlled experiments. Models must be designed to mimic the conditions expected in clinical use (e.g., precisely controlled temperature, blood flow, test material surface area:blood ratio (cm^2/mL blood), anticoagulant conditions, blood source, and contact duration). Examples of some application-specific *in vitro* models can be found in Chapter II.5.4 of this textbook. See also Münch et al., 2000.

Despite availability of various *in vitro* assays and models for characterization of materials with blood, lack of validation and questions on relevance to *in vivo* responses have made such testing more common in special characterization and feasibility studies, rather than as regulatory requirements. An exception here is the

---

[4]An *in vitro* metabolic activation system is commonly derived from a mammalian tissue homogenate (usually liver). The most commonly employed metabolic activation system is referred to as S9. This is a standard rat liver metabolic-activating system that refers to the supernatant fraction of a homogenate obtained after a 9000g centrifugation (Malling and Frantz, 1974).

TABLE II.3.3.3	Commonly applied in vitro tests by key category of material/device compatibility with the cellular and protein elements in blood		
In vitro Test Area	**Test**	**Assay Basis***	**Information Gained**
Thrombosis	Thrombus assessment	Assessment of extent and sites of thrombus formation using gross imaging and scanning electron microscopy (SEM)	Thrombus presence may indicate material or flow-related thrombogenesis. Caveat: may or may not be clinically relevant
Coagulation	Assays for coagulation proteins (examples include TAT and FPA)	*Enzyme-linked immunosorbant assay* for key coagulation factors. TAT is proportional to thrombin and FPA is proportional to fibrin.	Estimate of coagulation cascade activation. High levels may indicate extensive device or material-related thrombin activity and fibrin formation. Caveat: also reflects surgical trauma and/or injury, and levels may be subject dependent
Platelets and Platelet Function	Platelet counting, platelet degranulation assays, platelet stability assays	*Electronic particle counting and Enzyme-linked immunosorbant assay* for granule-release proteins e.g., βTG or PF4 [111]*In-labelled platelet studies*	Estimates platelets being consumed or activated in response to a material or device. Caveat: platelet aggregation, activation and release are highly impacted by thrombin, e.g., from surgical trauma and/or injury
Hematology	Hemolysis Differential cell blood count (CBC) analysis	*Colorimetric assay* for plasma free hemoglobin (pfHb); *Electronic particle counting* for CBC	pfHb indicates red blood cell damage in response to a material or device, either from physical forces or extracts/leachants from the device material(s); CBC provides basic monitor of cell numbers
Immunology	Complement pathway activation C3a, C5a, and SC5b9 proteins	*Enzyme-linked immunosorbant assay* for key complement protein fragments	May indicate device material has potential to activate the alternative complement pathway; Caveat: surface area and surface chemistry dependent; may or may not have clinical significance

TAT = thrombin-antithrombinIII complex; FPA = fibrinopeptide A; βTG = β-thromboglobulin; PF4 = platelet factor 4; C3a, C5a and SC5b9 are components of the complement system. Note: TAT, FPA, βTG, PF4, and C5a assays are more commonly used in characterization studies rather than as standard required testing.
*Samples from proper in vitro or in vivo simulated use.

in vitro use of radiolabeled platelets for platelet stability studies on storage containers for transfusions (Holme et al., 1993; BEST Collaborative, 2006). Most often, a device in its final design is tested *in vivo*, with a subsection of the study dedicated to characterizing blood material/device interactions.

For basic material characterization for interaction with blood, the most common *in vitro* screening tests continue to be the direct and indirect hemolysis assays (ISO 10993-4, 2002; ASTM, 2009). These particular assays may be viewed as special cytotoxicity tests where human or animal red blood cells are used rather than the mouse L929 fibroblastic cells applied in standard cytotoxicity testing. The other common *in vitro* hematological assay applied today is for complement pathway activation. Here, ELISA assays (enzyme-linked immunosorbent assays) for C3a and SC5b9 protein fragments are used to estimate a material's potential for activation of the alternative pathway complement system (see Chapter II.4.4 of this textbook). Controversy exists over the clinical meaningfulness of such testing on small surface area devices and the actual adverse events due to complement activation.

In Vitro Tests for Cytotoxicity: ISO 10993-5

A general sequence of events is assumed to take place upon exposure of a toxicant to a host. First, the element can remain locally or be transported systemically by a combination of active transport processes, for example via entry into the vasculature and diffusion through tissues. The toxicant can then either: (1) alter the local biological environment causing a general molecular, organelle, cellular or tissue/organ dysfunction; or (2) interact with specificity to a particular endogenous target molecule such as a protein, membrane component or DNA. Both scenarios can lead to perturbation(s) in normal cell function and repair processes, leading to cytotoxicity.

The exposure of a single environmental toxicant to a host is a slightly different situation compared to exposure to a minute, single or mixture of potential toxicants leaching from a medical device/material. Nevertheless, similar complex biological perturbations are believed to take place when toxicant exposure comes from a medical device material. Classic examples include chemicals that alter local pH; solvents and detergents that disturb cell membranes and alter transmembrane gradients; elements that physically deter normal inter- or extracellular transport phenomena; chemicals that facilitate aberrant phosphorylation of proteins; xenobiotics that dysregulate electrically excitable cells; and agents that disrupt mitochondrial function (Chapter II.3.3 of this textbook) (Gregus and Klaassen, 2003). Mediators of tissue inflammation and fibrosis, as well as agents causing necrosis and apoptosis, are other well-known examples. The phenomenon of fibrotic tissue encapsulation that is

TABLE II.3.3.4	In vitro tests under ISO 10993 Part 5: Tests for Cytotoxicity		
Assessment	**Test[1]**	**Assay Basis**	**Information Gained[2]**
Qualitative	**L929 Elution Test**	*Light microscopy and cell morphology scoring using mouse L929 fibroblast cells;* cells examined at 100× to evaluate cellular characteristics and the percent of apparent cell lysis according to a defined scoring system.	Determines if a device material *extract* has potential to cause cell morphology changes and/or lysis.
	Direct Contact Tests	*Light microscopy and cell morphology scoring following layering sample(s) onto mouse L929 fibroblast cell monolayers;* cells examined to evaluate cellular characteristics and the percent of apparent cell lysis according to a defined scoring system.	Determines if a device material *itself* has potential to be cytotoxic. Caveat: care must be taken to avoid confounding impact of uncontrolled physical interactions
	Indirect Contact Tests *Agar Diffusion Test* *Filter Diffusion Test*	Same as Direct Contact test but with test material physically separated from cell monolayer by a nominal 2 mm agarose layer or 0.45 μm pore cellulose acetate filter paper, respectively. Same scoring system as Direct contact.	Determines if a device material *itself* has potential to release agents that may be cytotoxic.
Quantitative[3]	**Neutral Red Uptake (NRU) Test**	*Colorimetric assay of NR uptake in BALB/c 3T3 cells.* NR acts via a non-cytotoxic penetration into live cells and accumulation in intracellular lysosomes. Cells exposed to a cytotoxic xenobiotic(s) show loss of integrity and function and decreased NR uptake and binding.	Determines if a device material extract has potential to be cytotoxic. Numerical assessment makes NRU assay less subjective than L929 test.
	V79 Colony Formation Assay	*Colony enumeration and calculation of plating (colony formation) efficiency using Chinese Hamster Lung cell (V79) culture system.* Plating efficiency of a test material is measured against the negative control group.	Determines if a device material extract has potential to be cytotoxic.
	MTT and Related Tests	*Microculture tetrazolium assay (MTA);* colorimetric assay using water-soluble MTT compound. Upon exposure to L929 cells, MTT is reduced enzymatically or through direct reaction with NADH or NADPH. A bight blue formazan product forms with intensity proportional to number of viable cells present.	Determines if a device material extract has potential to be cytotoxic. Note: other MTA tests that form similar formazan products are also used.

[1]See Website for assay details.
[2]Positive materials may require additional testing and justification to establish safe use.
[3]Common scoring criteria amongst the quantitative assessment methods determines non-cytotoxicity for plating or viability values >70% of negative control. Potential cytotoxic values fall below the 70% threshold.

invariably associated with implanted medical devices is yet another feature that distinguishes, and potentially limits, toxicant exposure associated with device materials (Chapters II.3.3 and II.4.2 of this textbook).

Chemicals that possess potentially harmful or adverse properties are referred to as *toxicants*. When released from a medical device or material, such elements can remain locally or be transported systemically by a combination of active transport processes, such as entry into the vasculature and diffusion through tissues. A toxicant can then either: (1) alter the local biological environment causing a general molecular, organelle, cellular or tissue/organ dysfunction; or (2) interact with specificity to a particular endogenous target molecule, such as a protein, membrane component or DNA. Both scenarios can lead to perturbation(s) in normal cell function and repair processes leading to cytotoxicity.

Table II.3.3.4 presents the most commonly used *in vitro* tests to assess medical devices or their component materials for cytotoxicity. It should be noted that these particular tests assess general toxicity pathways and mechanisms. Thus, the nature of the tests is not inclusive of all toxicity pathways. These particular tests have, however, demonstrated appropriate usefulness in human risk assessment, the main objective of the ISO 10993 testing. As with any test, each has its limitations and criticisms. Typically, exposure is only of short duration, only a few toxicity pathways are tested, and false positives can occur. In addition, some tests utilize a subjective visual morphological scoring procedure (Figure II.3.3.3), whereas others use rapid analysis with colorimetric methods and numerical assessment. Finally, one should be aware that the 2009 version of ISO 10993-5 recommends the quantitative cytotoxicity assessment over the qualitative methods, and that such methods
FIGURE II.3.3.3 Representative light microscopic images of L929 cells in the L929 Elution Test. (A) and (D) represent the negative and positive controls showing no cell cytoxicity and approximately 100% cytotoxicity, respectively. Images (B) and (C) represent approximately 50% and 80% cytotoxicity, respectively.

have a more stringent pass/fail criteria. See Table II.3.3.4 and website for further details of each test.

APPLICATION-SPECIFIC *IN VITRO* ASSAYS CONSIDERED IN PROOF-OF-CONCEPT TESTING

Classically, assessing the cell or tissue compatibility of a material or device has centered on applying *in vitro* and *in vivo* methodologies to establish a low risk for *adverse* impact on the host. However, biomaterials science is rapidly evolving in the area of proactive materials, that is those that actively present or impart *desirable* effects on certain cells and tissues. Concepts of this nature typically target one or more specific protein, cellular, or tissue reaction recognized to play a role in how the device or material interacts with the host in a specific application. The following three case examples are intended to illustrate this point, and to show how contemporary *in vitro* testing technology has played a role in demonstrating the capacity of special composite medical materials to improve certain cellular and tissue responses.

> Classically, assessing the cell or tissue compatibility of a material or device has centered on applying *in vitro* and *in vivo* methodologies to establish a low risk for *adverse* impact on the host. Biomaterials science, however, is rapidly evolving in the area of *proactive materials* (i.e., those that actively present or impart *desirable* effects on certain cells and tissues). Concepts of this nature typically target one or more specific protein, cellular or tissue reaction recognized to play a role in how the device or material interacts with the host in a specific application.

FUTURE CHALLENGES IN *IN VITRO* ASSESSMENT OF CELL AND TISSUE COMPATIBILITY

The task of regulatory agencies and device manufacturers is to select the appropriate combination of supporting information and testing that ensures product safety, device performance, and patient outcome. This task is becoming more complicated because of the expanding repertoire of device applications, specialty materials, and associated biological interfaces.

In light of this complexity, standard tests must be well-designed, scientifically sound, and broadly applicable and predictive. As a result, preclinical safety testing faces challenges which include: (1) questions about predictive power; (2) concerns with costs and completion times; (3) issues with the selection and design of appropriate animal models; (4) validation and acceptance of novel *in vitro* tests; and (5) lengthy development and approval timelines for new methods.

Thankfully, progress is being made in addressing these challenges. First, ISO 10993-1, which provides overall guidance for the biological evaluation of medical devices, was recently revised (2009). This version states that biological evaluation of medical devices or materials should follow a three-step process: (1) material characterization; (2) toxicological risk assessment; and (3) biological testing. Given the extensive information available today on medical device materials, including history of clinical use, ISO believes that focusing on characterization and risk assessment should reduce the amount of biological testing required.

In cases where new testing is indicated, ISO 10993-1 states that validated and reliable *in vitro* test methods: "shall

Case 1 | **Recombinant Human Bone Morphogenetic Protein (rhBMP-2) in Absorbable Collagen Sponge (ACS) Bone Grafts**

When bone becomes damaged through traumatic or degenerative processes, one form of therapy involves replacement of the compromised area with bone-graft material. Autologous tissue is a common choice, with iliac crest bone the preferred material given its availability and degree of cellularity which favors healing. Unfortunately, harvesting this bone graft often results in post-operative pain and increased morbidity. To reduce these complications, smaller amounts of harvested bone have been supplemented with either synthetic calcium phosphate ceramics or demineralized allograft bone. Still, harvesting of autologous bone requires a second separate surgical procedure, and regardless of quantity of the harvest, surgeons and patients preferred an alternative method. That alternative arrived with the discovery of osteoinductive factors isolated from demineralized bone matrix (Urist and Strates, 1971), now known as bone morphogenetic proteins (BMPs). When the human BMP-2 protein was recombinantly manufactured (rhBMP-2) and delivered on an absorbable collagen sponge (ACS) scaffold, it was found to induce new bone formation. This was first demonstrated using simple *in vitro* tests to gauge the bioactivity of the material. In demonstrating chemotactic properties, *in vitro* studies showed that rhBMP-2 stimulated specific chemotactic migration of bone-forming cells (Lind et al., 1996; Fiedler et al., 2002). *In vitro* studies also showed that rhBMP-2 could increase the proliferation of several pluripotent cell lines, which are capable of differentiating into osteoblasts (Yamaguchi et al., 1991; Mayer et al., 1996; Puleo, 1997; Wilke et al., 2001; Akino et al., 2003). In addition, *in vitro* studies of rhBMP-2 demonstrated that rhBMP-2 binds to specific receptors on the surface of certain stem cells (e.g., mesenchymal stem cells or MSCs), and causes them to differentiate into bone-forming cells (Schmitt et al., 1999; Wilke et al., 2001). Together these studies showed the crucial role that BMP could have on new bone growth. Today, given the capacity of rhBMP-2 to induce alkaline phosphatase (AP) activity (Cheng et al., 2003; Luu et al., 2007), an *in vitro* AP activity test has been developed for quality control assessment of commercial product. This test uses controlled exposures of rhBMP-2 to the W20-17 bone marrow stromal cell line in combination with the synthetic AP substrate p-nitrophenol phosphate to assess inductive capacity. Clinically, rhBMP-2 combined with ACS is now used as an effective substitute to autologous bone in certain bone graft procedures (see Figure II.3.3.4).
FIGURE II.3.3.4 Schematic showing the primary cell influences of BMP protein (Attraction, Reproduction, and Differentiation) that together lead to trabecular bone generation.

Case 2 Heparin Coatings in Blood-Contacting Medical Device Applications

Primarily from recognizing that processes associated with coagulation play a major factor in many of the adverse events observed with blood-contacting devices, material scientists have focused on ways materials can be made to better mimic the hemostatic properties of native endothelium. One early observation was that endothelial cell surfaces have high negative charges, and this characteristic may impart a portion of their hemostatic properties (i.e., by repelling the negatively-charged platelets (Coleman, 2000)). In addition, it was observed that *heparan* sulfate, a proteoglycan that is structurally and functionally similar to the anticoagulant heparin, is naturally present across the cell surface of vascular endothelium (Olsson et al., 2000). These molecules are chemically linked to endothelial cells in a manner that exposes the polysaccharide chains to protein molecules in the blood. One particular plasma protein, the serine protease inhibitor called antithrombin III (ATIII), upon binding

to a specific chemical sequence on the heparan sulfate molecule, develops a high specificity for deactivating key proteins in the coagulation process, namely thrombin and factor Xa (Marcum et al., 1984; Coleman, 2000). This is precisely the mechanism of action of heparin itself, a polysaccharide that is not naturally found in the circulatory system, but rather is ubiquitously present in connective tissue. Here, heparin binds to ATIII at a unique binding site; the ATIII molecular configuration is altered, increasing the rate of enzyme-inhibitor complex formation by a factor of 1000 or more (Rosenberg et al., 2001); then, enzyme-inhibitor complex detaches from heparin leaving it available to interact with other AT molecules (Olsson et al., 2000). Heparin is not consumed in this process, but rather it acts as a catalyst (see Figure II.3.3.5).

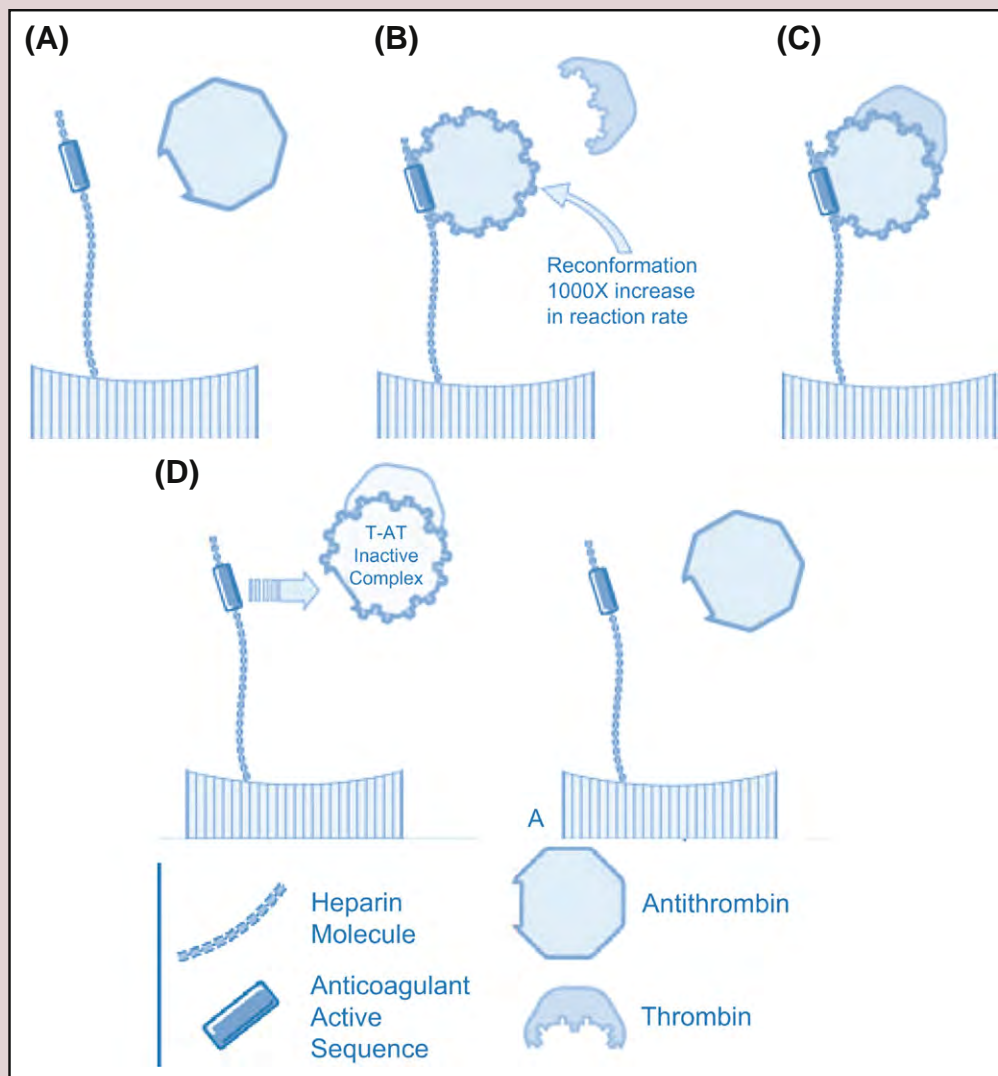
Pioneering work by Larm et al. (1983) first described a method of attaching heparin to solid materials through reactive aldehyde groups


FIGURE II.3.3.5 A. Heparin attached to a solid material is oriented so that its active sequence can interact with the blood elements. B. When heparin binds to AT, its tertiary structure changes resulting in a heparin-AT complex that has a much greater affinity for coagulation factors than AT alone. The heparin-AT complex has a 1000-fold increased affinity for interaction with thrombin compared to AT alone. C. For example, an active coagulation factor, Factor IIs (thrombin) in the blood flowing past the material binds to the heparin-AT complex and becomes inactivated. D. The thrombin-AT complex detaches from the heparin molecule and is eventually metabolized by the body. E. Similar to naturally occurring heparin sulfate on the vascular endothelium, immobilized heparin is not consumed by this cycle and remains available to attach to other AT molecules.

Case 2   Heparin Coatings in Blood-Contacting Medical Device Applications—*cont'd*

present at the ends of heparin molecules. Using this approach, the immobilized heparin mimics the orientation of the heparin sulfate molecule on the vascular endothelium, with heparin's active sequence exposed and available to interact with blood elements. Importantly, the active ATIII binding region does not become involved in the surface attachment chemistry (see Figure II.3.6).

Numerous *in vitro* approaches have been applied to establish the hematologic compatibility of such heparin-modified surfaces. The starting approach, however, is a demonstration in an *in vitro* system that the immobilized heparin applied to the surface retains its intended biological activity. Here, heparinized materials or devices are first exposed to an excess of ATIII. This saturates the ATIII

binding sites on the immobilized heparin. The uptake of this biologically active inhibitor is then quantified by subsequent exposure to a known quantity of active thrombin. Assessment of residual thrombin activity using a synthetic chromogenic substrate (e.g., S2238 or rhodamine 110, bis-[p-tosyl-L-glycyl-L-prolyl-L-arginine amide]) and analysis using a kinetic microplate reader completes the test. Immobilized heparin bioactivity is reported in units of international units of thrombin (T) deactivated per square centimeter of test material (IUT_{deac}/cm^2). Using this particular *in vitro* analysis, specific heparin activity can be measured on the various material components in cardiopulmonary bypass equipment that are coated with immobilized heparin.
FIGURE II.3.6 Attachment of heparin to material surfaces uses a stable covalent bond to the end of the molecule and orients the heparin so that its anticoagulant active sequence is free to interaction with the blood.

be considered for use in preference to *in vivo* tests," and that: "whenever possible, *in vitro* screening shall be carried out before *in vivo* tests are commenced." This policy is clearly intended to minimize the use of *in vivo* testing.

A second area of progress involves the development of *in vitro* assays that are designed to replace *in vivo* methods. Over the past few years, news articles and published reports have pointed to a paradigm shift in toxicology testing involving *in vitro* cell-based assays (NRC, 2007; Schmidt, 2009; US EPA, 2009). In the United States, the TOX21 partnership between the Environmental Protection Agency, National Toxicology Program, National Institutes of Health, and the US Food and Drug Administration (FDA) is an example of this shift. TOX21 is focused on applying new scientific tools in computational, informational, and molecular science to identify and characterize chemicals on the basis of how they activate toxicity pathways inside cells (preferably of human origin). This move away from traditional whole animal toxicity models to cell-based assays seeks to identify new mechanisms of chemical activity in cells, and to develop better predictive models of human response to toxicants. Results of these models will help regulators make more informed decisions, based on actual human toxicity data instead of animal data, which is often suspect and controversial.

The detailed information available today on medical device materials, often including extensive histories of clinical use, calls for evaluation of medical devices or materials to follow a three-step process: (1) material characterization; (2) toxicological risk assessment; and (3) biological testing. In the latter area, *in vivo* testing remains critical. However, technology is driving a move away from traditional whole animal toxicity models towards cell-based assays that identify actual mechanisms of chemical activity in cells. This, in turn, will lead to development of better predictive models of human response to toxicants. Results of these models will help regulators make more informed decisions, based on actual human toxicity data instead of animal data, which is often suspect and controversial.

The European Centre for the Validation of Alternative Methods is one of the leaders of the move towards *in vitro* methods. Over the past 10 years, ECVAM has validated or endorsed a number of alternative methods. These include the Embryonic Stem Cell Test (EST) for embryotoxicity, the Reduced Local Lymph Node Assay (rLLNA) for skin sensitization, along with the EpiSkin™ and EpiDerm™ *in vitro* tests for skin-irritation. To evaluate the skin-irritation assays, for example, ECVAM conducted a formal international validation study, with the goal of determining whether such human skin cell-based assays could accurately and reliably predict acute *in vivo* skin irritancy (Spielmann et al., 2007; Grindon et al., 2008a,b). Their multi-center blinded study and

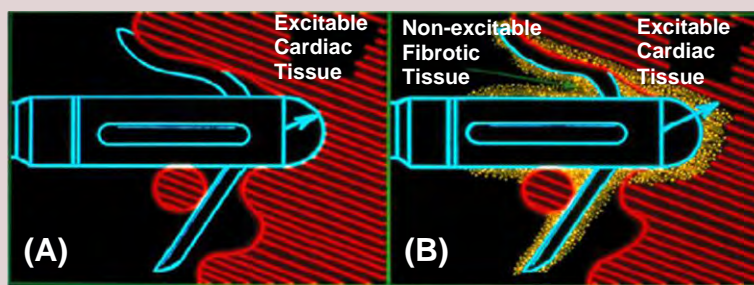
| Case 3 | **Steroid-Eluting Electrodes in Pacemaker Applications** |


FIGURE II.3.3.7 Cross section of typical tissue response at the interface of a cardiac pacing lead electrode and endocardial tissue. A: immediately at implantation, and B: after eight or more weeks after implantation. Non-electrically-excitable fibrotic tissue is seen around the electrode.

One problem of early lead electrodes used in cardiac pacing was that the pacing threshold often increased over time. *Pacing threshold* is the minimum voltage that the electrode needs to deliver to cardiac tissue in order to consistently depolarize/excite the muscle into contraction. An increase in this threshold can cause pacing failure and/or escalate energy consumption on the battery – a factor that can ultimately reduce the longevity of the implanted device. Such an increase in threshold was found to be associated with the inflammatory reaction at the electrode tip insertion site (Timmis et al., 1983; Benditt et al., 1989). In particular, an inflammatory response-induced tissue capsule formed around the electrode, resulting in an increase in impedance at the electrode–tissue interface (see Figure II.3.3.7). To mitigate this problem a process for delivering anti-inflammatory steroid drugs from the electrode tip was developed (see Figure II.3.3.8). Through gradual elution, the steroid mitigates the foreign-body response at the electrode tip, and results in minimal to zero threshold rise as a function of implant time (Benditt et al., 1989). In this case, a drug-imparted control of the cell and tissue response at the minute tip of the pacing device was seen to control a deleterious response that leads to shorter device life and less accurate sensing.

A critical development in this technology was demonstrating an appropriate and non-cytotoxic level of steroid delivered to the cardiac cells and tissues. To examine the delivery rate and prove this point, *in vitro* elution studies were conducted on test electrodes immersed in fresh pooled human plasma agitated at 37°C. Here the elution rate was seen to follow an exponential function that, when analyzed graphically, displayed a bimodal relationship. This is explained by considering the origin and the path the steroid must follow to reach the tissue. Initially, steroid within the electrode pores and on the surface of the silicone-steroid monolithic controlled-release device (MCRD "plug" located in the lead tip) readily dissolves and diffuses across a concentration
FIGURE II.3.3.8 Depiction of a tyned steroid-eluting pacing lead electrode positioned against cardiac tissue. The yellow zone represents steroid (S) eluting into the local tissue from a monolithic controlled release depot (MCRD) consisting of drug in a silicone matrix.

gradient to the exterior. Then, upon acclimation to exposure to the blood plasma and moisture penetration into the MCRD, additional dissolved steroid from within the MCRD faces the extra barrier of passing through the silicone matrix. Importantly, throughout the elution time course, the amount of steroid released remains lower than the threshold of toxicological concern for the targeted patient population.

follow-up work found that both methods exhibited high sensitivity and specificity. These findings led ECVAM to endorse both methods as stand-alone replacements for the rabbit skin-irritation test. This new *in vitro* toxicity testing approach will likely replace the Draize rabbit skin-irritation test globally.

Other governmental organizations dedicated to the validation of alternative methods include the Interagency Coordinating Committee on the Validation of Alternative Methods (ICCVAM) in the United States, the Japanese Center for the Validation of Alternative Methods (JaCVAM),

and the Korean Center for the Validation of Alternative Methods (KoCVAM). These groups are all part of a global consortium known as the International Cooperation on Alternative Test Methods (ICATM) which seeks to expand and strengthen cooperation, collaboration, and communications among national validation organizations on the scientific validation and evaluation of new alternative testing methods proposed for regulatory health and safety assessments (ICATM, 2009).

Efforts by these governmental organizations, along with work in academia and industry, will lead to the

development and adoption of more sensitive and predictive human cell-based *in vitro* tests designed to replace *in vivo* methods (Basketter, 2008; Natsch and Emter, 2008).

Finally, as the ISO 10993 standards have been revised, they have recognized new bioanalytical techniques. One example is the inclusion of the MTT (methylthiazoltetrazolium assay in ISO 10993-3 as a supplement or replacement for traditional categorical cytotoxicity analysis. Also, while not fully incorporated into ISO 10993-4 yet, ELISA data for complement testing has become a routine part of many preclinical evaluations involving blood-contacting devices. Other *in vitro* tests measuring factors indicative of material-related coagulation and thrombosis may follow.

SUMMARY REMARKS

This chapter has focused on current *in vitro* methods used to evaluate the biological compatibility of medical devices and materials. The methods were presented from two perspectives: (1) *in vitro* assays that are accepted internationally for preclinical biological safety evaluations and risk assessments; and (2) specialized material- and application-specific *in vitro* assays designed for certain cell and tissue responses. As the latter area is complex and diverse, important methods were presented in contemporary case examples. These cases demonstrated that specifically-designed *in vitro* assays have proven to be critical in moving new medical device therapies into clinical practice.

Today, materials in new device concepts do not often go through an early evaluation using the ISO 10993 process. Instead, engineers and material scientists more often use other types of tests in proof-of-concept studies, in which the majority of prototypes use well-characterized biocompatible materials with long histories of safe use. This approach is driven by the desire to bring new therapies to the market quickly, with the influence of new technologies that allow subtle changes or additions to existing materials that improve device performance via promoting improved cell and tissue interaction properties.

As the range of medical device materials and applications expands, the challenges faced by product engineers, materials scientists, regulatory agencies, and standards developers will certainly grow. Nevertheless, progress will no doubt continue to be made in the development and application of *in vitro* assays to support new therapies, improved medical materials, and advances in patient care.

CHAPTER II.3.4 *IN VIVO* ASSESSMENT OF TISSUE COMPATIBILITY

James M. Anderson[1] and Frederick J. Schoen[2]

[1]Department of Pathology, University of Cleveland, OH, USA

[2]Professor of Pathology and Health Sciences and Technology (HST), Harvard Medical School, Executive Vice Chairman, Department of Pathology, Brigham and Women's Hospital, Boston, MA, USA

INTRODUCTION

The goal of *in vivo* assessment of tissue compatibility of a biomaterial, prosthesis or medical device is to determine the biocompatibility (as a key component of safety) of the biomaterial, prosthesis or medical device in a biological environment. Indeed, biocompatibility is a critical element in the performance of an implanted medical device, and many complications of clinical devices derive from inadequate biocompatibility. Moreover, the concept of biocompatibility has evolved in recent years as biomaterials technology has become more sophisticated, particularly in permitting the biomaterial to effect complex, and potentially beneficial, interactions with the surrounding tissues (Hench and Pollak, 2002; Williams, 2008; and see Chapter II.3.2). Thus, the contemporary definition of biocompatibility focuses on the ability of a medical device to perform with an appropriate host response in a specific application, and biocompatibility assessment serves as a measurement of the magnitude and duration of the pathophysiologic mechanisms that determine the host response. From a practical perspective, the *in vivo* assessment of tissue compatibility of medical devices is carried out to determine that the device performs as intended, and presents no significant harm to

the patient or user simulating clinical use. In this chapter, the term "medical device" will be used to describe biomaterials, prostheses, artificial organs, and other medical devices, and the terms "tissue compatibility assessment," "biocompatibility assessment," and "safety assessment" will be considered to be synonymous.

> The *in vitro* assessment of tissue compatibility is necessary to establish the biocompatibility safety and function (efficacy) of a medical device and its components under conditions of intended use. Intended use conditions are also utilized to select *in vitro* tests and animal models that will provide essential information to determine biocompatibility.

Recently, extensive efforts have been made by government regulatory agencies, e.g. the US Food and Drug Administration (FDA), and standards organizations, e.g. ASTM International, the International Organization for Standardization (ISO), and US Pharmacopeia (USP), to provide procedures, protocols, guidelines, and standards that may be used in the *in vivo* assessment of the tissue compatibility of medical devices. This chapter draws heavily on the ISO 10993 standard, Biological Evaluation of Medical Devices, in presenting a systematic approach to the *in vivo* assessment of tissue compatibility of medical devices.

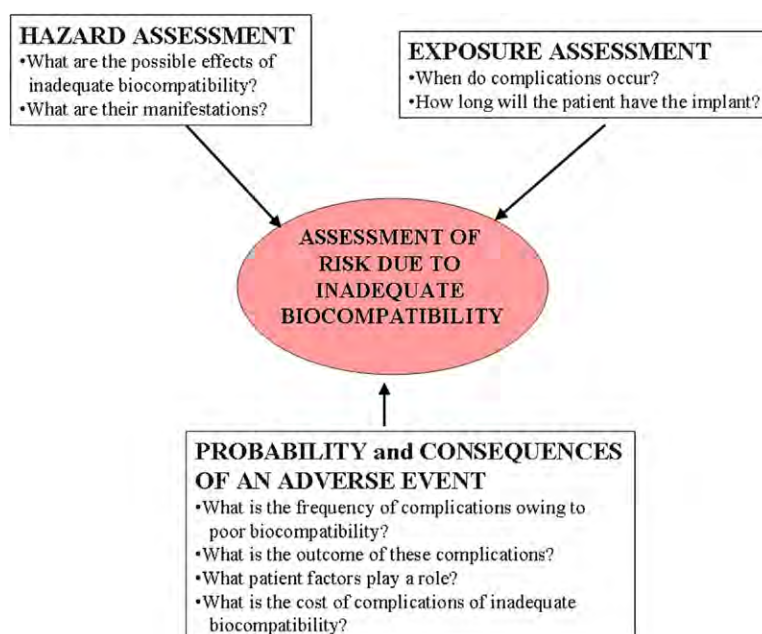
The nature and extent of risk due to inadequate biocompatibility may be conceptualized as shown in Figure II.3.4.1. The first consideration in the selection of biomaterials to be used in device design should be the chemical, toxicological, physical, electrical, morphological, and mechanical properties of the biomaterial(s) to fulfill the intended use. Relevant to the overall *in vivo* assessment of tissue compatibility of a biomaterial or


FIGURE II.3.4.1 The risks associated with inadequate biocompatibility are a composite function of the exposure (i.e., nature and duration), the hazard (i.e., effects on the recipient), and the probability and consequences of complications.

device is knowledge of the chemical composition of the materials, and the nature, degree, frequency, and duration of exposure of the device and its constituents to the tissues in which it will be utilized. Table II.3.4.1 presents a list of biomaterial components and characteristics that may affect the overall biological responses of the medical device. The range of potential biological hazards is broad, and may include short-term effects, long-term effects or specific toxic effects, which should be considered for every material and medical device. However, this does not imply that testing for all potential hazards will be necessary or practical.

SELECTION OF *IN VIVO* TESTS ACCORDING TO INTENDED USE

As it is recognized that biomaterials–tissue interaction may vary with anatomic site and duration of exposure, and application-specific conditions, *in vivo* tests for assessment of tissue compatibility are chosen to simulate end-use applications. To facilitate the selection of appropriate tests, medical devices with their component biomaterials can be categorized by the nature of tissue contact of the medical device, and by its duration of contact. Table II.3.4.2 presents medical device categorization by nature of tissue contact and contact duration. The tissue contact categories and subcategories, as well as the contact duration categories, have been derived from

standards, protocols, and guidelines utilized in the past for safety evaluation of medical devices. Certain devices may fall into more than one category, in which case testing appropriate to each category should be considered.

BIOMATERIAL AND DEVICE PERSPECTIVES IN *IN VIVO* TESTING

Two perspectives may be considered in the *in vivo* assessment of tissue compatibility of biomaterials and medical devices. The first perspective involves the utilization of *in vivo* tests to determine the general biocompatibility of newly developed biomaterials for which some knowledge of the tissue compatibility is necessary for further research and development. In this type of situation, manufacturing and other processes necessary to the development of a final product, i.e., the medical device, have not been carried out. However, the *in vivo* assessment of tissue compatibility at this early stage of development can provide additional information relating to the proposed design criteria in the production of a medical device. While it is generally recommended that the identification and quantification of extractable chemical entities of a medical device should precede biological evaluation, it is quite common to carry out preliminary *in vivo* assessments to determine if there may be unknown or as yet identified chemical entities that produce adverse biological reactions. Utilized in this fashion, early *in vivo* assessment of the tissue compatibility of a biomaterial may provide insight into the biocompatibility, and thereby may permit further development of this biomaterial into a medical device. Obviously, problems observed at this stage of development would require further efforts to improve the biocompatibility of the biomaterial, and to identify the agents and mechanisms responsible for the adverse reactions. As the *in vivo* assessment of tissue compatibility of a biomaterial or medical device is focused on the end-use application, it must be appreciated that a biomaterial considered compatible for one application may not be compatible for another.

The second perspective regarding the *in vivo* assessment of tissue compatibility of medical devices focuses on the biocompatibility of the final product, that is, the fabricated medical device in the condition in which it is to be implanted. Thus, issues related to desired fabrications, interactions between biomaterials, and to mechanical conductors, etc., may come into play. Although medical devices in their final form and condition are commonly implanted in carefully-selected animal models to determine function, as well as biocompatibility, it may be inappropriate to carry out all of the recommended tests necessary for regulatory approval on the final device. In these situations, some tests may initially be carried out on biomaterial components of devices that have been prepared under manufacturing and sterilization conditions, and other processes utilized in the final product (see Table II.3.4.3).

SPECIFIC BIOLOGICAL PROPERTIES ASSESSED BY *IN VIVO* TESTS

In this section, brief perspectives on the general types of *in vivo* tests are presented. Details regarding these tests are found in the lists of standards provided at the end of this chapter. ISO 10993 standards advise that the biological evaluation of all medical device materials include testing for cytotoxicity, sensitization, and irritation. (Cytotoxicity tests are *in vitro*.) Beyond these fundamentals, the selection of further tests for *in vivo* biocompatibility assessment is based on the characteristics and end-use application of the device or biomaterial under consideration.

Sensitization, Irritation, and Intracutaneous (Intradermal) Reactivity

Exposure to, or contact with, even minute amounts of potential leachables from medical devices or biomaterials can result in allergic or sensitization reactions. Sensitization tests estimate the potential for contact sensitization to medical devices, materials, and/or their extracts. Symptoms of sensitization are often seen in skin, and tests are often carried out topically in guinea pigs. Test design should reflect the intended route (skin, eye, mucosa) and nature, degree, frequency, duration, and conditions of exposure of the biomaterial in its intended clinical use. While sensitization reactions are immune system responses to contact with chemical substances, ISO guidelines suggest irritation to be a local tissue inflammation response to chemicals, without a systemic immunological component. The most severely irritating chemical leachables may be discovered prior to *in vivo* studies by careful material characterization and *in vitro* cytotoxicity tests. Irritant tests emphasize utilization of extracts of the biomaterials to determine the irritant effects of potential leachables. Intracutaneous (intradermal) reactivity tests determine the localized reaction of tissue to intracutaneous injection of extracts of medical devices, biomaterials or prostheses in the final product form. Intracutaneous tests may be applicable where determination of irritation by dermal or

mucosal tests is not appropriate. Albino rabbits are most commonly used.

Since these tests focus on determining the biological response of leachable constituents of biomaterials, their extracts in various solvents are utilized to prepare the injection solutions. Critical to the conduct of these tests is that the preparation of the test material and/or extract solution should be chosen to include testing for both water-soluble and fat-soluble leachables.

Systemic Toxicity: Acute, Subacute, and Subchronic Toxicity

Systemic toxicity tests estimate the potential harmful effects *in vivo* on target tissues and organs away from the point of contact (i.e., site of implantation) with either single or multiple exposures to medical devices, biomaterials, and/or their extracts. These tests evaluate the systemic toxicity potential of medical devices that release constituents into the body. These tests also include pyrogenicity testing, which assesses the induction of a systemic inflammatory response, often measured as fever.

In tests using extracts, the form and area of the material, the thickness, and the surface area to extraction vehicle volume are critical considerations in the testing protocol. Appropriate extraction vehicles, i.e., solvents, should be chosen to yield a maximum extraction of leachable materials for use in the testing. Mice, rats or rabbits are the usual animals of choice for the conduct of these tests, and oral, dermal, inhalation, intravenous, intraperitoneal or subcutaneous application of the test substance may be used, depending on the intended application of the biomaterial. Acute toxicity is considered to be the adverse effects that occur after administration of a single dose or multiple doses of a test sample given within 24 hours. Subacute toxicity (repeat dose toxicity) focuses on adverse effects occurring after administration of a single dose or multiple doses of a test sample per day during a period of from 14 to 28 days. Subchronic toxicity is considered to be the adverse effects occurring after administration of a single dose or multiple doses of a test sample per day given during a part of the lifespan, usually 90 days but not exceeding 10% of the lifespan of the animal.

Pyrogenicity tests are also included in the system toxicity category to detect material-mediated fever-causing reactions to extracts of medical devices or material. Although the rabbit pyrogen test has been the standard, the Limulus amebocyte lysate (LAL) reagent test has been used increasingly in recent years. It is noteworthy that no single test can differentiate pyrogenic reactions that are material mediated *per se* from those due to endotoxin contamination.

Genotoxicity

In vivo genotoxicity tests are carried out if indicated by the chemistry and/or composition of the biomaterial

(see Table II.3.4.1) or if *in vitro* test results indicate potential genotoxicity (changes in deoxyribonucleic acid (DNA) that could lead to changes in cellular proliferation, differentiation, and/or function). Initially, at least three *in vitro* assays should be used, and two of these assays should utilize mammalian cells. The initial *in vitro* assays should cover the three levels of genotoxic effects: DNA destruction; gene mutations; and chromosomal aberrations (as assessed by cytogenetic analysis). *In vivo* genotoxicity tests include the micronucleus test, the *in vivo* mammalian bone marrow cytogenetic tests – chromosomal analysis, the rodent dominant lethal tests, the mammalian germ cell cytogenetic assay, the mouse spot test, and the mouse heritable translocation assay. Not all of the *in vivo* genotoxicity tests need be performed; the most common test is the rodent micronucleus test. Genotoxicity tests are performed with appropriate extracts or dissolved materials using appropriate media, as suggested by the known composition of the biomaterial.

Implantation

Implantation tests assess the local pathological effects on the structure and function of living tissue induced by a sample of a material or final product at the site where it is surgically implanted or placed into an implant site or tissue appropriate to the intended application of the biomaterial or medical device. In some cases, the anatomic site of implantation used for biocompatibility evaluation is not the same as the site of ultimate use, but has representative mechanisms and consequences of tissue–biomaterials interaction (e.g., subcutaneous implantation in rodents of bioprosthetic heart valve materials to study calcification that occurs as a major clinical limitation in humans; see Chapter II.4.5). The most basic evaluation of the local pathological effects is carried out at both the gross level and the microscopic level. Histological (microscopic) evaluation is used to characterize various biological response parameters (Table II.3.4.4). To address specific questions, more sophisticated studies may need to be done. Examples include immunohistochemical staining of histological sections to determine the types of cells present, and studies of collagen formation and destruction. For short-term implantation evaluation out to 12 weeks, mice, rats, guinea pigs or rabbits are the most common animals utilized in these studies. For longer-term testing in subcutaneous tissue, muscle or bone, animals such as rats, guinea pigs, rabbits, dogs, sheep, goats, pigs, and other animals with relatively long life expectancy are suitable. If a complete medical device is to be evaluated, larger species may be utilized so that human-sized devices may be used in the site of intended application. For example, substitute heart valves are usually tested as heart valve replacements in sheep, whereas calves are usually the animal of choice for ventricular assist devices and total artificial hearts.

TABLE II.3.4.4	**Biological Response Parameters as Determined by Histological Assessment of Implants**
Number and distribution of inflammatory cells as a function of distance from the material/tissue interface	
Thickness and vascularity of fibrous capsule	
Quality and quantity of tissue ingrowth (for porous materials)	
Degeneration as determined by changes in tissue morphology	
Presence of necrosis	
Other parameters such as material debris, fatty infiltration, granuloma, dystrophic calcification, apoptosis, proliferation rate, biodegradation, thrombus formation, endothelialization, migration of biomaterials or degradation products	

In all aspects of biocompatibility testing, it is important to recognize that the effects of the material on the surrounding tissues are generally superimposed on the events occurring during physiological wound repair induced by the surgery of implantation. This is particularly important in shorter-term experiments.

Hemocompatibility

Hemocompatibility tests evaluate effects on blood and/or blood components by blood-contacting medical devices or materials. *In vivo* hemocompatibility tests are usually designed to simulate the geometry, contact conditions, and flow dynamics of the device or material in its clinical application. From the ISO standards perspective, five test categories are indicated for hemocompatibility evaluation: thrombosis; coagulation; platelets; hematology; and immunology (complement and leukocytes). Two levels of evaluation are indicated: Level 1 (required); and Level 2 (optional). Regardless of blood contact duration, hemocompatibility testing is indicated for external communicating devices – blood path indirect; external communicating devices – circulating blood; and blood-contacting implant devices. Chapter II.5.4 gives further details on the testing of blood–material interactions.

Several issues are important in the selection of tests for hemocompatibility of medical devices or biomaterials. In particular, the hemocompatibility depends not only on the materials characteristics, but also on the fluid mechanics of the device (i.e., stasis promotes thrombus formation), and the coagulatability of the blood. Thus, *in vivo* testing in animals may be convenient, but anatomic differences among species and species-related differences in blood reactivity must be considered, and these may limit the predictability of any given test in the human clinical situation. While blood values and reactivity between humans and nonhuman primates are very similar, European Community law prohibits the use of nonhuman primates for blood compatibility and medical device testing. Hemocompatibility evaluation in animals is complicated by the lack of appropriate and adequate test materials, for example, appropriate antibodies for immunoassays. Use

of human blood in hemocompatibility evaluation implies *in vitro* testing, which usually requires the use of anticoagulants that are not generally present with the device in the clinical situation, except for perhaps the earliest implantation period. Although species differences may complicate hemocompatibility evaluation, the utilization of animals in short- and long-term testing is considered to be appropriate for evaluating thrombosis and tissue interaction.

Chronic Toxicity

Chronic toxicity tests determine the effects of either single or multiple exposures to medical devices, materials, and/or their extracts during a period of at least 10% of the lifespan of the test animal, e.g., over 90 days in rats. Chronic toxicity tests may be considered an extension of subchronic (subacute) toxicity testing, and both may be evaluated in an appropriate experimental protocol or study.

Carcinogenicity

Carcinogenicity tests determine the tumorigenic potential of medical devices, materials, and/or their extracts from either single or multiple exposures or contacts over a period of the major portion of the lifespan of the test animal. Both carcinogenicity (tumorigenicity) and chronic toxicity may be studied in a single experimental study. With biomaterials, these studies focus on the potential for solid-state carcinogenicity, i.e., the Oppenheimer effect (see Chapter II.2.7). Thus, in carcinogenicity testing, controls of a comparable form and shape should be included; polyethyelene implants are a commonly used control material. The use of appropriate controls is imperative as animals may spontaneously develop tumors, and statistical comparison between the test biomaterial/device and the controls is necessary. To facilitate and reduce the time period for carcinogenicity testing of biomaterials, the FDA is exploring the use of transgenic mice carrying the human prototype c-Ha-ras gene as a bioassay model for rapid carcinogenicity testing.

Since tumors associated with clinical medical devices have been rare (see Chapter II.4.5) carcinogenicity tests should be conducted only if data from other sources suggest a tendency for tumor induction. However, considerations of carcinogenicity may become important in some future applications in which pleuripotential stem cells produced by any methodology are used.

Reproductive and Developmental Toxicity

These tests evaluate the potential effects of medical devices, materials, and/or their extracts on reproductive function, embryonic development (teratogenicity), and prenatal and early postnatal development. The application site of the device must be considered, and tests and/or bioassays should only be conducted when the device has a potential impact on the reproductive potential of the subject.

Biodegradation

Biodegradation tests determine the effects of a biodegradable material and its biodegradation products on the tissue response. They focus on the amount of degradation during a given period of time (the kinetics of biodegradation), the nature of the degradation products, the origin of the degradation products (e.g., impurities, additives, corrosion products, bulk polymer), and the qualitative and quantitative assessment of degradation products and leachables in adjacent tissues and in distant organs. The biodegradation of biomaterials may occur through a wide variety of mechanisms, which in part are biomaterial dependent, and all pertinent mechanisms related to the device and the end-use application of the device must be considered. Test materials comparable to degradation products may be prepared and studied to determine the biological response of degradation products anticipated in long-term implants. An example of this approach is the study of metallic and polymeric wear particles that may be present with long-term orthopedic joint prostheses. Moreover, for intentionally biodegradable scaffolds used in tissue engineering (see Chapter II.6.3), biodegradation and the attendant tissue response are important to follow histologically. Further insights on biodegradation are available in Chapters II.6.2 and II.6.3.

Immune Responses

Immune response evaluation is not a component of the standards currently available for *in vivo* tissue compatibility assessment. However, ASTM, ISO, and the FDA currently have working groups developing guidance documents for immune response evaluation where pertinent. Synthetic materials are not generally immunotoxic (see Chapter II.2.3). However, immune response evaluation is necessary with modified natural tissue implants such as collagen, which has been utilized in a number of different types of implants and may elicit immunological responses. The Center for Devices and Radiological Health of the FDA has released a draft immunotoxicity testing guidance document (Langone, 1998) whose purpose is to provide a systematic approach for evaluating potential adverse immunological effects of medical devices and constituent materials. Immunotoxicity is any adverse effect on the function or structure of the immune system or other systems as a result of an immune system dysfunction. Adverse or immunotoxic effects occur when humoral or cellular immunity needed by the host to defend itself against infections or neoplastic disease (immunosuppression) or unnecessary tissue damage (chronic inflammation, hypersensitivity or autoimmunity) is compromised. Potential immunological effects and responses that may be associated with one or more of these effects are presented in Table II.3.4.5.

Representative tests for the evaluation of immune responses are given in Table II.3.4.6. Table II.3.4.6 is not all-inclusive, and other tests that specifically consider possible immunotoxic effects potentially generated

TABLE II.3.4.5	Potential Immunological Effects and Responses
Effects	
Hypersensitivity	
Type I – anaphylactic	
Type II – cytotoxic	
Type III – immune complex	
Type IV – cell-mediated (delayed)	
Chronic Inflammation	
Immunosuppression	
Immunostimulation	
Autoimmunity	
Responses	
Histopathological Changes	
Humoral Responses	
Host Resistance	
Clinical Symptoms	
Cellular Responses	
T cells	
Natural killer cells	
Macrophages	
Granulocytes	

TABLE II.3.4.6	Representative Tests for the Evaluation of Immune Responses

Functional Assays	Phenotyping	Soluble Mediators	Signs of Illness
Skin testing	Cell surface markers	Antibodies	Allergy
Immunoassays (e.g., ELISA)	MHC markers	Complement	Skin rash
Lymphocyte proliferation	Chemokines	Immune complexes	Urticaria
Plaque-forming cells	Basoactive amines	Cytokine patterns (T-cell subsets)	Edema
Local lymph node assay	–	Cytokines (IL-1, IL-1ra, TNFα, IL-6, TGF-β, IL-4, IL-13)	Lymphade-nopathy
Mixed lymphocyte reaction	–	–	–
Tumor cytotoxicity	–	–	–
Antigen presentation	–	–	–
Phagocytosis	–	–	–

ELISA: Enzyme-linked immunosorbent assay; IL: Interleukin; TNF: Tumor necrosis factor; TGF: Transforming growth factor; MHC: Major histocompatibility complex.

by a given device or its components may be applicable. Examples presented in Table II.3.4.6 are only representative of the large number of tests that are currently available. However, direct and indirect markers of immune responses may be validated and their predictive value documented, thus providing new tests for immunotoxicity in the future. Direct measures of immune system activity by functional assays are the most important types of tests for immunotoxicity. Functional assays are generally more important than tests for soluble mediators, which are more important than phenotyping. Signs of illness may be important in *in vivo* experiments, but symptoms may also have a significant role in studies of immune function in clinical trials and postmarket studies.

Combination devices where drugs (or cells) are utilized within medical devices should also be considered for immune response evaluation. Hypersensitivity reactions have been reported with drug-eluting coronary stents (DES). With DES, concomitantly prescribed medications such as clopidogrel (platelet inhibitor) have been considered the causative agent for hypersensitivity, as well as the DES itself (Nebeker et al., 2006).

SELECTION OF ANIMAL MODELS FOR *IN VIVO* TESTS

Animal models are used to predict the clinical behavior, safety, and biocompatibility of medical devices in humans (Table II.3.4.7). The selection of animal models for the *in vivo* assessment of tissue compatibility must consider

TABLE II.3.4.7	Animal Models for the *In Vivo* Assessment of Medical Devices

Device Classification	Animal
Cardiovascular	
Heart valves	Sheep
Vascular grafts	Dog, pig
Stents	Pig, rabbit, dog
Ventricular assist devices	Calf
Artificial hearts	Calf
Ex vivo shunts	Baboon, dog
Orthopedic/Bone	
Bone regeneration/ substitutes	Rabbit, dog, pig, mouse, rat Dog, goat, nonhuman primate
Total joints – hips, knees	Sheep, goat, baboon
Vertebral implants	Rabbit, pig, dog, nonhuman primate
Craniofacial implants	Rabbit, dog
Cartilage	Dog, sheep
Tendon and ligament substitutes	Goat
Neurological	
Peripheral nerve regeneration	Rat, cat, nonhuman primate
Electrical stimulation	Rat, cat, nonhuman primate
Ophthalmological	
Contact lens	Rabbit
Intraocular lens	Rabbit, monkey

the advantages and disadvantages of the animal model for human clinical application. Several examples follow, which exemplify the advantages and disadvantages of animal models in predicting clinical behavior in humans.

> Preclinical testing in animal models is an important part of the regulatory process, used to determine the safety and efficacy of devices prior to human clinical trials. The choice of the animal model and the selection of *in vitro* tests should be made according to the intended use of the respective medical device, prosthesis or biomaterial.

A single test animal may not assess all pertinent clinically-important complications. For example, as described earlier, sheep are commonly used for the evaluation of heart valves (see Chapters II.3.7 and II.4.5). This is based on size considerations, and also the propensity to calcify tissue components of bioprosthetic heart valves and thereby be a sensitive model for this complication. Thus, the choice of this animal model for bioprosthetic heart valve evaluation is made on the basis of accelerated calcification, the major clinical problem, assessed in rapidly growing animals which has its clinical correlation in young and adolescent humans. Nevertheless, normal sheep may not provide a sensitive assessment of the propensity of a valve to thrombosis, which may be potentiated by the reduced flow seen in abnormal subjects, but diminished by the specific coagulation profile of sheep.

The *in vivo* assessment of tissue responses to vascular graft materials is an example in which animal models present a particularly misleading picture of what generally occurs in humans. Virtually all animal models, including nonhuman primates, heal rapidly and completely with an endothelial blood-contacting surface. Humans, on the other hand, do not show extensive endothelialization of vascular graft materials, and the resultant pseudointima from the healing response in humans has potential thrombogenicity. Consequently, despite favorable results in animals, small-diameter vascular grafts (less than 4 mm in internal diameter) usually yield early thrombosis in humans, the major mechanism of failure which is secondary to the lack of endothelialization in the luminal surface healing response.

Originally, the porcine coronary artery model was considered the model of choice for the evaluation of arterial stents. More recently, the rabbit iliac artery model for the evaluation of drug-eluting stents has been considered to be more realistic, as endothelialization is slower in the rabbit model than in the porcine model, and inflammation is not as extensive in the rabbit (Nakazawa et al., 2008). Thus, endothelialization, healing, and inflammation in the rabbit iliac artery model may be closer to these responses in humans than the porcine coronary artery model.

The use of appropriate animal models is an important consideration in the safety evaluation of medical devices that may contain potential immunoreactive materials. The *in vivo* evaluation of recombinant human growth hormone in poly(lactic-*co*-glycolic acid)(PLGA) microspheres demonstrates the appropriate use of various animal models to evaluate biological responses and the potential for immunotoxicity. Utilizing biodegradable PLGA microspheres containing recombinant human growth hormone (rhGH), Cleland et al. (1997) used Rhesus monkeys, transgenic mice expressing hGH, and normal control (Balb/C) mice in their *in vivo* evaluation studies. Rhesus monkeys were utilized for serum assays in the pharmacokinetic studies of rhGH release, as well as tissue responses to the injected microcapsule formulation. Placebo injection sites were also utilized, and a comparison of the injection sites from rhGH PLGA microspheres and placebo PLGA microspheres demonstrated a normal inflammatory and wound-healing response with a normal focal foreign-body reaction. To further examine the tissue response, transgenic mice were utilized to assess the immunogenicity of the rhGH PLGA formulation. Transgenic mice expressing a heterologous protein have been previously used for assessing the immunogenicity of structural mutant proteins. With the transgenic animals, no detectable antibody response to rhGH was found. In contrast, the Balb/C control mice had a rapid onset of high-titer antibody response to the rhGH PLGA formulation. This study points out the appropriate utilization of animal models to not only evaluate biological responses, but also one type of immunotoxicity (immunogenicity).

FUTURE PERSPECTIVES ON *IN VIVO* MEDICAL DEVICE TESTING

As presented earlier in this chapter, the *in vivo* assessment of tissue compatibility of biomaterials and medical devices is dependent on the end-use application of the biomaterial or medical device. In this sense, the development and utilization of new biomaterials and medical devices will dictate the development of new test protocols and procedures for evaluating these new products. Furthermore, it must be understood that the *in vivo* assessment of tissue compatibility of biomaterials and medical devices is open-ended, and new end-use applications will require new tests.

> The future development of medical devices is anticipated to provide more complexity to the composition and construction of these devices and, thus, to the array of potential biomaterials–tissue interactions. Thus, further studies will require a more sophisticated approach to test protocols and methodologies that must clearly identify biocompatibility and function. In this regard, new tests, methods, and animal models may have to be developed to adequately and appropriately characterize the biocompatibility and function of these new devices. Therefore, the development of guidelines and standards is dynamic and constantly evolving, driven by the complexity of new devices developed for application in tissue engineering, regenerative medicine, and nanomedicine.

Over the past half-century, medical devices and bio-materials have generally been "passive" in their tissue interactions. That is, a mechanistic approach to biomaterials–tissue interactions has rarely been used in the development of biomaterials or medical devices. Heparinized biomaterials are an exception to this, but considering the five subcategories of hemocompatibility, these approaches have minimal impact on the development of blood-compatible materials.

In the past decade, increased emphasis has been placed on bioactivity and tissue engineering in the development of biomaterials and medical devices for potential clinical application. Rather than a "passive" approach to tissue interactions, bioactive and tissue-engineered devices have focused on an "active" approach in which biological or tissue components, i.e., growth factors, cytokines, drugs, enzymes, proteins, extracellular matrix components, and cells that may or may not be genetically modified, are used in combinations with synthetic, i.e., passive, materials to produce devices that control or modulate a desired tissue response. Obviously, *in vivo* assessment of the targeted biological response of a tissue-engineered device will play a significant role in the research and development of that device, as well as in its safety assessment. It is clear that scientists working on the development of tissue-engineered devices will contribute significantly to the development of *in vivo* tests for biocompatibility assessment, as these tests will also be utilized to study the targeted biological responses in the research phase of the device development.

Regarding tissue-engineered devices, it must be appreciated that biological components may induce varied effects on tissue in the *in vivo* setting. For example, a simplistic view of the potentially complex problems that might result from a device releasing a growth factor to enhance cell proliferation is presented. The presence of a growth factor may result in markedly different cell proliferation, differentiation, protein synthesis, attachment, migration, shape change, etc., which would be cell-type dependent. Thus, different cell-type dependent responses in an implant site, reacting to the presence of a single exogenous growth factor, may result in inappropriate, inadequate or adverse tissue responses. These perspectives must be integrated into the planned program for *in vivo* assessment of tissue compatibility of tissue-engineered devices. Moreover, a major challenge to the *in vivo* assessment of tissue compatibility of tissue-engineered devices is the use of animal tissue components in the early phase of device development, whereas the ultimate goal is the utilization of human tissue components in the final device for end-use application. Novel and innovative approaches to the *in vivo* tissue compatibility of tissue-engineered devices must be developed to address these significant issues. Finally, the development of clinically useful tissue-engineered devices will require enhanced understanding of the influence of the patient and biomechanical factors on the structure and function of healed and remodeled tissues. It will also require new methodology for assessment of biocompatibility, and the dynamic progression of remodeling *in vivo* (Mendelson and Schoen, 2006).

Careful studies of retrieved implants to establish biomarkers and mechanisms of structural evolution will be critical (see Chapter II.1.5).

CHAPTER II.3.5 EVALUATION OF BLOOD–MATERIALS INTERACTIONS

Buddy D. Ratner[1] and Thomas A. Horbett[2]
[1]Professor, Bioengineering and Chemical Engineering, Director of University of Washington Engineered Biomaterials (UWEB), Seattle, WA, USA

[2]Bioengineering and Chemical Engineering University of Washington, Seattle, WA, USA

INTRODUCTION

Thousands of devices fabricated from synthetic materials or processed natural materials are interfaced with blood for a wide range of medical procedures (see Chapters II.5.3A–C, II.5.4, and II.5.5). Blood-contacting materials have a unique set of requirements, and most are quite different from implants in soft tissue or bone. The most obvious complication is thrombus or clot, but many other undesirable reactions can impact performance when a synthetic material is interfaced with blood. How can the biomaterials engineer know which materials might be best used in the fabrication of a blood-contacting device? It would be ideal if this chapter could end with a definitive list of "blood-compatible" biomaterials that might be used in blood-contacting medical devices (note that generalized suggestions are offered near the end of this chapter). The considerations driving the interpretation of blood interactions tests are sufficiently complex that such a list of materials cannot be presented. The reader should appreciate this point after working through Chapter II.3.5.

This chapter outlines methods and concerns in evaluating the blood-compatibility of biomaterials, and the blood-compatibility of medical devices. It does not automatically follow that if the materials comprising a device are blood-compatible, a device fabricated from those materials will also be blood-compatible. This important point should be clear upon completion of this chapter. Before considering the evaluation of materials

and devices, the reader should be familiar with the protein and cellular reactions of blood coagulation, platelet responses, and fibrinolysis, as discussed in Chapter II.2.6. The history of methods to assess blood-compatibility is addressed in Ratner, 2000.

BACKGROUND AND PRINCIPLES OF BLOOD–MATERIALS INTERACTIONS ASSESSMENT

What is Blood-Compatibility?

Blood-compatibility assessment would be straightforward if, following the introductory paragraph, there were a list of standard tests that might be performed to evaluate blood-compatibility. By simply performing the tests outlined in such a list, a material could be rated "blood-compatible" or "not blood-compatible." Unfortunately, no widely-recognized, standard list of blood-compatibility tests exists. Due to the complexity of blood–materials interactions (BMI), there is a basic body of ideas that must be mastered in order to appreciate what blood interaction tests actually measure. This section introduces the rationale for BMI testing, and addresses a few important measurement schemes.

"Blood-compatibility" can be defined as the property of a material or device that permits it to function in contact with blood without inducing adverse reactions. But this simple definition offers little insight into what a blood-compatible material is. More useful definitions become increasingly complex. This is because there are many mechanisms for the body to respond to material intrusions into the blood. A material that will not trigger one response mechanism may be highly active in triggering an alternative pathway. The mechanisms by which blood responds to materials have been discussed in Chapter II.2.6. A more recent definition of blood-compatibility integrates a multiparameter assessment of BMI, where some of the parameters are defined quantitatively (Sefton et al., 2000). This chapter will integrate many of these ideas, and provide a framework for BMI (and blood compatibility) assessment.

> Blood compatibility is impacted by the biochemistry of coagulation, the mechanisms of blood–materials interactions (BMI), and the design and function of a device in the bloodstream. This chapter will integrate many of these ideas, and provide a framework for BMI and blood compatibility assessment.

Blood-compatibility can also be viewed from a different perspective, i.e., by considering a material that is *not* blood-compatible (a thrombogenic material). Such a material would produce specific adverse reactions when placed in contact with blood: formation of clot or thrombus composed of various blood elements; shedding or nucleation of emboli (detached thrombus); the destruction of circulating blood components; activation of the complement system and other immunologic pathways (Salzman and Merrill, 1987). Most often, in designing blood-contacting materials and devices, our aim is to minimize these generally undesirable blood reactions. Are these reactions always undesirable? Consider the case of a hemostatic device rapidly inducing clotting.

Why Measure Blood-Compatibility?

Many devices and materials are presently used in humans to treat, or to facilitate treatment of, health problems. Such devices include the extracorporeal pump-oxygenator (heart-lung machine) used in many surgical procedures, hollow fiber hemodialyzers for treatment of kidney failure, catheters for blood access and blood vessel manipulation (e.g., angioplasty), heart assist devices, stents for luminally supporting blood vessels, and devices for the permanent replacement of diseased heart valves (prosthetic heart valves) and arteries (vascular grafts). Since these and other blood-contacting devices have been successfully used in patients for 30 or more years, and are judged to be therapeutically beneficial, it is reasonable to ask: (1) is there a continued need for assessing BMI; and (2) are there important problems that remain to be addressed? The answer in both cases is an emphatic "yes."

To address point (1) above, the ongoing need for BMI measurement, consider that existing devices are frequently modified by incorporation of new design features or materials primarily intended to improve durability, physical and mechanical characteristics, i.e., devices may be modified to improve characteristics other than BMI. However, since these changes may also affect blood responses, and since BMI are not entirely predictable based on knowledge of device composition and configuration, blood-compatibility testing is nearly always required to document safety.

There are substantial problems with devices used today in the bloodstream (point 2, above). The performance of many existing devices is frequently less than optimal (McIntire et al., 1985; Salzman and Merrill, 1987; Williams, 1987; Ratner, 1993, 2000, 2007; Wang and Tsai, 2010). For example, prolonged cardiopulmonary bypass and membrane oxygenation can produce a severe bleeding tendency. Mechanical heart valves occasionally shed emboli to the brain, leading to stroke. Angiographic catheters can also generate strokes. Synthetic vascular grafts perform less well than grafts derived from natural arteries or veins; graft failure due to thrombosis can lead to ischemia (lack of oxygen) and death of downstream tissue beds; small diameter vascular grafts (<4 mm i.d.) cannot be made. Thus, while performance characteristics have been judged to be acceptable in many instances (i.e., the benefit/risk ratio is high), certain existing devices could be improved to extend their period of safe operation (e.g., oxygenators), and to reduce adverse BMI long-term (e.g., heart valves). Further, many devices

are only "safe" when anticoagulating drugs are used (e.g., oxygenators, mechanical heart valves, hemodialyzers). Device improvements that would reduce adverse BMI, and thereby minimize the need for anticoagulant therapy, would have important implications both for health (fewer bleeding complications due to drug effects) and cost (complications can be expensive to treat). The reusability of devices that can undergo repeated blood exposure in individual patients (e.g., dialyzers) is also an important economic consideration.

For certain applications there are no devices presently available that perform adequately (due to adverse BMI), even when antithrombotic drugs are used. Thus, there are needs for devices that could provide long-term oxygenation for respiratory failure, cardiac support (total artificial heart), and intravascular measurement of physiologic parameters and metabolites (O_2, CO_2, pH, glucose). Also, there are demands for long-term, small diameter vascular grafts (<5 mm internal diameter) and other conduits (e.g., stents) for reconstruction of diseased arteries and veins. Overall, there is a compelling need for continued and improved methods for evaluating BMI.

What is Thrombogenicity?

A thrombogenic device may cause a localized accumulation of protein and cellular blood elements. Cardiovascular devices may also induce regions of disturbed flow or stasis that lead to the formation of blood clots. These accumulations or clots may compromise device functions, such as flow of blood through artificial blood vessels, the mechanical motions of heart valves, gas exchange through oxygenators, the removal of metabolic waste products through dialysis membranes, etc. Local blood reactions may also impact other parts of the host organism, i.e., systemic effects might be noted. Thus, thrombi may detach from a surface (embolize) and be carried downstream, eventually occluding a blood vessel of comparable size and impairing blood flow distal to the site of occlusion. Chronic devices may produce steady-state destruction or "consumption" of circulating blood elements, thereby lowering their concentration in blood (e.g., mechanical destruction of red cells by heart prostheses producing anemia or removal of platelets due to ongoing thrombus formation or platelet activation), with a concomitant rise in plasma levels of factors released from those blood elements (e.g., plasma hemoglobin, platelet factor 4). Mediators of inflammatory responses and vessel tone may also be produced or released from cells (e.g., platelets, white cells, the complement pathway) following blood–surface interactions that can affect hemodynamics and organ functions at other sites. Thus, "thrombogenicity" may be broadly defined as the extent to which a device, when employed in its intended use configuration, induces the adverse responses outlined above. While all artificial surfaces interact with blood, an acceptably nonthrombogenic device can be defined

as one which would produce neither local nor systemic effects with significant health consequence to the host organism.

> Thrombogenicity may be broadly defined as the extent to which a device, when employed in its intended use configuration, induces adverse responses.

With "thrombogenicity" now defined as adverse outcome events associated with device usage, the obvious goal is to design and improve devices using materials that are blood-compatible (nonthrombogenic) for specific applications. Ideally, the biomaterials engineer would like to consult a handbook for a list of materials useful in the fabrication of a blood-contacting device. Unfortunately, there is little consensus as to the materials that are blood-compatible (Ratner, 1984). Because of this lack of consensus, there is no "official" list of blood-compatible materials. As a result, in the construction of a new blood-contacting device the biomaterials engineer generally consults published studies or directly performs blood-compatibility assessment studies on candidate materials.

Understanding the blood-compatibility of specific materials used in blood-contacting devices is complex because:

(1) The types of blood-contacting devices used are numerous (see Chapter II.5.3), and the device design will impact the apparent thrombogenicity of materials used in those devices.
(2) Typically, blood-contacting devices are commercially manufactured, and manufacturers are, for competitive reasons, reluctant to discuss specific chemical compositions or changes made in response to the availability of materials.
(3) The possible blood responses are numerous, complex, dynamic, and often not fully-understood.
(4) It is difficult and expensive to measure device thrombogenicity (clinically significant local thrombosis or systemic effects) in a systematic way, in either experimental animals or humans (Williams, 1987, and this chapter).

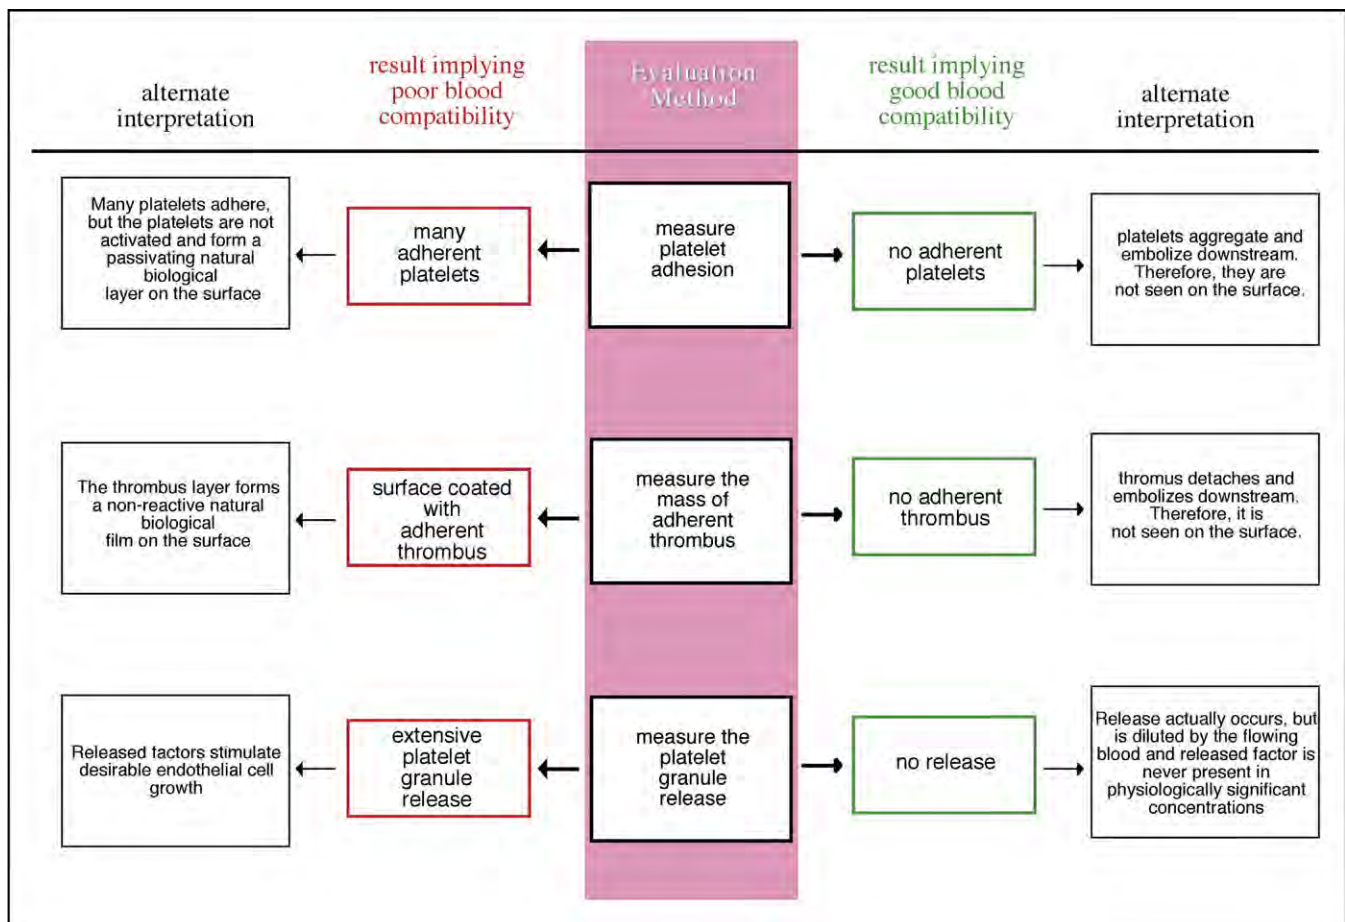
Most tests purported to measure blood-compatibility in fact evaluate certain blood–material interactions (BMI), which are the events that occur (and observations that are made) when blood contacts a material. Figure II.3.5.1 illustrates how alternate interpretations can be applied to data from "blood-compatibility" tests. This concept is further expanded upon in Figure II.3.5.2. These alternate interpretations often invalidate or modify conclusions drawn from such tests. For accuracy, the term "BMI assessment" will be used for the remainder of this chapter, instead of "blood-compatibility test." Based upon the characteristics of the evaluation method (i.e., what is really being measured) the biomaterials scientist
FIGURE II.3.5.1 Possible scenarios for blood–materials interactions and alternate interpretations of testing outcome. This example points out limitations of evaluating only local thrombus formation at fixed time points. (A) The device remains free of thrombus after exposure to blood; (B) a large thrombus forms, adheres tightly as is observed as an endpoint; (C) a large thrombus forms but detaches (embolizes); (D) the surface is highly reactive towards blood but deposited material is quickly removed through microembolism and/or lysis. Inspection of devices (C) and (D) could lead to the incorrect conclusion that these surfaces are blood compatible.


FIGURE II.3.5.2 Alternate scenarios that can be applied for interpreting results of blood–material interaction assays.

must relate the significance of the events being observed (the BMI) to the blood-compatibility of the material or device. A solid understanding of the physical and biological mechanisms of blood–materials interactions is required to make this connection in a rational way.

> Most tests purported to measure blood-compatibility in fact evaluate blood–material interactions (BMI), which are the events that occur when blood contacts a material. For example, is a material that adheres platelets not blood-compatible? Figures II.3.5.1 and II.3.5.2 demonstrate alternate interpretations of such data.

In more specific terms, BMI are the interactions (reversible and irreversible) between surfaces and blood solutes, proteins, and cells (e.g., adsorption, absorption, adhesion, denaturation, activation, spreading) that occur under defined conditions of exposure time, blood composition, and blood flow. Since each of these variables influence BMI, we generally cannot: (1) extrapolate results obtained under one set of test conditions to another set of conditions; (2) use short-term testing to predict long-term results; and (3) predict *in vivo* device performance based on BMI testing of materials *per se* in idealized flow geometries. Nonetheless, such tests have provided important insights into the mechanisms of thrombus formation in general, and the relationships between BMI and blood-compatibility. These studies also permit some general guidelines for device construction and, to a limited extent, may allow prediction of device performance in humans. These points are addressed in subsequent sections of this chapter.

The above considerations suggest that no material may be simply "blood-compatible" or "nonthrombogenic," since this assessment will depend strongly on details of the test system or usage configuration. In fact, under conditions of sluggish (low shear) blood flow or stasis, most if not all, polymeric materials may become associated with localized blood clotting and thus be considered "thrombogenic." This is because synthetic materials, unlike the vascular endothelium (the perfect "blood-compatible material" that lines all blood vessels), cannot actively inhibit thrombosis and clotting by directly producing and releasing inhibitors or by inactivating procoagulant substances. The possibility that there may be no "biomaterials solution" for certain situations or that device performance could be improved by emulating strategies found in nature, has led some investigators to consider coating devices with endothelial cells, antithrombotic drugs or anticoagulating enzymes. These approaches appear promising, and are being widely explored. As for conventional synthetic materials and devices, establishing the usefulness of biologic surfaces and drug delivery devices requires appropriate methods for evaluating their blood interactions. An important point is that we use millions of devices in contact with blood each year in patients with generally good outcomes. It is not that the

problem of blood-compatibility is impossible to solve, but outcomes can often be improved by optimizing BMI.

> We use millions of devices in contact with blood each year in patients with generally good outcomes. The problem of blood-compatibility is complex, but outcomes can often be improved by optimizing blood–materials interactions.

Key Considerations for BMI Assessment

In 1856 Rudolph Virchow implied that three factors contribute to the coagulation of the blood: blood chemistry, the blood-contacting surface, and the flow regime (commonly referred to as Virchow's triad – Figure II.3.5.3).

This assessment is still valid, and provides a framework for more formally introducing the variables important in any system intended to evaluate BMI. Also, the interaction time of blood with materials (ranging from seconds to years) has an impact on BMI. As described below, these variables may each profoundly influence the results and interpretation of BMI testing. It is assumed that the reader has reviewed the mechanisms of blood response to artificial surfaces, as outlined in Chapter II.2.6.

Blood: A Fragile Fluid that is Readily Compromised. The source of the blood and methods for its handling can strongly influence BMI. Human blood and blood from various animal species has been employed in BMI assessment *in vitro* and *in vivo*, both in the presence and absence of anticoagulants. Blood reactivity is also influenced by manipulations *in vitro*, the surface-to-volume ratio of blood in extracorporeal circuits, and the use of pumps for blood recirculation. These aspects are discussed below, and summarized in Table II.3.5.1.

Although there are general similarities in the blood chemistry of all mammals, there are also differences characteristic of each species. In particular, blood may vary with respect to blood proteins (concentrations and functionality), and cells that participate in coagulation, thrombosis, and fibrinolysis (Chapter II.2.6). The size of blood-formed elements may also differ. A comparison of blood chemistry between man and the more commonly used animal species has been published (McIntire et al., 1985). While human blood is obviously preferable for BMI, it is often impossible to use human blood in certain experiments. In addition, there are significant health concerns in experimenting with human blood, and animals are commonly used for both *in vitro* and *in vivo* studies. Unfortunately, most investigations have employed a
FIGURE II.3.5.3 Virchow's triad.

TABLE II.3.5.1	Factors Important in the Acquisition and Handling of Blood for BMI Experiments

- Species of the blood donor
- Health, gender, and age of the blood donor
- Blood reactivity of the donor (individual physiological differences)
- Time interval between blood draw and BMI experiment
- Care with which the puncture for the blood draw was made
- Temperature (for blood storage and testing)
- Anticoagulation
- Drugs and anesthetics present in the blood
- Blood damage due to centrifugation and separation operations
- Blood damage due to contact with foreign surfaces prior to the BMI experiment (syringe, needle, blood bag, bottles, tubing, etc.)
- Blood damage due to the air–blood interface
- Blood damage due to pumping and recirculation

single animal species or blood source. There have been few comparisons between human and animal blood responses for evaluating BMI in particular test situations (also see Chapter II.3.7). In many instances differences between human and animal blood responses are large, and such differences must be factored into interpreting experimental results. For example, the initial adhesiveness of blood platelets for artificial surfaces appears to be low in man and some primates, and high in the dog, rat, and rabbit (Grabowski et al., 1976). Following the implantation of chronic blood-contacting devices (e.g., vascular grafts) there may be large differences between man and other animal species in terms of device healing, which will be reflected as differences in the *time course* of BMI. Further, while laboratory animals serving as blood donors for BMI experiments may represent a relatively homogeneous population in terms of age, health status, blood responses, etc., the human donors of blood for research (and recipients of blood-contacting devices) may vary considerably in terms of these parameters. Consider, for example, human diet, drug use (e.g., aspirin, alcohol), overall health, and even donor sex (males and females were found to have different platelet responses in experiments in our laboratory). Thus, the results obtained with animal species must be viewed with caution if conclusions are to be drawn as to the significance of the results for humans. Even the blood drawn from one human can give misleading results when generalizations to all humans are attempted.

Despite these limitations, animal testing has been helpful in defining *mechanisms* of BMI and thrombus formation, and the interdependence of blood biochemical pathways, the nature of the surface, and the blood flow regime. In addition, while results of animal testing may not quantitatively predict results in man, in many cases results can be qualitatively similar. These aspects are discussed further below. In general, studies in lower animal species, such as the rabbit, rat, and guinea pig, may be useful to screen for profound differences between

materials, for example, by incorporation of an antithrombotic drug delivery system into an otherwise thrombogenic device. Short-term screening to identify markedly reactive materials, and longer-term studies to evaluate healing and its impact on BMI can also be performed in species such as dog and pig. When differences in BMI are likely to be modest (for example, as a consequence of subtle changes in surface chemistry or device configuration) the ranking of materials based on tests with lower animal species may be unrelated to results that would be obtained in man; studies with primates, which are hematologically similar to man, are more likely to provide results which are clinically relevant. However, even the relationships between human and primate BMI are also not well-established, and should therefore be interpreted with caution. And experimentation with primates is expensive, and raises ethical issues.

In vitro testing generally requires anticoagulation of the blood that can have a profound effect on BMI. *In vivo* testing and the use of extracorporeal circuits are also commonly performed with anticoagulants. Two anticoagulants are frequently used: sodium citrate, a calcium ion chelator required for certain reactions of platelets and coagulation proteins; and heparin, a natural polysaccharide used to block the action of the coagulation protease thrombin (Chapter II.2.6). Both can markedly affect BMI. In particular, the removal of calcium ions may profoundly depress platelet-surface reactions, and the capacity of platelets to form aggregates and thrombi. Thus, the relationship between BMI in the presence of citrate anticoagulant, and "thrombogenicity" in the absence of anticoagulant, is questionable. Similar concerns apply to heparin anticoagulation. Although this agent is less likely to interfere with the earliest platelet reactions, platelet thrombus formation may be impaired by inhibition of thrombin activity. The use of heparin is appropriate for evaluation of devices where heparinization is used clinically (e.g., oxygenators, dialyzers). In general, results with anticoagulated blood cannot be used to predict performance in the absence of anticoagulants. A discussion of anticoagulants in the context of BMI has been presented (McIntire et al., 1985).

Blood is a fragile tissue that begins to change from the moment it is removed from the body. It may become more active (activated) or less active (refractory). Thus, BMI evaluations with blood externalized from the normal circulatory system for more than a few hours are questionable. If purified blood components or cells are used (e.g., platelets, fibrinogen), studies must be performed to ensure that they remain functionally normal. In most cases the volume of blood used, relative to test surface area, should be large. Similarly, the area of nontest surfaces, including exposure to air interfaces, should be minimized. Changes in blood temperature, test surface temperature or exposure to bright light sources (Haycox et al., 1991) can also produce artifactual results. When blood is pumped, the recirculation rate (fraction of total

blood volume pumped per unit time) should be minimized, since blood pumping alone can induce platelet and red cell damage, platelet release reactions, and platelet refractoriness (Haycox and Ratner, 1993).

> Blood is a complex, fragile fluid, and outcomes of blood–materials interactions studies will be strongly impacted by the animal species (or human donor), blood handling protocols, and storage time.

Flow: Blood Interactions Dictated by Shear and Mass Transport. Blood flow controls the rate of transport (by diffusion and convection) of cells and proteins in the vicinity of artificial surfaces and thrombi. This subject has been reviewed (Leonard, 1987; Turitto and Baumgartner, 1987; and Chapter II.1.6). While physiological blood shear forces probably do not damage or activate platelets directly, such forces can dislodge platelet aggregates and thrombi (embolization) to distal circulatory beds. Platelet diffusion in flowing blood, and early platelet attachment to surfaces, may be increased 50–100-fold by the presence of red blood cells that greatly enhance the movement of platelets across parallel streamlines. At higher shear forces, red cells may also contribute chemical factors that enhance platelet reactivity (Turitto and Baumgartner, 1987).

A number of studies using well-characterized flow geometries have suggested that the initial attachment of platelets to artificial surfaces increases with increasing blood flow or, more specifically, with increasing wall shear rate (the slope of the velocity profile at the surface). Under conditions of low wall shear rate flow (less than ~1000 sec^{-1}) early platelet adhesion (over the first minutes of exposure) may depend more upon the platelet arrival rate (i.e., platelet availability) than on substrate surface properties (Friedman et al., 1970). Under these conditions the platelet–surface reaction rate is said to be *diffusion controlled*. At higher shear rates, platelet adhesion may depend less upon platelet transport to the surface, and more on the reactions triggered by surface properties (*reaction controlled*, Schaub et al., 2000); thus, studies designed to assess the role of surface properties are best performed under flow conditions where platelet transport is not limiting. Following initial platelet adhesion, subsequent processes of platelet aggregation and *in vivo* thrombus formation (over minutes to hours) are predominantly *reaction controlled*. For example, platelet accumulation on highly thrombogenic artificial surfaces (e.g., fabric vascular grafts) or biologic surfaces (e.g., collagen) may be rapid, and dependent on both the substrate reactivity and factors influencing platelet availability (shear rate, hematocrit, and the platelet content of blood) (Harker et al., 1991). Under other circumstances, the rate of platelet-surface interactions may be almost entirely reaction controlled. For example, with smooth-walled artificial surfaces which
FIGURE II.3.5.4 The effects of flow and material surface properties on platelet transport to, and reaction with, surfaces. One can define two rate processes: r_1, the rate of platelet transport from blood to the surface (higher in rapidly flowing blood); and r_2, the rate of reaction of a platelet with the surface. (a) In low wall shear rate blood flow, platelets can be slow to reach the surface and r_1 dominates the kinetics of the reaction – for reactive surfaces, the surface can be "starved" of platelets for reaction. (b) In high wall shear rate blood flow, platelets are transported to the surface much more rapidly than they can react with the surface, and the intrinsic reactivity of the surface, r_2, can be observed.

repeatedly embolize small platelet aggregates continuously over days, the overall rate of platelet destruction depends strongly on material properties, but not on blood flow rate or circulating platelet numbers over wide ranges of these variables (Hanson et al., 1980). These concepts of diffusion and reaction control are further explained in Figure II.3.5.4.

It has been observed that under arterial flow conditions (high wall shear rate), thrombus that forms *in vivo* may be largely composed of platelets ("white thrombus"), while thrombus that forms under venous flow conditions (low shear rate) may contain mostly red cells entrapped in a fibrin mesh ("red thrombus"). The process of platelet thrombus formation may not be affected by administration of heparin (i.e., arterial thrombosis may be heparin-resistant), while venous thrombosis is effectively treated with heparin. This insensitivity of platelet reaction to heparin in high shear blood flow is somewhat surprising, since the procoagulant enzyme thrombin, one of the most potent activators of platelets, is strongly inhibited by heparin. These observations have been incorrectly interpreted to mean that arterial thrombosis and venous thrombosis are separable processes, with the former depending only on platelet reactions, and the latter depending only on surface protein-triggered coagulation events. However, while platelet-dependent (arterial) thrombosis may be little affected by heparin, it is blocked quite effectively by other inhibitors of thrombin (Hanson and Harker, 1988; Wagner and Hubbell, 1990), indicating that heparin is limited in its capacity to block the thrombin enzyme when thrombin is produced locally in high concentrations through reactions which may be catalyzed on the platelet surface (Chapter II.2.6). The formation of fibrin, due to the action of thrombin

on fibrinogen, is also important for thrombus formation and stabilization since: (1) fibrinolytic enzymes can reduce platelet thrombus formation; and (2) arterial thrombi are often composed of alternating layers of platelets and fibrin. Thus, in most circumstances, thrombin is a key promotor of *local* platelet and fibrin accumulation (on surfaces) under both high shear and low shear conditions. Thrombi may differ in appearance, because under high flow conditions, thrombin and precursor procoagulant enzymes (e.g., Factor Xa) may be diluted sufficiently to prevent *bulk phase* clotting and trapping of red cells. These ideas have been addressed quantitatively (Basmadjian et al., 1997). Also, flow effects on surface-induced thrombosis have been reviewed, and the importance of pharmacological intervention on modulating this process has been described (Hanson and Sakaraissen, 1998). Thus, the shear dependency of surface thrombosis depends on the surface chemical composition. For example, anticoagulation effects may be more pronounced on a tissue factor-rich surface than on a collagen surface, particularly at low wall shear rates. Further, some platelet inhibitors such as aspirin are shear-dependent, while others seem not to be.

In summary, thrombus formation requires the transport by flow of platelets and coagulation proteins to surfaces. Fibrin polymerization, as well as local platelet activation and recruitment into growing thrombi, require conversion of prothrombin to thrombin, the end product of a sequential series of coagulation reactions that are also catalyzed by platelets, and may be amplified or inhibited by various feedback mechanisms (Chapter II.2.6). Blood flow regulates each reaction step, such that under low (venous) flow conditions fibrin formation is abundant; thrombi may resemble coagulated whole blood with many entrapped red cells. Under high (arterial) flows, platelets stabilized by much smaller amounts of fibrin may comprise the greater proportion of total thrombus mass.

> Thrombus formation requires the transport by flow of platelets and coagulation proteins to (and from) surfaces. Absence of flow, low shear flow, and high shear flow can each give dramatically different BMI results.

Surfaces: The Most Studied, and Least Well-Defined, of the BMI Variables. Many different artificial surfaces, in various device applications, are used in contact with blood. It is well-documented that surface physicochemical properties of materials can influence early events, for example, on protein adsorption (Chapter I.1.2) and platelet adhesion – yet how these effects relate to subsequent thrombus formation remains uncertain.

When placed in contact with blood most, if not all, artificial surfaces first acquire a layer of adsorbed blood proteins whose composition and mass may vary with time in a complex manner depending on substrate surface type (Chapter I.1.2). This layer mediates the subsequent attachment of platelets and other blood cells that can lead to the development of platelet aggregates and thrombi. The relationship between material properties, the protein layer, and the propensity of a material or device to accumulate thrombus is not well-understood because: (1) protein–surface reactions involve complex, dynamic processes of competitive adsorption, denaturation, and activation; (2) cell–surface interactions may modify the protein layer, i.e., cells may deposit lipid and protein "footprints" derived from the cell membrane; (3) the importance of specific adsorbed proteins for subsequent cell interactions, especially *in vivo*, is not well-defined; (4) there have been few *relevant* tests in which both protein adsorption and later thrombus formation have been assessed. Under conditions of low blood shear, the capacity of negatively charged surfaces (such as glass) to activate intrinsic coagulation (via Factor XII) can lead to thrombin production, with subsequent platelet deposition and fibrin clot formation. Under other circumstances the availability on surfaces of adhesive plasma proteins, such as fibrinogen, will be important for regulating cell attachment and subsequent thrombus formation (Horbett et al., 1986; Sivaraman and Latour, 2010).

With anticoagulated blood, initial platelet attachment to a variety of surfaces may be comparable and limited to a partial platelet monolayer, suggesting that surface properties may be "inconsequential" for early platelet adhesion, especially where platelet transport to the surface may be rate-limiting (Friedman et al., 1970). In the absence of anticoagulants, initial platelet attachment may vary, but no general relationship to substrate surface properties has been demonstrated. In attempts to establish such relationships, thrombus formation has been studied using devices implanted in animals and composed of various materials including polymers, metals, carbons, charged surfaces, and hydrogels. Correlations have been sought between the blood response and surface properties, such as charge (anionic-cationic), hydrophilicity, hydrophobicity, polarity, contact angle, wettability, and critical surface tension (Kaelble and Moacanin, 1977; McIntire et al., 1985; Salzman and Merrill, 1987; Williams, 1987). These parameters have not proven satisfactory for predicting device performance even in idealized test situations, reflecting the complexity of the phenomena being investigated, the limitations of animal experiments and, in some cases, inadequate characterization of material surface properties (see Chapters I.1.5 and III.1.4, and Ratner, 1993).

In many cases, material properties are constrained by the specific mechanical and morphological needs of the intended blood-contacting device application. For example, vascular grafts and the sewing ring of prosthetic heart valves are composed of fabric or porous materials to permit healing and tissue anchoring. Other materials must be permeable to blood solutes and gases (dialysis

and oxygenator membranes) or distensible (pump ventricles, balloon catheters). These design constraints often necessitate complex flow geometries. In general, devices with flow geometries that cause regions of flow recirculation and stasis tend to produce localized clotting in the absence of heparin anticoagulation. On a microscopic scale, surface imperfections, cracks, and trapped air bubbles may serve as foci to initiate thrombus formation. While surface smoothness is usually desirable, many devices having a fabric or microporous surface (e.g., vascular grafts) function well if the layer of thrombus that forms is not thick enough to interfere with device function (Salzman and Merrill, 1987).

The lack of consensus on the blood-compatibility of materials was pointed out by Ratner (1984). This is a consequence of the complex, multifactorial nature of blood–materials interactions. Assigning a label of "blood-compatible" or ranking materials as to their suitability for use in blood is still fraught with uncertainty. This is illustrated by three studies. One study, using a number of different screening assays, questioned the effects of surface properties on blood interactions, since trends from each of the assays could not be correlated (Sefton et al., 2001). Another study, using fluorescent fiber optic microscopy to observe platelet deposition ranked materials as to the magnitude of their interaction with blood (Schaub et al., 2000). The third study used a cone and plate viscometer for assessment, but conclusions were difficult to draw due to poor statistics, contradictory data, and sample quality issues (Węgrzyn et al., 2010). These three studies were well thought out efforts and offered insights into testing blood interactions and measuring BMI. Yet, taken as a set, they do not allow us to conclude which surface properties or biomaterials will yield the most blood-compatible material.

Blood Interaction Times with Materials and Devices. Different events may occur at short and long BMI times. A test performed where blood contacts a device for seconds or minutes may yield a result that will have little meaning for devices used for hours or days, or which may be implanted chronically. Thus, measurements of protein adsorption (an early event) can, in some cases, predict levels of platelet adhesion. But platelet adhesion alone is not an adequate measure of thrombogenicity, and it does not predict local or systemic thrombogenic effects that could be harmful to the host organism. Still, several studies indicate that an early maximum in platelet thrombus accumulation may be seen within hours of device exposure, and this can be sufficient to produce device failure (e.g., small diameter vascular graft occlusion) (Harker et al., 1991). Therefore, short-term testing (over hours) may be appropriate for predicting the clinical usefulness of devices that can produce an acute, severe thrombotic response. In general, the nature and extent of BMI may change continuously over the entire period of device exposure. An exception to this rule may be chronic implants that do not undergo tissue coverage

(e.g., heart valve struts, arteriovenous shunts), and which may interact with blood elements at a constant rate as shown, for example, by steady-state increases in rates of platelet consumption (Hanson et al., 1980).

EVALUATION OF BMI

A summary of some (or historically important) *in vitro* and *in vivo* testing procedures commonly used to evaluate BMI is presented in this section. A few relevant case studies with commentary are included. We emphasize that a thorough characterization of surface properties is critical for the interpretation of these tests (Chapters I.1.5 and I.2.12, and Ratner, 1993), since the surface composition of materials is often significantly different from "as received and labeled." A few specific tests that have been historically influential and tests that are used today are summarized in Table II.3.5.2.

BMI can be evaluated *in vitro* and *in vivo*. Also, we can look at the BMI of either the biomaterials in isolation in a test configuration or the blood interactions of real devices. There are typically unique apparatus and geometries for *in vitro*, *in vivo*, and device-based assays. However, there are commonalities in the measurements of blood parameters. For example, blood can be circulated through a tube *in vitro*, circulated through an implanted biomaterial shunt *in vivo* or circulated through a hemodiayzer (*in vivo* or *in vitro*). In all cases, the blood emerging from the test system might be assessed by a partial thromboplastin time (PPT) test, a laser scattering assay of emboli produced or a flow cytometric analysis of activated platelets. Thus, the methods for contacting blood with biomaterials, and the methods for assessing blood change, can often be considered independently.

TABLE II.3.5.2	A Partial List of BMI Tests

- Qualitative assessment (look at the thrombus)
  vena cava ring test (historical)
  thrombus adherent to a catheter in the bloodstream
- Count adherent blood elements
  various flow cells
- Observe and categorize platelet morphology
- Measure platelet release molecules
  bead column
  Chandler loop
- Clotting times and related coagulation assays
  Lee-White test (historical)
  activated partial thromboplastin time (APPT)
  catheter occlusion
- Measure soluble products of thrombosis
- Platelet consumption
- Fluorescence activated cell sorter (FACS) measures of activation
- Microparticles (FACS measurement)
- Embolus measurement
  renal embolus ring test (historical)
  light scattering
  Doppler ultrasound

In vitro Tests

In vitro BMI tests involve placing blood or plasma in a container composed of a test material, in a container containing the test material or recirculating blood through a flow system in which test materials contact blood under well-defined flow regimes that simulate physiologic flow conditions. Many flow geometries have been studied including tubes, parallel plates, packed beds, annular flows, rotating probes, and spinning disks. The historical (but still relevant) literature on these test methods has been reviewed (McIntyre et al., 1985; Turitto and Baumgartner, 1987), and has yielded considerable insight into how proteins and platelets are transported to, and react with, artificial surfaces. Such studies provided a wealth of morphologic information at the cellular level regarding details of platelet–surface and platelet–platelet interactions (Sakariassen et al., 1989). However, as discussed above, these tests are usually of short duration, and are strongly influenced by the blood source, handling methods, and the use of anticoagulants. Thus, *in vitro* test results generally cannot be used to predict longer-term BMI and *in vivo* outcomes, and can provide only the most general guidelines for the selection of materials for particular devices. However, *in vitro* tests may be useful for screening materials that are highly reactive towards blood.

Tests of the whole blood clotting time and variations thereof involve placing non-anticoagulated whole blood (or blood anticoagulated with sodium citrate which is then recalcified) into containers of test material (or adding the test material to the container), and measuring the time for a visible clot to form. Materials that quickly activate intrinsic coagulation and cause blood to clot within a few minutes (like glass surfaces) are probably unsuitable for use in devices with low shear blood flow or in the absence of anticoagulants. These tests are known by names such as whole blood clotting time (WBCT), activated partial thromboplastin time (APTT), and whole blood recalcification time (WBRCT). An older variant of these tests, frequently mentioned in the early biomaterials literature, is the Lee-White clotting time test.

Possibly the most commonly performed assay for BMI involves counting platelets adherent to surfaces and visualizing platelet reaction to surfaces. The limitations of these tests have been discussed, and are reiterated in this section. Still, these assessments are so commonly performed that some discussion is appropriate. The limitations of these platelet attachment tests are important to consider up front: (1) are the platelets mass transport-limited in arriving at the surface; (2) are dynamic events such as deadhesion, release, and/or emboli formation being missed due to limited time points for observation; (3) are the platelets active or refractory (unresponsive); (4) species differences in platelet adhesiveness can have large effects on the observed numbers of platelets; (5) platelets can spread into extremely thin surface films that are difficult to observe or count (Haycox and Ratner, 1993); (6) platelet adhesion studies are typically short-term, and thus generally have limited meaning for devices that reside for longer periods of time in blood. A promising approach to address the significance of surface adherent platelets for blood-compatibility is to consider not only platelet number, but also platelet morphology (Waples et al., 1996). Platelets on surfaces can appear discoid without dendrites (unactivated), and then might show various degrees of activation (spread, mildly dendritic, highly dendritic, etc.). Such platelet morphologies can be assessed using light microscopy, fluorescent methods, scanning electron microscopy or transmission electron microscopy.

Recirculation of heparinized blood or citrated blood through tubular devices and materials may lead to platelet activation and/or platelet deposition onto highly thrombogenic materials, with the appearance in plasma of proteins released from platelets (Kottke-Marchant et al., 1985; Haycox and Ratner, 1993). Thus, these and similar methods may identify materials which might cause rapid platelet accumulation *in vivo* over short time periods, and therefore be unsuitable for certain applications such as small diameter vascular grafts or blood conduits. Both recirculation tests and *in vitro* clotting assays can be considered for preliminary screening and identification of materials that could be highly thrombogenic. Most artificial surfaces in common use in blood-contacting devices would probably "pass" these tests. Since small differences in test results are of little significance for predicting material performance in actual use applications, these tests are not appropriate for optimizing or refining material properties. *In vivo* testing is more appropriate for discerning finer distinctions in blood reactivity, and such tests are discussed below.

Contemporary methods for evaluating damage to blood in *in vitro* test systems may expand the significance of these methods. For example, platelet-derived microparticles in blood have been used as a marker of blood damage induced by biomaterial surfaces (Gemmell, 2000; Blit et al., 2011).

In vivo Tests of BMI

Many studies have been performed in which test materials, in the form of rings, tubes, and patches, are inserted for short or long time periods into the arteries or veins of experimental animals (McIntire et al., 1985; Salzman and Merrill, 1987; Williams, 1987). Here are a few concerns and considerations for such tests.

(1) The timing and type of measurements may be such that important blood responses are unrecognized. In particular, the measurement of gross thrombus formation at a single point in time may lead to incorrect conclusions about local thrombus formation (e.g.,

Figure II.3.5.1), and does not provide assessment of systemic effects of thrombosis such as embolization and blood element consumption.

(2) With more commonly used animal species (e.g., dogs), blood responses may differ from humans both quantitatively and qualitatively.

(3) The blood flow conditions of the model may not be controlled or measured, and in fact, may not even be relevant for actual implant device geometries.

(4) There may be variable blood vessel trauma and tissue injury that can cause local thrombus formation through the extrinsic pathway of blood coagulation (Chapter II.2.6).

Evaluations of BMI may be performed in animals having arterio-venous (A-V) or arterio-arterial (A-A) shunts, i.e., tubular blood conduits placed between an artery and vein or between an artery and artery. A-V shunts have been studied in a variety of animals including baboons, dogs, pigs, and rabbits (McIntire et al., 1985). Qualitatively similar results have been obtained with shunts in dogs and baboons (Hanson et al., 1980; Sefton et al., 2000). An A-V shunt system is illustrated in Figure II.3.5.5. Once surgically established, shunts may remain patent (not occluded) for long periods of time (months) without the use of anticoagulants. Test materials or devices are simply inserted as extension segments or between inlet and outlet portions of the chronic shunt. These systems have many advantages: (1) blood flow is easily controlled and measured; (2) native or anticoagulated blood can be employed; (3) the animal's physiology removes damaged blood elements and makes new blood with each circulation through the body; and (4) both short-term and long-term BMI, including both local and systemic effects, can be evaluated. The downsides of these tests are demanding surgery, high expense,

and ethical issues associated with chronic shunting of larger animals.

As an example, consider the A-V shunt model in baboons – baboons are used because they are hematologically similar to man. The blood responses to tubular biomaterials and vascular grafts have been quantitatively compared with respect to: (1) localized thrombus accumulation; (2) consumption of circulating platelets and fibrinogen; (3) plasma levels of factors released by platelets and coagulation proteins during thrombosis; and (4) embolization of microthrombi to downstream circulatory beds (Harker et al., 1991). These studies in primates are consistent with observations in man that certain commonly used polymers (e.g., polytetrafluoroethylene, polyethylene, plasticized poly(vinyl chloride), silicone rubbers) and some vascular grafts (e.g., polytetrafluoroethylene) are relatively nonthrombogenic in extracorporeal circuits and arteries. Thus, results with shunt models, particularly in higher animal species, may be predictive of BMI in humans when employed under comparable flow conditions (laminar unidirectional flow with arterial shear rates). Since extracorporeal shunts exclude modulating effects of blood vessel cells and tissue injury, results with these models may be less relevant to the behavior of devices which are placed surgically or whose responses may be mediated by interactions with the vessel wall as well as the blood (e.g., heart valves, grafts, indwelling catheters, and sensors).

In vivo Evaluation of Devices

Since the blood response to devices is complex and not well predicted by testing of materials *per se* in idealized configurations, animal testing, and ultimately clinical testing, of functioning devices is required to establish safety and efficacy. Broad guidelines, based on the type of device
FIGURE II.3.5.5 Illustration of an arterio-venous (A-V) shunt placed between the femoral artery and vein (in the leg) of an experimental animal. Materials to be tested (in this case a tubular device) are interposed between inlet and outlet segments of the shunt.

TABLE II.3.5.3	Some Blood–Materials Responses and Their Evaluation	
Blood Components	**Blood Response**	**Assessment**[a]
Thrombus	Clot	Direct visual and histologic evaluation; noninvasive imaging (angiography, ultrasound, radioisotope, magnetic resonance); evidence of device dysfunction.
	Thromboembolism	Emboli detection (ultrasound, laser); evidence of organ/limb ischemia, stroke.
Platelets	Consumption	Increased removal of radioisotopically labeled cells; reduced blood platelet count.
	Dysfunction[b]	Reduced platelet aggregation *in vitro*; prolonged bleeding time.
	Activation	Increased plasma levels of platelet factor 4 and B-thromboglobulin; platelet membrane alterations (e.g., by flow cytometry).
Red cells[b]	Destruction	Decreased red cell count; increased plasma hemoglobin.
White cells[b]	Consumption/activation	Decreased counts of white cell populations; increased white cell plasma enzymes (e.g., neutrophil elastase).
Coagulation factors	Consumption[b]	Reduced plasma fibrinogen, factor V, factor VIII.
	Thrombin generation	Increased plasma levels of prothrombin fragment 1.2 and thrombin:antithrombin III complex.
	Fibrin formation	Increased plasma level of fibrinopeptide A.
	Dysfunction[b]	Prolonged plasma clotting times.
Fibrinolytic proteins	Consumption[b]	Reduced plasma plasminogen level.
	Plasmin generation	Increased plasma level of plasmin:antiplasmin complex.
	Fibrinolysis	Increased plasma level of fibrin D-dimer fragment.
Complement proteins[b]	Activation	Increased plasma levels of complement proteins C3a, C3b, C5a, C5b-9.

[a]Radioimmunoassays (RIA) and enzyme-linked immunoassays (ELISA) may not be available for detection of non-human proteins.
[b]Tests which may be particularly important with long-term and/or large surface area devices.

being considered, are given below and apply to both animal and clinical testing. A summary of *in vivo* blood responses to devices, and of commonly used methods which have proven useful for evaluating those responses, is given in Table II.3.5.3. Table II.3.5.4 lists the wide range of screens that have been used in one group over a decade to understand blood interaction with devices, specifically ventricular assist devices (Wagner et al., 2000).

Devices that have relatively small surface areas and are exposed for short periods of time (hours to days) include catheters, guidewires, sensors, and some components of extracorporeal circuits. With these devices the primary concern is the formation of significant thrombus that could interfere with device function (e.g., the thrombus blocks the diffusion of an analyte to a sensor), occlude the vessel, embolize spontaneously or be stripped from the device surface when it is removed from the body (e.g., during catheter withdrawal through a vessel insertion site) producing occlusion of distal vessels and tissue ischemia. Devices exposed for short periods which have large surface areas (dialyzers) and complex circuitries (pump-oxygenators) may, in addition, produce: (1) a marked depletion of circulating blood cells and proteins (e.g., platelets and coagulation factors); (2) an immune/inflammatory response through activation of complement proteins and white cells; and (3) organ dysfunction mediated by hemodynamic, hematologic, and inflammatory reactions. Mechanical devices that are used for long periods of time (heart assist devices, extracorporeal membrane oxygenators) may produce profound systemic effects and organ dysfunction such that their use in man remains problematic.

With both long-term and short-term device applications, thrombus formation can be assessed directly

TABLE II.3.5.4	Parameters Measured in the Assessment of Blood Interactions with Ventricular Assist Devices (VADs)
Flow Assessment	
Laser Doppler anemometry, fluorescent image tracking velocimetry	
Coagulation	
Prothrombin fragment F1.2, thrombin–antithrombin (TAT)	
Emboli	
Transcranial Doppler ultrasound, flow cytometric assays for the quantification of circulating platelet-containing microaggregates	
Fibrinolysis	
D-dimer	
Platelet Activation and Deposition	
Platelet factor 4 (PF4), beta thromboglobulin (BTG), flow cytometric detection of p-selectin expression, platelet deposition	
Complement	
C3a, C5b-9	
Leukocyte Activation	
Flow cytometric detection of monocyte tissue factor expression, monocyte–platelet microaggregates, granulocyte–platelet microaggregates	

(Based on Wagner et al., 2000).

and indirectly. Important indirect assessments include depletion from circulating blood of cells and proteins consumed in the process of thrombus formation, and the appearance in plasma of proteins generated in the process of thrombus formation (e.g., fibrinopeptide A, platelet factor 4). Direct assessment of blood flow rate,

flow geometry, and extent of flow channel occlusion can in many cases be achieved using sophisticated methods including angiography, ultrasound imaging, and magnetic resonance imaging. Devices that are removed from the circulation should be visually inspected to assess whether thrombus has formed at particular sites or on certain materials. Emboli in flowing blood may be detected using ultrasound and laser-based techniques (for example, Reynolds and Simon, 1980), although these methods are not used widely at present because of their complexity and expense (emboli detection will be elaborated upon below). Thrombus formation and rates of platelet destruction by both acutely placed and chronically implanted devices can be determined quantitatively by measurements of platelet lifespan and scintillation camera imaging of radioisotopically labeled blood elements (McIntire et al., 1985; Hanson et al., 1990).

In one study, a circulating loop system to assess materials under well-controlled conditions was directly compared to results obtained on an actual device in flowing blood (Münch et al., 2000). A Chandler loop was used as the well-defined test system. A cardiopulmonary bypass (CPB) device was used to observe blood reaction in a device. Both the recirculating loop system and the CPB device were surface treated with two types of heparin coatings. The parameters measured after blood flow were thrombin-antithrombin III (TAT) complex, platelet count, red blood cell count, white blood cell count, polymorphonuclear leucocyte elastase, and complement C3 activation. There were many observations reported, including some tests that showed no significant difference between the two surfaces in the loop model and statistically significant differences in the CPB model, and *vice versa*. The authors concluded: "In the more complex and realistic simulated CPB model, experimental design and cost factors prevented easy/optimum manipulation of critical variables such as blood donor (use of paired samples) and heparin level. Testing in the simpler loop model, on the other hand, readily offered manipulation of these variables, and produced endings which overlapped with observations from the more complex CPB model. Thus, the models described here complimented."

Finally, it is important to emphasize that thrombosis occurs dynamically, such that thrombi continuously undergo processes of both formation and dissolution. Device failure represents the imbalance of these processes. Older thrombi may also be reorganized considerably by the enzymatic and lytic mechanisms of white cells. While the initial consequences of surgical device placement include tissue injury, thrombosis due to tissue injury, and foreign-body reactions, the flow surface of long-term implants may become covered with a stable lining of cells (e.g., ingrowth of vascular wall endothelial and smooth muscle cells onto and into vascular grafts) or blood-derived materials (e.g., compacted fibrin). Certain reactions of blood elements (e.g., platelets, thrombin) may also stimulate the healing response. Ultimately,

long-term devices, such as the small caliber graft, may fail due to excessive tissue ingrowth that could be largely unrelated to biomaterials properties or may be stimulated by the biomaterials.

We summarize this section on device testing recognizing that many device applications described above, as well as laboratory and clinical methods for evaluating their biologic responses, will be unfamiliar to the bioengineer. However, it is important to appreciate that: (1) each device may elicit a unique set of blood responses, both short-term and long-term; (2) methods are available to assess systemic changes in the blood and host organism which indirectly reflect thrombus formation; and (3) localized thrombus formation can usually be measured directly and quantitatively. Whenever possible, serial and dynamic studies should be performed to establish the time course of ongoing thrombus formation and dissolution. These measurements will ultimately predict device performance, and allow for the rational selection of biomaterials that will minimize adverse blood–device interactions.

Contemporary Concepts in BMI Evaluation

A few trends in the literature describe powerful methods to assess BMI. Two of these will be highlighted here: flow cytometry and emboli detection.

The use of flow cytometry to analyze activation of blood elements can be an effective method of measuring blood cell reaction and isolating specific pools of cells that have or have not undergone reaction. The basic technology behind flow cytometry (sometimes called fluorescence activated cell sorting, FACS) involves the laser separation of fluorescently labeled cells from a narrow flow stream of cells. The fluorescently labeled cells can be diverted from the flow stream to another flow channel where they are counted and harvested. One of the earliest studies using flow cytometry for blood-compatibility studies showed that in contact with blood-activating synthetic materials, thrombotic membrane fragments called microparticles are released (Gemmell et al., 1995). Since that important study, flow cytometry has been used to look at the upregulation of platelet P-selectin (CD62), a consequence of α-granule release, monocyte and neutrophil CD11b (Mac-1 receptor) upregulation (Gemmell, 2000), platelet activation by annexin V binding to the negative phospholipid found on activated platelets (Wagner et al., 2000), and a number of other biospecific factors relating to platelet activation, white cell activation, and platelet aggregate formation. The power of the flow cytometry method resides in its ability to pinpoint an event in a large pool of cells that can be identified by a fluorescent tag. The method is applicable to blood that has been contacted with synthetic materials *in vitro* or *in vivo*.

The ability to go beyond measurements of adhesive phenomena in blood (accumulating thrombus or platelets), and to expand studies to non-adhesive encounters leading to blood activation and damage, represents an

important growth area for BMI evaluation. Cytometric studies allow us to do systemic measurements rather than just local assessment. Methods to study emboli production in real time permit a key, clinically relevant parameter, to be measured and quantified. Doppler ultrasound seems to have potential to do this, although the instrumentation is expensive. Other alternatives to study microemboli in blood include use of the Coulter counter on sampled blood, and filtration pressure methods. However, a method that seems to have excellent potential to advance our understanding of how surfaces induce emboli formation is laser light scattering. Initial developments making this method suitable for emboli analysis in whole blood were published over 20 years ago (Reynolds and Simon, 1980) and then used for the assessment of BMI in conjunction with a baboon shunt model (Garfinkle et al., 1984). New developments in light scattering instrumentation and data analysis should make laser microemboli detection a key tool for studying biomaterial reactions with blood (Solen et al., 2003).

Examples of BMI Evaluation

Five examples will now be presented that place many of the concepts discussed to this point in the context of real-world BMI testing.

Flow Cytometric Evaluation of Platelet Activation (Cao, 2006). Flow cytometry was used to measure platelet activation by polymer tubing filled with citrate anticoagulated blood. Tubes were agitated using a platform shaker at 100 rpm or 200 rpm for 1 hour at 37°C. After the incubation, blood samples were reacted with a dye labeled antibody for 20 minutes, fixed with paraformaldehyde, and analyzed on a FACS instrument. To restrict analysis to platelets only, only cells with a platelet-specific marker were counted. This was done with an antibody to CD61 antigen (GPIIIa), which is specific to platelets, but is not affected by platelet activation.

Antibodies specific to CD62 (antiCD62) and GPIIb/IIIa (PAC-1) were used to monitor exposure of these platelet activation-dependent markers. The PAC-1 antibody recognizes an epitope on the GPIIb/IIIa complex of activated platelets at or near the platelet fibrinogen receptor. It binds only to activated platelets, and is specific for this recognition site within GPIIb/IIIa. CD62 is a 140 kDa protein, also known as P-Selectin, GMP-140, and platelet activation-dependent granule membrane protein (PADGEM). CD62/P-selectin is stored in the α-granules of platelets, and is rapidly transported to the plasma membrane upon platelet activation.

Figure II.3.5.6 shows the increase in platelets expressing increased binding of PAC-1 and antiCD62 after exposure to various biomaterials (green bar). To correct for variations in the degree of platelet activation among donors, the activation for the biomaterials was normalized to that for the platelets in the starting blood
FIGURE II.3.5.6 Ratio of percentage of platelets expressing activation-dependent antibodies after exposure to biomaterials relative to percentage before any exposure to the biomaterial. ACD blood was used. Black bar: CD62p+; red: PAC-1+; green, CD62p+/PAC-1+. Results are shown for polyethylene (PE), heparinized polyethylene (PE + HBAC), an RF-plasma deposited PEG-like film (see Chapter I.2.12) (PE + Glyme), Tygon, Silastic, and polyurethane (PU). (Modified from Cao, 2006.)

before any biomaterials exposure. Thus, the ratio of percentage of platelets expressing activation-dependent antibodies after exposure to biomaterials at 200 rpm on a platform shaker relative to the percentage before any exposure to the biomaterial is plotted. As can be seen, there is considerable variation among the materials in the degree of activation they caused. The plot also shows the increase in platelets expressing only increased PAC-1 binding (red bars) or only increased binding of antiCD62 (black bars).

Platelet Adhesion Measured *In vitro* (Cao et al., 2006). Platelet adhesion measured under *in vitro* conditions is often used as an indicator of surface thrombogenicity, because adherent platelets can aggregate and promote clot formation.

Results of platelet adhesion to five different biomaterials are shown in Figure II.3.5.7. As shown, both the type of suspension used for the platelets and the biomaterial affect adhesion. This test indicated glyme treated tubes (an RF-plasma deposited PEG-like film, see Chapter I.2.12) were the least platelet adhesive, which would indicate they were likely to be more resistant to clot formation *in vivo*. The low reactivity of the glyme surfaces seen in *in vitro* adhesion assays was also seen i*n vivo*, as noted below.

Recalcified Plasma Clotting Times (Cao et al., 2007). In these studies, citrate-anticoagulated human platelet-poor plasma is brought to 20 mM $CaCl_2$ by addition of calcium from a 1 M stock solution, and then added to the wells of a plate containing the surfaces to be tested and incubated at 37°C with shaking. The plasma clotting time is measured as the time it takes for the plasma to undergo gelation, detected by loss of movement of the plasma in response to the rotation and shaking.

As seen in Figure II.3.5.8, the recalcified plasma times are short for glass (ca. 3 minutes), a thrombogenic material used as a positive control in studies of this type. A
FIGURE II.3.5.7 Platelet adhesion under three conditions onto the surfaces of different tubing segments (6 cm). Error bar represents SD. N = 5. Platelet adhesion was measured using washed platelets (purple bars), platelet-rich plasma (orange bars) or whole blood (blue bars), all under static conditions. The platelet suspension (washed platelets, platelet-rich plasma or blood) was drawn into sample tubes and incubated under static conditions at 37°C for 1.5 hours. Samples incubated with washed platelets had been preadsorbed with 1% plasma to allow fibrinogen adsorption, and then incubated with albumin to block residual sites. The number of adherent platelets was determined using an assay to measure lactate dehydrogenase (LDH) released from the lysed platelets. (Modified from Cao et al., 2006.)
FIGURE II.3.5.8 Clotting time of recalcified platelet-poor plasma in the presence of different materials. All samples were put in the wells of a 24-well polystyrene plate. "Polystyrene" indicates the well only. (N = 6, *, p <0.01, student's *t* test.) (Modified from Cao et al., 2007.)

second type of control must also be run, namely the clotting time for the container used to do the clotting time studies. In this case, the container was a multiwell polystyrene plate, and the data show that the clotting time was much longer (ca. 13 minutes) than for glass. Using a container with a long clotting time is important to make these assays useful. Thus, for example, clotting times for a polystyrene sample in a glass container would not be extended, i.e., the clotting time would still be short due to the glass, and the less thrombogenic nature of polystyrene could not be shown. Finally, as shown in Figure II.3.5.8, coating of polystyrene or FEP with the RF-plasma deposited glyme further extends the clotting time beyond that for the polystyrene dish control. Since tetraglyme coated materials strongly resist protein adsorption, and clotting by surfaces requires protein interactions with the surface, the results are as expected for a non-fouling surface.

Blood Interaction Studied Using an *Ex Vivo* Shunt.
An effective and relevant way to evaluate blood interactions of a series of polymers is to insert them in the form of tubes into a permanent *ex vivo* shunt in an animal, as illustrated in Figure II.3.5.5. The *ex vivo* method can be used for both acute (short-term) and chronic (or steady-state) evaluations of blood–materials reactivity.

Acute phase studies typically last a few hours, but occasionally up to one day. At the end of each experiment the test segments are removed and analyzed to determine the deposited material on the test segment, often with SEM (Cao et al., 2006). Another short-term assay using the *ex vivo* shunt employs dynamic scintillation camera (gamma camera) imaging to continuously measure the deposition of radiolabeled platelets on surfaces inserted in the shunt or to look for shed emboli captured in downstream (distal) microcirculatory beds (Schneider et al., 1989).

To characterize chronic interactions, the platelet consumption method has been used. In this method, the excess rate of disappearance of radiolabeled platelets from circulation is measured by taking blood samples at periods up to one week after placement of the test sample. As shown in Figure II.3.5.9, the consumption of platelets is strongly dependent on surface chemistry for a series of polyurethanes.

Thromboembolism. Clots released from biomaterial surfaces are of course not detected with examination of the surface of the biomaterial, so special methods are needed to evaluate thromboembolization. Examples of two methods will be given, one using light scattering to

detect flowing emboli, and the second using measurements of platelet accumulation in downstream organs of an animal.

As illustrated in Figure II.3.5.10 (Solen et al., 2003), light from a fiber optic illuminating flowing blood through tubing results in scattering of some of the light that can be detected with optical fibers placed at right angles to the incident beam. Red blood cells flowing through the tube generate a threshold background scattering level. Larger emboli increase the scattering intensity. The scattering intensity can be analyzed with a computer to count the number and size (related to size of the intensity peak) of emboli. The occurrence of thromboembolization leads
FIGURE II.3.5.9 Platelet consumption by a series of polyurethanes varying in surface hydrocarbon content. (Modified from Hanson et al., 1980.)
FIGURE II.3.5.10 A light scattering microparticle detector. (Based upon Solen et al., 2003.)

to accumulation of the emboli in downstream organs, which can be detected *in situ* using radiolabeled platelets and a gamma camera (Schneider et al., 1989).

What Materials Are Blood-Compatible?

The biomaterials community still awaits clear guidelines as to which materials are blood-compatible. But, from the perspective of one author of this article (Ratner), here are a few guidelines that you might use. First, the important distinction must be made that materials will perform differently in low wall shear rate blood flow (venous flow or static blood) and high wall shear rate blood flow (arterial flow). For low wall shear rate materials, heparinized surfaces are often good (although their period of performance may be limited), and hydrogels seem good. Excellent non-fouling surfaces are also promising (see Chapter I.2.10). For arterial blood flows, highly hydrophobic materials often show promise (silicones, fluoropolymers, and materials with surface-localized, long *n*-alkyl chains). Also, the exceptional non-fouling materials seem promising – these include good quality poly(ethylene glycol) surfaces, phosphatidyl choline-based surfaces, sulfobetaines, and carboxybetaines (see Chapter I.2.10). In all cases, the choice of materials will be dictated by the nature of the flow(s) in the actual device in the bloodstream, the mechanical properties required, the length of time in contact with the blood, the condition of the blood, and the consequences of embolization at the specific anatomical site. Trial and error optimization of suitable candidate materials may be needed to achieve performance appropriate to the specific application.

CONCLUSIONS

The most blood-compatible material known is the natural, healthy, living lining of our blood vessels. This "material" functions well by a combination of appropriate surface chemistries, good blood flow characteristics, and active biochemical processes involving removal of prothrombotic substances and secretion of natural anticoagulants. It seems unlikely that we will ever match this performance in a synthetic material or device, although attempts to imitate aspects of the natural system represent a promising strategy for developing a new generation of blood-compatible devices (for example see Chapters I.2.7 and I.2.8). At present, however, synthetic materials that perform less well than the vessel wall, but still satisfactorily, are needed. This chapter provides only a brief outline of the issues involved in evaluating materials and devices to find those that are minimally damaging or activating towards blood. The subject of blood-compatibility testing is complex, and advanced study of the subject is required before considering experiments intended to elucidate basic mechanisms or improve human health. Further discussion elaborating upon the complexity of the

issues involved in BMI testing can be found in Ratner, 1984, 1993, and 2000. Detailed discussion on the characterization of materials for biomaterials application and on BMI testing can also be found in a publication coordinated by the Device and Technology Branch of the National Heart, Lung and Blood Institute, NIH (Harker et al., 1993). Also, see ISO standard 10993-4 (Biological evaluation of medical devices – Part 4: Selection of tests for interactions with blood). The importance of ISO standards is elaborated upon in Chapter II.2.2.

CHAPTER II.3.6 ANIMAL SURGERY AND CARE OF ANIMALS

David Lee-Parritz
Department of Comparative Medicine, Genzyme Corporation, Framingham, MA, USA

INTRODUCTION

The appropriate use of animal models in biomaterials research allows prospective, controlled evaluation of disease processes and candidate therapeutics in a manner that is impossible in human patients or volunteers. Investigators must consider scientific, practical, and humane issues when developing studies that use animals. High-quality research requires close collaboration between veterinary and research professionals to guide model selection and development, minimize animal pain and distress, and to advance the scientific goals of the project. This chapter briefly reviews ethical and regulatory issues, describes available information resources and discusses the design of surgical facilities, animal selection, anesthesia, and analgesia.

ETHICAL AND REGULATORY OVERVIEW

Investigators and research institutions have an ethical and legal responsibility to consider animal welfare concerns in research using animals. Russell and Burch expressed the most widely understood ethical principles governing humane design of experiments using animals in 1959, summarized in the concept of the "three Rs:" *replacement*, *reduction*, and *refinement* (Russell and Burch, 1959). The first principle, *replacement*, states that non-animal models should be used instead of animals to the maximum extent possible. Although definitive safety and efficacy evaluation requires animal models, *in vitro* and *ex vivo* biocompatibility and efficacy screening methods are increasingly common in biomaterials research (Fujibayashi et al., 2003; Kirkpatrick et al., 2007; Pariente et al., 2000). These techniques reduce the total number of animals used, and may allow significant savings in time and resources compared to experimental surgical models. The principle of *reduction* states that investigators should use the minimum number of animals to allow statistically valid inferences to be drawn from the data. In this context, it is as important to avoid using too few animals as too many, because a study that is too small may require repetition. Important considerations in determining the statistical power of an animal experiment include inherent variability of the model, and expected efficacy of the test therapeutic. Consultation with a biostatistician may be useful to estimate required animal numbers. The most important of the "three Rs" is the principle of *refinement*, which states that investigators should use the least invasive and most modern techniques possible to minimize animal pain and distress (Orlans et al., 1998). Continuous refinement and improvement in animal husbandry and the diagnosis and control of infectious disease has greatly reduced nonexperimental morbidity and mortality in modern research facilities. Surgical models in particular have benefitted from advances in veterinary anesthesia, instrumentation, and monitoring, which have allowed further reduction and refinement of research animal use.

Widespread acceptance of the "three Rs" and continued public scrutiny of biomedical research oblige investigators and institutions to comply with strict regulatory standards governing all aspects of research animal use. In the United States, the United States Department of Agriculture (USDA), Public Health Service (PHS), and the Food and Drug Administration (FDA) are the primary agencies which regulate animal research. Federal animal welfare regulations embody the *US Government Principles for the Utilization and Care of Vertebrate Animals Used in Testing, Research, and Training* (National Research Council, 2010). *The Guide for the Care and Use of Laboratory Animals* (Guide) (National Research Council, 2010) elaborates upon the US Government Principles, and provides important reference materials to assist implementation. Federal regulations and the Guide assign primary responsibility for an animal research program to the Institutional Animal Care and Use Committee (IACUC). The institution's chief executive officer appoints the IACUC, which must minimally include a veterinarian, a scientist, a nonscientist, and an unaffiliated member. One member may fulfill more than one of these requirements. The veterinarian must have appropriate training and experience for the species and models in use. The IACUC has multiple responsibilities. It reviews and approves in advance all animal research protocols to ensure compliance with the US Government Principles. In addition, the IACUC regularly inspects the animal research facility, reviews the animal care and use program, and investigates allegations of animal mistreatment.

The specific focus of animal welfare regulations varies by agency. Well-publicized incidents (Wayman, 1966) of pet theft and their subsequent mistreatment in research laboratories prompted the United States Congress to enact the Animal Welfare Act (AWA) in 1966. The AWA required the Federal government to develop a mechanism to protect animals used in research, for exhibition, and sold as pets in interstate commerce. The AWA does not regulate the use of rats, mice or birds bred for research. In many institutions, the term "regulated species" refers to animals subject to the AWA. The USDA enforces the AWA through the Animal and Plant Health Inspection Service (APHIS). Registered facilities file annual reports of animal usage with USDA, and are subject to unannounced inspections of facilities and records by APHIS inspectors.

The Good Laboratory Practices (GLP) Act (21CFR58.90) requires the United States Food and Drug Administration to regulate preclinical research conducted in direct support of new drugs or medical devices.

The primary goal of the GLP regulations is to ensure reproducibility and integrity of data used to support new drug or device applications. The animal care provisions of the GLP are general. Animals must be "free of any disease or condition that might interfere … with the study." Standard operating practices (SOPs) must govern housing, feeding, and care of animals, and the food, water, and environment must be free of known contaminants.

The United States Public Health Service (PHS), through the National Institutes of Health (NIH), is the largest single sponsor of biomedical research using animals, and has adopted regulations to ensure humane and scientifically valid use of animals. The NIH Office of Laboratory Animal Welfare (OLAW) develops and implements standards for animal care and use at recipient institutions, as formulated in the Public Health Service Policy on Humane Care and Use of Laboratory Animals. Institutions receiving PHS support must file an "Animal Welfare Assurance" with OLAW indicating sufficient institutional resources to provide proper husbandry and veterinary care. Institutions must also indicate how they will approve and monitor research to ensure scientific integrity and prevent inhumane treatment of animals. Assurances are approved for five years, after which a new application must be submitted. The PHS Policy applies to all vertebrate animals, even those not regulated by the AWA (Office for the Protection from Research Risks, 1996).

The Association for the Assessment and Accreditation of Laboratory Animal Care, International (AAALAC) is a nongovernmental independent organization that assists and accredits research institutions seeking to maintain the highest standards of laboratory animal care and use. Approximately 770 research facilities in the United States and in 29 other countries hold AAALAC accreditation. AAALAC policies are determined by the Board of Trustees, representing more than 50 scientific, educational, and professional organizations involved with biomedical research use of animals. AAALAC uses the Guide and applicable governmental guidelines to evaluate the quality of an institutional animal care and use program. The AAALAC Board appoints the Council on Accreditation which reviews, grants or suspends accreditation based on a triennial program review and site visit by at least one Council member and an *ad hoc* consultant. OLAW accepts AAALAC accreditation as strong evidence that an institution's animal care and use program is in substantial compliance with the PHS Policy. AAALAC guidelines apply to all live vertebrate animals used in research.

Research using endangered species is generally allowed only for the direct benefit of animals with spontaneous disease. Although rare in biomedical research laboratories, the use of endangered species is regulated by the Endangered Species Act. Use of endangered species is governed by the Convention on International Trade in Endangered Species (CITES), and regulated by the Fish and Wildlife Service of the US Department of the Interior. The provisions of CITES apply to all animals, living or dead. Other agencies which regulate the use of research animals include the Centers for Disease Control (importation of non-human primates and other animals which may harbor zoonotic agents) and the International Air Transport Association (transportation of living animals by air) (National Research Council, 2010). The use of narcotics and barbiturates in experimental anesthesia and analgesia is regulated by the US Drug Enforcement Administration (DEA), which requires users to obtain proper permits, ensure appropriate drug security, and maintain proper records.

INFORMATION RESOURCES

Research animals require specialized care that recognizes anatomic and physiologic similarities and differences between species. These differences determine routine husbandry and behavioral needs, and may influence model selection and interpretation of data. Animals vary greatly in their response to anesthetics and other drugs, and anatomical differences often pose significant challenges to endotracheal intubation, surgical approach, and intravenous access.

Veterinarians offer important expertise to investigators using animals. Laboratory animal medicine is a subspecialty of veterinary medicine which involves additional training and acquisition of skills in the diagnosis and treatment of laboratory animal diseases, development of new experimental techniques, and provision of specialized preoperative, intraoperative, and postoperative care. Most large research institutions have at least one staff veterinarian trained and experienced in laboratory animal medicine. Smaller institutions may use consultant veterinarians. Large research programs may also include veterinarians as part of the research team. Other veterinary specialties of potential value in a biomaterials research program include surgery, anesthesia, pathology, and internal medicine. The Academy of Surgical Research (ASR) and the American Association of Laboratory Animal Science (AALAS) sponsor technician training and certification programs in routine and specialized animal care and use. Certified technicians and technologists can provide valuable support and management roles in the experimental surgery laboratory.

Many information resources are available to biomaterials investigators using animals. Several excellent textbooks discuss general laboratory animal medicine (Fox et al., 2002) and basic biology and methodology for rodents (Sharp and LaRegina, 1998), rabbits (Manning et al., 1994; Harkness and Wagner, 1995; Suckow and Douglas, 1997), swine (Bollen et al., 2000; Swindle, 2007) and small ruminants (Borkowski and Allen, 1999). Specialized texts provide detailed reviews of anesthetic techniques (Tranquilli et al., 2007; Fish et al., 2008), infectious disease (National Research Council,

1991; Straw et al., 2006), and drug dosages (Hawk et al., 2005; Plumb, 2005) for experimental animals. Finally, the Internet has excellent resources for laboratory animal users, including reference material, bibliographical databases, and discussion groups on a variety of technical and regulatory topics. The NetVet portal is an excellent entry point to web-based laboratory animal resources (http://netvet.wustl.edu/vet.htm). Other useful websites include OLAW (http://grants.nih.gov/grants/olaw) and the Animal Welfare Information Center (http://awic.nal.usda.gov/).

SURGICAL FACILITY DESIGN

Quality surgical research requires the use of appropriately designed, equipped, and managed surgical facilities. The Guide requires the use of aseptic technique for all survival surgical procedures on laboratory animals, including rodents. Essential components of aseptic techniques include patient preparation (clipping and disinfection of the surgical site), surgeon preparation (surgical attire, surgical hand scrub, sterile gloves), and the use of sterile instruments. Effective training and staffing levels are necessary to reduce the chance of contamination of instruments and the sterile field (draping, traffic control) (National Research Council, 2010).

Surgical suites represent significant institutional investments that must remain functional for many years. Design and configuration of operating room facilities requires careful planning and consultation with users, veterinarians, laboratory planners, and engineers to meet current scientific and regulatory requirements with appropriate flexibility for possible future changes.

Minimum functional components of the survival surgery suite include dedicated areas for surgery, animal preparation, surgeon's scrub, postoperative recovery, and surgical support. In the United States, Federal regulations require the use of dedicated surgical suites for major survival surgery on regulated species other than rats, mice, and birds. Surgical suites must allow aseptic surgery, animal preparation, and surgeon scrub to occur in separate dedicated rooms, arranged to facilitate entry and exit of animals and staff while minimizing unnecessary traffic. Animal recovery may often occupy the same room as anesthesia induction and preparation. The Guide permits rodent survival surgery in any procedure space provided necessary conditions for asepsis are present (National Research Council, 2010).

Many research institutions maintain centralized experimental surgery suites to maximize economies of scale and efficient use of skilled support staff. Support spaces in large surgical suites are generally configured to allow two or more operating rooms to run simultaneously from shared animal and surgeon preparation rooms. Smaller specialized facilities may be appropriate to accommodate unique experimental requirements. Principles of research animal operating room design have been described (Ruys, 1991; Hessler and Lehner, 2008; National Research Council, 2010).

Other functional areas commonly required in an experimental surgery suite are: pharmacy, including secure storage of controlled substances; instrument cleaning and sterilization; and record keeping. The use of inhalant anesthesia requires appropriate active scavenging capability. Secure data collection and storage require network connections, and possibly other information technology capabilities. Radiography and other imaging modalities are often necessary in experimental surgical studies, and may be conveniently located within or adjacent to the surgery suite.

PREOPERATIVE PREPARATION AND MONITORING

Careful preoperative preparation is necessary before invasive surgical procedures. Preoperative preparation includes fasting, premedication, establishment of vascular access, and surgical site preparation. Removal of food and contact bedding is necessary for dogs, swine, and ruminants to prevent regurgitation and aspiration pneumonia. Gastric dilatation may also occur in improperly fasted swine and ruminants. Preoperative fasting is not routine in rodents and rabbits. These species have a high metabolic rate, and are prone to hypoglycemia from prolonged withdrawal of food. Furthermore, they do not vomit and therefore are unlikely to develop aspiration pneumonia. Fasted or not, many species hoard food between the upper molars and the cheek. For this reason the anesthetist should carefully examine the oral cavity during anesthetic induction and remove materials which can be aspirated or pushed into the trachea during endotracheal tube placement. Premedication with analgesic and sedative drugs reduces animal anxiety, facilitates anesthetic induction, and prevents postoperative hyperalgesia and allodynia.

Hypothermia impairs wound healing, and predisposes animals to infection and other postoperative complications. Anesthesia itself is a major risk factor for hypothermia because anesthetic-induced peripheral vasodilation increases conductive heat loss. Many anesthetic and analgesic agents interfere with hypothalamic thermoregulatory systems and the shivering reflex. Cold dry anesthetic gases promote evaporative heat loss from the respiratory tract. Prolonged exposure of the abdomen or thorax during surgery allows heat loss through radiation. Small animals such as rats and mice develop hypothermia more rapidly than larger animals, because they have a large surface area in proportion to body weight. A comprehensive approach to maintenance of normothermia should include minimization of surgical time and exposure of body cavities, and the use of warmed fluids and humidified gases. Care and frequent body temperature monitoring are necessary to prevent hyperthermia, which can rapidly be fatal.

Supplementary heat sources including heated surgical tables and circulating warm air or water blankets are extremely valuable. A recent report evaluated rectal temperature in isoflurane-anesthetized Sprague-Dawley rats and CF-1 mice placed on a circulating warm water blanket or a reusable microwavable warming pad (SnuggleSafe®). Control animals were placed on a stainless steel surgical table with a surface temperature of 21°C–22°C. Surgery was not performed. All control animals became severely hypothermic by the end of the 60 minute test period, and mice lost significantly more heat than rats (–9.9°C versus –4.42°C from baseline). Animals which received supplemental heat support from either source remained essentially normothermic throughout the study (Taylor, 2007).

Preoperative placement of a venous cannula and intraoperative intravenous fluid administration maintains tissue perfusion and electrolyte balance, and allows delivery of emergency drugs when necessary. Appropriate fluids and administration rates for intraoperative maintenance include lactated Ringers solution or normal saline, 5–10 ml/kg/hr. Intraoperative hydration allays dehydration if delayed recovery or physiologic compromise delays spontaneous re-feeding after surgery. Intraperitoneal or subcutaneous fluid administration is a practical alternative to the intravenous route in low risk rats and mice, because intravenous cannulation is difficult in these species.

Minimum monitoring should include core temperature, heart rate, respiratory rate, oxygen saturation, and end-tidal carbon dioxide concentration. Cost-effective devices readily allow determination of these parameters for rabbits and larger animals. Specialized devices are available for reliable assessment of rats and mice. Monitoring of additional parameters such as electrocardiogram, expired anesthetic agent concentration, and arterial blood gases or hematologic or serum biochemical parameters may be indicated for specific studies and will require specialized instrumentation and training.

ANESTHESIA

Overview

Anesthesia provides reversible elimination of pain and is essential to all surgical procedures. The ideal anesthetic preserves cardiac output and other physiologic parameters, provides intraoperative analgesia that extends to the postoperative period, and is reversible and safe for the patient, surgical personnel, and environment. Experimental animal surgery almost always occurs under general anesthesia, which additionally renders the animal unconscious and immobile. Local or regional anesthetic techniques are often useful to reduce general anesthetic and postoperative analgesic requirements in major procedures.

Anesthetic agents for experimental surgery may be administered by injection or inhalation. Several considerations should determine the selection of anesthetic agents for experimental surgery. Balanced anesthetic techniques combine two or more sedative, hypnotic, and analgesic agents to reduce adverse effects and increase physiologic stability and analgesia compared to single-agent methods. The Guide requires institutional approval and veterinary participation in the selection of anesthetic agents for experimental surgery (National Research Council, 2010).

Selection of anesthetic technique will vary with the experiment. The anesthetist must maintain oxygenation, perfusion, metabolic balance, and normal core body temperature. Severe or prolonged alterations of these parameters may impair wound healing, predispose to infection or introduce significant scientific variation. Most surgical studies use young adult healthy animals which present minimal anesthetic risk for brief procedures. Unexpected disease may occur in any animal, however, and for this reason all animals should receive appropriate physical examination before anesthetic induction. Extensive procedures or studies with diseased animals pose significant anesthetic challenges and generally require an anesthetist with specialized training and experience.

The American Society of Anesthesiologists (ASA) anesthetic risk assessment categories classify anesthetic risks based on the animal's age, underlying health status, and other risk factors. Anesthetic, intraoperative and postoperative care and resource requirements can then be determined appropriately. A six-month-old normal Sprague-Dawley rat undergoing implantation of a permanent venous catheter, for example, would be considered ASA category I and require standard anesthetic protocols. By contrast, an 18-month-old Sprague-Dawley rat with advanced experimental myocardial insufficiency following coronary artery ligation would be considered ASA category III or IV, and require correspondingly more intense anesthetic support and monitoring (Tranquilli et al., 2007).

Anesthetics are potent medications which may confound experimental results, either directly or through alteration of normal physiology. Investigators should select agents carefully, and maintain anesthetic and analgesic protocols constant across groups and between experiments to minimize these effects. Pilot studies may be necessary to identify the best agent for specific models, as the following recent report illustrates. Weanling swine were used to evaluate colorimetry, transepidermal water loss, and laser Doppler perfusion imaging to determine the progress of wound healing and efficacy of candidate treatments. Animals were anesthetized with each of three different protocols: ketamine/xylazine (K/X); tiletamine/zolazepam/xylazine (T/X); or tiletamine/zolazepam/xylazine/isoflurane (T/X/I) three times at 24–48 hour intervals, separated by a seven day washout period. The T/X and T/X/I regimens depressed transepidermal water loss less than did K/X. The mechanism was unknown, but possibly associated with differential effects of anesthetic drugs on cutaneous blood flow. The study also identified a progressive reduction in cutaneous blood flow readings

during the three day experiment, presumably the result of anesthetic accumulation following multiple doses (Graham et al., 2004).

Injectable anesthesia is popular in experimental surgery. The principal benefits of injectable anesthetic techniques are ease of administration and operator safety. Injectable techniques usually use a combination of agents given by the intramuscular or, for rodents, intraperitoneal routes. Intravenous anesthesia, by continuous or intermittent bolus infusion, may be appropriate in larger animals. Most injectable agents or combinations provide 15–30 minutes of anesthesia. Significant individual, species, and strain variation in the response to injected anesthetics is common. Injectable anesthetics are often used to induce anesthesia before endotracheal intubation and maintenance inhalation anesthesia. Prolonged recovery and physiologic imbalance may follow repeated administration of injectable agents to maintain anesthesia during long procedures. As reversal of injectable agents is often impossible, the operator must avoid administration of an accidental overdose. In addition, the operator must be careful not to breach aseptic technique when administering supplemental anesthetic. Many injectable anesthetic agents have a moderate-to-high abuse potential; therefore, investigators who use these agents in research must register with the United States Drug Enforcement Administration, and maintain proper records and storage facilities.

Inhalation anesthesia, usually with isoflurane or sevoflurane, allows the operator a high degree of control over anesthetic depth, and is the technique of choice for prolonged or invasive surgery. Inhalation anesthesia for major surgery requires a precision vaporizer and endotracheal intubation to allow proper control of anesthetic depth and the airway. Controlled ventilation further facilitates maintenance of normal tissue oxygenation and carbon dioxide balance, and allows rapid increase or decrease of anesthetic depth when necessary. Controlled ventilation is mandatory for intrathoracic procedures, because many laboratory animals lack a complete mediastinum and develop bilateral pneumothorax following thoracotomy. Endotracheal intubation requires special laryngoscopic equipment and training to prevent laryngeal trauma or esophageal placement.

Anesthetic administration by facemask may be appropriate for brief or noninvasive procedures. Prolonged inhalation by mask is undesirable because it does not protect the airway from aspiration in the event of vomiting or allow positive pressure ventilation in an emergency. A tight fitting mask and active scavenging are necessary to maintain anesthetic depth and reduce operator exposure to waste anesthetic agents.

Anesthetic Agents

Ketamine and Tiletamine. Ketamine and tiletamine are dissociative anesthetics commonly used in experimental surgery because they maintain cardiac output and provide good analgesia with a high margin of safety. Dissociative anesthetics are NMDA (N-Methyl-D-aspartate) antagonists which produce unconsciousness and analgesia through selective disruption of ascending impulses to conscious brain centers, rather than through generalized depression of the central nervous system. Dissociative anesthetics are almost always used in combination with other agents. When used as a sole agent, surgical anesthesia is rarely achievable at safe dosage levels. Other significant disadvantages include unacceptable muscle rigidity, salivation, and seizures, especially in dogs (Lin, 2007; Tranquilli et al., 2007; Meyer and Fish, 2008).

Ketamine solutions are acidic, and perivascular infiltration and large volume intramuscular injection will produce pain and tissue irritation. Telazol® is a commercial mixture of the dissociative agent tiletamine and the benzodiazepine zolazepam. The product is supplied in a sterile vial, which is reconstituted with 5 ml of sterile water. Reconstituted vials contain 50 mg/ml of each agent and may be kept for 48 hours at room temperature or for 14 days in a refrigerator. Telazol® has similar anesthetic efficacy as ketamine/xylazine or ketamine/diazepam. Telazol® may also be combined with xylazine or medetomidine for greater anesthetic depth.

Sedatives. Xylazine (Rompun®), medetomidine (Domitor®) and dexmedetomidine (Dexdomitor®) are common adjuncts to ketamine anesthesia. These agents are alpha-2 adrenergic agonists with potent sedative and analgesic activity. They lack adequate potency to be sole agents for general anesthesia, but may provide adequate sedation for dressing changes, suture removal, and other minor procedures. Coadministration with ketamine generally provides up to 30 minutes of anesthesia with excellent muscle relaxation, smooth recovery, and a moderate degree of postoperative analgesia in many species. These combinations are also useful for anesthetic induction prior to endotracheal intubation and subsequent inhalation anesthesia. Intramuscular administration is preferable, because transient hypertension and cardiac arrythmia can occur after rapid intravenous boluses. Xylazine is the most commonly used alpha-2 agonist in rodents. Medetomidine has increased specificity for the alpha-2 receptor, and increased analgesic potency compared to xylazine. Medetomidine is preferred over xylazine in dogs (Lemke, 2007). Medetomidine is a racemic mixture of the active R and inactive L isomers. Dexmedetomidine is a pure preparation of the R-isomer and produces physiologic and analgesic effects similar to medetomidine at approximately half the dose.

Several side-effects are associated with alpha-2 agonists and are more significant following IV administration. Xylazine commonly induces vomiting in dogs. All alpha-2 agonists significantly depress cardiac output at standard anesthetic doses and may cause severe bradycardia. Cardiac depression is frequently subclinical in young healthy animals. Decompensation may occur in aged animals or those with clinical or experimentally

induced illness. The mechanism of alpha-2-agonist associated bradycardia is complex and may require combined anticholinergic (atropine or glycopyrollate) and specific antagonist (yohimbine or atipamezole) therapy.

A distinct advantage of the alpha-2 agonist sedatives is the availability of specific antagonist drugs. Yohimbine effectively reverses xylazine, and atipamezole is the recommended reversal agent for medetomidine (Lemke, 2007). These drugs effectively speed recovery following minor procedures, and may also be used in an anesthetic emergency.

Other adjuncts may also be used to allay animal anxiety and provide muscle relaxation. Acepromazine provides excellent sedation in many species, and protects the myocardium from catecholamine-induced arrhythmias. Disadvantages of acepromazine include hypotension secondary to adrenergic blockade and prolonged recovery. Benzodiazepines such as diazepam, midazolam, and zolazepam provide excellent short-term sedation with little effect on blood pressure (Lemke, 2007).

Propofol. Propofol is a non-narcotic, injectable sedative and hypnotic agent commonly used for anesthetic induction and for brief procedures in dogs, swine, and small ruminants. Propofol is insoluble in water and is available as an oil-based emulsion in single-dose ampules and multiple-dose vials for intravenous administration. Bacterial growth will occur rapidly in contaminated solutions, and vials should be used or discarded the day they are opened. Anesthetic induction and recovery are smooth. The duration of anesthesia following a single bolus intravenous injection in dogs is approximately 20 minutes. Prolonged anesthesia is possible using intermittent bolus injections or continuous rate infusions. Propofol has little analgesic activity, and should be used in combination with narcotics or alpha-2 agonists for painful procedures. Side-effects of propofol include apnea, bradycardia, and hypotension. The incidence of apnea is related to the total dose and rate of injection, and resolves spontaneously as the drug distributes. Manual ventilation may be necessary if apnea is prolonged. Human patients commonly report transient pain at the injection site. Unlike ketamine and the barbiturates, accidental perivascular propofol injection does not produce tissue damage (Branson, 2007).

Barbiturates. The barbiturates are among the oldest anesthetic agents and remain useful for some experimental applications. Barbiturates act through general depression of the central nervous system. There is dose-dependent depression of respiration and cardiac output. Hepatic metabolism terminates the activity of long-acting oxybarbiturates such as sodium pentobarbital. Rapid redistribution into adipose tissue followed by hepatic detoxification characterizes the metabolism of the short-acting thiobarbiturates thiamylal and thiopental.

The principal advantage of sodium pentobarbital for general anesthesia is the ability to rapidly induce deep anesthesia with a single agent. Several disadvantages limit sodium pentobarbital's utility in prolonged or invasive procedures. Progressive cardiovascular depression occurs with prolonged anesthesia. Despite sleeping times of 5–15 hours, surgical anesthesia is often present only for 30–60 minutes in most species because this agent provides very little analgesia. Stormy recovery with vocalization and an unstable gait is common. Rapid-acting intravenous thiobarbiturates provide about 10 minutes of general anesthesia, and are useful for anesthetic induction. Barbiturate solutions are strongly alkaline and require intravenous or intraperitoneal administration to avoid pain and tissue necrosis (Branson, 2007). The therapeutic index of most barbiturates is very low: most laboratories use these agents primarily for euthanasia.

Nonstandard Injectable Anesthetics. Specific experimental situations may require the use of nonstandard anesthetics. These agents include chloral hydrate, alpha-chloralose or urethane. Chloral hydrate and alpha-chloralose preserve motor and sensory nerve function, but are poor anesthetics with minimal analgesic effect except at very high dosages. Alpha-chloralose and urethane result in stable cardiovascular performance during prolonged anesthesia. Urethane is mutagenic and carcinogenic in experimental animals, and may be used only for nonsurvival procedures. Urethane may also be hazardous to research staff after prolonged contact. Because of these constraints, most IACUCs require investigators to justify the use of nonstandard agents on scientific grounds (Meyer and Fish, 2008).

Inhalation Anesthetics. Isoflurane and sevoflurane are the agents of choice for clinical and experimental inhalation anesthesia. These agents are poorly soluble in blood and undergo minimal metabolism. As a result, recovery after anesthetic discontinuation is rapid, even in animals with significant hepatic or renal impairment. Dose-dependent cardiac depression may occur during prolonged procedures. A balanced anesthetic technique combining narcotic analgesics and muscle relaxants to reduce the required concentration of isoflurane is suggested for long procedures on animals with cardiac disease. Unlike the obsolete agents halothane and methoxyflurane, isoflurane and sevoflurane do not sensitize the myocardium to catecholamine-induced arrhythmias (Steffey and Mama, 2007; Brunson, 2008). As sole agents, isoflurane and sevoflurane are relatively poor analgesics and should be used in combination with sedatives and narcotics or nonsteroidal anti-inflammatory drugs (NSAIDs) for optimal intraoperative and postoperative pain control. These anesthetics are halogenated drugs which must be scavenged with activated charcoal canisters or by connection to an active exhaust circuit (Steffey and Mama, 2007; Brunson, 2008).

Older inhalation anesthetics occasionally used in experimental surgery include diethyl ether, chloroform, and nitrous oxide. Although ether is inexpensive and readily available from chemical supply houses without

prescription, significant disadvantages include flammability and the risk of explosion if peroxides form when ether evaporates to dryness. Mask induction with ether is unpleasant for the patient. High lipid solubility prolongs recovery and analgesia is poor. Repeated exposure to chloroform or methoxyflurane is toxic to the operator. Nitrous oxide provides slight analgesia when administered at high concentrations, but is not an effective anesthetic in animals. The maximum allowable concentration of nitrous oxide is 80% in oxygen, beyond which hypoxemia is likely. As activated charcoal does not absorb nitrous oxide, active exhaust scavengers are required when using nitrous oxide for anesthesia. Nitrous oxide diffuses out of the bloodstream to gas-filled body cavities such as the gastrointestinal tract. This property may cause significant distension of the rumen in sheep and goats. Most institutions strongly discourage the use of these agents without specific scientific justification (Brunson, 2008).

Bell jar administration of volatile anesthetics is no longer acceptable in most institutions. Chloroform, ether, and methoxyflurane have a low vapor pressure and achieve anesthetic concentrations when allowed to evaporate in a closed container, but these agents pose unacceptable risks to animals and operators. Isoflurane and similar modern agents are highly volatile and rapidly attain toxic levels in a nose cone or closed container. Investigators familiar with bell jar administration of obsolete agents commonly experience unacceptable animal mortality when attempting to use isoflurane in the same manner.

ANALGESIA

Prompt recognition and adequate treatment of postoperative pain are key responsibilities of experimental surgeons. Experimental surgical procedures rarely, if ever, directly benefit the research subject and impose a substantial moral requirement on investigators to prevent or minimize any discomfort related to the experiment. The scientific community has accepted that comparable mechanisms govern the production and response to pain in animals and humans, as the widespread use of animal models in pain research confirms. Animal welfare regulations and accreditation guidelines require the use of sedatives, analgesics or anesthetics for procedures which "may cause more than momentary or slight pain or distress" (Office for the Protection from Research Risks, 1996). Additionally, untreated pain increases catecholamine secretion and causes stress, which introduces experimental variation by impairing wound healing and immune function (Lee-Parritz, 2007). Animal welfare regulations require investigators to justify withholding of analgesics to the IACUC on scientific grounds.

Recognition of postoperative pain is difficult in most laboratory animal species. Anorexia, lethargy, piloerection, and wound hypersensitivity indicate the presence of moderate to severe pain, but absence of these signs does not necessarily prove that the animal is pain-free. Behavioral and physiological factors complicate the diagnosis of less severe pain, which may still require treatment to assure animal well-being. Rodents, for example, are nocturnal animals and are normally less active during the day than at night. Rodents typically nibble small amounts of food at frequent intervals. As a result, pain induced inhibition of activity or feeding is difficult for research staff to recognize. In addition, rodents issue distress calls at ultrasonic frequencies that are inaudible to human beings (Lee-Parritz, 2007). Most animals effectively conceal subtle signs of pain and distress from research staff. Animal husbandry staff may notice subtle signs of pain or distress in research animals that are not apparent to investigators. For these reasons, animal welfare regulations counsel investigators that surgical procedures that would induce pain in a human would produce pain in an experimental animal, unless convincing evidence to the contrary exists (National Research Council, 2010).

Narcotics remain the analgesics of choice for severe pain in most species. Adverse effects of narcotics include dose-dependent sedation, hypoventilation, anorexia, and constipation. These effects are more pronounced with pure agonists such as morphine than with partial agonists, such as butorphanol and buprenorphine. Buprenorphine is widely used in veterinary medicine because it provides excellent analgesia at a convenient dose interval (8–12 hours), and has minimal depressant effects on respiration and cardiac output (Lee-Parritz, 2007; Lamont and Mathews, 2007). Dosage and dose intervals of the narcotic analgesics vary widely between species because of the higher metabolic rate of the smaller species, as well as species-specific responses to the agents. In comparison to larger animals, rodents require very high doses of most narcotics in proportion to their body weight for effective analgesia (Lamont and Mathews, 2007; Lee-Parritz, 2007).

Fentanyl is a highly effective narcotic analgesic. Parenteral fentanyl has a very short half-life, and can be rapidly titrated to effect as a continuous rate infusion in a balanced anesthetic protocol. The fentanyl transdermal patch provides effective analgesia for up to 72 hours as a sole agent or in multimodal analgesic regimens. Several factors may affect transdermal fentanyl absorption, including temperature, skin thickness, and blood supply. Care and consistency in application is necessary to prevent toxicosis or inadequate analgesia. The patch should not be under an occlusive dressing, on a patient's recumbent side or where it will be in contact with supplementary heat devices used during anesthesia, as these practices may cause significant increase in drug release from the patch. Patches should be placed at least 12 hours preoperatively to ensure adequate blood levels at the time of incision. Poorly applied patches may dislodge and be eaten, causing fatal fentanyl overdose. Facilities which use fentanyl patches should stock naloxone (0.1 mg/kg IV, repeated as necessary) for emergency

use in case of accidental patch ingestion (Lamont and Mathews, 2007; Lee-Parritz, 2007).

Nonsteroidal anti-inflammatory drugs (NSAIDs) are most effective against moderate pain of musculoskeletal origin, including incisional pain from ventral abdominal incisions in swine and other large animals. NSAIDs are of particular value in orthopedic procedures. The principal side-effects of many NSAIDs include increased bleeding from reduced platelet activity or gastric irritation secondary to prostaglandin inhibition. Although clinically significant impairment of blood clotting ability is rare, gastric toxicity remains a concern, particularly in dogs (Lamont and Mathews, 2007; Lee-Parritz, 2007).

It is advisable to use multimodal analgesia consisting of local anesthetics, NSAIDs, and narcotics whenever possible. The use of agents from two or more analgesic classes will act at several complementary steps in the pain cascade. This strategy will generally have additive or synergistic activity with reduced potential for drug toxicity. Preoperative analgesic and local anesthetic administration will significantly reduce intraoperative anesthetic requirements, and likely reduce acute and chronic postoperative pain. Local anesthetics are most often administered to the incision or regionally at the time of surgery, but may be of significant value in the postoperative period as well.

The possible effect of analgesic treatment on wound healing is controversial. Most NSAIDs block COX-1 and COX-2 to a variable degree, and COX-2 plays an important role in wound healing. A study of the effect of continuous diclofenac administration for 10 days to rats with experimental dorsal skin incision demonstrated reduced fibroblast numbers in treated versus control rats, but no difference in epidermal thickness or clinical healing (Krischak et al., 2007). In another model, rats undergoing experimental medial collateral ligament transaction demonstrated improved healing at day 14 following 6 days' treatment with the NSAID piroxicam compared to controls. Animals which received naproxen, rofecoxib, acetaminophen or butorphanol at the same dose schedule demonstrated healing similar to controls (Hanson et al., 2005). A third study evaluated the effect of continuous celecoxib or indomethacin treatment versus controls on bone repair in a rat femur fracture model. Recipients of either NSAID had increased fibrous tissue compared to control at 4 and 8 weeks, but all groups demonstrated equivalent morphological and functional healing by 12 weeks (Brown et al., 2004). A rabbit spinal fusion model demonstrated equal fusion rate and strength at 8 weeks when animals received either ketoprofen or tramadol for 8 days after surgery (Urrutia et al., 2007). These results suggest that NSAIDs may have a small, agent-specific effect on experimental wound healing. The applicability of studies based on extended treatment protocols to the relatively brief treatment periods required for acute pain control requires further study. Narcotic analgesics have not been demonstrated to impair wound healing, and

may actually speed recovery in specific settings (Peyman et al., 1994). Consistent administration of standard analgesic drugs across experimental groups, guided by pilot studies when necessary, should allow effective analgesic therapy without compromising the scientific validity of the study.

SPECIES-SPECIFIC RECOMMENDATIONS

The following sections provide general recommendations for the selection, care, and experimental use of laboratory animal species commonly used in biomaterials research. When appropriate, separate recommendations will be made for brief or noninvasive procedures. For detailed discussion of anesthesia for specific procedures or disease conditions, the reader is advised to consult the references or a veterinary specialist.

Rodent

Animal Selection and Preoperative Preparation. Specific pathogen-free rodents should be used for all surgical procedures to reduce morbidity and mortality from chronic respiratory disease. Infectious agents commonly implicated in chronic respiratory disease of rodents include *Mycoplasma pulmonis*, Sendai virus, and cilia-associated-respiratory (CAR) bacillus (National Research Council, 1991; Fox et al., 2002). Other infectious agents may alter immune function or impair detoxification of anesthetic or experimental drugs. Several commercial vendors supply common strains of laboratory rodents free from infection with these and other infectious agents. These animals are known as specific pathogen-free (SPF) animals, and should always be used for survival surgical procedures to minimize experimental variability and reduce surgical mortality. The specific panel of excluded agents may vary according to the vendor. The institution should adopt standard operating procedures to prevent introduction of rodent infectious agents, and should regularly survey all holding areas for evidence of infection. Introduction of SPF animals to rooms with enzootic viral infection may result in rapid onset of severe clinical disease. Cedar or pine shavings sometimes used for contact bedding contain aromatic compounds that induce hepatic microsomes and alter hepatic detoxification of anesthetics (Gaertner et al., 2008). To ensure uniform response to anesthetics and experimental drugs, rodents should receive heat-treated wood chip, corncob or cellulose bedding. A conditioning period of at least three days after purchase will ensure that animals have recovered from dehydration and stress associated with shipping. Rodents do not vomit, and preoperative fasting is not recommended. If otherwise indicated, fasting in rodents should be kept to a minimum (2–3 hours) to avoid hypoglycemia and shock (Flecknell et al., 2007).

General Anesthesia. Most surgical procedures in rodents are brief. Small body size and limited vascular

access complicate anesthesia and intraoperative support of rodents. Nevertheless, skilled operators with appropriate instrumentation can accomplish delicate vascular surgery and other procedures in rats and mice with minimal postoperative mortality. Endotracheal intubation and positive pressure ventilation is also possible and requires the use of customized equipment (Gaertner et al., 2008).

Several anesthetic combinations are appropriate for brief, noninvasive procedures in rodents. Tribromoethanol (Avertin®) provides light anesthesia for 10–20 minutes in mice. Prepared solutions must be stored in the dark at 4°C to avoid production of gastric irritant decomposition compounds. The standard anesthetic dose is 0.2 ml/10 gm of a 1.2% solution. This anesthetic is most appropriate for brief, minimally painful procedures in mice, such as retro-orbital blood sampling, embryo transfer, vasectomy, and tail biopsy (Gaertner et al., 2008). Tribromoethanol is contraindicated in rats because peritoneal fibrosis and peritonitis is common following intraperitoneal injection in this species (Reid et al., 1999). Although propofol is intended only for intravenous administration, a recent report described effective surgical anesthesia of 20–30 minutes' duration and smooth recovery following intraperitoneal administration of propofol (75 mg/kg, mouse; 100 mg/kg rat), medetomidine (1–2 mg/kg, mouse; 0.1 mg/kg rat) and fentanyl (0.15–0.20 mg/kg, mouse; 0.1 mg/kg rat) to CD-1 mice and Wistar rats (Alves et al., 2009, 2010).

Intraperitoneal injection of ketamine (40–100 mg/kg) and xylazine (3–10 mg/kg) provides 20–60 minutes of surgical anesthesia in most rodent species. Muscle relaxation and analgesia are good. Anesthetic duration varies in a dose-dependent manner. If necessary, supplemental administration of ketamine will prolong anesthesia. Ketamine volumes commonly required for rats and mice require division of an IM (intramuscular) dose between two or more sites if the IP (intraperitoneal) route is contraindicated. Yohimbine (1–2 mg/kg IP) will reverse xylazine-associated sedation and speed recovery from anesthesia, but will also likely reverse residual xylazine-induced analgesia. Side-effects of general anesthesia in rodents may include hypercarbia, hypoxemia, and hypotension although these effects are less evident with ketamine and xylazine in comparison with sodium pentobarbital. Medetomidine and dexmedetomidine are safe but short acting in rodent species, and have not replaced xylazine in most models (Gaertner et al., 2008).

Barbiturates such as sodium pentobarbital (30–70 mg/kg IP) are occasionally used in rodent experimental surgery. Disadvantages of these agents include brief periods of effective anesthesia, prolonged recovery, and poor analgesia. In addition to environmental factors discussed earlier, rodents also display marked individual and strain variability in the response to sodium pentobarbital. Pretreatment with buprenorphine prior to incision prolongs the period of effective anesthesia,

and lowers the required dose of sodium pentobarbital (Roughan et al., 1999). One report described the use of methohexitone (44 mg/kg of a 6.46 mg/ml solution IP) to achieve 2 minutes of chemical restraint for oral examination in C3H/Neu mice with recovery in 10–15 minutes. The major disadvantage of this technique was a very narrow therapeutic window: 40 mg/kg produced no immobility, whereas 50 mg/kg produced 40% mortality (Dorr and Weber-Frisch, 1999).

Isoflurane provides excellent anesthesia in rats and mice. This agent may be used both for brief restraint and for procedures of up to several hours' duration. Isoflurane requires the use of a precision vaporizer to maintain consistent anesthetic concentration. Rapid induction of anesthesia occurs following placement of animals into an induction chamber containing 3–4% isoflurane in oxygen. Most animals awake 1–2 minutes after removal from the chamber, which is sufficient time for retro-orbital blood sampling or tail biopsy. To maintain anesthesia for longer periods, the animal's head and nose may be placed into a customized nose cone connected to a non-rebreathing anesthetic circuit and scavenger. Concentrations of 2–3% isoflurane are commonly used for maintenance. The absence of the pedal withdrawal reflex confirms adequate anesthetic depth. Rodent nose cones are easily fashioned from funnels or disposable syringe barrels. For procedures requiring positive pressure ventilation, endotracheal intubation is easily accomplished. Techniques for endotracheal intubation for rodents have been described (Gaertner et al., 2008).

Analgesia. Buprenorphine is the most widely used analgesic in rodents. Buprenorphine is a mixed mu agonist/antagonist and a kappa receptor agonist with approximately 25–40 times the analgesic potency of morphine. The relative activity at each receptor may be dose-dependent. This agent provides safe and effective analgesia for 6–12 hours after dosing. The current recommended dose for most rodent indications is 0.03–0.05 mg/kg IP or SQ (subcutaneous) (Lee-Parritz, 2007; Curtin et al., 2009).

For procedures under isoflurane or sodium pentobarbital, buprenorphine should be given at least one hour before incision. The anesthetist should be aware of the anesthesia-sparing effects of buprenorphine, and be prepared to reduce the isoflurane vaporizer setting 30–50% as necessary (Brunson, 2008). For procedures conducted under ketamine/xylazine anesthesia, buprenorphine should be given only when the animal has regained sternal recumbency during recovery. Preoperative administration of buprenorphine or other narcotics may cause unpredictable increases in anesthetic depth when using ketamine/xylazine combinations for anesthesia. Local infusion of lidocaine (up to 1 ml/kg of 1.0% lidocaine or 0.25% bupivicaine) before surgical incision will provide additional intraoperative and postoperative analgesia (Lee-Parritz, 2007).

Clinically significant side-effects of buprenorphine include consumption of bedding (pica), and excessive

licking or biting of the limbs and cage which may also be directed to the surgical incision. These effects are more common at high doses (0.1–0.3 mg/kg) and can often be managed through temporarily placing animals on a wire grid during the immediate postoperative period or substitution of a synthetic for a natural bedding substrate. A generalized increase in activity and a reduction of ventral grooming may also occur. These effects most likely represent a direct effect of the drug, and do not necessarily indicate the presence or absence of pain (Lee-Parritz, 2007).

The NSAIDs ketoprofen, carprofen, and meloxicam are the next most widely used analgesics. These drugs block the formation of inflammatory mediators associated with surgical injury, and also act centrally to inhibit secondary allodynia. The current recommended dose for meloxicam is 1 mg/kg PO (*per os* or orally) or SQ in rats, and up to 10 mg/kg in mice. The dose for ketoprofen and carprofen in rats is 5 mg/kg SQ. The dose interval for these agents has not been critically evaluated in rodents, but is 12–24 hours in other species. The NSAIDs are highly effective pre-emptive analgesics when administered one hour or more before surgery, but isoflurane vaporizer settings typically do not require adjustment (Lee-Parritz, 2007).

There are few reported adverse side-effects associated with NSAIDs in rodents. Diffuse intestinal ulceration may occur at high doses, especially in animals with concurrent disease. Most NSAIDs inactivate platelet function to some extent through cyclooxygenase-mediated inactivation of thromboxane. This may slightly prolong the bleeding time, but rarely causes adverse clinical effects in humans even when administered preoperatively (Lee-Parritz, 2007).

Acetaminophen (paracetamol) is a nonsteroidal analgesic which lacks significant anti-inflammatory properties. The drug is readily available in a palatable over-the-counter pediatric syrup formulation (Children's Tylenol®). Several studies suggest a possible role for this agent in rat analgesia, although specific evaluation for postoperative pain control is lacking. Reported effective dose ranges are 100–300 mg/kg twice a day. These studies suggest that acetaminophen may be effective for mild-to-moderate postoperative pain in rats. Although it is convenient to administer analgesics in drinking water, anorexia in the immediate postoperative period associated with anesthetic recovery and abdominal discomfort may reduce drug intake precisely when pain is maximal. Analgesic activity has not been assessed in mice, for which the LD50 (lethal dose to 50% of the subjects) is close to the doses evaluated for analgesia in rats (Lee-Parritz, 2007).

Rabbit

Animal Selection and Preoperative Preparation. Infection with the respiratory pathogen *Pasteurella multocida* is extremely common in conventional rabbits. Colonization of the upper respiratory tract may be clinically silent, but may spread to the lungs, middle ear, and brain in crowded or stressed conditions and produce characteristic disease syndromes (Harkness and Wagner, 1995; Lipman et al., 2008) and compromise long-term surgical studies. *Pasteurella*-negative rabbit colonies are available and should be used for all surgical protocols. Rabbits do not vomit, and aspiration pneumonia is therefore not a concern. Adult rabbits will tolerate an overnight fast without difficulty, and the resulting reduction in stomach contents may help maintain adequate oxygenation during spontaneous respiration under anesthesia. Rabbits weighing less than 2 kg should not be fasted, as hypoglycemia and metabolic acidosis may be significant (Lipman et al., 2008). Prolonged fasting may cause dehydration and subsequent intestinal motility disorders (Lipman et al., 2008). Traumatic lower-back fracture is common when inexperienced staff handle rabbits. The best way to handle rabbits is to grasp the scruff of the neck with one hand while supporting the rump and hind legs with the other. Sudden onset of flaccid paraplegia in rabbits is almost always the result of lower-back fracture, and warrants immediate euthanasia (Harkness and Wagner, 1995). Rabbits should never be lifted, moved or restrained by the ears.

Brief Procedures. Combined administration of ketamine (35–50 mg/kg IM) and xylazine (5–10 mg/kg IM) provides excellent anesthesia for a variety of applications in the rabbit. General anesthesia lasts for 30–60 minutes, and provides adequate analgesia and restraint for procedures of moderate intensity. Supplemental use of a narcotic analgesic such as buprenorphine (0.05 mg/kg IM) prolongs anesthesia and improves analgesia. Propofol administered by intravenous bolus or constant rate infusion produces light anesthesia suitable only for intubation or nonpainful procedures such as imaging. Telazol® should not be used for survival procedures in rabbits, because renal tubular damage is a common complication even at standard anesthetic dosages (Lipman et al., 2008).

General Anesthesia. The intramuscular ketamine/xylazine combination suggested for brief procedures is also an excellent induction agent prior to endotracheal intubation for inhalation anesthesia. Intravenous administration of ketamine and xylazine through the ear vein will achieve rapid induction, but care is required to minimize skin irritation from perivascular infiltration. Mask induction is rarely indicated because apnea, breath holding, bradycardia, and struggling are common when unsedated rabbits are exposed to isoflurane, and because operator exposure to waste anesthetic is difficult to avoid in this setting (Flecknell et al., 1999).

Propofol (10–20 mg/kg IV [intravenous]) is an effective rabbit anesthetic induction agent which produces significantly faster postoperative recovery than ketamine/xylazine in animals maintained on sevoflurane. In a recent report, rabbits anesthetized with propofol and maintained on sevoflurane were extubated 2 ±1 minutes, and achieved sternal recumbency 8 ±0.3 minutes after discontinuation

of sevoflurane. Recovery following isoflurane anesthesia should be similarly rapid. By contrast, anesthetic recovery following ketamine/xylazine or ketamine/medetomidine may require up to 120 minutes. Animals should receive preoperative analgesics and be preoxygenated by mask before propofol administration. The initial dose of 10 mg/kg should be administered by hand over 60 seconds (~0.17 mg/kg/s), with additional small increments as required to allow endotracheal intubation. Propofol is not suitable as a sole agent because respiratory arrest may occur, particularly following rapid infusion (>0.25 mg/kg/s) (Allweiler et al., 2010).

Endotracheal intubation of the rabbit may be difficult because of several distinctive anatomic features. The prominent incisor teeth, long oropharynx and limited mobility of the temporomandibular joint hinder direct visualization of the larynx from the front, and require the use of a pediatric laryngoscope with a size 0–1 Wisconsin or size 1 Miller blade. Lidocaine spray on the vocal cords is necessary to prevent further narrowing of the larynx through laryngospasm. Benzocaine spray (Cetacaine®) produces methemoglobinemia in rabbits and should be avoided. The laryngeal opening is often smaller than the diameter of the trachea, requiring the use of a small endotracheal tube (2.5–4 mm). The tongue is short, friable, and difficult to grasp. Supine, prone or lateral positions are all suitable for endotracheal intubation. Hyperextension of the neck will straighten the larynx and facilitate proper tube placement. Blind intubation of the trachea is easily accomplished with practice. The tube is placed in the supraglottic region and advanced toward the larynx in coordination with respiration. Identification of normal breath sounds, visualization of condensate on a dental mirror or capnometry may be used to confirm proper tube placement (Harkness and Wagner, 1995; Lipman et al., 2008). Anesthetic maintenance with isoflurane usually requires a vaporizer setting of 1–4%. Absence of the pinna withdrawal reflex is the best indicator of a surgical anesthetic plane in the rabbit. Many rabbits retain the corneal and pedal withdrawal reflexes even under very deep anesthesia (Lipman et al., 2008; Muir, 2007).

If an anticholinergic agent is required, investigators should be aware that approximately 50% of rabbits produce atropinesterase (AtrE) as a genetically determined trait. Glycopyrrolate resists AtrE, and is therefore recommended over atropine for rabbits. Glycopyrrolate prevents xylazine-associated bradycardia in rabbits (Lipman et al., 2008).

Analgesia. Behavioral signs of postoperative pain in rabbits are vague and inconsistent, and may include lethargy, tooth grinding, and increased activity directed toward the painful area. Anorexia is a common sign of postoperative pain in rabbits. Untreated anorexia can create serious secondary disease, including generalized gastrointestinal stasis, rapid weight loss, and fatal hepatic lipidosis (Lipman et al., 2008).

The best indicator of GI (gastrointestinal) health in the rabbit is the quantity and consistency of fecal pellets. Dehydration and anorexia result in a reduced number of firm, dry pellets. Treatment of anorexic postoperative rabbits should be directed to relief of underlying pain if present and towards restoration of normal gastrointestinal function. A high fiber supplement such as Oxbow Critical Care or blenderized rabbit chow is preferred over low fiber nutritional gels such as Nutrical® to restore normal gut motility. Aggressive analgesia, fluid therapy, and force-feeding may be necessary in some cases.

Narcotic analgesics are preferred for treatment of moderate to severe postoperative pain in rabbits. Buprenorphine (0.01–0.05 mg/kg SQ BID/TID [twice or three times a day]) is the narcotic of choice, because it provides effective analgesia at a convenient dosing interval and is generally well-tolerated. The fentanyl patch (25 μg/hr) is an alternative narcotic analgesic option that provides continuous analgesia up to 72 hours without the requirement for regular injections. Fentanyl patches achieve effective blood levels approximately 12 hours after application, and should be applied the night before surgery. Alternatively, the patch may be applied at the time of surgery, with a single dose of buprenorphine to provide 8–12 hours of bridging analgesia. Clip the fur well and use tissue adhesive (Nexaband® or equivalent) if necessary around the edge of the patch to ensure good skin adhesion. Inadequate fur removal will greatly reduce drug absorption. Use of depilatories such as Neet® for hair removal results in increased drug absorption, and may cause toxicity (Foley et al., 2001).

The NSAIDs are also highly effective in rabbits, particularly for musculoskeletal pain or co-administered with narcotics for multimodal analgesia. Flunixin (1.1 mg/kg SQ q24h), carprofen (4 mg/kg SQ q24h), and meloxicam (0.3 mg/kg PO q 24h) all demonstrate good clinical efficacy in rabbits (Lipman et al., 2008). Oral meloxicam oral suspension (Metacam®, 1.5 mg/ml) has recently undergone pharmacokinetic evaluation in rabbits. Oral administration of 0.3 mg/kg once a day produced blood levels comparable to those shown to be clinically effective in other species for up to 24 hours. Repeated administration of 1.5 mg/kg/day for five days did not result in drug accumulation or drug toxicity. Although rabbits demonstrate more rapid metabolism of meloxicam than other species, delayed gastrointestinal absorption of the drug allows maintenance of effective blood levels throughout the dose period (Turner et al., 2006).

Dog

Animal Selection and Preoperative Preparation. Appropriate vendor selection and conditioning procedures are necessary to identify pre-existing cardiovascular or renal diseases, malnutrition or parasitism that can significantly complicate anesthesia and surgery. Heartworm disease, a result of *Dirofilaria immitis* infestation,

causes eosinophilia and right heart failure. Intestinal parasites, including roundworms (*Toxocara canis*), hookworms (*Ancylostoma caninum*), and whipworms (*Trichuris vulpis*) cause eosinophilia, diarrhea, and general debilitation. All of these parasites are susceptible to common anthelmintics. A calm behavioral profile, reinforced by habituation to the research staff and regular training, is important for animals on long-term studies that call for frequent handling. Purpose-bred dogs have a known pedigree and health history, and often present a more consistent physiological profile than random-source dogs. Random-source dogs are significantly less expensive than purpose-bred dogs, but often have health and behavioral disorders which render them unsuitable for long-term studies (Dysko et al., 2002).

Brief Procedures. Calm dogs may be trained to cooperate in noninvasive clinical procedures, thereby avoiding the need for sedatives or anesthetics. Short acting anesthetics may be required for more invasive procedures. The preferred technique for short-term injectable anesthesia in dogs is coadministration of a dissociative anesthetic with a sedative or tranquilizer and an anticholinergic drug. All of these drugs are suitable for intravenous administration to achieve rapid induction and recovery, and provide adequate anesthetic depth to allow endotracheal intubation before prolonged procedures. Intravenous ketamine (5–10 mg/kg) and diazepam or midazolam (0.2–0.5 mg/kg) provides 5–15 minutes of light anesthesia suitable for dressing changes, radiography or other minor procedures. Medetomidine (10–40 μg/kg IM) or dexmedetomidine (5–20 μg/kg IM) are also appropriate for this purpose, and may be rapidly reversed with atipamezole (50–200 μg/kg) (Lemke, 2007). Supplementation of medetomidine or dexmedetomidine with ketamine (3 mg/kg) and an opioid such as butorphanol (0.2–0.4 mg/kg) is advisable before major procedures (Bednarski, 2007; Armitage-Chan, 2008).

For longer procedures, intramuscular administration of ketamine (10 mg/kg) and xylazine (0.7–1.0 mg/kg) produces 20–30 minutes of anesthesia. Telazol® (6–8 mg/kg), xylazine (0.7–1 mg/kg) and butorphanol (0.2 mg/kg) produce up to one hour of anesthesia. Anticholinergics (atropine 0.04 mg/kg or glycopyrrolate 5–10 μg/kg) are often useful when using ketamine or xylazine to counteract excessive salivation or bradycardia. Supplemental administration of one-third to half of the original dose will usefully prolong the effective anesthetic period by 30–50%. Ketamine is not acceptable as a sole anesthetic in dogs, because of excessive muscle tone, salivation, and the frequent occurrence of seizures (Bednarski, 2007; Armitage-Chan, 2008).

Slow intravenous bolus injection of propofol (6–8 mg/kg) provides safe and effective anesthesia for approximately 10 minutes followed by complete recovery within approximately 30 minutes. Intermittent boluses of approximately 0.5–2.0 mg/kg or a continuous rate infusion (0.15–0.40 mg/kg/min) are suitable for prolonged procedures. Apnea is a common consequence of rapid IV injection and requires assisted ventilation until the drug wears off. Premedication with acepromazine, medetomidine or morphine will reduce the induction and maintenance doses of propofol by 30–40%. Short-acting barbiturates such as sodium thiopental (8–12 mg/kg IV) or methohexital (4–8 mg/kg IV) provide about 15 minutes of light anesthesia, but have a lower margin of safety than dissociative anesthetics or propofol (Bednarski, 2007; Armitage-Chan, 2008).

General Anesthesia. Inhalant anesthetics such as isoflurane are most appropriate for prolonged or invasive procedures in the dog. Dogs are prone to vomiting under anesthesia, and proper preoperative fasting and endotracheal intubation are vital to prevent aspiration pneumonia. Premedication with the sedative and analgesic drugs previously discussed will allay anxiety, reduce postoperative pain, and reduce the required concentration of isoflurane for maintenance anesthesia. Rapid anesthetic induction may then be accomplished through slow intravenous administration of thiopental (8–12 mg/kg IV), methohexital (4–8 mg/kg IV) or propofol (2–4 mg/kg IV) to effect. Mask induction is rarely indicated in dogs, and should only be used in premedicated animals to reduce struggling (Bednarski, 2007; Armitage-Chan, 2008).

Endotracheal intubation of dogs is easily accomplished. A variety of endotracheal tube diameters should be available to accommodate individual and breed differences in tracheal diameter. Direct visualization and intubation of the larynx of most dogs is possible without a laryngoscope. A wire stylet and a laryngoscope with an appropriate-sized Miller or Bizarri-Guiffrida blade should be available to accommodate unexpected difficulties. The animal is placed in sternal recumbency, and an assistant holds the mouth open and extends the tongue to expose the larynx. Judicious application of lidocaine spray to the vocal cords will prevent laryngospasm and facilitate intubation in small dogs. After verifying accurate placement, the cuff is inflated and the tube is secured with gauze tied over the maxilla or behind the head (Hartsfield, 2007).

Inhalant anesthesia with isoflurane may be maintained for several hours. The anesthetic concentration should be varied according to the animal's clinical status. In general, a vaporizer setting of 1–3% will produce adequate anesthesia in dogs. Signs of adequate anesthesia include absent flexor withdrawal or corneal blink reflexes; stable heart rate and respiratory rates in response to surgical stimuli; and moderate to relaxed jaw tone. The eye will generally be central in very light or deep anesthesia and rotate ventromedially at medium anesthetic depth, but this sign is unreliable in animals which receive ketamine for induction (Muir, 2007). Paralytic agents are rarely indicated for experimental surgery in dogs. When these agents are used, the heart rate and blood pressure should be monitored

and additional anesthetic administered as necessary to maintain homeostasis. Ketamine and xylazine used for induction will wear off after 30–60 minutes and require an increase in isoflurane concentration or use of supplemental analgesics to prevent sensation. The use of an "MLK" (morphine/lidocaine/ketamine) continuous rate infusion is an appropriate method to achieve balanced anesthesia at very low isoflurane vaporizer settings and maintain adequate perfusion without unnecessary prolongation of anesthetic recovery (Armitage-Chan, 2008). Isoflurane will accumulate in tissues during long procedures and multimodal analgesics often allow significant reduction of the isoflurane vaporizer settings. The vaporizer setting should generally be reduced toward the end of prolonged procedures, to avoid unnecessarily long recovery periods.

Analgesia. Diagnosis of pain in dogs is more reliable than in non-domestic species. Consistent signs of pain include vocalization, drooping of the head and neck ("hang-dog" expression), and site-specific behaviors (sensitivity to palpation, limping, biting or licking the incision). The Glasgow Composite Pain Scale (GCPS) is easily taught and demonstrates good interobserver reliability. A trained observer can evaluate a dog using this scale in approximately 5 minutes. Dogs receive a score of 0 (no pain) to 24 (severe pain), and should receive supplemental analgesia for a score greater than 6 (Hellyer et al., 2007).

Opioid analgesics are preferred for moderate to severe pain in dogs. The recommended dose of buprenorphine in dogs is 0.02 mg/kg IM every 8–12 hours. Fentanyl patches (2–5 µg/kg/h) are useful for postoperative pain longer than 24 hours' duration, but must be placed at least 12 hours before surgery to achieve effective blood levels. Epidural analgesia provides excellent pain relief with fewer systemic side-effects than parenteral injection. Epidural administration of analgesics can be readily accomplished by trained staff, and provides up to 12–24 hours of analgesia following a single injection. Morphine and oxymorphone are the most commonly used epidural analgesics. The alpha-2 agonists xylazine and medetomidine are also effective by this route, but may produce significant bradycardia and hypotension (Foley et al., 2001).

The NSAIDs are highly effective analgesics in dogs, and may provide effective analgesia up to 24 hours after a single dose. Adverse effects of the NSAIDs include gastritis, which may proceed to ulceration. For this reason, NSAIDs are most appropriate for acute postoperative pain control, and not for treatment of chronic pain conditions in dogs. Recommended NSAIDs for dogs include ketoprofen, meloxicam, and carprofen.

A recent report evaluated pain following routine ovariohysterectomy in dogs receiving buprenorphine (0.02 mg/kg single preoperative dose IM), carprofen (4.0 mg/kg single preoperative dose IM) or combined preoperative buprenorphine/carprofen. All dogs were premedicated with acepromazine, induced with propofol, and maintained on isoflurane. All treatments produced significant pain relief, but 10–20% of the dogs required rescue analgesia for breakthrough pain up to 6 hours after surgery. The carprofen group demonstrated the lowest mean GCPS score at all time points. There was no significant additive analgesic effect following combined buprenorphine/carprofen treatment. Dogs which received buprenorphine or combination analgesia required a lower induction dose of propofol, and experienced a quicker anesthetic recovery than dogs which received only carprofen. All animals were essentially pain-free by 24 hours after surgery (Shih et al., 2008). The duration of analgesic treatment required following orthopedic or major abdominal or thoracic procedures commonly used in biomaterials research is likely to be longer than the 24 hours required following ovariohysterectomy, and generally requires multimodal therapy for optimal control.

Pig

Animal Selection and Preoperative Preparation. Swine are commonly used in experimental surgery because of anatomic and physiologic similarity to humans in many models. Advantages to the use of pigs in the laboratory include low cost, ready availability, and ease of acclimation to the laboratory. Disadvantages include the uncooperative nature of pigs with respect to most clinical procedures, limited number of intravenous access sites, and relative difficulty of endotracheal intubation.

Because animals larger than 100 kg are difficult to handle in the laboratory, selective breeding has produced several types of miniature swine for research. The Gottingen minipigs and the Yucatan micropigs achieve a maximum bodyweight of 35–55 kg at 2 years of age. The Hanford and Yucatan minipigs are somewhat larger, and weigh 70–90 kg at 2 years of age. By contrast, adult crossbred farm pigs weigh 90–110 kg at 6 months of age, and 200–300 kg at 2 years of age (Bollen et al., 2000; Swindle, 2007). Juvenile crossbred farm pigs are less expensive than minipigs or micropigs, and are often used for short-term surgical studies. Juvenile farm pigs gain 2–4 kg/week and require larger pens as they grow, to maintain facility compliance with the Guide (National Research Council, 2010). The choice of research subject should include practical considerations such as length of study and maximum allowable body size, as well as the physiological characteristics of the different breeds (Bollen et al., 2000).

Careful evaluation of the vendor health program is required to reduce experimental morbidity from unrelated clinical conditions. Chronic respiratory disease is common in commercial swine operations. Although subclinical infections are common, transportation, anesthesia, and surgery may activate latent infections and result in excess morbidity and mortality. Causative agents

in affected pigs include *Mycoplasma hyopneumoniae*, *Haeomophilus pleuropneumoniae*, *Bordetella bronchiseptica*, and *Actinobacillus pleuorpneumoniae* (Straw et al., 2006). Many commercial breeders of laboratory minipigs and micropigs maintain specific pathogen-free (SPF) herds that are free from infection with these agents. Rapid infection with respiratory pathogens occurs when SPF pigs are cohoused with conventional swine.

Malignant hyperthermia (MH) is an autosomal dominant trait that causes affected animals to develop marked hyperthermia (rectal temperature >41°C), and extensor muscle rigidity and necrosis after exposure to environmental extremes or halothane or isoflurane anesthesia. The disease has been described only in farm animals bred for rapid growth, and is becoming increasingly rare as commercial breeders identify and cull carrier pigs. Affected pigs are still encountered sporadically in farm pigs used for experimental surgery. The condition has not been described in minipigs or micropigs. MH has not been reported in other commonly used laboratory animal species. Known MH carriers should not be used for experimental surgery. Treatment of animals which develop MH during an experimental procedure requires immediate termination of anesthesia, whole body cooling, and administration of corcticosteroids, sodium bicarbonate, and dantrolene sodium (3–5 mg/kg IV) (Swindle, 2007; Smith et al., 2008).

Food and contact bedding must be removed 6–8 hours prior to general anesthesia (Swindle, 2007). Water may be offered until 2 hours before anesthesia. The presence of food in the stomach frequently results in gastric distension, hypoventilation, and tachycardia during prolonged general anesthesia, requiring prompt decompression through orogastric intubation (Thurmon and Smith, 2007).

Brief Restraint. Pigs may be easily trained to accept handling for physical examination, blood collection through a vascular access port, and dressing changes. The acclimation period following arrival to the facility before study initiation is an appropriate training time. Uncooperative pigs may require chemical restraint for minor clinical procedures. Slings and hammocks are available which will allow restraint of calm pigs up to 50 kg for up to several hours (Swindle, 2007). The Panepinto sling was specifically designed for the veterinary practice and laboratory environments, and is easy to operate and sanitize. Sedation may be necessary to facilitate initial placement of animals into the sling. Azaperone (4 mg/kg IM) is a useful agent for this purpose. For more invasive procedures, a mixture of Telazol®(4.4–6.6 mg/kg IM), xylazine (2.2 mg/kg IM), and atropine (0.05 mg/kg) provides approximately 30 minutes of anesthesia suitable for minor surgery, followed by smooth recovery. Endotracheal intubation for subsequent maintenance on isoflurane is also possible after Telazol® and xylazine induction (Bollen et al., 2000; Swindle, 2007). Alternative agents such as ketamine, ketamine/xylazine or Telazol® produce light anesthesia insufficient for surgery

or intubation, and characterized by rough recovery (Ko et al., 1993, 1995).

Delayed recovery complicated by hindleg weakness may occur following Telazol®/xylazine administration in mature pigs, and is mediated by the zolazepam component of the proprietary Telazol® mixture. For this reason, many clinicians prefer to use a "cocktail" made by adding 2.5 ml of ketamine (100 mg/ml) and 2.5 ml of xylazine (100 mg/ml) to 1 vial of unreconstituted Telazol® powder. The resulting solution contains equivalent dissociative anesthetic potency to standard mixtures, with significantly less zolazepam, and is administered at a dose of 1 ml/35–75 kg IM (Thurmon and Smith, 2007).

General Anesthesia. Prolonged or invasive procedures are best conducted under isoflurane anesthesia. Endotracheal intubation is warranted for general anesthesia in swine to protect the airway and allow for controlled ventilation when required. Required equipment for endotracheal intubation of swine includes a laryngoscope with a 20–25 cm straight blade and a selection of cuffed tubes of appropriate size (4.5–8 mm). Endotracheal intubation is possible with the pig in dorsal, ventral or lateral recumbency. Two anatomic characteristics can complicate the procedure. First, the soft palate is long and must be displaced dorsally for visualization of the larynx. Second, the laryngeal diverticulum distal to the larynx may "trap" the tip of the endotracheal tube unless the tube is gently twisted as it passes over the epiglottis. After intubation, maintenance anesthesia usually requires an isoflurane vaporizer setting of 1.5%–2.5% in oxygen. The actual concentration of isoflurane will vary according to the anesthetic induction regimen, type of procedure, and concurrent use of other narcotic and sedative agents. Administration of Telazol® and xylazine for anesthetic induction has a substantial isoflurane-sparing effect that may last for the first 30–60 minutes of anesthesia. Adequate surgical anesthesia is indicated by absence of the pedal withdrawal reflex, minimal jaw tone, and stable heart rate and blood pressure (Thurmon and Smith, 2007; Smith et al., 2008).

Analgesia. Diagnosis of pain in swine may be challenging. Pain scoring systems reported by some investigators have not been validated in large-scale studies. Although an indirect measure, depressed appetite is the most consistent indicator of pain in postoperative pigs. In addition, pigs in pain generally exhibit impaired activity and depressed attitude compared to normal pigs.

Narcotics are commonly used postoperative analgesics in swine. Buprenorphine is the most widely used narcotic, because it provides excellent analgesia at a convenient dose interval with few side-effects. The fentanyl patch (5 µg/kg/hr) is effective in swine, and reduces the need to handle animals during the immediate postoperative period, when struggling may increase pain at the incision line or predispose to dehiscence. The 50 µg/hr patch produced therapeutic blood levels and clinically effective pain control for up to 48 hours in Yorkshire-cross

white female pigs (26.2 ±2.1 kg) following experimental thoracotomy. Control pigs receiving buprenorphine (0.10 mg/kg) also experienced adequate pain control, but exhibited higher pain scores and required treatment at 4–8 hour intervals. Fentanyl patches should be applied in the dorsal mid-scapular region to prevent accidental dislodgement and ensure consistent absorption (Harvey et al., 2000). Group-housed pigs may remove and consume patches applied to cage mates and develop acute narcotic overdose.

The NSAIDs are highly effective analgesics in swine. Carprofen (2 mg/kg SQ or PO q24h), meloxicam (0.4 mg/kg SQ q24h), and flunixin (1–4 mg/kg SQ or IM q24h) have been used as sole agents or in combination with opioid local anesthetics. Gastric irritation has not been reported following short-term use, but may be a concern in animals which require chronic therapy (Thurmon and Smith, 2007; Smith et al., 2008).

Sheep and Goats

Animal Selection and Preoperative Preparation. Sheep and goats are desirable research animals, because the adult body weight is comparable to humans and they are hardy, inexpensive, and have a calm disposition. Sheep are particularly useful for reproductive research because investigators may easily obtain cohorts of pregnant animals with known gestational age and hysterotomy, and fetal manipulation is possible with a low postoperative abortion rate. Cardiovascular research also uses sheep and goats because the ratio of the size and weight of the heart and other thoracic organs to body weight is similar to humans (Riebold, 2007).

The quality of sheep and goats used in research often depends on the source. Surgical and transportation stress will reduce resistance to disease. Vendors should avoid mixing multiple sources of animals in one flock to ensure a consistent health profile. Similarly, research institutions should use animals from a single vendor to reduce the possibility of introducing unfamiliar infectious agents to stressed animals. Preventive health measures, including immunizations and anthelmintic treatments, should be provided at least one month before shipment. Recommended immunizations for sheep and goats include *Clostridia spp.*, *Pasteurella multocida*, *P. hemolytica*, contagious ecthyma, and parainfluenza III. A conditioning and quarantine period after arrival allows recovery from shipping stress, acclimation to the facility, and reduces transmission of infectious diseases to resident animals (Delano et al., 2002).

Facilities should adopt measures to prevent transmission of zoonoses from sheep and goats. Silent infection with *Coxiella burnetti*, the causative agent of human Q fever, is common in sheep. Fetal membranes and amniotic fluid from infected animals carry large numbers of hardy organisms. Human infection occurs from direct contact with infected materials or from fomites. Signs of

Q fever infection in humans range from subclinical disease to severe flu-like symptoms, pneumonia, endocarditis, and death. Serologic evaluation of sheep is difficult because animals may shed large numbers of organisms in the absence of detectable antibody. Contagious ecthyma ("orf") is a poxvirus-induced papular disease of sheep and goats. Infected animals frequently have lesions on the mucocutaneous junctions of the head, which can spread to humans by direct contact. Affected animals and humans develop long-lasting immunity and usually recover in 10–14 days. Effective vaccines for sheep and goats are available (National Research Council, 1997).

Careful preoperative preparation of the rumen is required for safe anesthesia of sheep and goats. Adult animals require withdrawal of food and water for at least 12–24 hours before surgery to reduce rumen size and digestive activity. Rumen distension and hypoventilation are common when dorsal or lateral positioning of ruminants is required for anesthesia. Preoperative passage of a 1–2 cm diameter thick walled stomach tube into the rumen allows intraoperative aspiration of gas and fluid if required. Placement of a cuffed endotracheal tube should immediately follow anesthetic induction to prevent aspiration pneumonia. Aspiration pneumonia can be fatal after regurgitation because rumen fluid contains numerous anaerobic bacteria. Infant ruminants (<30 days of age) lack a functional rumen and do not require preoperative fasting (Riebold, 2007).

Brief Restraint. Sheep and goats are docile and rarely require sedation for blood sampling, dressing changes or other routine procedures. For more invasive procedures, animals may be sedated for 10–20 minutes with a low dose of xylazine (0.02–0.15 mg/kg IV or 0.05–0.3 mg/kg IM). Yohimbine (1 mg/kg IV) or atipamezole (0.02–0.06 mg/kg IV) (Muir, 2007) reverse xylazine-induced sedation when necessary. Research staff should be mindful of the much lower xylazine dose required for ruminants compared to other species. By contrast, the dose of medetomidine is similar in most laboratory animal species (30 µg/kg). Animals in late pregnancy should not receive xylazine to avoid fetal hypo-oxygenation secondary to depressed maternal cardiac output. The benzodiazepines diazepam (0.25 mg/kg IV) and midazolam (1.3 mg/kg IV) produce muscle relaxation and sedation in sheep and goats, with less depression of cardiac output than is seen with xylazine. Flumazenil (1 mg IV) reverses benzodiazepine-induced sedation. Ataxia and excitement are common following benzodiazepine administration (Riebold, 2007).

General Anesthesia. Isoflurane is the anesthetic of choice for general anesthesia of sheep and goats. Intravenous administration of ketamine (2.75 mg/kg) and diazepam (0.2 mg/kg) or xylazine (0.1 mg/kg) rapidly induces light anesthesia of 10–20 minutes duration suitable for endotracheal intubation. Propofol (4.0–6.0 mg/kg IV to effect) is a suitable alternative for brief procedures or to facilitate intubation and maintenance on isoflurane for

longer procedures (Riebold, 2007). In a study comparing propofol to ketamine/xylazine/halothane for subcutaneous biomaterial implantation, propofol recipients exhibited better cardiovascular and respiratory parameters than ketamine/xylazine/halothane recipients. These animals also demonstrated a more rapid and smoother anesthetic recovery (Lin et al., 1997). Thiopental (25 mg/kg IV) is an alternative induction agent; however, significant disadvantages include regurgitation, profuse salivation, and irritation from perivascular infiltration (Dorr and Weber-Frisch, 1999). Profuse salivation follows the administration of most anesthetic drugs in ruminants. Administration of anticholinergic drugs is *not* recommended in ruminants, because these agents may increase salivary viscosity and impair gastrointestinal motility. Anesthetized ruminants should be positioned with the head down to encourage drainage of saliva away from the airway (Riebold, 2007; Thurmon and Smith, 2007).

Endotracheal intubation requires a laryngoscope with a 20–30 cm blade. Vinyl or silicone cuffed tubes 10–16 mm in diameter are suitable for most sheep and goats. An assistant positions the animal in sternal recumbency, extends the neck, and holds the mouth open. The anesthetist visualizes the epiglottis with the laryngoscope and intubates the trachea during inspiration. Prior application of 2% lidocaine spray to the vocal cords prevents laryngospasm. The use of a stylet may help deflect the tip of the tube into the larynx. A mouth gag is often necessary to prevent damage to the tube by sharp molar teeth. After inflation of the cuff, the tube is secured with gauze to the mandible. Isoflurane vaporizer settings of 0.75–1.0% are often sufficient to maintain general anesthesia in sheep and goats. Absence of chewing motions in response to stimulation indicates an adequate surgical plane. The presence of a centrally positioned eyeball with a dilated pupil and absent palpebral reflex indicates very deep anesthesia (Riebold, 2007).

Analgesia. The NSAIDs are highly effective in small ruminants, and are recommended for first-line treatment unless scientifically contraindicated. Flunixin (1.1–2.2 mg/kg), ketoprofen (3.3 mg/kg), and carprofen (0.7 mg/kg) provide effective analgesia for up to 24 hours after dosing. When used at a dose of 4.0 mg/kg, carprofen provides therapeutic blood levels for at least 72 hours (Thurmon and Smith, 2007). All NSAIDs should be administered parenterally in small ruminants. The intravenous route is preferred for animals with severe acute pain, but the subcutaneous and intramuscular routes have been widely reported.

Opioid analgesics may be indicated as a supplement or as primary analgesics in some cases. The epidural space is easily accessed in small ruminants. Epidural morphine (0.1 mg/kg diluted in sterile saline) administered in the lumbosacral or sacrocaudal spaces provides up to 12 hours of analgesia (Riebold, 2007). The transdermal fentanyl patch (50 µg/hr) produces effective blood levels in sheep and goats for up to 72 hours. The dose rate is lower than otherwise expected for an animal this size, because of significant recirculation from the rumen to the bloodstream, bypassing hepatic detoxification pathways, and animals should be observed for excessive sedation or excitement (Valverde and Doherty, 2008).

A recent report demonstrated the superiority of transdermal fentanyl over parenteral buprenorphine in a multimodal analgesic regimen following experimental tibial osteotomy and locking compression plate placement in mature Polypay-cross ewes. The fentanyl group received transdermal fentanyl patches (2 µg/kg/hr) on the lateral antebrachium 12 hours before surgery. Control animals received buprenorphine (0.01 mg/kg every 6 hours beginning at anesthetic induction). All animals received the NSAID phenylbutazone (2.2 mg/kg IV every 24 hours) for 3 days beginning at anesthetic induction. Blinded observers evaluated the animals for pain every 12 hours for 72 hours, including a final observation 12 hours after patch removal or the last dose of buprenorphine. Fentanyl recipients required a lower dose of diazepam during anesthetic induction, and exhibited lower pain scores than buprenorphine recipients throughout the observation period, although no animals required rescue analgesia. The buprenorphine group exhibited an increased pain score 12 hours after the last dose of analgesic, suggesting possible rebound hyperalgesia (Ahern et al., 2009).

Ruminants are more sensitive to systemic effects of local anesthetics than other species. The mean fatal dose of lidocaine in sheep is 30.8 mg/kg, compared to 80 mg/kg in dogs, and seizures may occur following administration of 10 mg/kg. The maximum suggested dose of lidocaine for sheep and goats is 0.5 ml/kg of a 2% solution. For wide infiltration, 2% lidocaine may be diluted to 1%. Signs of systemic local anesthetic overdose include seizures, respiratory depression, bradycardia, hypotension, and collapse.

SUMMARY

Animal models are an invaluable resource in biomaterials research. Surgery is often required in biomaterials models. Animal welfare regulations in most countries require scientists to use animal models only when necessary, and use the minimum number of animals consistent with good experimental design. All necessary steps must be used to prevent and treat pain or distress associated with experimental manipulation.

CHAPTER II.3.7 LARGE ANIMAL MODELS IN CARDIAC AND VASCULAR BIOMATERIALS RESEARCH AND ASSESSMENT

Richard W. Bianco, Karen R. Wasiluk,
Jessica M. Voight, Matthew T. Lahti,
Andrew L. Rivard, and Robert P. Gallegos
Department of Surgery, University of Minnesota, Minneapolis, MN, USA

INTRODUCTION

The purpose of using animal models in preclinical evaluation of biomaterials is to provide a preliminary assessment of human safety and efficacy relative to the manufacturer claims and comparable technology that can be used as an appropriate control standard. Although absolute unequivocal results cannot be obtained regarding human safety and efficacy, use of animal models have long been employed and have positively effected changes that have resulted in improved health and increased longevity for humankind. The importance of preclinical investigation has been realized by many great investigators including Charles Darwin, who poignantly describes this link in a letter to a Swedish professor of physiology in 1881 (Darwin, 1959): "I know that physiology cannot possibly progress except by means of experiments on living animals, and I feel the deepest conviction that he who retards the progress of physiology commits a crime against mankind."

The development of new technologies, including *in vitro* methods and computer modeling, that has occurred in the last few decades has enhanced the approach to the study of physiology. However, the use of *in vivo* models still remains a necessity in investigations into certain physiologic phenomena, especially those related to the pathophysiologic mechanisms of disease, as *in vitro* studies are limited to the assessment of durability of the test material and hemodynamic performance. Traditional small animal models (e.g., rats, mice, guinea pigs, hamsters, and rabbits) have provided the scientific community access to physiological *in vivo* models to study mechanisms relating to human disease and basic biological processes. For the evaluation of cardiac and vascular biomaterials, however, investigations using larger domestic animals have proven to be more appropriate as these models incorporate anatomical and physiological characteristics more closely resembling those observed in humans. These similarities allow for the development of models where devices are implanted in a site intended for clinical use (i.e., site-specific), and allow for a more accurate prediction of the safety and clinical efficacy of either a bioprosthetic device or a biomaterial.

In this chapter, we will focus on three commonly used animal models for *in vivo* biomaterials research and testing in cardiac and vascular surgery: pigs; cows; and sheep. The chapter will begin with current recommendations for *in vivo* preclinical evaluation of cardiac and vascular devices, in both traditional and minimally-invasive settings, will continue with a short discussion on responsible use of animals in the assessment of biomaterials and biomedical devices, and will be followed by specific considerations and examples of existing animal models for each species. Finally, we will discuss conventionally-placed devices and percutaneously-placed devices, as well as potential future directions. Figure II.3.7.1 shows representative cardiac valves that are widely used clinically.

RECOMMENDATIONS FOR PRECLINICAL ASSESSMENT

The purpose of preclinical *in vivo* assessment is to provide an estimation of device safety (primary) and efficacy (secondary) in humans. This assessment is a mandatory requirement prior to the initiation of the next phase of device evaluation, namely clinical trials. The International Standards Organization (ISO), in conjunction with the American National Standards Institute, Inc. (ANSI) and the Association for the Advancement of Medical Instrumentation (AAMI), has defined regulatory requirements governing preclinical studies which are specific to cardiovascular valve prostheses (ANSI/AAMI/ISO 5840:2005 (AAMI, 2005)), and to cardiovascular implants and tubular vascular prostheses (ANSI/AAMI/ISO 7198:1998/2001/(R)2004 (AAMI, 2001)). These documents govern all aspects of evaluation, from the initial *in vitro* assessment to the final packaging requirements. These requirements must be reviewed and, if necessary, revised every five years to reflect the advancements in the rapidly evolving fields of biomaterial and bioprosthetic device development. In addition, these requirements also strive to meet the challenge of ensuring that compliant preclinical assessments provide an accurate correlation of *in vitro* and *in vivo* performance, as well as a basis for comparison with future clinical results.

The preclinical assessment of biomaterials and bioprosthetic devices is the final investigational step prior to human implantation, thus evaluation must ensure that the devices assessed will perform at least as well in humans as those bioprostheses currently in use. We will limit our discussion to the established standards for *in vivo* preclinical evaluation of cardiac valvular and tubular vascular prostheses, both those placed conventionally and those placed percutaneously. The standards that apply to the experimental methodology used in the investigation and the specific study criteria that must be met, as well as required results documentation, will be delineated. Following this, a short discussion on the future directions of these standards and the predicted impact these changes may have on the study of these types of devices will be presented.

CURRENT RECOMMENDATIONS

Cardiac Devices

Rationale. Safety assessment is the primary outcome of preclinical studies, with an emphasis on risk analysis in humans. Prior to clinical trials, all new or modified heart valve designs must be evaluated in a standardized, reproducible animal model. The evaluation must use adequate numbers of the experimental devices and concurrent controls implanted in a site-specific fashion, and must involve the use of risk analysis. Neither endpoints nor a defined animal model of preclinical assessment are specified in regulatory documents. Inherent in the preclinical assessment is an evaluation of the performance characteristics of cardiac devices, such as surgical handling characteristics, hemodynamic performance, and the development of valve-related pathology. Although it is not feasible to assess the long-term durability of a cardiac device using an animal model, valuable hemodynamic performance and biological compatibility data can be obtained. Additionally, *in vivo* testing may expose unanticipated side-effects of the device. ISO 5840 guidelines were developed to guide designers and investigators, and to ensure that new or modified cardiac valvular prostheses are assessed in a uniform manner.

Major changes between ISO 5840:2005 (AAMI, 2005) and its previous iteration, ISO 5840:1996 (AAMI, 1996), include:

1. Incorporating risk-based analysis and placing the responsibility on the manufacturer to continually evaluate both known and theoretical risks of the device;
2. Detailing best practice methods for verification testing appropriate to heart valve substitute evaluation;
3. Requiring a collaborative environment between the device developer and the regulatory body regarding safety and device performance; and
4. Outlining a system to assist a surgeon in selecting a device of appropriate size for placement in a patient.

Methods. Current regulatory requirements defined in ISO 5840 have been revised to specifically address risk analysis in devices representing major design or material changes, recognizing that such changes may result in dramatic (sometimes catastrophic) changes in performance and safety. The changes to guidelines call for expansion of study design to include a minimum of 10–15 experimental devices of clinical quality, with 2–4 concurrent control devices implanted in each clinically-intended surgical site, followed by subsequent comprehensive observation for at least six months. ISO 5840 requirements state that control devices must be clinically-approved devices of a design similar to that of the experimental device, and must be constructed from the same materials, which can be problematic in the case of a newer polymeric material. Minor modifications to devices (i.e., a sewing ring alteration) may involve a less rigorous assessment, as determined by risk analysis, although it is important to accurately distinguish between a major and a minor modification (see Box 1).

In all preclinical assessments, performance criteria must take into consideration animal–device interactions, individual biological variation, and the small numbers of devices implanted for evaluation. In addition, a complete pathological examination of all animals evaluated

In an effort to render a mechanical heart valve more resistant to endocarditis, the sewing ring was redesigned to include impregnation with antibiotics. During *in vivo* preclinical assessment, unexpected thromboses were observed with each valve tested (see Figure II.3.7.2), resulting in the failure of this modified valve to proceed to clinical trials. Risk analysis is a critical component of preclinical assessment, and no assumptions can be made as to the importance of any modification to a device. Although there is biological variability, especially given the relatively low numbers of animals, it is important to separate outcomes that are device-related from those that are the result of the animal model chosen. However, a catastrophic failure, such as this example, must result in a complete review of the *in vivo* testing results, and reassessment of the suitability of the animal model chosen.
FIGURE II.3.7.2 Example of a thrombosed mechanical valve in which a minor modification to the sewing ring resulted in an unexpected outcome of the preclinical assessment and failure of the valve.

must be performed by a veterinary pathologist to distinguish model versus device complications. It is sometimes difficult to completely separate the outcomes due to the device from model-related outcomes. The exception is when the assessment of a device results in catastrophic failure.

Further specifications require each animal in which a cardiac device has been implanted to undergo a postmortem examination. This ensures that data will be obtained from all animals; whether or not they survive for the suggested minimum time of six months. An evaluation of hemodynamic performance of the device during or after the implantation period must be performed. This assessment should include measurement of the pressure gradient across the implanted device at a cardiac index of approximately 3 L/min/m² to mimic human conditions. Additionally, an assessment of resting cardiac output and prosthesis regurgitation should be performed. A pathological evaluation of the study animals should also be performed, and should include an assessment of the major organs for valve-related pathology; an evaluation

for any device-related hematological consequences; and an assessment of any structural changes of the heart valve substitute.

ISO 5840 criteria for the evaluation in preclinical *in vivo* assessment are specific to acute or chronic settings, both of which provide valuable information. Acute settings focus on hemodynamic performance, ease of surgical handling, and acoustic characteristics of the implanted device. Chronic settings include the previously mentioned issues as well as hemolysis, potential thromboembolic complications, calcification, pannus formation/tissue ingrowth, structural deterioration and non-structural dysfunction, erosion caused by cavitation, and assessment of valve and non-valve related pathology (ANSI/AAMI/ISO 5840:2005, Annex G (AAMI, 2005)).

Previous ISO standards (ANSI/AAMI/ISO 5840:1996) relating to preclinical assessment of a device outlined requirements stating that at least six animals should be implanted with the experimental device or test article, and an additional two animals should be implanted with control devices for each assessment. A follow-up of at least six months was required for animals implanted with the test article which needed to include hemodynamic measurements, serial blood samples, and extensive pathological evaluation. No animal model was specified in the standards. These minimum requirements are rarely sufficient for adequate assessment of a bioprosthetic device, but may retain some value in the assessment of devices in which only minor modifications have been made, as long as concurrent controls are included and historical data is considered. The design of a preclinical assessment according to the updated regulatory requirements now must consider risk analysis, which is based on the device as well as the manufacturer claims attributed to it, and whether the device is novel or just an incremental modification of an existing device. Inherent in the risk-based approach outlined in the current ISO standards is encouragement for the manufacturer to strive for continued improvements in device design, as well as to ensure safety and efficacy of a device with less reliance on years of clinical assessment for verification of effectiveness.

Reporting. Documentation of results from preclinical evaluations is integral to this process and should be in the form of an official written report describing findings of the investigation in detail. This report should include the name of the institution(s) and investigator(s) involved in the study. A detailed description of the animal model used in the investigation, and the rationale for its use, should also be included. A pretest health assessment, including study animal age at the time of implantation, should also be included for each animal used in the study. A description of the operative procedure, including the suture technique, the orientation of the heart valve substitute, and any operative complications, must be detailed. Descriptions of any adjuvant procedures the animals underwent during the study period (e.g., phlebotomy, angiography) should also

be provided. The results of all blood tests, including a statement of the time elapsed between implantation and procurement of the sample should be provided. Blood tests should include an evaluation of the hematologic profile (with emphasis on hemolysis), and blood chemistries. Additionally, the report should include a subjective assessment of specific surgical handling characteristics of the device and any accessories. This assessment should include a discussion of unusual and/or unique attributes the device might possess. The report must contain a complete list of medications administered to the animals during the study period. Finally, the report should contain the results obtained from the hemodynamic studies to assist in the assessment of hemodynamic performance.

Pathologic documentation should include a gross and microscopic report on each animal in which a heart valve substitute was implanted, including any animal that did not survive the minimum post-implantation period. Documentation should include visual records of the heart valve substitute *in situ*, and evidence of any thromboembolic events occurring in the major organs. The cause of death of any animal that was not euthanized at the study endpoint must be investigated and reported. Detailed examination of the explant must be performed, with specific attention to any structural changes in the device. If appropriate, further *in vitro* functional studies of the heart valve substitute should be undertaken, such as hydrodynamic testing.

Pathologic assessment is crucial in the evaluation of the safety profile of the test device, and input from both a veterinary pathologist and a physician pathologist are ideal and necessary for the complete assessment of device safety. It is the role of the veterinary pathologist to decipher whether any pathologic findings are due to device malfunction or the inherent physiology of the animal. It is then the role of the physician pathologist to assess the *in situ* findings, and correlate them with a potential clinical performance in humans.

Vascular Devices

Rationale. As with cardiac devices, the purpose of *in vivo* preclinical testing of vascular prostheses is to evaluate the characteristics of a prosthetic that are difficult, if not impossible, to obtain using *in vitro* testing models. The capacity of the prosthesis to maintain physiologic function when used in the circulatory system, the biologic compatibility of the prosthetic, and the surgical handling characteristics of the prosthesis are all important features that can be evaluated using an *in vivo* model and cannot be obtained with *in vitro* testing methods. This testing is not intended to demonstrate the long-term performance of the prosthesis, but rather the short-term (less than 20 weeks) response and patency of the prosthesis being investigated.

Methods. In designing an experimental protocol that will ensure clinical relevance, researchers should consider the intended application of the device being studied, as well as the necessary diameter and length of the prosthesis. Additionally, investigators should reflect on any specific biological characteristics of the chosen animal model, and the impact of those characteristics on their conclusions. Current ISO requirements state that a rationale for the use of a particular species, the site of implantation, the selection of a control prosthesis, the method and interval of patency observations, and the number of animals used in each group being studied be provided. Each type of prosthesis shall have been tested by implantation at the intended, or at an analogous, vascular site in not fewer than six animals for not less than 20 weeks in each animal, unless a justification for a shorter-term study can be provided. A prosthesis must not be tested in the species from which it was derived, unless appropriate justification can be provided. Angiography or Doppler should be used to monitor the duration of patency for each prosthesis, and the results recorded. Each investigation should include a control group in which a clinically-approved vascular prosthesis is implanted and studied in the same fashion as the experimental prosthesis.

Preoperative data should include the sex and weight of the animal, documentation of satisfactory preoperative health status, and any preoperative medications. Operative data must include the name of the implanting surgeon and a detailed description of the surgical procedure, to include the type and technique used in performing the proximal and distal anastomoses. The *in situ* length and diameter of the prosthesis, in addition to any adverse intraoperative events (e.g., transmural blood leakage), must also be documented. Postoperative medications, patency assessments (method and interval from implantation), and any adverse event or deviation from protocol must be noted. Loss of patency before the intended study duration does not necessarily exclude the animal from the study population used to assess prosthetic function and host tissue response. Reports from all animals implanted with either test or control prostheses, including those excluded from the final analyses, shall be recorded. Termination data should include an assessment of prosthesis patency (documenting the method used), and an assessment of prosthesis explant pathology.

Reporting. At the conclusion of the study, a detailed report should be compiled in which the study protocol is delineated. The report should include: the rationale for selection of animal species; implantation site; control prosthesis; method of patency assessment; and the intervals of observation. Additionally, documentation of sample size and pertinent operative, perioperative, and termination data must be presented. The results should include the patency rates and any adverse event that was encountered during the study interval, and should be compared between the study and control groups. All animals entered into the study must be accounted for in the report. If data are excluded a rationale must be provided. A summary of the gross and microscopic

pathology, including photographs of the prosthesis *in situ* and micrographs, should also be provided. In addition to these objective results, a subjective statement of the investigator's opinion of the device must be included. Again, for this reason, it is important to include the input of a veterinary pathologist to decipher device malfunction from animal physiology, as well as a physician pathologist to correlate pathologic findings with potential clinical performance. Finally, conclusions drawn from the study and a summary of the data auditing procedures should be documented.

RESPONSIBLE USE OF ANIMALS

Introduction

As discussed in greater detail in Chapter II.3.6 of this book (Animal Surgery and Care of Animals), there are two basic principles governing the use of animals in research, education, and testing: (1) scientific reliance on the use of live animals should be minimized; (2) pain, distress, and other harm to laboratory animals should be reduced to the minimum necessary to obtain valid scientific data. Strict adherence to these basic ethical principles will not only enhance the quality of each *in vivo* preclinical evaluation, but will also ensure that current and future generations of scientists will be able to employ all valid tools available to predict clinical safety of either new or modified medical devices and other technology designed to improve human health.

Investigator and Institutional Responsibilities

When considering appropriate animal models for biomaterials research, the investigator and sponsoring institution should first assess their responsibilities with respect to federal, state, and local laws and regulations. Additionally, given the growing public and political sensitivity to the use of research animals, all laboratories using animals must recognize and comply with current definitions of humane animal care and use. The importance of this issue is reflected in a resolution adopted by the American Association for the Advancement of Science, February 19, 1990. This section briefly presents legal obligations and responsibilities of both the institutional administration's veterinary care program and the investigator, and provides some practical guidelines for responsible use of laboratory animals.

The Animal Welfare Act (Public Law 89-544, as amended) provides federal regulations governing laboratory animal care and use (Title 9 of the Code of Federal Regulations (CFR), Chapter 1, subchapter A: Animal Welfare, Parts 1, 2, 3) which are enforced by the Animal and Plant Health Inspection Service (APHIS), US Department of Agriculture. The Animal Welfare Act covers specific species including dogs, cats, non-human primates, guinea pigs, hamsters, rabbits, and "any other warm-blooded animal, which is used or is intended for use in research, teaching, testing, experimentation …" (9 CFR subchapter A, Part 1, Section 1.1). Species specifically exempt from the Animal Welfare Act include birds, rats, and mice bred for use in research, as well as horses and livestock species used in agricultural research. Institutions using species covered by the Animal Welfare Act must be registered by APHIS. Continued registration is dependent on the submission of annual reports to APHIS by the institution, as well as maintaining a satisfactory rating upon inspection of the institution's animal facility during unannounced site visits by APHIS inspectors. The Animal Welfare Act provides specifications for animal procurement (i.e., from licensed suppliers), husbandry, and veterinary care that are used to determine compliance with the Animal Welfare Act. The annual report supplied to APHIS should contain a list of all species and the numbers of animals used by the institution in the previous year. The animals listed in the annual report must be categorized by the level of discomfort or pain they were thought to experience in the course of the research, education or testing process they were used for.

In 1985 amendments were made to the Animal Welfare Act (7 U.S.C. 2131, *et seq*.) and ultimately implemented on October 30, 1989, August 15, 1990, and March 18, 1991. These amendments extended the Act to require institutions to perform administrative review and provide a mechanism to control animal research programs (Federal Register, Vol. 54, No. 168, pp. 36112–36163; Vol. 55, No. 36, pp. 28879–28881; Vol. 56, No. 32, pp. 6426–6505). Specifically, the new regulation requires that all animal research protocols be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) before the initiation of the study. Furthermore, the submitted protocols must state in writing that less harmful alternatives were investigated, with justification as to why those methods are not suitable, and that the proposed research is not unnecessarily duplicative. Additional requirements increase the scope of husbandry requirements for laboratory dogs and non-human primates.

The other relevant federal body is the National Institutes of Health (NIH). The Health Research Extension Act of 1985 (Public Law 99-158) required the director of NIH to establish guidelines for the proper care of laboratory animals, and gave IACUC oversight of that care. Broad policy is described in the Public Health Service Policy on Humane Care and Use of Laboratory Animals (NIH, 2002), which identifies the Guide for the Care and Use of Laboratory Animals (NIH, 1985a) as the reference document for compliance. This policy applies to all activities involving animals either conducted or supported by the US Public Health Service (PHS). An institution cannot receive funding from the NIH or from any other PHS agency for research involving the use of animals, without a statement of assurance on file with the PHS Office for Protection from

Research Risks (OPRR) ensuring compliance with these guidelines.

As required by the Animal Welfare Act, PHS policy mandates that each institution provide an annual update on animal research use and IACUC review of animal protocols and facilities to be submitted to the Office of Laboratory Animal Welfare (OLAW) within the NIH. Unlike the Animal Welfare Act, however, the PHS policy covers all vertebrate species, does not include an enforcement arm for routine inspections (but does provide for inspection in cases of alleged misconduct), and penalizes noncompliant institutions by withdrawing funding support.

State and local laws and regulations may also affect animal research programs. This legislation imposes restrictions on the acquisition of cats and dogs from municipal shelters. Within the past decade several states have also enacted registration and inspection statutes similar to the Animal Welfare Act. In several states, court rulings have required IACUC reports and deliberations at state-supported institutions to be conducted in public (e.g., Florida, Massachusetts, North Carolina, and Washington).

Housing and Handling

The physical and psychological well-being of laboratory animals is determined in large part by their environment. Careful attention to housing and handling of any investigational animal is crucial to avoid improper handling or care which may result in exposure of the animal to undue stress. The Institute of Laboratory Animal Resources of the National Academy of Sciences publishes a detailed guide with specific recommendations for the housing of many laboratory animal species (*Guide for the Care and Use of Laboratory Animals*, Commission on Life Sciences, 2011). Adequate assessment of available facilities and their compliance with these regulations must be considered an essential component of any animal investigation. This assessment should be done not only for regulatory affairs compliance, but also for scientific accuracy, as data obtained from subjects that are not cared for properly may be inaccurate.

Euthanasia

In addition to housing and handling, investigators must become familiar with the methods appropriate to the practice of humane euthanasia techniques. Indications for the application of euthanasia in a study include such inviolable situations such as: (1) study protocol completion; or (2) undue suffering of an individual study subject that may be displaying cachexia, anorexia or a moribund state. In this phase of the investigation, as in all other phases of an animal investigation, great care should be taken to avoid subjecting the animal to undue stress. Humane euthanasia techniques used should result in rapid unconsciousness followed by cardiac and respiratory arrest. The 1993 Report of the American Veterinary Medical Association (AVMA, 1993) provides descriptions of acceptable techniques for euthanasia, and is an invaluable resource for investigators in the process of designing and performing a study; the most recent revision of these guidelines was in 2007, with a minor update in 2009 (AVMA, 2007; Nolen, 2009).

ANIMAL MODELS AND SPECIES CONSIDERATION

Choice of an Appropriate Animal Model

In determining which model is most appropriate for an *in vivo* assessment to best evaluate the likely human response to the device, it is first necessary and most important to outline the clinical goals of the bioprosthetic test device and choose the animal model that has been shown to permit control of the greatest number of variables. The closer the *in vivo* assessment parallels a clinical situation, the more clinically applicable are the results of the assessment. That being said, the sheep is often the superior model in cardiovascular research, as it is relatively easy to control many variables. In addition, the physiological parameters of sheep often approximate the human condition, especially with respect to thrombogenicity. In contrast, swine tend to be exquisitely sensitive to exogenous anticoagulation therapy in an unpredictable fashion. In our experience, when anticoagulation therapy is utilized in swine, the results generated are a series of anecdotes that relate more to each individual animal's differing level of thrombogenicity, rather than to a herd response to a device. If anticoagulation therapy is necessary, it is most important to consider the entire herd of test and control subjects, and dose them with equal amounts of anticoagulation therapy so that any effect this may have on the study outcome will be demonstrated in each of the animals. However, an ideal study protocol should incorporate no anticoagulation therapy for any animal, because it naturally crafts a more aggressive assessment of the test device and there is no need to address the variable effect of anticoagulation therapy in each animal. In general, although representative drugs and dosages may be stated in this chapter, the investigator with direct responsibility for animal studies is well advised to consult an experienced veterinarian for selections and dosages of drugs, as practice may change over time and unforeseen complications may arise.

Canine

The history of the use of canines in experimental surgery is extensive. Early experimental surgery required an animal model that was inexpensive, readily available, and easily managed. The solution to this problem came in the form of mongrel dogs. Dogs could be obtained from pounds inexpensively and were often familiar with humans.

Cardiopulmonary bypass, coronary artery bypass, and early valve studies were all developed primarily with the canine model. The evaluation of artificial heart valves began in the 1950s, using a canine model and valves created from materials such as polyurethane (Akutsu et al., 1974; Doumanian and Ellis, 1961). The canine model is suitable for testing both synthetic and biosynthetic vascular grafts used for coronary artery bypass. The canine model represents the gold standard for *in vivo* models of coronary artery bypass, and offers several advantages including: (1) a large historical database for comparison; (2) ease of cardiopulmonary bypass; and (3) the availability of autologous saphenous vein for grafting allows researchers to easily perform positive controls.

Interestingly, few studies involving PCI (percutaneous coronary intervention) for stent placement have been performed using this gold standard model (Schatz et al., 1987; Roubin et al., 1990). Because of the recent shift away from the canine as a model for chronic device evaluation, the current standard uses a swine model. Overall, the canine model has provided a long history of significant contributions to our understanding of cardiovascular physiology, and to the development and testing of cardiovascular biomaterials and devices. In more recent times, there has been a shift away from the canine model for many studies, because of public concerns and rising animal costs. Today, the emotional import of using canines for research has prohibitively increased their cost, and society no longer deems dogs appropriate for chronic studies. As a result, models using other large domestic animals have become widely used for ongoing biomaterials research.

Swine

Introduction. It is believed that the majority of the breeds of swine we now know are descended from the Eurasian wild boar (*Sus scrofa*). Archaeological evidence from the Middle East indicates domestication of the pig occurred as early as 9000 years ago, with some evidence for domestication even earlier in China. From here, the domestic pig spread across Asia, Europe, Africa, and ultimately North America (Towne and Wentworth, 1950; Mellen, 1952; Clutton-Brock, 1999a). Today, swine serve many purposes in society, ranging from food source and pets to biomedical research subjects. In this latter role, swine have proven useful during the past four decades in studying a variety of human ailments, including cardiovascular (Ramo et al., 1970; Cevallos et al., 1979), gastrointestinal (Kerzner et al., 1977; Leary and Lecce, 1978; Pinches et al., 1993), and hepatic diseases (Mersmann et al., 1972; Soini et al., 1992; Sielaff et al., 1997). Studies in swine have also provided extensive information in the areas of organ transplantation (Calne et al., 1974; Marino and De Luca, 1985; Grant et al., 1988; Al-Dossari et al., 1994; Granger et al., 1994).

Multiple authors have reported advantages of using swine in large animal models for biomedical research including, but not limited to, anatomic and physiologic similarities to humans, low cost, availability, and the ability of swine to produce large litters of hearty newborns (Stanton and Mersmann, 1986; Swindle, 1992; Tumbleson and Schook, 1996; Swindle, 2007). In addition, naturally occurring models of human disease (e.g., atherosclerosis) can be found in various strains of swine, making them ideal candidates for the study of these disease processes. Also helpful to investigators using swine is a large body of agricultural literature in the areas of swine nutrition, reproduction, and behavior that may have applications in biomedical research. For all these reasons, the use of swine has become increasingly popular in the biomedical research laboratory.

Comparative Anatomy and Physiology

Swine are the single readily-available species in which cardiovascular anatomy and physiology most closely resembles those in humans, likely because of a similar phylogenetic development that led to an omnivorous species with a cardiovascular system that has accommodated to a relative lack of exercise (McKenzie, 1996). The heart of an adult swine weighs 250–500 grams and comprises approximately 0.25% of the body weight (Ghoshal and Nanda, 1975), similar to that of humans. The coronary vasculature of a pig heart is nearly identical to that of humans in anatomic distribution, reactivity, and paucity of collateral flow (Hughes, 1986). The right and left coronary arteries are similar in size to each other. The left coronary artery supplies the greater part of the wall of the left ventricle and auricle, including the interventricular septum, by means of its circumflex and paraconal interventricular branches. The right coronary artery supplies the wall of the right ventricle and the auricle via its circumflex and subsinuosal branches (Ghoshal and Nanda, 1975). These similarities make swine ideal for studies of both ischemia/reperfusion and coronary stent technology.

There are certain cardiovascular anatomic differences between swine and humans that must be considered when using swine as investigational subjects. First, the left azygous vein drains directly into the right atrium in swine, compared to drainage into the brachiocephalic vein in humans (Ghoshal and Nanda, 1975). Second, there are only two arch vessels coming off the aorta in swine. The most proximal of these is the brachiocephalic trunk, which gives rise to the right subclavian and a common carotid trunk that bifurcates into the right and left carotid arteries. The second arch vessel is the left subclavian artery (Ghoshal and Nanda, 1975).

Electrophysiological parameters of pigs more closely resemble those of humans than any other non-primate animal. These parameters include similar P- and R-wave

amplitudes, P–R intervals of 70–113 msec (longer in older animals), mean QRS duration of 39 msec, a Q–T interval of 148–257 (again longer in older animals), as well as ventriculoatrial (V–A) conduction when the right ventricular endocardium is stimulated faster than normal sinus rate (Hughes, 1986). These similarities make the pig a good model for studying pacemakers. Some investigators have found swine to be highly susceptible to ventricular arrhythmias, often requiring prophylactic

pharmacologic protection (i.e., lidocaine, flecainide or bretylium). Alternatively, other investigators have exploited this ventricular instability to study "induced" tachyarrhythmias, and the pharmacologic agents and/or electrical interventions used in their management (Hughes, 1986).

Physiologically, swine have hemodynamic and metabolic values that are similar to those of humans (Tables II.3.7.1 and II.3.7.2). They also share similar

TABLE II.3.7.1	Hemodynamic Values of Species Used to Evaluate Cardiac and Vascular Bioprostheses			
Hemodynamic Values	Bovine	Swine	Ovine	Human
Heart rate (beats/min)	119 ± 27	105 ± 10	95 ± 24.2	70 ± 14
Mean arterial pressure (mm Hg)	117 ± 18	102 ± 9	70 ± 24	95 ± 11
Systolic pressure (mm Hg)	137 ± 9	127 ± 8	85 ± 3	126 ± 14
Diastolic pressure (mm Hg)	108 ± 15	86 ± 7	58 ± 15	79 ± 10
Stroke volume (ml/beat/kg)	91.5 ± 23.3	1.34 ± 0.26	1.03 ± 0.78	1.14 ± 0.31
Cardiac index (ml/min/kg)	113 ± 42	99 ± 19.9	115 ± 30.8	93 ± 20
Systemic vascular resistance (dyn sec cm^{-5})	1168.5 ± 176.1	2759 ± 70	1463 ± 183	1200 ± 600
Pulmonary vascular resistance (dyn s cm^{-5})	73.3 ± 51.2	441 ± 62	180 ± 53	120 ± 30
Resting total O_2 consumption (O_2/min/kg)	Unknown	6.6 ± 1.27	6.7 ± 3.0	3.9 ± 1.9

Values represent mean ± standard deviation.

pulmonary function parameters, such as respiratory rate and tidal volumes (Willette et al., 1996). Although they have lower levels of hemoglobin, circulating red cell volume, arterial oxygen saturation, and markedly lower venous oxygen saturations, they have similar platelet function and lipoprotein patterns. Other physiologic characteristics that may play a role in experimentation include a higher core body temperature, a contractile spleen that sequesters 20–25% of the total red cell mass, very fragile arteries and veins, a higher plasma pH, and a higher plasma bicarbonate level. Swine also have 50% more functional extracellular space than humans, and a slightly increased volume of total body water (Swindle et al., 1986; Hannon et al., 1990). However, individual swine test subjects tend to be more sensitive to anticoagulation therapy. Thus, if anticoagulation is utilized during the procedure, each animal will likely require a different dosage of anticoagulation, resulting in a series of individual anecdotes that are not easily summarized or generalized.

Perioperative Care

Anesthesia. Swine should be fasted at least 12 hours prior to the induction of anesthesia, longer if one desires the large bowel to be empty prior to surgery. Unless gastric surgery is to be performed, the animals may be given water without restriction. It is common to administer an intramuscular (IM) pre-anesthetic agent followed by an intravenous (IV) anesthetic agent after IV access has been obtained. IM injections can safely be administered in the neck just behind the ear, in the triceps muscle of the forelimb or in the semimembranosus–semitendinosus muscles of the hindlimb. IV access is most commonly obtained in the lateral auricular veins (Riebold and Thurmon, 1985; Swindle and Smith, 1994; Swindle, 1994; Smith et al., 2008). The pre-anesthetic/anesthetic protocol used in this laboratory involves the administration of an IM injection of a combination drug (Telazole) consisting of a dissociative anesthetic and a tranquilizer (tiletamine and zolazepam) at a dose of 2–4 mg/kg for sedation. Following this, IV thiopental sodium (6–25 mg/kg) is administered if necessary. Endotracheal (ET) intubation follows and anesthesia is maintained via inhaled isoflurane (1–2 volume %). Commonly used anesthetics, doses, and routes of delivery are given in Table II.3.7.3.
Analgesia. Postoperative analgesia is a very important component of any animal experiment. Appropriate use of postoperative analgesia involves rapid recognition of discomfort and appropriate therapy. When in pain or distress swine will demonstrate changes in social behavior, gait, posture, and a lack of bed-making. Most swine will become very reluctant to move when in pain and, if forced to move, will vocalize with even greater enthusiasm than they generally display (Gross, 1994). Buprenorphine is currently the analgesic of choice used in swine, effective when administered at 0.05–0.1 mg/kg

every 8–12 hours (Swindle and Smith, 1994; Swindle, 1994). Standard narcotics such as morphine and fentanyl are effective pain relievers, but have a very short half-life in swine. Additional analgesic agents are listed in Table II.3.7.4.

EXISTING MODELS

Cardiac Devices

Orthotopic valve replacement in large animals is an important component of preclinical prosthetic valve assessment for the initial evaluation of surgical handling characteristics, hemodynamic performance, and valve-related pathology. Early investigators using swine for cardiovascular research described difficulties with venous access (Swan and Piermattei, 1971), anesthesia (Piermattei and Swan, 1970), cardiopulmonary bypass (Swan and Meagher, 1971), and several anatomic peculiarities (Swan and Piermattei, 1971). Subsequently, cardiovascular surgical procedures using swine have become technically feasible, and several investigators have conducted acute and chronic studies for the assessment of hemodynamic profiles of cardiac prostheses (Hasenkam et al., 1988a,b, 1989; Hazekamp et al., 1993). However, only a few long-term swine studies have been performed to examine the potential of prosthetic heart valve implants for thrombogenicity (Gross et al., 1997; Henneman et al., 1998; Grehan et al., 2000).

It has been reported that heart valve replacement in swine requires certain measures not needed with other species. These include the use of a crystalloid prime without plasma volume expanders (especially starch-based), prophylactic administration of pharmacological protection against ventricular arrhythmias, insurance of adequate hypothermic cardioprotection during the time of cross-clamp, administration of "shock" doses of corticosteroid just prior to reperfusion, and the use of inotropic support during bypass weaning (Gross et al., 1997). In our experience, (see later discussion) however, we have found some of these precautions unnecessary for the successful use of the pig in the evaluation of cardiac prostheses.

In our investigation, 22 swine underwent mitral valve replacement with no operative deaths. All animals were weaned from cardiopulmonary bypass without inotropic assistance. No cardioplegic protection was used, and only mild total body hypothermia was instituted. Pathologic analysis of valves explanted from animals surviving more than 30 days demonstrated extensive fibrous sheath formation leading to valve orifice obstruction and restriction of leaflet motion in a significant number of animals. The extensive fibrous sheath formation (and subsequent valvular dysfunction) represents a chronic tissue response observed in many species following mitral valve replacement. This chronic tissue response, however, was noted to have developed sooner in swine

TABLE II.3.7.3	Anesthetics and Sedatives Acceptable for Use in Species Used to Evaluate Cardiac and Vascular Biomaterials							
	Dose/kg			Route of Delivery

than in our previous studies involving prosthetic valve implantation into other species (i.e., sheep). Additionally, we did not find this model to be useful in predicting device-related thrombogenicity, as there were no clinical or pathologic differences observed among the valve designs studied (Grehan et al., 2000). The utility of swine in predicting the thrombogenic potential of cardiac valvular prostheses is therefore limited.

Improved biotechnology has brought left ventricular assist devices (LVAD) into the clinical arena as a bridge to transplantation therapy for patients with end-stage cardiac disease or those suffering from acute myocardial infarction (Frazier et al., 1992; Oz et al., 1997; Park et al., 2000). Clinical observations of patients who have received LVAD have revealed that these patients have a propensity for developing right ventricular dysfunction. To study this phenomenon, a model of iatrogenic congestive heart failure (CHF) using seven days of rapid pacing to induce cardiomyopathy has been developed in swine (Chow and Farrar, 1992). This model has been used to investigate the hemodynamics and septal positioning of the assist devices that may contribute to right ventricular dysfunction (Chow and Farrar, 1992; Hendry et al., 1994).

Vascular Devices

Initially, the pig was developed as a model to study solid organ transplantation. However, more recently its use has made an impact on the study of vascular disease. The pig is currently the species of choice for *in vivo* evaluation of vascular stents, restenosis biology, and balloon injury. The advantages of using swine include: (1) easy access to coronary arteries with present catheterization and angioplasty techniques; (2) coronary arteries of sufficient size for catheters used in adult humans; (3) balanced coronary circulation that is anatomically similar to humans; (4) spontaneous development of atherosclerosis; and (5) comparable coagulation and fibrinolytic systems and lipid metabolism to humans (Fritz et al., 1980; White et al., 1989; Karas et al., 1992; Willette et al., 1996).

Numerous *in vitro* studies indicate that the coagulation and fibrinolytic systems in swine closely resemble those of humans (Wilbourn et al., 1993; Karges et al., 1994; Reverdiau-Moalic et al., 1996; Gross, 1997), which would suggest that this may be the ideal species for the preclinical evaluation of the thrombogenic potential of a prosthetic device. *In vivo* studies specifically looking at the thrombogenicity of implantable devices, both cardiac and noncardiac, have already been performed in swine (Rodgers et al., 1990; Walpoth et al., 1993; Scott et al., 1995). Previous *in vivo* studies of artificial valves identified a relationship between postoperative thrombus formation and bacteremia. Other significant factors impacting survival include a combination of preoperative antibiotics, postoperative anticoagulation, short bypass times, and aseptic blood sampling techniques (Bianco et al., 1986). Table II.3.7.5 outlines various antibiotics used in cardiovascular *in vivo* studies and their suggested dosing regimens.

Similar investigations have shown that stent thrombosis may occur early in swine *in vivo* models (within 6 hours of implantation), suggesting that if a pig survives the first 12 hours (coronary stent remains patent), it is highly likely that it will not suffer a stent occlusion later (Schwartz and Holmes, 1994). Observations of such rapid restenosis led Schwartz and Holmes to suggest that the pig should be used as an accelerated thrombotic model capable of predicting stent thrombosis within hours of implant (Schwartz and Holmes, 1994). Stenting or balloon inflation in the swine model leads to intimal smooth muscle cell proliferation that closely resembles the cell size, density, and histopathological appearance of that seen in human restenosis (Karas et al., 1992; Bonan et al., 1996; Willette et al., 1996). Additionally, as in humans, there is a predictable relationship between vascular injury and restenosis (i.e., more neointima is formed with deeper lesions) (Willette et al., 1996; Jordan et al., 1998).

Although investigation of stents and balloon injury has mainly been done using coronary arteries (Karas et al., 1992; Bonan et al., 1996; Willette et al., 1996), studies using other arteries, such as the iliacs, have also been performed (White et al., 1989). Swine have also been used to study the feasibility of percutaneous repair of abdominal aortic aneurysms (AAA). Jordan et al. (1998) developed an AAA model using rectus abdominus fascia, and demonstrated prolonged survival in stented AAA in comparison to unstented controls. Unfortunately, this AAA model did not accurately mimic aneurysms seen in humans, as the AAA created was saccular and did not reproduce the geometric configuration or collateral circulation and back bleeding observed in human disease (Jordan et al., 1998). Whitbread et al. (1996) created an AAA model in swine by interposing fusiform segments of glutaraldehyde-treated bovine internal jugular vein into the infrarenal aorta. This resulted in a pulsatile, nonthrombogenic AAA that approximates human dimensions (20 mm) and geometry (fusiform) (Whitbread et al., 1996). Both AAA models have been used to develop stents and stent placement technology with the goal of reducing the pulsatility and diameter of the aneurysm while maintaining location of the stent without occluding nearby vessels.

Swine models have become useful and popular to study biomaterials and the devices manufactured from these materials. Anatomic and physiologic similarities to humans have made swine the species of choice to study many cardiac and vascular prostheses, especially in acute studies looking at hemodynamic profiles of different devices. However, difficulties with husbandry and species temperament, and a rapid rate of somatic growth, have made swine less desirable as models for the chronic evaluation of devices in our experience.

TABLE II.3.7.5 | Antibiotics Acceptable for Use in Large Animal Models

Drug Name	Dose/kg			Frequency[a]	Route of Delivery[b]

Bovine

Introduction. There are many species of cattle which are generally bred as livestock for meat and dairy production, as well as draft animals. Cattle have long been domesticated since Neolithic times as a distinct species as the genus *Bos*, and are often hybridized between closely related species. Cattle are raised in herds and graze in large areas of grassland or in feedlots. Cattle are of moderate intelligence and vocalize occasionally with a characteristic lowing sound, bawling or bellowing. The animals are usually mild mannered, slow moving, usually cooperative, and can be controlled behaviorally by education or with barriers.

Aside from antibody production, the cow is not often used in biomedical research, because of their size and husbandry needs. The cow's ability to produce milk is a potential source for genetically engineered proteins; that, however, remains ethically controversial. The calf has been used in cardiovascular research for both ventricular assist device testing and valve implantation. Ventricular assist devices are generally too large to be tested with smaller animals such as the dog, and pigs are not cooperative enough.

Comparative Anatomy and Physiology

Interestingly, the bovine genome has been recently mapped with about 80% of the genome similar to that of humans, despite obvious phenotypic differences. Cattle are ungulates and ruminants with a four-compartment stomach for digestion. Microbes in the rumen decompose cellulose into carbohydrates and fatty acids, and synthesize amino acids from urea and ammonia. The gestation period for a cow is nine months and a newborn calf weighs about 25–45 kg.

The bovine heart comprises 0.4%–0.5% of the body weight, which in the adult weighs about 2.5 kg. Aside from the normal mammalian structure of the heart, the bovine heart differs in that the great cardiac vein drains directly into the azygos. A semilunar valve (Thebesian valve) at the margin of the azygos and right atrium allows for unidirectional coronary venous flow. As the calf grows older, two bones called the *ossa cordis* develop in the fibrous aortic ring at the attachments of the right and left semilunar cusps. The bovine aortic arch consists of a common trunk that symmetrically branches into the right and left brachiocephalic arteries, supplying the head and upper extremities.

The bovine ventricles lend a conical appearance to the apex, with both an anterior and posterior interventricular groove, as well as an intermediate lateral groove for vessels. The left auricle is larger than the right atrial appendage. The left coronary artery is also larger than the right. The left coronary artery divides into the paraconal interventricular and circumflex branches. The circumflex artery courses in the coronary groove under the cardiac vein, and gives off a prominent subsinuosal

interventicular branch which descends to the apex. The interventricular artery descends anteriorly to anastomose with a branch of the subsinuosal. As mentioned above, the right coronary artery is smaller than the left and lies in the right coronary groove covered by the right atrial appendage and terminates in small branches that anastomose with the subsinuosal interventricular artery.

Rheologic conditions are altered with different velocities of blood flow and blood stasis in animals following implantation of cardiac devices. As one of the fundamental homeostatic mechanisms of mammalian biology, the blood coagulation system establishes a delicate balance between the procoagulant and anticoagulant functions of blood and the vessel wall, thereby guarding against excesses in either direction and normally preventing unwanted hemorrhage or thrombosis. Despite all efforts to achieve effective anticoagulation, the risk of thromboembolic events is still approximately 30% in humans. The main reason for clot formation is the contact between blood components and foreign surfaces. System components induce a cascade of interacting proteases, accelerating steps that provide amplification, a variety of balanced feedback controls, and, most importantly, tightly regulated activation. Unfortunately, the range of biocompatibility assays for the evaluation of blood contacting materials is limited using the bovine model. Recent reports to quantify bovine circulating activated platelets have been developed using the monoclonal antibodies to BAQ125, GC5, and annexin V (Baker et al., 1998; Snyder et al., 2002). Additional assays to quantifying bovine platelets which have human analogs are now possible using platelet-expressing CD62P and CD63. CD62P (p-selectin, platelet activation dependent granule external membrane protein (PADGEM), granule membrane protein-140 (GMP-140)) and CD63 (lysosomal-membrane-associated glycoprotein 3 (LAMP-3), granulophysin, LIMP, PLTGP40, gp55) are both expressed on the surface of platelets following activation and degranulation (Snyder et al., 2007).

Perioperative Care

Anesthesia. Calves should be fasted for 12–18 hours preoperatively to decrease the likelihood of regurgitation during the induction of anesthesia and ET intubation. Typically, a sedative is administered IM to allow easy and safe placement of IV catheters for controlled administration of medication. Several sedatives are useful in the pre- and postoperative periods to aid in animal handling and for performing minor procedures (Table II.3.7.3). A common protocol uses ketamine, 10 mg/kg IM as a pre-anesthetic sedative. Anticholinergics or parasympatholytics, especially atropine, have been used on induction of anesthesia to decrease salivary and respiratory tract secretions. Table II.3.7.3 lists the recommended dosing of such agents. Once the sedative has taken effect, IV catheters can be easily introduced into the external jugular,

cephalic or saphenous veins. Following placement of a secure IV catheter and the administration of short-acting relaxing agents (Table II.3.7.3), ET intubation can be safely performed using standard cuffed ET tubes 10–16 mm in internal diameter. Placement of the orogastric tube typically follows ET intubation. Orogastric intubation is especially important if preoperative fasting does not occur. The endotracheal tube can then be connected to a conventional anesthetic ventilator to maintain a deep plane of anesthesia. Preferred inhalation anesthetics for bovine are halothane (1.5–2.5%) or isoflurane (1.5–3%). **Analgesia.** Calves are stoic and it is uncommon for them to vocalize when they are in pain. A reluctance to move, favoring the procedural site, excessive licking or scratching of the site, kicking, lack of appetite, and/or a depressed attitude are behaviors that may indicate a calf is experiencing pain. Scheduled medication administration and periodic evaluation of behavior can help to ensure adequate pain relief. Commonly used analgesics include narcotics administered via a subcutaneous, IV or epidural route. Nonsteroidal anti-inflammatory agents can be used in divided doses for additional analgesia. Table II.3.7.4 lists recommended dosing of additional analgesics.

EXISTING MODELS

Cardiac Devices

The calf model was first used extensively in cardiovascular research in the 1980s for the purpose of calcification studies (Schoen et al., 1985; Dewanjee et al., 1986a,b). A review of the current literature reflects diminished utilization of this model, accounting for only 6.5% reported animal studies, primarily because it shares many of the limitations noted with the pig model Figure II.3.7.3. A major limitation for chronic survival studies is the rapid somatic growth of the calf, contributing to both anatomic and hemodynamic alterations that undermine the validity of long-term follow-up studies. The rapid somatic growth in the calf is associated with dramatic elevation in cardiac output, well above the maximum observed in humans. In fact, if the bovine model were used for a standard six-month trial, the cardiac output (CO) would be expected to be nearly three times greater than that of the adult human at the end of six months.

Anatomically, the calf valve annulus is larger than that of humans (Tables II.3.7.1 and II.3.7.6) (Gallegos
Valve type	Total	Total number of subjects in study					
		Sheep	**Pig**	**Calf**	**Dog**	**Goat**	**Primate**
Tissue (stented and stentless)	591 (58.4)	495 (83.7)	47 (7.9)	12 (2.0)	29 (4.9)	5 (0.8)	3 (0.5)

et al., 2005). Therefore, implantation of a prosthetic valve of a size that would be typically utilized in an adult human would result in patient prosthesis mismatch if placed in the calf aortic position. The result of patient prosthesis mismatch produces outflow obstruction, with valves sized for clinical relevance, and any additional growth may contribute to paravalvular leak development, as was observed in the pig model (Linden et al., 2003). It is well-known that a valve's effective orifice area (EOA) significantly impacts on the incidence of heart failure symptoms, adverse cardiac events, preoperative mortality, LV impairment, and is associated with short- and long-term mortality (Pibarot et al., 1998; Pibarot and Dumesnil, 2000, 2001; Blais et al., 2003). Indeed, this was actually reported in a bovine valve study whereby a majority of calves were actually in heart failure, given that the mean CO was only 12 ± 6 l/min with the study valve in place, when the expected normal value would be in the range of 18–20 l/min, based on animal weight and study duration (see Table II.3.7.6). Unfortunately, the calf model is not an ideal animal for testing prosthetic valves in a preclinical setting, because of the growth that causes an inherent patient prosthesis mismatch.

On the other hand, the bovine model is the most commonly used model for ventricular assist devices (Litwak et al., 2008). Calves are used in preclinical studies to provide information about the function, biocompatibility, and efficacy of ventricular assist devices (VAD). The VAD is a blood pump system designed to palliate severe congestive heart failure, and is a system composed of inflow and outflow cannnulae, connectors, and controllers. The blood contacting surfaces are procoagulant and activate blood clotting, so every attempt is made in the preclinical setting to minimize adverse events. Numerous VAD systems have been developed and implanted in calves with a variety of adverse events, such as thrombus, obstructions or kinks, mechanical, electrical or software failures that can occur within any component of the LVAD.

Clearly, valve replacement in the calf model is representative of the patient prosthesis mismatch condition, rather than an ideal *in vivo* model for replacement human valves. Choice of the animal model to study the replacement valve's hemodynamic characteristics should ideally reduce or eliminate confounding factors, such as patient prosthesis mismatch. Therefore, the calf model

is not an ideal animal for testing prosthetic valves in a preclinical setting, because of the growth that causes an inherent patient prosthesis mismatch, as mismatch is strongly predictive of congestive heart failure following aortic valve replacement as well as re-operation (Ruel et al., 2004a,b). Thus, bovine models are best suited for acute studies in which somatic growth would not bias results or specifically to study the effect of patient–prosthesis mismatch itself.

Vascular Devices

There are no widely-used bovine *in vivo* models of vascular devices, so we will not discuss them further.

Ovine

Introduction. As a gentle, docile animal, sheep were among the first species to be domesticated, approximately 10,000 years ago as evidenced by pictures and statuettes depicting sheep in the Middle Eastern region. They remain popular to this day as a source of both food and goods. The prevailing theory for the origin of the domestic sheep is that they originated from the wild sheep known as mouflon (*Ovis musimon*). Currently, mouflon can be found in two separate geographic locales: Asiatic mouflon in Asia Minor and southern Iran; and European mouflon on the islands of Sardinia and Corsica (Clutton-Brock, 1999b). The rapid expansion of agriculture and human consumption has been both the cause and effect of routine crossbreeding of sheep. Currently more than 200 different breeds exist worldwide. Common breeds used in surgical research include smaller breeds commercially used for meat, such as the Hampshire and Dorset varieties, or the larger sheep, often used for wool commercially, such as the Merino and Rambouillet breeds.

Comparative Anatomy and Physiology

Specific organ differences between humans and sheep are notable (e.g., ruminant gut anatomy). However, in many instances the similarity in organ size of adult sheep to their human counterparts allows adequate approximation for the study of mechanical and bioprosthetic biomaterials and devices prior to human implantation. The ovine thorax has an exaggerated conical shape with

a narrow spax (cranial aperture or thoracic inlet) and a caudal thoracic aperture that is six times wider. Cardiopulmonary anatomy is generally similar to that of humans, making sheep ideal models for cardiac research; however, a few anatomic differences require consideration (Hecker, 1974), for example, the single brachiocephalic artery arising from the aortic arch. In addition, tracheal anatomy varies slightly from humans, with the cranial lobe of the right lung arising directly from the trachea rather than the right mainstem bronchus. This variation can pose a difficulty during endotracheal intubation on induction of anesthesia, and can result in nonventilation of a significant pulmonary segment (Carroll and Hartsfield, 1996).

Physiologic parameters (heart rate, blood pressure, cardiac index, and intracardiac pressures) have been established through numerous studies in both anesthetized and conscious sheep, including the percentage of blood flow to each major organ system (Matalon et al., 1982; Nesarajah et al., 1983; Newman et al., 1983). In most instances, the hemodynamic and metabolic values are similar to those of other large mammals, including humans (Tables II.3.7.1 and II.3.7.2).

In cardiovascular bioprosthesis studies, similarities between human and animal hematologic systems are important. Although there are differing blood groups, typing is unnecessary, as transfusion has never been necessary in our experience of over 30 years of working with sheep. There have been occurrences of a reaction, most often a dermatological response, which is easily treated with diphenhydramine. A comparison of the coagulation parameters and hematologic profiles between sheep and humans reveal some differences, which become important in assessing the thrombogenicity of implanted cardiovascular prostheses. Notably, sheep possess decreased fibrinolytic activity and increased platelet number and adhesiveness (Gajewski and Povar, 1971; Tillman et al., 1981; Karges et al., 1994).

Perioperative Care

Anesthesia. Sheep should be fasted preoperatively to decrease the likelihood of regurgitation on induction of anesthesia and ET intubation. The reticulum, the most proximal rumen, has no sphincter mechanism at its oral end and often needs intubation and suction decompression to prevent regurgitation and aspiration (Holmberg and Olsen, 1987; Carroll and Hartsfield, 1996). Orogastric intubation is especially important if preoperative fasting does not occur. Typically, a sedative is administered IM to allow easy and safe placement of IV catheters for controlled administration of medication. Several sedatives are useful in the pre- and postoperative periods to aid in animal handling, and for performing minor procedures as shown in Table II.3.7.3. Large named veins such as the internal or external jugular or femoral veins can be used to secure IV access for fluid administration and frequent blood draws. Specialized catheters such as pulmonary artery catheters or long-term tunneled venous catheters (Hickman) may also be placed in these easily accessible, large veins (Tobin and Hunt, 1996). Following placement of a secure IV catheter and the administration of short-acting relaxing agents, ET intubation can be safely accomplished using standard cuffed ET tubes 5–10 mm in internal diameter. Anticholinergics or parasympatholytics, especially atropine, have been used on induction of anesthesia to decrease salivary and respiratory tract secretions. Use of these agents, however, is controversial in ruminants such as sheep, goats, and cattle because they inhibit gastrointestinal smooth muscle activity, which can cause rumen stasis in sheep (Carroll and Hartsfield, 1996). Table II.3.7.3 lists the recommended dosing of anesthetic agents.

Analgesia. Scheduled medication administration and periodic evaluation of behavior can help to ensure adequate pain relief. Sheep should be assessed for changes from their preoperative temperament. Sheep tend to react stoically to pain, and their refusal to move can often indicate even minor discomfort (Carroll and Hartsfield, 1996). Other common clinical signs of postprocedural pain include tachycardia, tachypnea, grunting, grinding teeth, decreased appetite, vocalization on movement, and guarding of the operative site. Commonly used analgesics include narcotics administered via a subcutaneous, IV or epidural route. Nonsteroidal anti-inflammatory agents (NSAIDs) can be used in divided doses for additional analgesia. Table II.3.7.4 contains recommended dosing of analgesics.

EXISTING MODELS

Cardiac Devices

Because of the similar anatomic and physiologic characteristics of sheep and humans discussed earlier, sheep are often used in cardiovascular biomaterial research, and several models have been developed for studying compatibility and function of biomaterials. A total artificial heart model was developed in sheep at the University of Utah's Artificial Heart Laboratory in the 1980s (Holmberg and Olsen, 1987). Other studies examined the potential use of synthetic or xenograft pericardial substitutes to reduce adhesion formation following coronary artery bypass or valve replacement (Gabbay et al., 1989; Bunton et al., 1990).

Many investigators have employed sheep in the preclinical testing of mechanical valves in both the aortic and mitral positions (Barak et al., 1989; Vallana et al., 1992; Irwin et al., 1993; Cremer et al., 1995; Bhuvaneshwar et al., 1996; Okazaki et al., 1996). Our experience discovered that the use of juvenile sheep (younger than 20 weeks) results in an excellent long-term model for mechanical prosthetic valve evaluation. Careful standardization to prevent infectious complications,

short cardiopulmonary bypass time, whole sheep blood transfusion to minimize anemia, and rumen decompression with an orogastric tube to prevent vena caval compression were found to be useful in the successful implementation of this model (Irwin et al., 1993).

Acute and chronic models of stented bioprosthetic valves are well established through several studies in both the mitral and aortic position in sheep (Gott et al., 1992; Liao et al., 1993; Bianco et al., 1996; Vyavahare et al., 1997; Northrup et al., 1998; Ouyang et al., 1998; Salerno et al., 1998; Spyt et al., 1998). Sheep grow at a rate that is comparable to human growth, which allows for comparative analysis. In contrast, larger ruminants such as cattle and large varieties of swine experience rapid and prolonged growth until reaching a large adult size (Bianco et al., 1996; Grehan et al., 2000; Gallegos et al., 2005). Such rapid growth can cause difficulties in size matching between prosthetic valves and the native valve annulus, resulting in paravalvular leaks and functional valve stenosis (Braunwald and Bonchek, 1967; Gallo and Frater, 1983; Spyt et al., 1998). Premature leaflet calcification can occur in stented bioprosthetic valves because of abnormal mechanical loading characteristics. This is most consistently reproduced in juvenile sheep (younger than 6 months). We and others currently employ a model in sheep younger than 20 weeks to study both the dynamic environment related to growth of the sheep and the chronic effect of calcification in stented porcine bioprosthetic valves in the aortic position (Gott et al., 1992; Liao et al., 1993; Bianco et al., 1996; Ouyang et al., 1998).

Sheep also provide an important model for the study of low-profile stentless aortic valves (David et al., 1988; Brown et al., 1991; Hazekamp et al., 1993; Schoen et al., 1994; Salerno et al., 1998). In this regard we found that, with careful surgical technique including a two-thirds transverse aortotomy for superior exposure and meticulous avoidance of coronary ostial obstruction by the scalloped valve edges, sheep provide an excellent *in vivo* preclinical model to test these aortic valves (Salerno et al., 1998).

In addition to the subcoronary implantation of these stentless devices, this laboratory has also developed a juvenile sheep model of aortic root replacement to allow for the preclinical evaluation of new or modified stentless devices using implantation techniques that parallel those seen in clinical practice. Again, careful attention to surgical technique proved to be very important in the success of this model, including creation of very generous-sized coronary buttons, inclusion of a posterior "rim" of native aorta in the proximal anastamosis, and the creation of a tension-free distal anastamosis by removing little if any native aorta (Grehan et al., 2001).

Vascular Devices

In addition to cardiac devices, researchers have studied the interface between blood and several biomaterial surfaces in the evaluation of biosynthetic vascular grafts placed in sheep. Several authors have noted the reduction in thrombogenicity provided by endothelial seeding of small-diameter synthetic vascular grafts constructed of expanded PTFE or woven Dacron® prior to placement in sheep (James et al., 1992; Taylor et al., 1995; Dunn et al., 1996; Poole-Warren et al., 1996; Jensen et al., 1997). Placement of vascular grafts composed of several engineered surface textures into sheep has also been performed in order to assess characteristics of the pseudointima layer (Fujisawa et al., 1999). Additionally, the important problem of intimal hyperplasia in the venous anastomosis of high-flow arteriovenous fistulas has recently been evaluated in a sheep model (Kohler and Kirkman, 1999).

Recent progress in the development of large-vessel endovascular stents has occurred in part due to research with specific vascular disease models in adult sheep, and has been increased by continued development of minimally invasive techniques. As in graft studies, there is significant interest in both the short- and long-term patency of endovascular stents. Stent incorporation into native tissue and the role of foreign-body reaction in normal arterial systems with respect to thrombogenicity and intimal hyperplasia has been evaluated in sheep aortic and iliac arteries (Rousseau et al., 1987; Neville et al., 1994; Schurmann et al., 1998; White et al., 1998). Current efforts have been directed at determining the role of endovascular stenting in the prevention of rupture of abdominal aortic aneurysms, and the prevention of complications such as spinal cord ischemia through the use of these stents (Boudghene et al., 1998; Beygui et al., 1999).

Current cardiovascular research has embraced the humane use of sheep for the testing of a variety of cardiac and vascular devices composed of many different biomaterials. In all of these investigations, sheep have proved a useful and reliable model, as evidenced by this laboratory's continued success using both juvenile and adult sheep for a variety of investigations. Figure II.3.7.3 depicts the relative use of various large animals for preclinical assessment of valves, with a reported 78% of studies using an *in vivo* sheep model. Current research indicates a trend towards an even broader application of emerging endovascular technologies. For many reasons, including their anatomic and physiologic similarities to humans, and a mild temperament that facilitates handling, the benefits of using sheep in preclinical studies continue to outweigh the use of other large animals in future investigations into biomaterials testing and development.

TESTING HIERARCHIES

Conventionally-Placed Devices

Conventional coronary artery bypass grafting (CABG) continues to be one of the mainstays of cardiovascular surgery (Wilson and Ferguson, 1995). Coronary artery

disease remains the leading cause of death of people in developed countries, and an average of 800,000 CABG operations take place annually (Caparrelli et al., 2009). This requires the harvesting of one or more peripheral veins to reroute coronary vasculature and circumvent around an occlusion within the lumen of an artery while the patient is on cardiopulmonary bypass (Wilson and Ferguson, 1995). There are known risks for patients undergoing this surgical procedure, but the procedure itself is somewhat standardized and a common practice for surgeons. Similarly, the development and surgical implant of prosthetic valves dates back to the mid-20th century, and has proven to be another one of the greatest successes in surgery. Surgical valve replacement is well-established, and approximately 200,000 aortic valve replacements are performed annually worldwide (Fann et al., 2008). Advances in cardiopulmonary bypass, improved hemodynamic monitoring and perioperative care, and structural and hemodynamic improvements in prosthetic valves have aided in this success. Valve replacement surgery is now considered to have low operative mortality and constantly improving long-term survival rates (Fann et al., 2008; Christofferson et al., 2009). Its only limiting factor is the risk of conventional surgery on a patient with multiple comorbidities, a risk that obviously directly applies to patients undergoing CABG as well.

Percutaneously-Placed Devices

In cardiovascular surgery there is a current trend toward minimally-invasive placement of devices, rather than traditional surgical placement of devices (Mack et al., 2008). In addition, the responsibility of device placement is shifting from the cardiothoracic surgeon to the interventional cardiologist (Mack et al., 2008). The driving forces of this shift in medical practice are that the patient population as a whole is aging, and it is becoming increasingly difficult to care for their multiple comorbidities. Previously, many patients were deemed non-surgical candidates, due to the risks imposed by conventional cardiovascular surgical practices and the consequences of surgery in a patient with multiple comorbidities (Fann et al., 2008; Caparrelli et al., 2009) A percutaneous, or minimally-invasive, intervention is the process of inserting a needle and catheter into a vessel, and then utilizing a wire to guide the catheter through the lumen of the vessel to the desired site of intervention. The cardiac or vascular device to be placed in the patient can first be packaged inside of the catheter and released *in vivo* at the appropriate anatomical site. This technique facilitates the placement of devices such as prosthetic valves or vascular stents. Given the nature of this less invasive option, interventional cardiologists are optimistic about its possible use in patients who were previously not candidates for the conventional surgical approach due to its associated risks. Minimally-invasive placement of devices is generally thought to be less risky

than conventional surgery, putting less overall stress on the patient, and dramatically shortening the recovery period (Fann et al., 2008; Caparrelli et al., 2009). However, little is known at this point regarding the long-term safety and efficacy of devices placed percutaneously, as well as the delivery method itself.

The shift from conventional coronary artery bypass grafting to the percutaneous placement of stents in the treatment of coronary artery disease was first recognized approximately 20 years ago (Wilson and Ferguson, 1995). There are now two options for the placement of stents in diseased arteries including drug-eluting stents, as well as bare metal stents.

The development of percutaneous valve replacement stems from the successes of other catheter-based vascular procedures, such as carotid and coronary stenting. The percutaneous placement of cardiac valves is currently under investigation in clinical trial; however, clinical trials were initiated prior to the development of an animal model for *in vivo* assessment (Fann et al., 2008). Thus, chronic performance remains unknown, as there is no chronic animal model representing *in vivo* valvular stenosis. Very little preclinical data is currently available on the effects of crimping the valve within the catheter during the actual procedure, the risk of migration of the device from its intended location, and the complications that arise from expanding and retaining the native diseased valve (Fann et al., 2008). In addition, there is always a chance that unexpected consequences may have been revealed by *in vivo* assessment, precisely the reason it is conducted. These clinical trials may have been initiated prematurely, as they must now function as an assessment of both the safety and efficacy of percutaneous valve placement (Gallegos et al., 2005). There are still several issues that need to be considered regarding the minimally-invasive placement of prosthetic valves, including device loading, vascular access, adequate device positioning and anchoring, ideal leaflet material, stent or frame characteristics for the valve, and optimal method of delivery (Huber et al., 2005; Flecher et al., 2007; Fann et al., 2008).

There are currently two classes of cardiac devices available for valve replacement, including bioprosthetic valves made of porcine aortic valve cusps or bovine pericardium, as well as mechanical heart valves (Gallegos et al., 2005). Each type of valve has known advantages and disadvantages based on outcomes in the conventional placement of these devices. For example, mechanical valves rarely require future replacements, regardless of the duration of the patient's life. However, patients with mechanical valves historically have been required to take lifelong prophylactic anticoagulation therapy in an effort to avoid a thrombotic event (Gallegos et al., 2005). Conversely, bioprosthetic (tissue) valves necessitate the use of anticoagulation far less frequently than mechanical valves, but these same tissue valves have a known risk of calcification and/or tearing, often necessitating replacement within

10–15 years (Gallegos et al., 2005). The known rate of thromboembolic complications in bioprosthetic valves is between 0.9% and 2.2% per patient year without anticoagulant therapy (Nowell et al., 2007), based on multiple retroactive studies, which is less frequent than that observed with mechanical valve replacement with subsequent long-term anticoagulation therapy (Gallegos et al., 2005). This makes bioprosthetic heart valves a desirable alternative to mechanical valves for patients who may not be candidates for lifelong anticoagulation therapy. However, if a patient outlives the 10–15 year lifespan of the bioprosthetic valve they will require continued surgical replacement of additional valves.

There are known specific developmental priorities for the improvement of heart valve prostheses. One is to design a mechanical valve with center flow and a tri-leaflet configuration that is superior to other valves in hemodynamics. Another is to modify tissue valves in such a way as to minimize calcification and prevent disintegration, which may require investigating new preservation chemistry. The last future developmental priority is to design a completely new synthetic valve made of new materials. New advancements are continuously being made in the method of delivery and placement of valves, and this should continue to drive the design of new valves (Gallegos et al., 2005).

Two key issues must be independently resolved with respect to new vascular stents and prosthetic valves placed using percutaneous minimally-invasive catheter techniques. These include: (1) delivery of the device to the intended site; and (2) chronic performance of the device within a physiologic human condition or preferably a model in lieu of this condition (Christofferson et al., 2009). It is important to separate these issues during the preclinical assessment, and it is not recommended that both be assessed in a single animal model. Arguably, chronic performance is the more important issue of the two, as it directly predicts patient outcomes and disease treatment. The only way to develop an understanding of the chronic performance of a device is to assess the placement in a large number of animals for a long period of time. It is immensely important to match the animal to the device, rather than to match the device to the selected animal in preclinical assessment. Generally, the most successful *in vivo* assessments of bioprosthetic (tissue) valves have been conducted using juvenile sheep, while the most successful assessment of vascular stents have used an *in vivo* swine model (Gallegos et al., 2005). It is also a challenge to correctly identify the control group in a preclinical assessment of the minimally-invasive placement of devices. Since percutaneous valve placement was intended only for patients deemed non-surgical candidates, should the control group be subjects undergoing the conventional placement or solely medical management of valvular disease? Again it is the role of the study director to determine which control group best aligns with the goals of the preclinical device assessment.

CURRENT RECOMMENDATIONS AND FUTURE DIRECTIONS

The use of animals to predict clinical safety is an essential (and required) phase in the development of new or modified medical device technology. It is extremely unlikely, however, that preclinical use of animal models to assess new technology will ever evolve to the point that absolute statements can be offered regarding future clinical performance. Therefore, the enhancement of the predictive qualities of human safety and efficacy based on preclinical *in vivo* evaluations should be our priority.

Enhanced prediction of human safety and efficacy can be achieved by developing increasingly more relevant models of human disease, and developing models in which new or modified devices are implanted orthotopically in each intended clinical location (site specific testing). Additionally, each preclinical study design should include an appropriate control "arm." This "arm" of the study should include animals implanted with a device that is currently approved and being used clinically. The control device should be of similar design (or preservation technique) as the device undergoing investigation, and should be implanted using the same techniques. The use of concurrent control implants offers several advantages. First, it provides a direct clinical bridge to assess performance of a new or modified device. Second, it provides an assessment of the model utilized in the investigation relative to a device with a known clinical history. Finally, it can reduce the number of implants required in each investigation by providing a correlation to historical animal and clinical data.

The use of animals to predict human safety will, and should, remain a crucial part of the regulatory requirements governing medical device development and modification. In order to enhance the predictive quality of preclinical *in vivo* evaluations, current models need to be refined and new models need to be developed that more closely mimic both human disease and the intended clinical use of the device under investigation. As these models are developed and perfected they should become part of the current standards to be met by investigators working in prostheses development. In addition, each preclinical evaluation should include the concurrent implantation of appropriate control devices, so that comparisons of the investigational data obtained can be made to that of concurrent and historic animal and clinical control data. This will allow more accurate assessments of both the investigational device and the model to be made.

CHAPTER II.3.8 MICROSCOPY FOR BIOMATERIALS SCIENCE

Kip D. Hauch[1] and Buddy D. Ratner[2]
[1]University of Washington, Seattle, WA, USA
[2]Professor, Bioengineering and Chemical Engineering,
Director of University of Washington Engineered Biomaterials
(UWEB), Seattle, WA, USA

The microscope is so widely used in all branches of science and technology that it is almost iconic of research or science. The scientist relies heavily on vision; thus the advent of the light microscope is among the earliest, and arguably most powerful, tools in the history of science. Today, microscopy in its various forms still remains as a pre-eminent tool at the forefront of scientific exploration. Thus, the biomaterials scientist makes extensive use of both light and electron microscopes to help fabricate and characterize new materials, coatings, and devices, and to study the behavior of cells and tissues at the biomaterials interface. This chapter will familiarize the reader with the more common microscopy tools used in current biomaterials research. The key concepts of magnification, resolution, and contrast are first introduced and then their meaning explored in the context of light microscopy. Digital imaging is very briefly addressed. Attention then moves to the electron microscopies, specifically scanning electron microscopy (SEM). Finally, new developments in optical microscopy are addressed that are shattering limitations of microscopy that have inhibited progress for hundreds of years. Fortunately, the ubiquitous importance of microscopy in the practice of science means that there exist numerous excellent resources to consult on these topics. A brief guide to some useful resources is found at the end of the chapter.

MAGNIFICATION, RESOLUTION, AND CONTRAST

The art of scientific instrumentation is to devise tools to observe natural phenomena and present them appropriately to our senses for interpretation (e.g., to our eyes as an image). Three concepts apply to this process: magnification; resolution; and contrast. The three concepts are interdependent, and frequently limitations in one aspect or another leads to trade-offs.

Magnification is the appropriate scaling of the phenomena to our detectors (ultimately, for our purposes here, the human visual system). In a standard light microscope this is accomplished through the millennia old traditions of refracting light through curved glass lenses (e.g., an objective lens or an ocular). In the electron microscope, as well as the other scanning microscopies (e.g., laser scanning confocal, multiphoton, scanning tunneling or atomic force microscopies), photons or electrons are used to probe the sample discretely at a single point. The location of this sampling point is then rastered across the sample. Magnification is achieved by displaying the combined results from this "probing" on a more appropriate scale.

Resolution is dependent on the information present in the collected data sufficient to allow one to achieve perception. In microscopy we are usually interested in spatial resolution – the ability to resolve one location from another in an image. Resolution is often limited by the physical nature of the probe and/or the measurement of the signal thereof.

Contrast is the ability to detect specific differences in the signal. More than just signal/noise, contrast implies some aspect of specificity – the ability to tell one particular part of an image or signal from another. Resolution and contrast are often related – one is often gained at the expense of the other. With respect to light microscopes, the fundamental limits of magnification and resolution have generally been reached long ago. New and varied methods for the generation of contrast are what lead to the many different modalities of light microscopy and, as will be shown here, continue to be a source of technological development.

CONFIGURATIONS

A specimen can be imaged by passing illuminating photons or electrons through the sample (transmission microscopy, diascopic illumination) or by reflecting the illumination off the sample (reflected microscopy, episcopic illumination) to a detector.

In transmission microscopy, the sample must be thin enough to allow the probe to pass through the sample and reach the detector. For example, in transmitted light microscopy (probe = photons), samples may be up to 100 μm thick (although for typical high-resolution histology work, sections of tissue are prepared that are nominally only 5 μm thick.) In transmission electron microscopy (TEM, probe = electrons), samples are prepared that are only 50 nm thick.

Reflected techniques are used when the sample is opaque. The sample must reflect the illumination or otherwise generate a signal that is directed from the surface back to a detector. Reflected light is how we are used to viewing the everyday world around us. Reflected light techniques include simple magnifying hand lenses, stereoscopes and dissecting/operating room microscopes, and compound microscopes commonly used in the material sciences or manufacturing sector. As will be discussed, fluorescence-based techniques are almost always performed with episcopic illumination. Scanning electron microscopy (SEM) can be considered in this category as well, although the signal generated is somewhat more complex than simply the detection of reflected electrons.

LIGHT MICROSCOPY

The biomaterials scientist relies daily on a variety of light microscopes for tasks, ranging from routine materials inspection to detailed complex biologic analyses. The interests of the biomaterials engineer are often focused

on the biologic responses at the cell–biomaterial interface. These are studied *in vitro*, e.g., using cell culturing approaches or studied *in vivo* through the examination of a tissue–implant interface. In this regard, the microscopy needs of the biomaterials scientist overlap significantly with those of the molecular cell biologist or pathologist. The presence of a biomaterial in the sample is often just another (sometimes complicating) factor to be dealt with.

Platforms

Light microscopes can be configured on several different platforms – for different purposes and with varying levels of customization. Hand lenses, loupes, stereoscopes, and dissecting microscopes are essential for fabrication and inspection of small biomedical devices and coatings. Likewise, operating microscopes are often helpful for implant work in small animal models. An upright microscope is one in which the sample is observed from above by an objective lens. Upright microscopes are used most often for histology work, and are equipped with high-resolution but short working-distance optics. A typical sample might be a slice of tissue mounted between a microscope slide and a coverslip. An inverted microscope is the mainstay of the tissue culture laboratory, where specimens are viewed through objective lenses positioned underneath the specimen stage. This allows for the observation of live cells in culture, e.g., through the transparent bottoms of tissue culture flasks or multiwell plates. The large open stage of the inverted instrument allows for more experimental versatility, e.g., the use of complicated flow cells, micromanipulators or environmental enclosures. An inverted instrument is often equipped with slightly lower resolution, but longer working-distance optics. Either platform may be augmented for the specialized techniques to be discussed later, namely phase contrast, differential interference contrast, and fluorescence microscopy. With respect to research-grade instruments, there are more similarities than differences in the capabilities of the upright and inverted platforms. However, it is crucial that the choice of instrument platform and the experimental design receive mutual consideration early in the experimental planning stages.

Magnification in Light Microscopy

Magnification refers to the ratio of a feature dimension in the presented image to the corresponding feature dimension in the original specimen. In common practice, the range of magnification available in light microscopy reaches from 5× to about 1000× (a 100× objective lens and a 10× ocular). These values describe the magnification of the sample at the plane of the primary detector – our eyes at the ocular. Herein lies the danger for the modern microscopist, since invariably it is not our eyes, but rather a digital camera that acquires an image for

dissemination to our colleagues. The camera does not use the 10× ocular; rather it uses a combination of extension tubes, transfer optics, intermediate magnifiers or reducers, camera coupling lenses, etc. Further, the acquired digital data are then displayed on computer monitors directly as images or embedded in mixed content files (.pdf) at different "zoom levels;" printed on paper for reports, reduced in journal pages or printed onto large poster boards for conferences; perhaps even displayed using data projectors onto huge screens in an auditorium. What then does magnification mean?

The days of conveying the level of magnification in an image by reporting the magnification of the objective lens alone or using vague terms such as "low power" or "high power," are long gone. In the digital age it is far preferable to include an accurate size scale bar as part of every published image. This is conveniently done by separately acquiring an image containing objects of known size, most commonly a stage micrometer available through any microscopy supply house. With an image containing an object of known dimension, it is then straightforward to establish the relationship between distance (μm) in the specimen and pixels, the individual element of the acquired digital image. A scale bar can then be embedded in the images used for presentation, and measurements of feature size reported directly in appropriate units. Further; no matter how the image is then later displayed, the viewer will have a direct feel for the size of the features in the image. Modern software makes these operations relatively painless, and the side-by-side presentation of images taken at macroscopic, microscopic, and nanoscopic scales makes this practice indispensable to the scientific audience.

Resolution in Light Microscopy

The Rayleigh criterion is often used to describe the resolving power in light microscopy:

$$d = 1.22\lambda / (NA_{condenser} + NA_{obj}) \text{ for brightfield}$$

and:

$$d = 0.61\lambda / NA_{obj} \text{ for fluorescence}$$

where λ is the wavelength of light. NA is the numerical aperture of the condenser or objective lens and is defined as:

$$NA = n \sin\Theta$$

where n is the index of refraction of the medium between the lens and the sample (1.0 for air, 1.515 for oil), and Θ is the half-angle of the cone of light collected by the lens (Figure II.3.8.1). Similarly, the depth of focus, which is the thickness in the sample within which features will all appear in focus, is given by:

$$Z = n\lambda / NA_{obj}^2$$
FIGURE II.3.8.1 The concept of numerical aperture (NA). The value, Θ, is half the acceptance angle of the lens, n is the refractive index of the medium between the sample and the objective, $n = 1.00$ for air, $n = 1.515$ for oil.

These equations are idealized and are based on the first overlap of the diffraction patterns of two infinitely small point sources in the specimen. For monochromatic light at 546 nm and a high-quality oil immersion lens with an NA of 1.3, this equates to a resolving power of about 0.26 μm, (often called the diffraction limit), easily adequate to resolve many subcellular organelles. Most modern research-grade microscopes are quite capable of realizing this resolution limit. However, the use of polychromatic white light may increase this value two-fold. Further, the large values of NA_{cond}, which lead to optimal resolution, actually reduce the contrast available in the image. Thus, we may achieve superb resolution, but not be able to distinguish the features that we seek to resolve! Here we find one of the classic trade-offs: between resolution and contrast.

It is important to understand the resolution available in an image when considering the tools for digital image acquisition. Ideally, the physical size of the individual sensing elements (e.g., the pixel on a digital imager) will be less than half the smallest resolvable feature size, after magnification by the objective and any intermediate magnifiers between the microscope and the imaging plane. The appropriate matching of physical pixel size in the detector to the resolving power of the optics is crucial, and if overlooked can result in degraded system performance. One finds that our eyes, and high-quality film, are well suited to the task. Lower power but relatively higher NA objectives (e.g., 10×/0.4, 20×/0.75) are the most demanding, i.e., they require the smallest pixels, and hence largest number of pixels in the detector.

Note: New microscopy techniques are revolutionizing ideas about the resolution achievable in the visible range.

They will be introduced toward the end of this chapter to highlight trends that are radically altering the future of microscopy.

Contrast and the Various Modes of Light Microscopy

The interaction of light with matter is what generates the contrast that we detect in a microscope image. Light can be characterized by its amplitude, wavelength, phase, and polarization. Unfortunately, our human eyes, and most other electronic detectors, are sensitive only to amplitude and wavelength! Thus, a light microscope must convert these many interactions of light and matter into differences in amplitude or wavelength that can be detected in the image. The various ways in which contrast is generated lead to the various light microscopy techniques or modalities. These are described here in quite general terms – the reader is encouraged to explore the many excellent introductory texts on optical microscopy for more thorough coverage.

Transmitted Light Microscopy

The simplest way to view a thin specimen is to shine light through the specimen and view the magnified image directly. In this method, brightfield, we rely on the sample to provide its own contrast. Different features in the specimen may absorb some of the light and/or do so unequally at various wavelengths, thus leading to amplitude or color contrast. In many instances this may work – but consider a layer of unadulterated cultured cells on a glass slide. These cells, if well spread, may only be a few microns thick; made mostly of water, they absorb very little light and provide almost no contrast. Indeed it may be very difficult to see the unstained cells at all!

Another technique is darkfield microscopy. In darkfield the sample is illuminated obliquely, at such glancing angles that the illuminating light, if undisturbed by the specimen, does not even enter the objective lens. Thus, the empty areas (the background areas or "surround") in the image are completely black. Only where elements in the sample scatter light into the objective lens is light collected. Thus, a darkfield image appears as pinpoints of light on a black background. Darkfield is particularly effective if the specimen contains small particulates.

Adding Contrast Agents: Chromophores and Fluorophores

How then can one generate more contrast in a specimen? The simplest answer is to cheat! Exogenous contrast agents can be added to the specimen. These are strongly absorbing or fluorescing large molecules or nanoparticles that are placed into the sample and ideally reside only in certain structures or features the investigator has chosen.

This, of course, is what is done in the staining of cells or tissue sections for histology. Many of these chromophores or stains date to ancient times when they were used to dye biologic materials, such as plant and animal tissues, skins or textile fibers. Perhaps the most common histologic stains are hematoxylin and eosin (H and E). Hematoxylin (which appears blue) is termed a basophilic dye and binds to basic components such as those found in the cell nucleus. Eosin (which appears pink and is also quite fluorescent) is acidophilic and generally stains cytoplasmic proteins. A plethora of histologic stains is available to stain a myriad of cells or structures within cells and tissues. Other common examples include Masson's trichrome, which is used to stain connective tissue or fibrosis around implants (collagen is blue or green); alizarin red, for calcific deposits; ver Hoeff's for elastin; Geimsa and Wright's stain for blood cells; and the Gram stain for bacteria.

It is easy to see the beauty in chromophores (both literally and figuratively), since not only do they generate contrast in the image, but they do so with specificity (i.e., they provide useful information). The investigator can see not only the cell, but can now also see which part is a nucleus, can determine the specific location of structural proteins, etc. This power of specificity can be enhanced by directly (covalently) linking chromophores or fluorophores to specific proteins or other molecules of interest, and then identifying and following the location of these reporter-linked conjugates on surfaces, inside cells, and in tissues.

Further, chromogenic substrates have been synthesized for certain key enzymes. These substrates are converted from colorless to colored (or otherwise undergo a color change) upon cleavage by the enzyme. Examples are the many substrates available for horseradish peroxidase, alkaline phosphatase, and β-galactosidase. These substrates can be used to detect enzymatic activity directly in certain cells and tissues.

Reaching yet another level of specificity, these enzymes can be conjugated to antibodies to impart molecular-level specificity in their binding. Thus, the location of specific molecular antigens can be elucidated by allowing these antibody conjugates to bind, and then revealing the location of the antibodies by using the chromogenic substrates. This process (immunohistochemistry) is directly analogous to forms of the enzyme-linked immunosorbent assays (ELISA) used on the benchtop. Alternatively, the antibodies may be labeled directly with a fluorophore (direct immunofluorescence) or their locations revealed by the binding of a second labeled antibody that recognizes the first (secondary or indirect immunofluorescence). Finally, similarly labeled nucleic acid strands can be used to probe for and reveal the presence of certain sequences of genomic material in cells (*in situ* hybridization) or on surfaces (so-called microarray analysis), and thus give a glimpse into the genomic profile of cells and tissues.

The immense power and versatility afforded by the use of chromophores and fluorophores is now made clear. Beyond simply generating contrast, they provide molecular-level specificity. This enables the investigator not only to simply visualize cells and structures, but also to begin to ask specific cell-physiology and bioengineering questions: is a particular species (a molecule, protein, receptor, enzyme) present? If so where is it, when does it appear, and in what quantities? Here in this generation of contrast lies the power of modern microscopy and its contribution to the cell biology and pathology fields so integral to the study of the biomaterials–biology interface. Because fluorophores play such a prominent role in these techniques, and since their use requires specialized technical approaches, fluorescence microscopy will be addressed in more detail in a separate section.

Optical Tricks: More Contrast – But No Cheating

So far, to generate contrast we have relied on the inherent contrast in the specimen (often inadequate) or the addition of contrast agents. Many of these contrast agents are toxic to cells. Histologic stains are typically used on tissue sections where cells have been fixed, embedded in a support matrix, and sliced open. Probes that bind to intracellular components have to cross the cell membrane; thus cells are permeabilized to allow access. Although there are "vital dyes" that can be used on living cells, many of the approaches described above interfere with the normal physiologic functioning of the cell. Thus, they are best suited for endpoint analysis. How then can one more safely generate contrast in living cells? How can one generate contrast without the addition of these exogenous agents? How can one generate contrast without "cheating?"

Fortunately, the answer lies in several types of optical "tricks." Cells have limited ability to cause absorbance or color changes. However, there is plenty of diffraction (bending of light around organelles), refraction (bending of light at interfaces of structures with different indices of refraction, e.g., membranes), and other optical phenomena that can be used to our advantage. Unfortunately, our eyes are insensitive to all but changes in light intensity and color. The tricks, therefore, will be used to convert these other phenomena into differences in intensity or color, which we then can detect. These techniques all involve optical elements placed in the light path that modulate the incoming light, as well as elements that modulate the light collected by the objective. As such, the sample usually resides in the middle of these two elements, and thus these can be thought of as the "sandwich techniques" (Foster, 1997).

Polarization

Molecules and materials that exhibit a strong regular repeat in their electronic structures are likely to induce

orientationally specific changes in polarization during their interactions with light. Examples of such polarizing (birefringent) materials include metals, inorganic and organic crystals, collagen, certain organelles, muscle sarcomeres, and many others. Recall that light polarized by a polarizing filter will not be transmitted through a second polarizing filter oriented at 90° to the first (extinction). If the first filter is placed in the illumination path before reaching the sample, and the second filter is placed in the imaging path after sample, extinction will take place. No light will get through, provided that the sample does not impart any additional polarization to the transmitted light. However, if the sample *does* impart additional polarization, the conditions for extinction will be unsatisfied, and the location of the polarizing materials will be immediately revealed. The degree of this additional polarization induced by the sample can even be measured with yet a third polarizing element (a compensator). The directionality of the polarization can be determined by rotating the specimen stage.

Synthetic polymers, of course, can also contain strong regular repeats in their electronic structure. This can be very useful in locating and identifying remnants of implanted polymeric materials in explanted tissue. The polarization induced by polymers can also be a disadvantage, however, as the plastics used in common tissue culture ware make polarization microscopy nearly impossible using these substrates.

Phase Contrast and Hoffman Modulation Contrast

While there may be little amplitude change when light traverses a cell, there is plenty of diffraction of light by organelles, structures, and membranes. These rays that have interacted with the specimen experience a (unnoticeable) change in phase, having experienced an optical path-length difference $\lambda = (n_2 - n_1)$ (thickness). Typically, the light is retarded in phase by an amount approximately $-\lambda/4$. In the 1930s, Dutch physicist Fritz Zernicke invented a method to convert these phase changes into changes in intensity. The result was phase contrast microscopy, and the method helped foster the major advances in cell biology developed through the study of living cells in culture. For his work, Zernicke received the Nobel Prize in 1953.

The key to phase contrast is to somehow separate those rays of light that pass through the specimen undisturbed (undiffracted) and thus contribute to the background (called the surround, S), from those rays that have been diffracted by interaction with the specimen (D). This can be accomplished spatially at a special plane in the optical path, the diffraction plane. At this plane an image is not formed; rather one can envision that rays of light are separated spatially by their degree of diffraction. Here, each can be manipulated or treated

selectively. In phase contrast, an annulus is placed in the illumination light path in a plane conjugate to this diffraction plane (Figure II.3.8.2). This results in a ring or cone of illumination approaching the specimen. Next, a special plate is placed at the diffraction plane, beyond the sample (actually located within the objective lens). This plate is constructed such that its thickness is less in a ring shaped region that matches exactly that of the ring in the annulus plate. Thus, rays of light that are not diffracted (S) will pass through this "phase ring," while diffracted rays (D) will pass through the remaining portions of the phase plate. This phase ring results in a relative $+\lambda/4$ advancement in the phase of light that is undiffracted. Further, this ring is made semitransparent, so that the light transmitted (i.e., the light that will contribute to the background in the final image) is reduced in intensity, and thus appears gray. The diffracted rays have already experienced a retardation in their phase, caused by their interactions with the specimen $(-\lambda/4)$. When the surround (S) and the diffracted rays (D) are recombined in the real image plane, the resulting phase difference is $\lambda/2$ and destructive interference takes place. Now, the changes in phase are converted to a reduction in intensity – which is made manifest in the recombined image as areas of dark (black).
FIGURE II.3.8.2 Phase contrast microscopy in an inverted microscope.

We see that phase contrast is again a "sandwich technique," utilizing a phase ring in the illumination path and a matching ring in the image-forming path. The sample is in the middle. This latter ring is actually physically built into the objective lens, and thus phase contrast microscopy requires a special phase contrast objective and the use of a matching and carefully aligned phase annulus for each objective. Fortunately, phase contrast objectives can also be used for routine brightfield observation and most fluorescence applications, so for many laboratories they are good value.

Phase contrast is ideal for thinly spread cells, such as those in cell culture. They appear in high contrast, their organelles and pseudopodia revealed in areas of bright and dark on a gray background. Rounded cells, however, are surrounded by a strong halo of bright light. Simple phase contrast systems (often with fixed and prealigned annuli) are commonplace on inexpensive inverted microscopes found in tissue culture suites.

In Hoffman modulation contrast, use is made again of the spatial separation of diffracted and undiffracted rays at the diffraction plane (Figure II.3.8.3). This time, instead of a cone of illumination, an asymmetric slit is placed in the illumination path. Again, a modulation plate is built into the objective placed at the diffraction plane. Also again, a semitransparent region is constructed to catch
FIGURE II.3.8.3 Hoffman modulation contrast. Oblique illumination is provided by an off-axis slit in the condenser aperture. A modulator plate with matching complementary slit is placed in the objective back aperture and differentially blocks one sideband of diffracted light. (From Murphy, 2001.)

the rays of light emanating from the illumination slit and transversing the specimen undisturbed, thus resulting in a gray background. To one side of this surround region in the modulation plate, the plate is made fully transparent, while to the other side the plate is made opaque. The result then is that rays that are diffracted slightly in one direction appear quite bright, while rays diffracted in the opposite direction appear dark. In the recombined real image these variations in intensity appear as shades from light to dark across structural boundaries in the specimen. Our eyes conveniently interpret these gradations as shadows. The specimen takes on a distinct and crisp three-dimensional appearance. Hoffman modulation contrast also requires the use of special objectives and illumination systems. Its use is compatible with tissue culture plasticware, unlike the other, more familiar shadow-like technique, DIC, which is discussed next.

Differential Interference Contrast Microscopy

The techniques discussed so far have converted differences in the optical path length through the specimen into variations in image intensity by utilizing oblique illumination and tricks at the diffraction plane. In differential interference contrast (DIC) microscopy, also called Nomarski, gradients in optical path length are sensed in a slightly different way – by splitting the incoming light into two parallel rays and allowing each ray to sample nearby areas of the sample, before being recombined to form an image. DIC is akin to an imaging version of a dual-beam interferometer.

DIC starts with linearly polarized light; thus a polarizer is again the first extra element in the illumination path (Figure II.3.8.4). Next, mounted near the condenser is a modified Wollaston prism that separates the incoming light into two parallel rays. These two rays of light are physically separated by a small fraction of a micron – indeed, a distance less than the resolved distance of the microscope. These two rays traverse the specimen, and should they experience the same optical path through the specimen (i.e., no optical path difference), they are then recombined by a second prism located beyond the objective, again at the diffraction plane. This recombined light is again linearly polarized, and can be selectively rejected by the use of a second polarizer (termed an analyzer) oriented at 90° to the first. In the presence of an optical path difference (e.g., due to a gradient in the index of refraction in the sample), the two rays are recombined and result in an elliptically polarized beam, which is now only partially attenuated by the analyzer. Thus, gradients in refractive index present in the sample are converted into gradients in intensity in the image. Our eyes perceive these as shadows, and the sample takes on the striking appearance of three-dimensional relief. In practice, the objective prism is typically offset slightly so that the surround is not purely attenuated (black), but
FIGURE II.3.8.4 Differential interference contrast on an upright microscope. Light is first linearly polarized, then split by the condenser prism (#1) into two spatially separate beams (shown as solid and dashed). If the two beams do not experience an optical path difference (inset), then they are recombined by the objective prism (#2) into a single ray that is again linearly polarized. This ray is then rejected by the second polarizer (the analyzer). If the two beams do experience an optical path difference in the sample, then the recombined ray is elliptically polarized and is partially transmitted by the analyzer. In this way spatial difference or gradients of refractive index in the sample are converted to differences in intensity. (After Murphy, 2001.)

rather appears in shades of gray along the diagonal of the image.

Since DIC utilizes polarization in generating the contrast, it is not suitable for use with tissue culture plasticware, which will induce extraneous polarization. DIC produces crisp, clear images in unstained specimens, with extraordinarily shallow depth of focus. This makes it ideal for optical sectioning tasks. DIC components are expensive, and must be made from strain-free glasses. DIC is particularly amenable to combination with fluorescence techniques – where the fluorescence labeling provides the spatial localization of specific intracellular features (e.g., a nucleus or cytoskeleton), and DIC provides clarity to the body of the cell and other organelles.

FLUORESCENCE MICROSCOPY

Like chromophores, fluorophores are (usually) exogenous large molecules whose unique spectral properties make them readily identifiable under the microscope, and thus generate contrast. Fluorescence techniques have had a wide-ranging and tremendous impact in the fields of molecular and cell biology, genomics, biophysics, bioengineering, and many others.

In the process of fluorescence, the fluorophore absorbs energy of a particular wavelength. While a small amount of this absorbed energy is lost to heat, the remainder is very quickly given up by the fluorophore as it re-emits the energy as light of a slightly longer (less energetic) wavelength. The difference between these excitation and emission wavelengths is called the Stokes shift, and provides the basis upon which the incoming and outgoing (emitted) light can be spectrally separated.

Fluorescein (known, together with its covalent linkage group isothiocyanate, as FITC) is perhaps the best known fluorophore. Today, there exist hundreds of new fluorophores, with various chemistries and spectral properties ranging from those excited by light in the UV range to the far red. The synthesis of new fluorophores with improved properties (e.g., increased quantum efficiency, resistance to photobleaching, narrower spectral characteristics) is an active enterprise. Excellent resources are available from vendors to help guide the choice of fluorophores for a myriad of applications (e.g., Molecular Probes, Inc.).

The applications of fluorescence are indeed numerous. As discussed earlier, fluorophores can be conjugated to a variety of biologically important molecules (lipids, membrane components, proteins, enzymes, antibodies, nucleotides, specific organelles) to serve a variety of reporting functions. Just a few common examples are the fluorophore DAPI to label cell nuclei and observe nuclear fragmentation during apoptosis; fluorescent conjugates of the mushroom toxin phalloidin which bind to f-actin in the cytoskeleton; and DiI for long-term cell tracking. The enzymatic activity of cells can be assessed by fluorescence, e.g., in the Live/Dead® cell assay (Molecular Probes, Inc.), where a masked nonfluorescent form of the green fluorophore calcein is cleaved by intracellular esterases in living cells, while dead cells fail to exclude the nuclear binding dye ethidium homodimer from their nuclei, which are then stained red. In this and many other systems, simultaneous labeling and imaging of multiple fluorophores is the norm.

Fluorophores can also be used to sense microenvironmental parameters, e.g., pH or the concentration of various ions such as Na^+, K^+, Cl^-, Ca^{2+}. The technique of FRAP, fluorescence recovery after photobleaching, can be used to study the intracellular dynamics or mobility of labeled macromolecules. In the technique named FRET, Förster resonance energy transfer, the proximity of two labeled molecules (or even two labeled domains on the same macromolecule) can be detected, as a donor fluorophore directly excites an acceptor fluorophore only when the two species are within a molecular distance of each other. This is truly an intermolecular ruler. Finally, the gene for the photoprotein from the jellyfish

Aqueorea victoria, green fluorescent protein (GFP), has been cloned. This has been used to create numerous fluorescent chimeric proteins that can be directly expressed in living cells. A number of mutations have yielded blue, cyan, and yellow variants. Another class of photoproteins, dsRed, from anemone is also in use. These advances give biologists unprecedented power to observe the processes of protein expression in cell populations.

Instrumentation for Fluorescence

Because of the small number of fluorophores often present and the potentially low quantum efficiency, fluorescence techniques require special, strong illumination sources. These are typically mercury or xenon arc lamps or lasers. Fluorescence benefits from the use of very efficient collection optics, i.e., objective lenses with the highest possible NA. Detection is typically achieved with sensitive imagers, e.g., cooled CCD (charge-coupled device) cameras or photomultiplier tubes (PMTs).

Fluorescence microscopy can be performed on upright or inverted microscopes equipped with an arc lamp, and appropriate filters and mirrors. This is known as wide-field fluorescence microscopy. (An alternative technique, laser scanning confocal and multiphoton instruments will be discussed in the next section.) In wide-field epi-fluorescence microscopy, illumination light from an Hg arc lamp is first passed through a band-pass filter that rejects all light except those wavelengths required to excite the fluorophore (the excitation band pass filter) (Figure II.3.8.5). Next, this excitation light hits a special mirror, the dichroic mirror, located directly behind the objective lens. The purpose of the dichroic mirror is to reflect shorter wavelength excitation light, but allow longer wavelength emission light to pass. The shorter wavelength excitation light is reflected by the dichroic

FIGURE II.3.8.5 Filter set. Dashed line represents shorter wavelength excitation light; solid line is longer wavelength emission light.

mirror into the objective and delivered to the specimen. There the light is absorbed by the fluorophore and re-emitted at a longer wavelength. This light is emitted in all directions; however, a portion of the emitted light is collected again by the objective lens to form the image. This light passes back through the objective, and again hits the dichroic mirror. Now the longer wavelength emitted light is passed by the dichroic mirror (not reflected), and the beam travels on to one last filter. This last filter, the emission filter or barrier filter, rejects all but the emission wavelengths, thus leaving a clean signal that is composed only of light from the excited fluorophore. This illumination is apiscopic, a reflected light technique. The substrate can be opaque as long as the fluorophore is accessible at the surface.

The three filter elements, the excitation filter, the dichroic mirror, and the emission filter, together form a filter set. Each filter set is specific to the spectral characteristics of one particular fluorophore. More complex filter sets that allow for the simultaneous use of two or more fluorophores are available, but it is usually more convenient to capture separate images, each comprising the signal from an individual fluorophore, and then overlay these images later.

Confocal Microscopy: A Special Tool for Fluorescence Microscopy

Excited fluorophores in the sample send their emitted light in all directions. In wide-field fluorescence microscopy it is inevitable that, in addition to the fluorescence emanating from the fluorophores residing in the in-focus plane, some fluorescence from slightly out-of-focus planes (above and below the desired focal plane) will also be collected and contribute to the image. The result can be a muddled or hazy image, especially in thick or highly scattering specimens. A solution is the confocal microscope.

In a laser scanning confocal microscope (LSCM), a physical barrier (a pinhole) is placed at a confocal location in the imaging path between the objective and the detector (Figure II.3.8.6). This pinhole allows only those rays of light that emanate from precisely the focal plane of the objective lens to pass through to the detector. The result is a very clean, if very weak, signal. Further, instead of flooding the field of view with illumination from an arc lamp, a laser is used to excite the fluorophore. The laser beam forms a small diffraction-limited spot in the plane of the specimen. This spot is then rastered across the specimen using scanning mirrors and optics. Instead of imaging the entire field of view at once with an imager, a simpler more sensitive PMT can be used in synchrony with the laser to simply count the photons arriving as a result of the laser illumination at each location in the specimen. The completed image is then composed by digitally presenting the measured intensities at each location
FIGURE II.3.8.6 Laser scanning confocal microscopy. The sample is illuminated by a laser that is reflected into the objective via a dichroic mirror. This beam forms a diffraction-limited spot in the specimen at the focal plane. This beam is rastered across the specimen by scanning mirrors (not shown). Fluorescence from the focal plane is captured by the objective, passes through the dichroic mirror and emission filters, and arrives precisely at the opening of the pinhole aperture, which is found directly in front of the detector (a photomultiplier tube). Fluorescence from an out-of-focus plane (a below-focus plane is shown, dotted) arrives to either side of the pinhole and is rejected. (After Murphy, 2001.)

(pixel) in the specimen. The diffraction-limited illumination spot provides for superb lateral resolution, and the confocal pinhole rejects all out-of-focus fluorescence contributions. The result is a crisp, clean image that represents a thin optical plane virtually sliced through the specimen. By repeating the process at different focal planes (with the help of nanometer-resolution stepper motors attached to the focus drive) one can collect images from hundreds of planes in thick specimens (up to 100–200 μm deep) and composite these into three-dimensional fluorescent representations of the sample.

Laser scanning confocal microscopes were once considered to require a dedicated operator to care for complex lasers, complicated electronics, and fragile detectors. Presently, the advent of solid-state lasers and simpler, more robust electronics, scanners, and detectors has led to new generations of confocal instruments that promise improved affordability and ease of use. Like wide-field fluorescence, laser scanning confocal microscopy can be implemented on either upright or inverted platforms.

Two new advances in confocal microscopy are worthy of note. The first is the use of multispectral array detectors and spectral unmixing to provide for the simultaneous use of up to eight fluorophores. This technology is featured in an instrument produced by Zeiss. The second is the advent of the multiphoton microscope.

A fluorophore can be excited equally well by one properly tuned excitation photon or by two excitation photons, each half the nominal excitation energy (twice the wavelength), or by three excitation photons, each a third the nominal excitation energy, etc. These multiple excitation photons must all reach the fluorophore molecule at precisely the same time, however; at least within the fluorescence decay lifetime of the fluorophore, which is measured in nanoseconds. This requires a femtosecond pulsed laser excitation source at long wavelengths (almost infrared). There are several advantages to this mode of illumination. First, longer wavelengths can penetrate deeper into cells and tissue, and do so with less biologic damage. Second, the pulsed nature of the excitation laser means that lower energy doses are delivered to the specimen. The effective excitation volume, the volume at the focal point of the objective where the spatial and temporal density of excitation photons is actually great enough to trigger a fluorescence emission, is exceedingly small – in the order of femtoliters. Thus, the emission signal produced and detected is always of very high spatial resolution, in both lateral as well as axial dimensions.

DIGITAL IMAGING

It is not enough that we build instruments to produce magnified and resolved images of the microscopic world. We must be able to detect these images, to visualize the information, record and archive images, and make useful quantitative measurements of our observations. This is the science of imaging.

Detectors: Eyes, Film, Digital Imagers

Our human eyes are by far the most commonly used and relied upon detectors in light microscopy. Together with the ocular lenses, the lens of the eye serves as part of the microscope system and the final image is focused on the retina, the detector. The human eye is a remarkable, yet limited, living detection instrument. Obviously, our eyes are acutely tuned to the visible portion of the light spectrum, with the greatest sensitivity found in the mid-green. The eye can be very sensitive (as few as 100 photons in the dark-adapted eye), and can adapt to a wide range of signal intensity from very dim to very bright. However, this adaptation takes time; and the intra-scene dynamic range, the range of dim to bright within one field of view, is only about 1000-fold. The individual sensing elements in the eye, the rods and

cones, have an effective size of about 2 μm, which can be compared to the pixel size in other detectors. The signal response in the eye is nonlinear, and the signals from our eyes receive considerable postprocessing by the visual systems in the brain. This is particularly true with regard to edges, shadows, and objects in motion. We are all familiar with many "optical illusions" that prey upon some of the foibles of the human visual system. As discussed earlier, we make use of some of these illusions in light microscopy, e.g., the gradations of intensity in DIC and Hoffman are interpreted as shadows, when really there is little topographic information in the image.

Unfortunately, scientists with photographic memory are rare; thus the storage and archival capability of the human visual system is nil. The quantitative abilities of the eye are also limited. Although we can distinguish thousands of colors, we can barely discern between roughly 64–100 different gradations of gray (intensity)! Thus, data that come from human observations are qualitative or semiquantitative at best. The scientist must rely on careful subjective measurements, ideally with standardized scoring schemes, copious controls, blinded observers, and comparisons between multiple independent observers.

For more than a century the standard media for imaging was photographic film. Film can be made to detect broader spectral ranges than the eye, can be very sensitive, and has a dynamic range of about 2.5 log units. The grain size (individual sensing element or pixel) in film is typically 30 μm. The archival capability of film is excellent, and when properly used, the signal response can be made to be linear, and the data analyzed quantitatively. However, the cost, time, and chemical reagents required for film development are significant. The replacement of film with digital imagers in modern scientific imaging is essentially complete.

Digital Imaging Devices

Solid-state imaging devices are now a common part of our everyday world. Digital imaging devices are found in photocopiers, scanners, professional and consumer-grade video cameras and still cameras, surveillance cameras, toys, personal computers, and cell phones. The medical and scientific imaging fields have benefited greatly from this explosion of technology. The gaps in performance and sensitivity between consumer-grade and research-grade imagers are quickly closing.

The most common digital imaging device is the charge-coupled device (CCD). A CCD is a silicon chip that comprises a physical array of photodetectors, which correspond to the picture elements (pixels) in the image. As photons arrive at each photodiode they are converted to electrons, and the charges are accumulated and held locally on the chip in a potential well. Later, these groups of charges are transferred off the chip in a sequential manner, and the signal from each well is amplified and converted to a voltage. At this point the signal is still analog. An analog-to-digital converter is used to convert the steady stream of voltages into an array of numeric values that represent the relative intensity of photons at each photodiode in the detector array. It is this array of numbers that is the digital image.

Charge-coupled devices are available in several different architectures. In a full-frame camera, every spot on the chip is exposed to light. A physical shutter is used to control the exposure. After the exposure, the shutter is closed, and the charges are transferred and read. The operation is much like that found in a standard film camera. In a frame transfer camera, the CCD array is divided into two separate adjacent fields. The first is used for sensing light, while the second area on the chip is protected from light by an opaque mask and is used only to transfer and hold charges. The frame transfer camera has the advantage of speed. Thus, in a frame transfer camera, one image is acquired in the sensing region; then the charges are transferred quickly to the masked area. While the charges in the masked area are being read out, a new image can be acquired in the sensing region. Finally, many modern cameras take this concept one step further by simply masking every other line of photodiodes on a chip, a so-called interline camera. This allows for imaging at video frame rates; built-in microlenses can be used to funnel photons away from the masked pixels and to the sensing pixels.

The performance of a scientific imaging device depends on several important parameters. The resolution is determined by the number of sensing elements (photodiodes, i.e., pixels), as well as the physical size of each photodiode. The size of each element also determines the capacity of each well, i.e., the number of charges that can be held before reaching saturation. This "full-well capacity" determines the dynamic range, which is the range between the brightest and the darkest intensities possible in the image. The sensitivity is determined by the signal:noise ratio. The signal is affected by the quantum yield, which is the ratio of charges created to photons hitting the detector. The quantum yield can vary significantly with wavelength. The noise in the signal can arise from several factors. At very low light levels, the stochastic nature of the incoming photons themselves contributes some variability, the "shot noise." Thermal events also generate electrons in the chip. Thus, very sensitive detectors are often cooled with thermoelectric cooling devices or even liquid nitrogen to reduce this "thermal noise." Finally, noise can be generated in the process of transferring, reading, and amplifying the signals, and this "read noise" often scales with the speed of the reading process. Thus, very different and specialized imaging systems are used for various imaging tasks: e.g., very low-light fluorescence imaging; video-rate imaging or very high-speed imaging for following millisecond or microsecond events.

Although there is some variation in the quantum efficiency with wavelength, a CCD camera is basically a monochrome imaging detector. Often this is adequate. For example, in fluorescence imaging the signal is ideally composed of only single-emission-wavelength photons – fluorescence microscopy is actually a monochrome technique! But, as discussed earlier in this section, we often use multiple colored stains to create complex contrast in an image, and this requires a color imaging device.

A color CCD camera achieves color sensitivity by using filters to separate the image into its red (R), green (G), and blue (B) components. This can be accomplished in several different ways. In the first example, a separate tunable color filter is placed in front of a monochrome camera. The filter is sequentially set for red, green or blue, and three separate images are acquired. The images can then be compiled computationally to represent the color digital image. An advantage is that the full resolution of the imaging camera is maintained; however, the time required for the acquisition of three images means that the sample must hold still for a while (no sample motion). In the second approach, a prism is used to split the incoming image into three separate images, representing red, green, and blue. Three separate imaging chips are placed after the prism to collect the three separate images simultaneously. However, the third and most common approach is to use microprisms or colored filters mounted as a mask directly on the chip itself. In this arrangement, some photodiodes will be assigned to sense red, some green, and some blue. A computer algorithm keeps track of which pixels are which, and then combines the signals from adjacent R, G, and B sensing pixels and reports the result as one "virtual" pixel with R, G, and B values. Since the values from three (or more typically four) photodiodes are used to create one pixel, some resolution is sacrificed. Like all other areas of computing and electronics, imaging technology is advancing at a very rapid pace. Thus the reader is urged to consult current literature and vendor specifications for the latest advancements.

Digital Images, Image Processing, and Image Output

A full treatment of image processing and image analysis is beyond the scope of this chapter. However, a few thoughts are worthwhile for any scientist dealing with image data.

A digital image is ultimately an array of numbers where the value at each location in the array represents the intensity of one pixel in the image. A color image is represented by three values at each pixel. This array of numbers may be stored electronically in any of a myriad of proprietary file formats or in cross-platform formats such as bitmap (.bmp) or TIFF (.tif). In any event, the data should always be safely stored and archived in their raw, unadulterated form, before any image-processing steps or image-compression methods are applied. Subsequent processing steps should always be applied to a copy of the original data. Most vendors of imaging devices also offer software that controls image acquisition and offers some image-processing capabilities. Common image-processing packages include the NIH IMAGE software available from the US National Institutes of Health, Research Services Branch (http://rsb.info.nih.gov/nih-image), as well as programs primarily meant for the professional graphic arts world, such as Adobe® Photoshop®. There is often uncertainty about the scientific propriety of digital image manipulation. In general, the least amount of processing necessary is preferable, and no processing should be applied if quantitative data are being extracted from the images. Certain modest operations such as histogram stretching (which is scaling the intensity values in an image so that they span a wider range of output values) or gamma correction (a nonlinear display of data to accentuate dim features while maintaining bright features) are commonly applied for aesthetic images where quantitative analysis is not employed. Scientific guidelines are beginning to be formulated, and a good reference is the Microscopy Society of America's policy statement (www.microscopy.org). As with any treatment of scientific data, the methods of image manipulation must be documented and communicated such that others are capable of reproducing the findings from the raw data set or through independent experimental work.

Of course, the road to imaging productivity is not complete until the image is communicated to others in the scientific community. Image output must be considered as part of the scientific process. Digital images are embedded in other media files and viewed using a variety of means. Typical CRT computer monitors or LCD displays unfortunately have fairly limited resolution, displaying only about a million pixels at roughly 70 dots per inch (dpi). Scientific journals typically print at about 300 dpi. Standard data projectors also only display about a million pixels; the fact that the image is hugely magnified on a screen does not "create" added resolution. Likewise, images overly enlarged for printing on scientific posters can suffer if they do not contain sufficient resolution (pixels). If color information is important, then special care must be taken to ensure color fidelity throughout the image acquisition, display, and output processes. The responsibility for clear unbiased image presentation ultimately lies with the scientist. The image must be presented to the audience with adequate magnification, resolution, and contrast, such that an independent observer can identify the features that are important and independently reach the conclusions the author wishes to convey.

ELECTRON MICROSCOPY

The resolution of any probing technique is ultimately dependent upon the size of the probe and the nature of the probe–specimen interaction. The Rayleigh criterion

above describes how resolving power is related to wavelength in light microscopy. How then can we achieve much greater resolution? Although we can certainly use shorter wavelengths, the visible light spectrum is actually quite limited. To make really large strides in the achievement of resolution, the answer is to reduce the size of the probe drastically, and use electrons. Electrons indeed provide extraordinary resolution. However, in addition to interacting with the samples, electrons are also absorbed and scattered by even the small molecules in the atmosphere. Thus, electron microscopy techniques must be conducted under high-vacuum conditions such as those described in Chapter II.1.4.

Electron microscopy can be performed in either transmission or reflected modes. In transmission electron microscopy (TEM), images are formed by diffraction or phase contrast mechanisms, much as has been described earlier for transmitted light microscopy. The detectors are phosphor screens coupled with digital imagers. Samples must be very, very thin (50 nm). This is achieved by embedding samples in hard plastic resins and using very sharp diamond knife ultramicrotomes. TEM provides extraordinary resolution of organelle and membrane structures in single cells. For biomaterials, there is perhaps no other instrument that provides a higher resolution image of the intimate cell membrane–biomaterial interface. Unfortunately, the challenging nature and limitations of TEM sample preparation mean that this technique is under-utilized in biomaterials. By far the most common electron microscopy tool is scanning electron microscopy (SEM).

Scanning Electron Microscopy

The scanning electron microscope was developed in the 1960s and 1970s, and has had a tremendous impact on the materials sciences and engineering fields, as well as the biologic community. SEM provides three-dimensional-like topographical information of bulk specimens at nanometer resolutions. It is remarkable that, while complex to generate, SEM images are easily accessible for even a child to interpret. The SEM has been truly instrumental in opening doors to the micro- and nano-world for the general public. In biomaterials, the SEM is on an equal footing with Light Microscopy, as it is used to study the micro- and nanoscale structure of materials and devices, and cell–biomaterial interactions.

The scanning electron microscope (Figure II.3.8.7) is somewhat analogous to the scanning confocal microscope discussed earlier. Instead of a diffraction-limited laser beam, a beam of electrons is focused and swept across the surface of the specimen. The interaction of the electrons with the sample is localized and results in the generation of a signal, in this case other electrons escaping the specimen. These electrons are collected and counted by a detector, just as the photons are collected and counted by a photomultiplier tube (PMT)
FIGURE II.3.8.7 Schematic drawing of the electron column in an SEM showing the electron gun, lenses, the scanning system, and the electron detector. (From Goldstein et al., 2003.)

in LSCM. The counts collected at each raster point are then compiled into a digital image. The LSCM has very shallow depth of focus, and three-dimensional information has to be reconstructed by taking many images at various focus planes. A key advantage of the SEM is its extraordinarily large depth of focus, allowing for the direct imaging of complex, even somewhat tortuous, microscale structures.

To start with, in SEM, we require a plentiful (bright) and narrow beam of electrons for illumination. Conventional SEMs generate electrons by heating a hairpin-shaped filament of tungsten. The emitted electrons are quickly focused to a point by the Wehnelt cap, and then accelerated toward an anode at high voltage. Alternatively, a crystal of LaB_6 can be used as a source – this provides 5–10× greater brightness (more electrons), but requires a higher vacuum (10^{-4} Pa) and is much more expensive. Many modern instruments now utilize an alternative source, the field emission (FE) gun. The element is again tungsten, but the filament is now shaped into a very sharp wire tip (<100 nm radius). Electrons are pulled from the tip by a very high electric field, either without (cold field emission) or with (Schottky or thermal FE) the aid of heating. An FE source can provide a very narrow beam that is 1000× brighter than the conventional thermal source. However, the vacuum required at the tip is much higher, in the order of 10^{-9} Pa.

Focusing the illuminating beam of electrons onto the sample is accomplished by lenses; however, these lenses

are electromagnetic, not glass. Typically one or two condenser lenses begin to narrow the beam down, and a final "objective" lens focuses the beam onto the sample. Scanning coils are used to deflect the beam slightly from side-to-side, to accomplish the rastering of the beam across the specimen. Unlike glass lenses, the focal length of magnetic lenses can be changed simply by changing the magnetic field. A beam-limiting aperture is placed in the path, and is used to limit the diameter of the probe and ensure a narrow beam angle. A standard conically shaped objective lens can accommodate almost any size sample capable of fitting into the chamber. The lens may reside 1–20 mm away from the sample (the working distance). If the sample is small enough, it may actually be placed inside the objective lens field (an immersion lens instrument) with the advantages of lower aberrations, smaller probe size, and greater resolution.

Operation of the instrument requires balancing several operational parameters and making trade-offs. The diameter of the probe, the number of electrons in the probe (probe current), and the aperture angle are all crucial and quite interrelated parameters. Resolution is dependent upon small probe size, but there must be sufficient electrons to generate contrast (probe current): the familiar resolution/contrast trade-off again. Aperture angle also affects these, as well as determining the depth of focus. Thus, operational parameters such as source current, condenser strength, working distance, aperture size, and acceleration voltage are all adjusted depending upon the particular needs of the situation: e.g., high-resolution imaging, large depth of focus, a need for high current or surface sensitivity (low voltage).

The probe diameter of the incident electron beam may be as small as a few nanometers as it arrives at the surface. Unfortunately, the signal that is measured arises from interactions of this beam from within a much larger volume in the sample, the interaction volume. The incoming electrons may result in several measurable

signals upon hitting the specimen (Figure II.3.8.8). First, the very energetic electrons may bounce off, or far more likely, bounce through the upper layers of the specimen, before getting turned around and again escaping the sample and returning to the chamber. These elastically scattered electrons are detected as backscattered electrons (BSEs). Depending on their energies, and the nature of the specimen (e.g., the atomic number), these backscattered electrons might travel as deep as 5–10 μm into the sample, and re-emerge as far as a micrometer or two away from their point of entry. Next, as these BSEs are bouncing through the specimen, much weaker secondary electrons (SEs) are generated. If these secondary electrons are generated near enough to the sample surface (say within five mean free path lengths), then they too will escape and can be detected as a secondary electron signal. Not only can secondary electrons be generated and escape near the point of entry of the incident beam, but secondary electrons can also be generated near the point of exit of a BSE, and these also escape and count toward the measured SE signal. Finally, escaped BSEs that hit the walls of the chamber can also generate SEs, and these too are counted. Most commonly, the signal used to form an image is the combination of counts from BSEs and all the SEs mentioned. Understanding the size and depth of the interaction volume in the specimen is crucial to interpreting the resolution and surface sensitivity in SEM imaging.

The detector is most commonly an Everhart–Thornly (E-T) detector located somewhere on the wall of the chamber. The E-T detector works by attracting escaped electrons (BSEs and all the SEs) with a positively biased grid placed directly in front of a positively charged scintillator. Electrons hitting the scintillator generate photons of light that are carried out of the chamber through a light guide to a PMT, where they are counted. A negative bias on the grid will result in only the BSEs being detected.
FIGURE II.3.8.8 Signal generation in SEM. Incident electrons enter the sample, collide with sample atoms, and may eventually exit the sample as backscattered electrons (BSE). Secondary electrons (SE$_I$, SE$_{II}$) are generated and can escape the sample if they are generated close enough to the surface (typically within five mean free path lengths). BSEs can also collide with the chamber walls or other components to generate even more secondary electrons (SE$_{III}$). The electrons are drawn to the E-T (Everhart–Thornly) detector by the positively charged Faraday cage and the positively charged coating on the scintillator (S). The electrons are converted to photons and carried by the light guide (LG) out of the chamber, where the photons are counted by a photomultiplier tube (PMT). (After Goldstein et al., 2003.)

All the incident electrons used for illumination have to be drained somewhere. Thus, samples need to be conductive (or at least semiconductive) and grounded to the instrument. When current is unable to be discharged adequately it builds up on the surface, and is manifest as "charging" in the image that degrades system performance. For this reason, many nonconducting samples (including biologic samples and polymers) are often coated with a very thin layer of metal, typically Au/Pd. The energetic incident electrons can also be damaging to some beam-sensitive samples, including polymers and delicate biologic structures.

Elemental Analysis in the SEM

In addition to the BSE and SE discussed above, incident electrons may also cause the emission of X-rays from the sample. Measurement of the energy and intensity of these X-rays can provide for elemental composition mapping across the specimen. This technique, energy dispersive X-ray (EDX) analysis, is conceptually the reverse of ESCA or XPS, discussed in the chapter on surface analysis. This technique is electrons in, X-rays out.

Low-Voltage Imaging

Another key advantage of instruments designed around FE sources is that they can be operated at very low accelerating voltages, as low as 100 eV as compared to the typical 5–30 KeV in conventional instruments. This results in a much smaller interaction volume and thus more sensitivity to surface topography. The samples receive less beam damage, and in fact many samples may be imaged without a metalized coating.

Variable Pressure and ESEM

A major drawback to SEM is the requirement of operating under high vacuum, 10^{-3}–10^{-6} Pa or even lower pressures. Biologic samples must be fixed and dehydrated in the hope that the structure will be preserved somehow under vacuum. Polymers too can undergo significant structural rearrangement when under high-vacuum conditions (e.g., hydrogels). Porous structures such as bone can be difficult to pump down to such vacuum levels.

Solutions are now appearing in the form of the Environmental SEM (ESEM) and numerous variable pressure (VP) SEM instruments. The approach in both instruments is the same: basically, to make a "leaky" SEM. These instruments are differentially pumped, meaning that the portions of the instrument housing the electron gun and optics are kept under high vacuum, while the sample chamber is allowed to reach some larger (but not really atmospheric) pressure. The opening between the optics column and the specimen chamber (the leak) is kept as small as possible, and the sample is kept as close to this opening as possible, so that the incident electrons have only a short distance to travel through the scattering gas atmosphere. The ESEM, which has several fairly elaborate differential pumping systems, can reach chamber pressures as high as 2700 Pa (20 torr) and utilizes a special SE detector capable of operating in the presence of such gas pressures. This pressure is the saturated vapor pressure of water at room temperature, and thus fully hydrated specimens can be viewed directly. All SEM vendors now offer some form of these variable-pressure systems with chamber pressures reaching 250 Pa (2 torr) and utilizing a variety of detectors. This pressure is not adequate to keep samples fully hydrated, but samples can be observed "partially hydrated."

The advantages are obvious. Cells and tissues have been imaged under fully hydrated conditions. Colloids, emulsions, and hydrated polymers are no longer excluded from SEM analysis. The resolution in this operating mode, however, does not equal that under high vacuum, and scattering of the incident beam from column to sample is the culprit. For this reason, standard thermal electron guns and high accelerating voltages are typically used. Fortunately, the presence of the gas near the sample means that charging is much reduced. The flexibility offered by this mode of operation is tremendously attractive, and "VP-capable" SEMs have become big sellers.

Focused Ion Beam Instruments

Instead of an incident beam of electrons, a focused beam of positively charged ions can be delivered to the specimen, e.g., gallium ions from a liquid metal ion gun. This beam can also be used to generate images of very high resolution, but the technique is destructive. However, this can be an advantage, in that the focused ion beam (FIB) can be used as an extremely precise machining tool at the microscopic and, indeed, nanoscopic scale. Several new instruments now combine a FIB column with a SEM column, to create the ultimate fabrication and imaging instrument for nanoscale engineering.

THE REVOLUTION IN OPTICAL MICROSCOPY

Since the time of Anton van Leeuwenhoek (1632–1723) (he is often referred to as the father of microscopy), microscopists striving to resolve smaller and smaller objects have been challenged by the so-called diffraction limit. Experimentally observed by Ernst Abbe in 1873, and then refined a few years later by Lord Rayleigh, for light microscopy the limit for x,y resolution is approximately 200–250 nm. In the last 20 years, new imaging modes have evolved that go well beyond the diffraction limit, with resolutions approaching 20 nm. Of course, we can always use energetic shorter wavelength radiation with the SEM and TEM, but we lose the advantage of seeing living cells in action, and the ability to use color

(dyes, fluorophores) to enhance the information content of the image. So, this section will briefly address new optical methods permitting imaging of wet and living systems. Methods of this type are often categorized as super-resolution microscopy or nanoscopy.

The revolution in optical microscopy methods started with the laser scanning confocal microscope (LSCM), discussed earlier. The use of the scanned pinhole reduces the effect of diffraction on image formation, thereby increasing the possible x,y resolution to approximately 180 nm. The 4Pi laser scanning fluorescence microscope (first demonstrated in 1991) improved the image resolution to 80–150 nm by using two objective lenses focused to the same spot. These methods used clever technologies to improve resolution, but did not side-step the physics of the diffraction limit. Stimulated emission depletion microscopy (STED), first proposed in 1994, did indeed demonstrate that by using nonlinear de-excitation of fluorescent dyes, the diffraction limit could be significantly exceeded, and resolution to 16 nm could be observed. In 2006, photoactivated localization microscopy (PALM) was reported using photo-switchable fluorescent probes to reconstitute images from thousands of localized molecules. A related method, stochastic optical reconstruction microscopy (STORM), developed about the same time, also provides super-resolution images. Figure II.3.8.9 shows a STORM image of cell microtubules compared to an image recorded by conventional immunofluorescence methods. PALM and STORM images approach 20 nm x,y resolution. The physics permitting PALM, STORM, and other related methods to far exceed the diffraction limit is beyond the scope of this chapter, so a bibliography of review articles specifically focused on super-resolution microscopy is presented at the end of this chapter.

CONCLUSIONS

Although many of the techniques discussed here can trace their roots back for centuries, advances in modern microscopic imaging continue to abound. This section has not addressed scanning tunneling microscopy (STM) and atomic force imaging (AFM), important newer molecular imaging tools (see Chapter I.1.5). Surface analytical tools, such as ESCA and SIMS, are now being adapted to provide imaging capability at the microscopic scale. Conventional medical imaging tools, such as X-ray computed tomography (CT) and magnetic resonance imaging (MRI), are now being practiced at nearly microscopic resolutions. Electron tomography applied in high-voltage TEM instruments is revealing extraordinary three-dimensional representations of intracellular organelles and other structures. Modern computing power is reinvigorating the serial sectioning and reconstruction approaches of the past. The detection of intrinsic fluorescence via second harmonic generation in the multiphoton microscope is opening new doors to the imaging of biologic structures deeper in tissues. Optical coherence tomography promises important advances in tissue imaging for both clinical and research use. New nanoparticle fluorophores (quantum dots) provide extraordinarily bright emissions with narrow spectral signatures, enabling even further advancements in multi-label fluorescence imaging, biophotonics, and biosensors. Finally, new optical microscopy strategies for "breaking" the diffraction limit permit almost molecular-level views into living cells.

Microscopy is often assumed to be only about magnifying small objects. This is not totally inaccurate, but gives a poor description of how microscopy is used in modern science. The wealth of microscopy tools available to the modern scientist allows one to move beyond
FIGURE II.3.8.9 Cell microtubules imaged by conventional fluorescence microscopy and STORM. (A) Cell microtubules by conventional indirect immunofluorescence imaging; (B) 3D STORM image of the same area, with the z-position information indicated by the color scale bar. (From Huang et al., 2008. *Science* **319,** 810–813.)

simple visual exploration, and to begin to ask tailored mechanistic questions, pose hypotheses, and prove them with solid quantitative data. This is essential for scientific publication, as well as for the documentation required by regulatory agencies. The detailed description of structure; the localization of species in two and three dimensions with molecular specificity; the ability to follow and visualize molecular biological process such as gene expression over time – these are all powerful tools in the biomaterial scientist's arsenal. To be successful, the scientist must include microscopy and imaging considerations from the very onset of any experimental planning.

Degradation of Materials in the Biological Environment

CHAPTER II.4.1 INTRODUCTION: THE BODY FIGHTS BACK – DEGRADATION OF MATERIALS IN THE BIOLOGICAL ENVIRONMENT

Buddy D. Ratner

Professor, Bioengineering and Chemical Engineering, Director of University of Washington Engineered Biomaterials (UWEB), Seattle, WA, USA

The biological environment, seemingly a mild, aqueous salt solution at 37°C, is, in fact, surprisingly aggressive and can lead to rapid or gradual breakdown of many materials. Some mechanisms of biodegradation have evolved over millennia specifically to rid the living organism of invading foreign substances – these same mechanisms now attack our contemporary biomaterials. Other breakdown mechanisms have their basis in well-understood chemical and physical principles, and will occur in a living organism or in a beaker on a laboratory bench. After this introduction, four chapters (II.4.2, II.4.3, II.4.4, and II.4.5) directly address degradation. The first three of these consider breakdown in the biological environment. Chapter II.4.5 describes another type of degradation, calcification, which can lead to device failure and can exacerbate other degradation mechanisms. In addition, many of the textbook chapters address degradation in other contexts. Chapter I.2.6 reviews the chemistry of polymers designed to be biodegradable. Chapter III.1.4 addresses device failure, sometimes related to unintentional degradation. Most of the device-specific chapters consider degradation issues.

The biomaterials of medical devices are usually exposed to varying degrees of cyclic or periodic stress (humans ambulate and the cardiovascular system pumps). Abrasion and flexure may also take place. Such mechanical challenges occur in an aqueous, ionic environment that can be electrochemically active to metals, and plasticizing (softening) to polymers. It is well-known that a material under mechanical stress will degrade more rapidly than the same material that is not under load.

Specific biological mechanisms are also invoked. Proteins adsorb to the material and can enhance the corrosion rate of metals. Cells (especially macrophages) adhere to materials via those interfacial proteins, and can be activated to secrete powerful oxidizing agents and enzymes intended to digest or dissolve the material. The secreted, potent degradative agents are concentrated in the space between the adherent cell and the biomaterial upon which they act, undiluted by the surrounding aqueous medium. Also, bacteria, bacterial biofilms (Chapter II.2.8) and yeast can enhance degradation and corrosion rates.

To understand the biological degradation of implant materials, synergistic pathways must be considered. For example, cracks associated with stress crazing open up fresh surface area to reaction. Swelling and water uptake can similarly increase the number of sites for reaction, and provide an access route for degradative agents into the "core" of the biomaterial. Amorphous material at metal (and polymer) grain boundaries can degrade more rapidly, leading to increases in surface area and localized stresses. Degradation products can alter the local pH, catalyzing further reaction. Hydrolysis of hydrophobic polymers can generate hydrophilic species, leading to polymer swelling and providing an entry mechanism for degrading species to transport into the bulk of the polymer. Cracks might also serve as sites for the initiation of calcification.

Biodegradation is a term that is used in many contexts. It can be used for reactions that occur over minutes or over years. It can be engineered to happen at a specific time after implantation or it can be an unexpected long-term consequence of the severity of the biological environment. Implant materials can solubilize, crumble, become rubbery or become rigid with time. The products of degradation may be toxic or irritating to the body or they may be designed to perform a pharmacologic function.

Calcification, a process we strive for in bone healing, is undesirable in most soft tissue contexts. Calcific mineral can interfere with the mechanical function of devices, induce cracking in polymers and embolize, leading to complications downstream. Implants based on natural tissue are particularly subject to calcification, but calcification is reasonably common in synthetic polymer devices.

Here are a few interesting biomaterial degradation issues that might stimulate further thinking on this subject in conjunction with the tutorial chapters in this section.

- Consider strategies used to create materials that degrade at controlled rates, versus strategies for synthesizing biostable materials intended for long-term performance in the body.
- Consider the degradation of materials commonly used in medicine that do not have well-defined breakdown mechanisms. Some examples include poly(ethylene glycol), hydroxyapatite, and some polysaccharides. How does the body deal with these common materials?
- A new class of biomaterials is now under development that degrades on cue. The cue might be thermal, photonic or enzymatic. Ingenious chemical design principles are being applied to create such materials, but how might the body react to the products generated by a sudden breakdown of the structure?
- Learn about new strategies to stabilize materials against degradation, for example, vitamin E loading of orthopedic polymers, and incorporation of poly-isobutylene segments into elastomers.
- Endovascular stents are among the most widely used of all medical devices (Chapter II.5.3.B). A new generation of biodegradable stents is expected to have huge impact on cardiovascular therapies. Consider how biodegradable poly(lactic acid) or magnesium or iron will perform in the complex intra-vascular environment.
- For a medical device intended for years of service, especially a device where failure can lead to death, how can we test and qualify the device for the expected period of service? Are there useful *in vitro* tests? Are there relevant and justified animal models?
- Henry Petroski and other authors have discussed the important role of failure in advancing engineering design. Consider medical device failure, past and present, associated with degradation, and how these unintended complications will lead to better medical devices. A few examples include the degradation of polyurethane pacemaker leads, the breakdown of a protective sheath on the tailstring of the Dalkon Shield IUD, and the wear debris associated with the oxidation of ultra-high molecular weight polyethylene in hip prostheses.

Degradation in biological environments is seen with metals, polymers, ceramics, and composites. It is observed to some degree in most long-term implants, and even in some medium-term and short-term implants. Often, its initiation, mechanism, and consequences are incompletely defined. Biodegradation as a subject is broad in scope, and critical to device performance. It rightfully should command considerable attention for the biomaterials scientist. This section introduces biodegradation issues for a number of classes of materials, and provides a basis for further study on this complex but critical subject.

CHAPTER II.4.2 CHEMICAL AND BIOCHEMICAL DEGRADATION OF POLYMERS INTENDED TO BE BIOSTABLE

Arthur J. Coury
Coury Consulting Services, Boston, MA, USA

Biodegradation is the chemical breakdown of materials by the action of living organisms that leads to changes in physical properties. It is a concept of vast scope, ranging from decomposition of environmental waste involving microorganisms to host-induced deterioration of biomaterials in implanted medical devices. Yet it is a precise term, implying that specific biological processes are required to effect such changes (Williams, 1989). This chapter, while grounded in biodegradation, addresses other processes that contribute to the often complex mechanisms of polymer degradation. Its focus is the unintended chemical breakdown in the body of synthetic solid-phase polymers. (See Chapters I.2.6 and II.4.3 for a description of systems engineered to break down in the body.) The factors impacting the undesired biodegradation of polymeric implants are largely well-defined, although some recent progress (to be noted) has been made in mitigating such degradation.

POLYMER DEGRADATION PROCESSES

Pre-Implant Degradation

Polymeric components of implantable devices are generally reliable for their intended lifetimes. Careful selection and extensive preclinical testing of the compositions, fabricated components, and devices usually establish functionality and durability. However, with chronic, indwelling devices, it is not feasible during qualification (typically short-term testing) to match all implant conditions in real time for years or decades of use. The accelerated aging, animal implants, and statistical projections employed cannot expose all of the variables that may cause premature deterioration of performance. The ultimate measure of the acceptability of a material for a medical device is its functionality for the device's intended lifetime as ascertained in human post-implant surveillance (Coury, 1999).

No polymer is totally impervious to the chemical processes and mechanical action of the body. Generally, polymeric biomaterials degrade because body constituents attack the biomaterials directly or through other device components, sometimes with the intervention of external factors.

Numerous operations are performed on a polymer from the time of its synthesis to its use in the body (see

TABLE II.4.2.1	Typical Operations on an Injection-Moldable Polymer Biomaterial
Polymer: Synthesis, extrusion, pelletizing	
Pellets: Packaging, storage, transfer, drying	
Components: Injection-molding, post-mold finishing, cleaning, inspecting, packaging storage	
Device: Fabrication storage (presterilization) cleaning, inspecting, packaging, storage (packaged), sterilization, storage (sterile), shipment, storage (pre-implant), implantation, operation in body	

Table II.4.2.1). Table II.4.2.1 lists mechanisms of physical and chemical deterioration, which may occur alone or in concert at various stages of a polymer's history. Moreover, a material's treatment prior to implantation may predispose it to stable or unstable end-use behavior (Brauman et al., 1981; Greisser et al., 1994; Ling et al., 1998). A prominent example of biomaterial degradation caused by pre-implant processing is the gamma irradiation sterilization of ultra-high molecular weight polyethylene used in total joint prostheses. The process generates free radicals within the material that react with oxygen to produce undesirable oxidation products. Chain oxidation, scission, and cross-linking can occur for periods of months to years, causing loss of strength and embrittlement with limited shelf-life (Furman and Li, 1995; McKellop et al., 1995; Weaver et al., 1995; Daly and Yin, 1998; Blanchet and Burroughs, 2001; Kurtz et al., 2005; Rimnac and Pruitt, 2008). Recent attempts to mitigate degradation effects by gamma sterilization in inert atmospheres instead of air and the use of anti-oxidants such as Vitamin E have provided some improvement in the long-term *in vivo* performance of polyethylene joint components (Booth, 1995; Medel et al., 2009; Crowninshield and Muratoglu, 2008). Polypropylene and polytetrafluoroethylene are also notable as polymers that are predominately, but not entirely (Liebert et al., 1976), chemically stable in the body, but can be severely degraded (during processing) by sterilization with ionizing radiation (Williams, 1982; Portnoy, 1997). Gamma irradiation may also cause optical changes such as darkening of poly(methyl methacrylate) intraocular lenses (Hoffman, 1999). It is crucially important, therefore, that appropriate and rigorous processing and characterization protocols be followed for all operations (Coury et al., 1988; Shen et al., 1999).

Post-Implant Degradation Forces

After a device has been implanted, adsorption and absorption processes occur. Polymeric surfaces in contact with body fluids immediately adsorb proteinaceous components, and the bulk begins to absorb soluble components such as water, ions, proteins, and lipids. Cellular elements subsequently attach to the surfaces and initiate chemical processes. With biostable components,

this complex interplay of factors is of little functional consequence. At equilibrium fluid absorption, there may be some polymer plasticization causing dimensional and mechanical property changes (Coury et al., 1988). On the surface, a powerful acute attack by cells and many chemical agents, including oxidants and enzymes, will have been substantially withstood, although inconsequential, superficial surface changes may occur. With the resolution of this acute inflammatory phase, a fibrous capsule will likely have formed over the device, and the rate of release of powerful chemicals from activated cells will have markedly decreased.

For those polymers subjected to chemical degradation *in vivo*, few if any reports have comprehensively described the sequential processes and interactions that produce the deleterious effects. Rather, explant analysis and occasionally metabolite evaluation are used to infer reaction pathways. Analysis of chemically degraded polymers has almost always implicated either hydrolysis or oxidation as an essential component of the process.

HYDROLYTIC BIODEGRADATION

Structures of Hydrolyzable Polymers

Hydrolysis is the scission of susceptible molecular functional groups by reaction with water. Hydrolysis may be catalyzed by acids, bases, salts or enzymes. It is a single-step process in which the rate of chain scission is directly proportional to the rate of initiation of the reaction (Schnabel, 1981). A polymer's susceptibility to hydrolysis is the result of its chemical structure, its morphology, its mass and dimensions, and the body's environment.

In a commonly used category of hydrolyzable polymeric biomaterials, functional groups consist of carbonyls bonded to heterochain elements (O, N, S). Examples include esters, amides, urethanes, carbonates, and anhydrides (Figure II.4.2.1). Other polymers containing groups such as ether, acetal, nitrile, phosphonate, sulfonate, sulfonamide or active methylenes hydrolyze under certain conditions (Figure II.4.2.1). Hydrolytically susceptible groups exhibit differing rates of degradation which are dependent on the intrinsic properties of the functional group, and on other molecular and morphological characteristics. Among carbonyl polymers with oxygen hetero-atoms attached, anhydrides display the highest hydrolysis rates followed, in order, by esters and carbonates. Polymers containing such groups, in fact, comprise many of the intentionally-resorbable devices (Chapter II.4.3). Other carbonyl-containing groups such as urethane, imide, amide, and urea can demonstrate long-term stability *in vivo* if contained in a hydrophobic backbone or highly crystalline morphologic structure. Groups that are normally very stable to hydrolysis are indicated in Figure II.4.2.2.

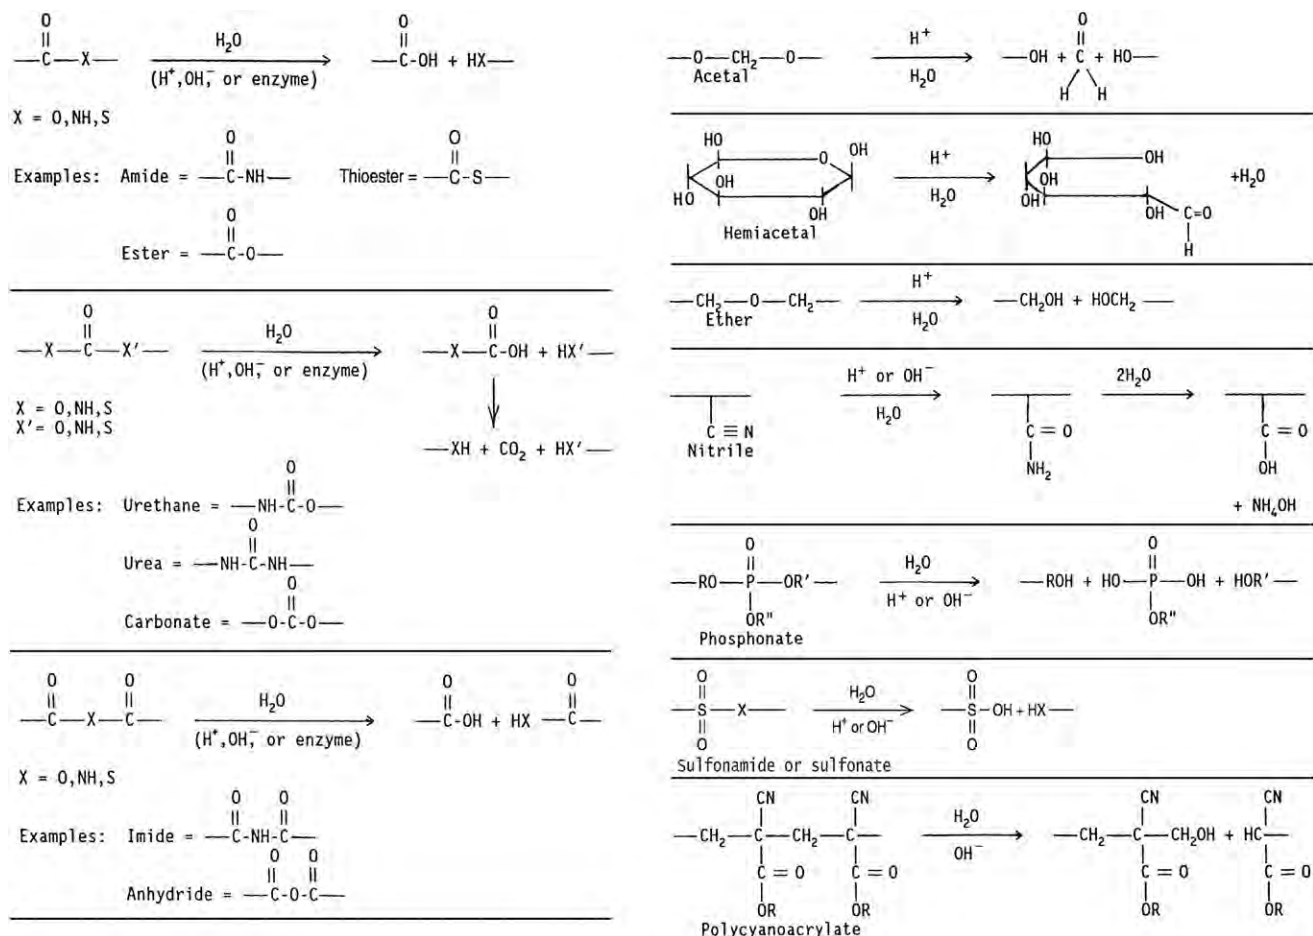
The rate of hydrolysis tends to increase with one or more of the following: a high proportion of hydrolyzable


FIGURE II.4.2.1 Hydrolyzable groups in polymer biomaterials.
FIGURE II.4.2.2 Groups highly stable to hydrolysis.

groups in the main or side chain; other polar groups which enhance hydrophilicity; low crystallinity; low or negligible cross-link density; a high ratio of exposed surface area to volume; and, in some cases, mechanical stress. Porous hydrolyzable structures undergo rapid property loss relative to monolithic structures, because of their large surface area. Factors that tend to suppress hydrolysis rate include hydrophobic molecular moieties

(e.g., hydrocarbon or fluorocarbon), cross-linking, high crystallinity due to chain order, thermal annealing or orientation, low stress, and compact shape (low surface-to-volume ratio). While the molecular weight of linear polymers *per se* may not have a great effect on the hydrolysis induced degradation rate, physical property losses may be retarded for a given number of chain cleavage events with relatively high molecular weight polymers. Property loss caused by chain cleavage is more pronounced in polymers with weak intermolecular bonding forces.

Host-Induced Hydrolytic Processes

The body is normally a highly controlled reaction medium. Through homeostasis, the normal environment of most implants is maintained at isothermal (37°C), neutral (pH 7.4), aseptic, and photo-protected aqueous steady-state. By *in vitro* standards, these conditions may appear mild. However, complex interactions of humoral and cellular components of body fluids involving activators, receptors, inhibitors, etc., produce aggressive responses to any foreign-bodies through the processes of cell adhesion, cell activation, chemical reaction, and particulate transport.

Several scenarios leading to hydrolysis in the host can be considered. For all scenarios, hydrolysis can only occur at a site other than the surface of a polymer mass after water permeates to the site. The first scenario considers water at pH 7. Water is capable of hydrolyzing certain polymers (e.g., polyglycolic acid) at a significant rate (Chapters I.2.6 and II.4.3, and Zaikov, 1985). However, this simple hydrolysis mechanism is unlikely to be significant in polymer compositions selected for long-term *in vivo* biostability.

Next, ion-catalyzed hydrolysis offers a likely scenario in body fluids. Extracellular fluids contain ions such as: H^+, OH^-, Na^+, Cl^-, HCO_3^-, PO_4^{3-}, K^+, Mg^{2+}, Ca^{2+}, and SO_4^{2-}. Organic acids, proteins, lipids, lipoproteins, etc., also circulate as soluble or colloidal components. It has been shown that certain ions (e.g., PO_4^{3-}) are effective hydrolysis catalysts, enhancing, for example, reaction rates of polyesters by several orders of magnitude (Zaikov, 1985). Ion catalysis may be a surface effect or a combined surface–bulk effect, depending on the hydrophilicity of the polymer. Very hydrophobic polymers (e.g., those containing <2% water of saturation) absorb negligible concentrations of ions. Hydrogels, on the other hand, which can absorb large amounts of water (>15% by weight) are essentially "sieves," allowing significant levels of ions to permeate and be absorbed with consequent bulk hydrolysis via acid, base or salt catalysis.

Localized pH changes in the vicinity of the implanted device, which usually occur during acute inflammation or infection, can cause catalytic rate enhancement of hydrolysis (Zaikov, 1985). Organic components, such as lipoproteins, circulating in the bloodstream or in extracellular fluid, appear to be capable of transporting catalytic inorganic ions into the polymer bulk by poorly defined mechanisms.

Enzymes generally serve a classic catalytic function, altering reaction rate (via ion or charge transfer) without being consumed by modifying activation energy, but not thermodynamic equilibrium. While enzymes function in extracellular fluids, they are most effectively transferred onto target substrates by direct cell contact (e.g., during phagocytosis). Hydrolytic enzymes or hydrolases (e.g., proteases, esterases, lipases, glycosidases) are named for the molecular structures they affect. They are cell-derived proteins which act as highly specific catalysts for the scission of water-labile functional groups.

Enzymes contain molecular chain structures and develop conformations that allow "recognition" of chain sequences (receptors) predominately found on biopolymers. Complexes form between chain segments of the enzyme and the biopolymer substrate which result in enhanced bond cleavage rates. Lacking the recognition sequences of susceptible natural polymers, most synthetic polymers are more resistant to enzymatic degradation than natural polymers. Nevertheless, comparative studies have shown some enhancement of hydrolysis rates by enzymes, particularly with synthetic polyesters and polyamides (Kopecek and Ulbrich, 1983; Zaikov, 1985; Smith et al., 1987). Apparently the enzymes can recognize and interact with structural segments of the polymers, or more accurately, of the polymers coated with serum proteins, to initiate their catalytic action *in vivo* (Pitt, 1992).

Enzymes with demonstrated effects on hydrolysis rates can be quite selective in the presence of several hydrolyzable functional groups. For example, poly(ether urethane ureas) and poly(ester urethane ureas) exposed to hydrolytic enzymes (an esterase, cholesterol esterase, and a protease, elastase) were observed for rate of hydrolysis and hydrolytic site. Enzyme catalysis was clearly observed for the ester groups, while the hydrolytically susceptible urea, urethane, and ether groups did not show significant hydrolysis, as indicated by release of radio-labeled degradation products (Santerre et al., 1994; Labow et al., 1995, 2002a).

Many enzymes exert predominantly a surface effect because of their molecular size, which prevents absorption. Even hydrogels (e.g., poly(acrylamide)), which are capable of absorbing certain proteins, have molecular weight cut-offs for absorption, and can exclude large enzymes. However, as the degrading surface becomes roughened or fragmented, enzymatic action may be enhanced as a result of increased surface area if the substrates remain accessible to phagocytic cells that express the active enzymes. Implanted devices that are in continuous motion relative to neighboring tissue can provoke inflammation, stimulating enzyme release.

Hydrolysis: Preclinical and Clinical Experience

A discussion of *in vivo* responses of several prominent polymer compositions known to be susceptible to hydrolysis follows. The structures of these polymers are described in Chapter I.2.2.

Polyesters. Poly(ethylene terephthalate) (PET), in woven, velour or knitted fiber configurations, remains a primary choice of cardiovascular surgeons for large-diameter vascular prostheses, arterial patches, valve sewing rings, etc. It is a strong, flexible polymer, stabilized by high crystallinity as a result of chain rigidity and orientation, and is often considered to be biostable. Yet, over several decades, there have been numerous reports of long-term degeneration of devices *in vivo*, owing to breakage of fibers and device dilation. Proposed causes have been structural defects, processing techniques, handling procedures, and hydrolytic degradation (Cardia and Regina, 1989).

Systematic studies of PET implants in healthy dogs have shown slow degradation rates, which were estimated to be equivalent to those in humans. For woven patches implanted subcutaneously, a mean total absorption time by the body of 30 ± 7 years, with 50% deterioration of fiber strength in 10 ± 2 years was projected. In infections in dogs, however, where localized pH dropped to as low as 4.8, degradation was enhanced exponentially, with complete loss of properties within a few months (Zaikov, 1985). Human implant retrieval studies have shown significant evidence of graft infection (Gumargalieva et al., 1982; Vinard et al., 1991). Besides the obvious pathological consequences of infection, the enhanced risk of polymer degradation due to local pH and oxidative agents is a cause for concern.

Aliphatic polyesters are most often intended for use as biodegradable polymers, with polycaprolactone, for example, undergoing a significant decrease in molecular weight, as indicated by a drop of 80–90% in relative viscosity within 120 weeks of implant (Kopecek and Ulbrich, 1983).

Poly(ester urethanes). The earliest reported implants of polyurethanes, dating back to the 1950s, were cross-linked, aromatic poly(ester urethane) foam compositions (Bloch and Hastings, 1972; Blais, 1990). Their use in plastic and orthopedic reconstructive surgery initially yielded promising results. Acute inflammation was low. Tissue ingrowth promoted thin fibrous capsules. However, within months they were degraded and fragmented, producing unsatisfactory chronic effects (Bloch and Hastings, 1972). Foci of initial degradation of those polymers are generally considered to be the polyadipate ester soft segments that undergo hydrolysis (Figure II.4.2.3). By comparison, corresponding poly(ether urethanes) are very resistant to hydrolysis, although more susceptible to oxidation (see the section, below, on oxidative biodegradation). Whether such hydrolytically degraded poly(ester urethanes) subsequently produce meaningful levels of aromatic amines (suspected carcinogens) by hydrolysis of urethane functions *in vivo* is an unresolved subject (Blais, 1990; Szycher and Siciliano, 1991).

It is noteworthy that poly(ester urethane) foam-coated silicone mammary implants have survived as commercial products for decades (Blais, 1990), despite their known propensity to degrade. Apparently, the type of fibrous capsules formed, initially by ingrowth into the degradable foam, was favored by some clinicians over those caused by smooth-walled silicone implants. In large devices, unstabilized by tissue ingrowth, the frictional effects of sliding may cause increased capsule thickness and contraction (Snow et al., 1981), along with extensive chronic inflammation.
FIGURE II.4.2.3 Structure of implantable poly(ester urethane), poly(ether urethane), and poly(ester urethane urea).

Polyamides. Nylon 6 (polycaproamide) and nylon 6,6 [poly(hexamethylene adipamide)] contain a hydrolyzable amide connecting group, as do proteins. These synthetic polymers can absorb 9–11% water, by weight, at saturation. It is predictable, then, that they degrade by ion-catalyzed surface and bulk hydrolysis (Figure II.4.2.1). In addition, hydrolysis due to enzymatic catalysis leads to surface erosion (Zaikov, 1985). Quantitatively, nylon 6,6 lost 25% of its tensile strength after 89 days, and 83% after 726 days in dogs (Kopecek and Ulbrich, 1983). An example of polyamide degradation of particular consequence involved the *in vivo* fragmentation of the nylon 6 tail string of an intrauterine contraceptive device. This string consisted of a nylon 6-sheath around nylon 6 multifilaments. The combination of fluid absorption (>10%) and hydrolysis was claimed to produce environmental stress cracking. The cracked coating allegedly provided a pathway for bacteria to travel from the vagina into the uterus, resulting in significant pelvic inflammatory disease (Hudson and Crugnola, 1987).

Degradation of a polyarylamide intended for orthopedic use (the fiber-reinforced polyamide from *m*-xylylene diamine and adipic acid) was also shown in a rabbit implant study. Although the material provoked a foreign-body reaction comparable to a polyethylene control, surface pitting associated with resolving macrophages was noted at 4 weeks, and became more pronounced by 12 weeks. This result was not predicted, since polyaryl-amides are very resistant to solvents and heat (Finck et al., 1994).

Polyamides with long aliphatic hydrocarbon chain segments (e.g., polydodecanamide) are more hydrolytically stable than shorter chain nylons, and correspondingly degrade slower *in vivo*.

Poly(alkyl cyanoacrylates). This class of polymers used as tissue adhesives is noteworthy as a rare case in which carbon–carbon bonds are cleaved by hydrolysis (Figure II.4.2.1). This occurs because the methylene ($-CH_2-$) hydrogen in the polymer is highly activated inductively by electron-withdrawing neighboring groups. Formation of the polymer adhesive from monomers is base catalyzed, with adsorbed water on the adherend being basic enough to initiate the reaction.

Catalysts for equilibrium reactions affect the reverse, as well as the forward reaction. Therefore, water associated with tissue can induce polycyanoacrylate hydrolysis by a "reverse Knoevenagel" reaction (Figure II.4.2.1). More basic conditions and (as suggested by *in vitro* cell culture or implant studies) enzymatic processes are much more effective at inducing hydrolysis. In chick embryo liver culture (a rich source of a variety of enzymes), poly(methyl cyanoacrylate) degraded much faster than in cell culture medium alone. In animal implants, poly(methyl cyanoacrylate) was extensively degraded within 4–6 months (Kopecek and Ulbrich, 1983). Higher alkyl (e.g., butyl) homologs degraded slower than the methyl homolog, and were less cytotoxic (Hegyeli, 1973; Vauthier et al.,

2003). Octyl cyanoacrylate polymer, introduced to the device field as a dermal tissue adhesive (Singer et al., 2008), promises to be the most stable cyanoacrylate device composition to date, based on increased hydrophobicity. Preclinical and clinical studies have yielded promising results with use of octyl cyanoacrylate as a surgical sealant (Barbarini Ferraz et al., 2009; Carr, 2011), and recently, a composition containing the monomers octyl cyanoacrylate and butyl lactoyl cyanoacrylate was FDA (US Food and Drug Administration) approved as a blood vessel anastomotic sealant (US FDA, 2010).

Polymers Containing Hydrolyzable Pendant Groups

Certain polymers intended for long-term implantation consist of biostable main chain sequences and hydrolyzable pendant groups. Poly(methyl methacrylate) (PMMA) used in bone cements and intraocular lenses is an example of a hydrophobic polymer with a stable hydrocarbon main chain and hydrolyzable ester side groups. It has been proven, over decades of use, to provide reliable, stable service, with hydrolysis rates being so slow as to be inconsequential.

Another polymer system with a hydrocarbon backbone, poly(methyl acrylate-*co*-2-hydroxyethyl acrylate) also contains hydrolyzable ester side groups. This polymer, which forms hydrogels in an aqueous environment, has been used as a "scleral buckling" device for retinal detachment surgery. Basically, the dry polymer, shaped as a band or ring, placed as a "belt" around the sclera, expands through hydration to create an indentation in the zone of the retinal detachment to re-establish retinal contact. The device is left in place as a permanent implant (or "exoplant" as it is sometimes called because it is external to the sclera) (Braunstein and Winnick, 2002). This hydrogel device, introduced into clinical practice in the 1980s (Refojo and Leong, 1981; Colthurst et al., 2000), apparently performed satisfactorily for years as an approved product. However, in the 1990s, reports of long-term complications of these hydrogel scleral buckles began to surface (Hwang and Lim, 1997; Roldan-Pallares et al., 1999). The hydrogel structures resumed swelling, sometimes with fragmentation, after maintaining stable dimensions for years. One report described a difficult explantation 13 years after implantation (Braunstein and Winnick, 2002). An article described three unique complications from hydrogel sclera buckle use: orbital cellulitis mimicry; fornical shortening with orbital prosthetic intolerance; and orbital pseudo-tumor (Bernardino et al., 2006). Those buckles remained in place for 7 to 15 years, with a mean time of 10.7 years. In a study of 15 patients with 17 scleral buckles, all reported complications within 4 to 14 years (Figures II.4.2.4, II.4.2.5, II.4.2.6). Removal of the buckles was technically difficult and post-operative complications were significant, although immediate palliative

relief was experienced after surgery. Pressures applied to the eye by the swelling have led to blindness and loss of the eyeball. Hydrogel scleral buckles are no longer used in retinal surgery (Watt, 2001).
FIGURE II.4.2.4 A subconjunctival and subpalpebral hydrogel explant interferes with ocular motility, especially on attempted gaze up and to the right. (From J. J. Kearney et al. (2004). *Am. J. Ophthal.,* 137.)
FIGURE II.4.2.5 A washed 4 mm hydrogel explant showing multiple fragments of a swollen explant and a 3 mm silicone sponge explant for comparison. The sponge was removed at the same surgical sitting as the hydrogel explant. (From J. J. Kearney et al. (2004). *Am. J. Ophthal.,* 137.)

Very little speculation has been provided in published articles about the mechanism of failure of acrylate scleral buckling devices other than that chemical degradation has occurred (Roldan-Pallares et al., 1999). I suggest that a likely mechanism involves hydrolysis of the ester side groups enhanced by the hydrophilic nature of the polymer (as contrasted to hydrophobic polymers such as PMMA). Hydrolysis of either of the two acrylate esters in the polymer chain provides an acrylic acid moiety. Linear poly(acrylic acid) is fully water soluble, and each hydrolytic event renders the polymer more hydrophilic and subject to enhanced swelling. This process is slow but inexorable in the case of the scleral buckling device. The valuable lesson is that devices with intrinsically susceptible groups can eventually degrade by predictable mechanisms. This may take longer than is required for pivotal preclinical qualification studies (typically two-year animal implants). In fact, Bernardino et al. (2006), in discussing long-term hydrogel implants, warn: "Patients with newer uses of hydrogel, such as orbital expanders, should also be observed for long-term complications." If late degradation is suspected, therefore, accelerated aging studies should be performed *in vitro* with correlations made to *in vivo* studies. Such efforts give valuable, if not completely trustworthy, information (see the section above "Polymer Degradation Processes").

OXIDATIVE BIODEGRADATION

Oxidation Reaction Mechanisms and Polymer Structures

While much is known about the structures and reaction products of polymers susceptible to oxidative biodegradation, confirmation of the individual reaction steps has not yet been demonstrated analytically. Still, mechanistic inferences are possible from extensive knowledge of physiological oxidation processes and polymer oxidation *in vitro*.

The polymer oxidation processes to be discussed may be consistent with a homolytic chain reaction or a heterolytic mechanism. Species such as carbonyl, hydroxyl, and chain scission products are detectable in these types of processes. Classic initiation, propagation, and
FIGURE II.4.2.6 Left panel: Computed tomography scan showing a hydrogel implant in the anterior orbit of the right eye. Right panel: Magnetic resonance image of the left orbit shows an expanded hydrogel explant. (From J. J. Kearney et al. (2004). *Am. J. Ophthal.,* 137.)

termination events for homolysis and ionic heterolytic processes are detailed in Figure II.4.2.7.

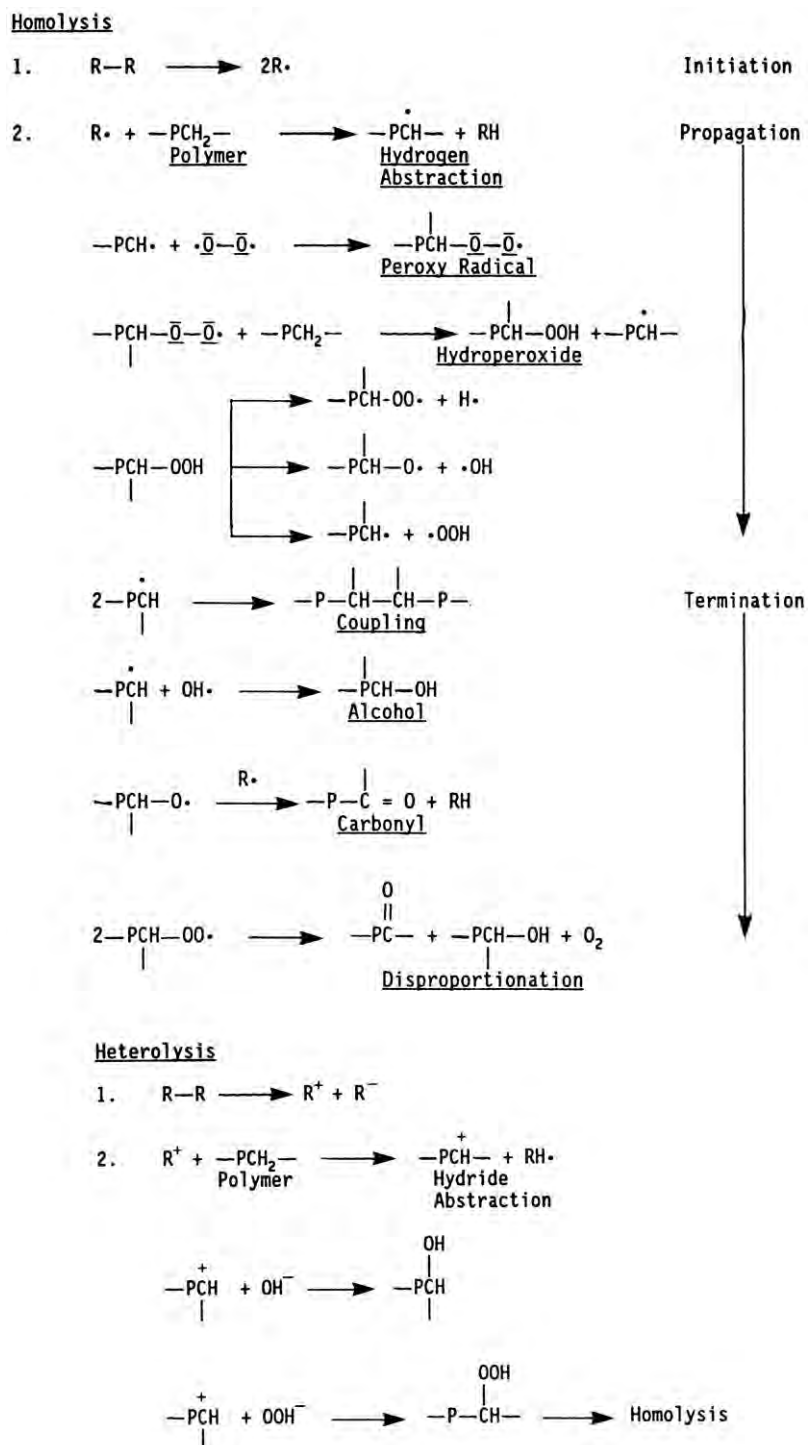
The principles of polymer degradation resistance stated in the section on hydrolyzable polymers (e.g., group frequency, crystallinity, hydrophobicity) are valid for predicting relative oxidation resistance of polymers, except where particularly oxidation-susceptible groups are present. Sites favored for initial oxidative attack, consistent with a homolytic or heterolytic pathway, are those that allow abstraction of an atom or ion, and provide resonance stabilization of the resultant radical or ion. Figure II.4.2.8 provides a selection of readily oxidized groups and the atom at which initial attack occurs. In Figure II.4.2.9, examples of radical and ion stabilization by resonance in ether and branched hydrocarbon structures are provided. Peroxy, carbonyl, and other radical intermediates are stabilized by similar resonance delocalization of electrons from the elements C, O, H or N.


FIGURE II.4.2.7 Proposed homolytic chain reaction and heterolytic oxidation mechanisms.
FIGURE II.4.2.8 Readily oxidizable functional groups (* is site of homolysis or heterolysis).

Two general categories of oxidative biodegradation, based on the source of initiation of the process, are direct oxidation by the host and external environment-mediated oxidation.

Direct Oxidation by Host

In these circumstances, host-generated molecular species effect or potentiate oxidative processes directly on the polymer. Current thinking, based on solid analytical evidence, is that such reactive molecules are derived from activated phagocytic cells responding to the injury and the properties of the foreign-body at the implant site (Zhao et al., 1991). The two major types of these cells are the neutrophils (polymorphonuclear leukocytes, PMNs) and the monocytes. The latter, which are found in circulation, can differentiate upon attachment to tissue and divide into macrophage and foreign-body giant cell (FBGC) phenotypes (see Chapter II.2.2) (Ziats, 1988).

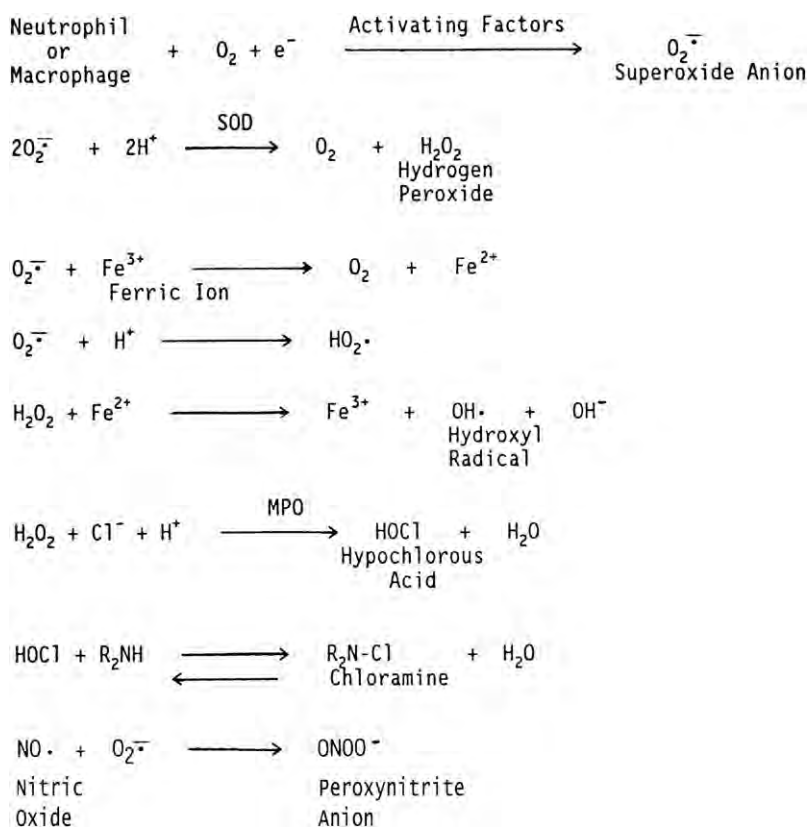
Much work is underway to elucidate the sequence of events leading to phagocytic oxidation of biomaterials. Certain important processes of wound healing in the presence of biologically derived foreign-bodies such as bacteria and parasites are showing some relevance to biomaterial implants (Northup, 1987).
FIGURE II.4.2.9 (A) Resonance stabilization of ether and hydrocarbon radicals; (B) Resonance stabilization of ether and hydrocarbon cations.


FIGURE II.4.2.10 Generation of potential oxidants by phagocytic processes.

Neutrophils, responding to chemical mediators at the wound site, mount a powerful but transient chemical attack within the first few days of injury (Test and Weiss, 1986; Northup, 1987). Chemically susceptible biomaterials may be affected if they are in close apposition to the wound site (Sutherland et al., 1993). Activated macrophages subsequently multiply and subside within days at a benign wound site or in weeks if stimulants such as toxins or particulates are released at the site. Their fusion products (foreign-body giant cells) FBGCs, can survive for months to years on the implant surface. Macrophages also remain resident in the collagenous foreign-body capsule for extended periods.

While it is recognized that the mechanism of cellular attack and oxidation of biomaterials is as yet unconfirmed, the following discussion attempts to provide logical biological pathways to powerful oxidants capable of producing known degradation products.

Both PMNs and macrophages metabolize oxygen to form a superoxide anion (O_2^-). This intermediate can undergo transformation to more powerful oxidants, and conceivably can initiate homolytic reactions on the polymer. Superoxide dismutase (SOD), a ubiquitous peroxidase enzyme, can catalyze the conversion of superoxide to hydrogen peroxide which, in the presence of myeloperoxidase (MPO) derived from PMNs, is converted to hypochlorous acid (HOCl). A potent biomaterial oxidant in its own right (Coury et al., 1987), hypochlorite (ClO$^-$)

can oxidize free amine functionality (e.g., in proteins) to chloramines that can perform as long-lived sources of chlorine oxidant (Test and Weiss, 1986; Figures II.4.2.10, II.4.2.11). Hypochlorite can oxidize other substituted nitrogen functional groups (amides, ureas, urethanes, etc.) with potential chain cleavage of these groups.

The following paragraphs describe potential cooperative reactions involving acquired peroxidase and free ferrous ions. Macrophages contain essentially no MPO, so their hydrogen peroxide is not normally converted to HOCl. However, PMN-derived MPO can bind securely to foreign-body surfaces (Locksley et al., 1982), and serve as a catalyst reservoir for macrophage- or FBGC-derived HOCl production. If free ferrous ion, which is normally present in negligible quantities in the host, is released to the implant site by hemolysis or other injury, it can catalyze the formation of the powerfully oxidizing hydroxyl radical via the Haber–Weiss cycle (Klebanoff, 1982; Figure II.4.2.10).

Figure II.4.2.11 shows radical and ionic intermediates of HOCl that may initiate biomaterial oxidation. Figure II.4.2.12 is a diagram showing a leukocyte phagocytic process that employs endogenous MPO catalysis of HOCl formation. In a more general sense, the MPO may come from within or outside of the cell.

The foregoing discussion of sources of direct oxidation focused primarily on acute implant periods in which bursts of PMN activity followed by macrophage activity normally resolve within weeks. However, since the

foreign-body subsequently remains implanted a sustained if futile attempt to phagocytose an implanted device provides a prolonged release of chemicals onto the biomaterial. This phenomenon, called exocytosis, occurs over months to possibly years (Zhao et al., 1990), and results

primarily from the macrophage-FBGC line. It can contribute to long-term chemical degradation of the polymer.

The oxidation processes induced by phagocytes are the result of oxidants produced by general foreign-body responses, not direct receptor–ligand catalysis by oxidase

enzymes. Attempts to degrade oxidatively susceptible polymers by direct contact with oxidase enzymes have produced short-range or limited effects (Sutherland et al., 1993; Santerre et al., 1994).

Macrophages mediate other processes, such as fibrous capsule formation, around the device. Their release of cellular regulatory factors stimulates fibroblasts to populate the implant site and produce the collagenous sheath. Any knowledge of the effects of factors such as fibroblasts or fibrous capsules on rates and mechanisms of polymer degradation is, at this time, rudimentary.

Stress Cracking

An important category of host-induced biodegradation with an oxidative component is stress cracking as manifested in poly(ether urethane) elastomers implants. It differs from classic environmental stress cracking (ESC), which involves a susceptible material at a critical level of stress in a medium that may permeate and swell the polymer but does not dissolve the polymer. Classic ESC is not accompanied by significant chemical degradation (Stokes, 1988). In contrast, stress cracking of polyurethanes is characterized by surface attack of the polymer, and by chemical changes induced by relatively specific *in vivo* or *in vitro* oxidizing conditions. Conditions relevant to stress cracking of certain poly(ether urethane) compositions are stated in Table II.4.2.3.

Experimental information on the stress cracking of poly(ether urethanes) and poly(ether urethane ureas)

(e.g., the polymers described in Figure II.4.2.3) has provided insights which may be valid for these and other compositions that can be oxidized, for example, polypropylene (Liebert et al, 1976; Altman et al., 1986) or polyethylenes (Wasserbauer et al., 1990; Zhao et al., 1995).

Poly(ether urethanes), which are resistant to hydrolysis *in vivo*, are used as connectors, insulators, tines, and adhesives for cardiac pacemakers and neurological stimulators (Figure II.4.2.13). They have performed with high reliability in chronic clinical applications since 1975. Certain poly(ether urethane) pacing leads have displayed surface cracks in their insulation after residence times *in vivo* of months to years. These cracks are directly related in frequency and depth to the amount of residual stress (Figures II.4.2.14, II.4.2.15) and the ether (soft segment) content of the polyurethane (Coury et al., 1987; Martin et al., 2001).

Morphologically, the rough-walled cracks display regular patterns predominately normal to the force vectors, occasionally with "tie fibers" bridging the gaps, indicative of ductile rather than brittle fracture (Figures II.4.2.16, II.4.2.17). Infrared (IR) analysis indicates that oxidation does not take place detectably in the bulk, but only on the surface where extensive loss of ether functionality (as seen in the ether IR stretch, 1110 cm^{-1}) and enhanced absorption in the hydroxyl and carbonyl

regions are observed (Stokes et al., 1987). Possible mechanisms for the oxidative degradation of ethers are presented in Figure II.4.2.18. The participation of molecular oxygen in the degradation mechanism is supported by studies which showed that poly(ether urethane urea)
FIGURE II.4.2.17 Single stress crack in pacemaker lead tubing with rough walls and "tie fibers" indicative of ductile fracture (×700).

degradation *in vitro* correlated with oxygen diffusion into the polymer bulk after surface oxidation was initiated by hydrogen peroxide/cobalt chloride (Schubert et al., 1997a,b).

In a seminal study, Zhao et al. (1990) placed polyurethane tubing under strain in cages permeable to fluids and cells (therefore under high initial stress, which was subject to subsequent stress relaxation), and implanted them in rats. In certain cases, anti-inflammatory steroids or cytotoxic polymers were co-implanted in the cages. Implants of up to 15 weeks were retrieved. The only pre-stressed samples to crack were those that did not reside in the cages with the cytotoxic co-implants. The authors concluded that adherent cells caused the stress cracking, and cell necrosis or deactivation inhibited crack induction.

Subsequently, viable phagocytic cells were implicated as a cause of crack initiation *in vivo* (Zhao et al., 1991). By removing adherent foreign-body giant cells after a 10 week implantation of a curved poly(ether urethane urea) film in a wire cage, exposed foreign-body cell "footprints" showed localized surface cracking in the order of several microns deep and wide. Adjacent areas of polymer which were devoid of attached cells were not cracked. Owing to relatively low stresses in the implanted film, deep crack propagation was not observed.

In vitro studies of strained (Stokes, 1988) and unstrained poly(ether urethane) films (Phua et al., 1987; Ratner et al., 1988; Bouvier et al., 1991; Wiggins et al., 2003) using oxidants, enzymes, etc., have sought to duplicate *in vivo* stress cracking. Although some surface chemical degradation with products similar to those seen *in vivo* was demonstrated, stress crack morphology was most closely matched *in vitro* in two studies. A test which involves immersing stressed poly(ether urethane) tubing in a medium of glass wool, hydrogen peroxide, and cobalt chloride produces cracks which duplicate those produced *in vivo*, but with rate acceleration of up to seven times (Zhao et al., 1995). These investigators also showed that human plasma proteins,
Homolysis
FIGURE II.4.2.18 Pathways for oxidative fragmentation of poly-ethers.

particularly alpha-2-macroglobulin and ceruloplasmin, enhance *in vitro* stress cracking by oxidants in patterns morphologically similar to those observed *in vivo* (Zhao et al., 1993). The potential of macrophages to contribute to stress cracking of poly(ether urethanes) was verified in an *in vitro* study which succeeded in potentiating

macrophage oxidative effects with ferrous chloride, and inhibiting them with the anti-inflammatory steroid dexamethasone (Casas et al., 1999). In another study, comparable crack patterns were produced when specimens of stressed tubing in rats were compared with those incubated with PMNs in culture (Sutherland et al., 1993). Moreover, this study revealed a difference in chemical degradation products with time of implants which correlated with products from oxidants generated primarily by PMNs (HOCl) and macrophages (ONOO⁻). Early implant times, activated PMNs, and HOCl caused preferential decrease in the urethane oxygen stretch peak, while longer implant times and ONOO⁻ caused selective loss of the aliphatic ether stretch peak (by infrared spectroscopy).

Taken together, the foregoing observations are consistent with a hypothesized two-step mechanism for stress cracking *in vivo*. In the first step, surface oxidation induces very shallow, brittle micro-cracks. The second step involves propagation of the cracks in which specific body fluid components act on the formed cracks to enhance their depth and width, without inducing major detectable bulk chemical reactions. Should this hypothesis prove correct, the term "oxidation-initiated stress cracking" would be reasonably descriptive.

The above description of stress cracking has generally considered static stress, such as that entrained in polymers during the cooling of molten parts or the assembly of components. Dynamic stresses and strains such as those occurring during the operation of diaphragm or bladder heart pumps or artificial joints can cause related cracking in areas of high flex. The cracking has been purported to increase with time of device operation, but to display only minor surface chemical changes (Tomita et al., 1999; Wu et al., 1999).

The stress cracking related in entrained stress in the polymer has been controlled by reducing residual stress, isolating the polymer from cell contact (Tang et al., 1994), protecting the polymer from stress-cracking media or using stress crack-resistant polymers (e.g., in the case of polyurethanes, ether-free compositions) (Coury et al., 1990; Takahara et al., 1994; Tanzi et al., 1997), and use of antioxidants such as hindered phenols (e.g., vitamin E, Monsanto Santowhite powder) (Schubert et al., 1997a,b). Stress cracking is next compared with another type of degradation, metal ion-induced oxidation.

Device- or Environment-Mediated Oxidation

Metal Ion–Induced Oxidation. A process of oxidative degradation that has, thus far, only been reported clinically for poly(ether urethane) pacemaker leads, requires, as does stress cracking, a very specific set of conditions. The enabling variables and fracture morphology are quite different from stress cracking, although oxidative degradation products are similar. Biodegradation of

implanted devices through stress cracking always occurs on polymer surfaces exposed to cells, and provides characteristic rough-walled fissures (indicative of ductile fracture) oriented perpendicular to the stress vector (Figures II.4.2.14–II.4.2.17). Metal ion-induced oxidation initiates on the enclosed inner surfaces of pacing lead insulation near corroded metallic components and their entrapped corrosion products. Smooth crack walls and microscopically random crack orientation is indicative of brittle fracture (Figures II.4.2.19, II.4.2.20). Macroscopically, crack patterns that track metal component configurations may be present (Figure II.4.2.21). Degradation products that may be found deeper in the bulk than with stress cracking are again indicative of brittle fracture.

This phenomenon called metal ion-induced oxidation has been confirmed by *in vitro* studies, in which poly(ether urethanes) were aged in metal ion solutions of different standard oxidation potentials. Above an oxidation potential of about +0.77, chemical degradation was severe. Below that oxidation potential, changes in the polymer that are characteristic of simple plasticization were seen (Coury et al., 1987; Table II.4.2.4). This technique also showed that metal ion-induced oxidation was proportional to the ether content of the polyurethane (Coury et al., 1987; Table II.4.2.5).

The effect of various metals on oxidation *in vitro* and *in vivo* has also been studied. Different metallic components of pacing lead conductors were sealed in poly(ether urethane) (Dow Pellethane 2363–80A) tubing and immersed in 3% hydrogen peroxide at 37°C for up to six months (Stokes et al., 1987) or implanted in rabbits for up to two years (Stokes et al., 1990). Both techniques resulted in corroded metals and degraded tubing lumen surfaces under certain conditions within 30 days. In particular, the *in vivo* interaction of body fluids with cobalt and its alloys resulted in oxidative cracking of the polymer.

The metal ion-induced oxidation process clearly involves corrosion of metallic elements to their ions, and subsequent oxidation of the polymer. In operating devices, the metal ion may be formed by solvation, galvanic or electrolytic corrosion, or chemical or biochemical oxidation (Figure II.4.2.22). In turn, these metal ions develop oxidation potentials that may well be enhanced in body fluids over their standard half-cell potentials. As strong oxidants, they produce intermediates or attack the polymer to initiate the chain reaction (Figure II.4.2.23). Metal ion-induced oxidation is therefore the result of a highly complex interaction of the device, the polymer, and the body.

Should metal ion-induced oxidation be a possibility in an implanted device, several approaches are available to control this problem. They are not universally applicable, however, and should be incorporated only if functionality and biocompatibility are retained. Potentially useful techniques include using corrosion-resistant metals, "flushing" corrosive ions away from the susceptible polymer, isolating the metals and polymer from electrolyte solutions, incorporating appropriate antioxidants, and using oxidation-resistant polymers.

To address oxidation susceptibility, polyurethane elastomers with enhanced oxidation stability have been developed. They should be ether- and ester-free, and generally contain unconventional soft segments, including,

for example, hydrogenated polybutadiene, polyisobutylene, polydimethylsiloxane, polycarbonate, and dimerized fatty acid derivatives (Coury et al., 1990; Pinchuk et al., 1991; Takahara et al., 1991, 1994; Kato et al., 1995; Mathur et al., 1997; Hernandez et al., 2007; Kang et al., 2010; Desai et al, 2011). In implant tests, they have shown reduced tendency to stress crack, and some

of them have shown high resistance to metal ion oxidants *in vitro*. Early attempts to stabilize polyurethanes by laminating more biostable polymers (such as silicone rubbers) to tissue-facing surfaces have met with limited success in dynamic applications, due to the delamination tendencies (Pinchuk, 1992). In 2006, the first new polyurethane composition in decades was introduced as pacemaker/defibrillator lead insulation It is an aromatic polyurethane with soft segments of mixed polysiloxane/polyether composition (Simmons et al., 2004). Indications are that it demonstrates physical properties superior to silicone elastomers (Parmar, 2012). Some studies show improved, but not total degradation resistance of this material when compared to poly(ether urethanes) (St Jude Medical, Inc., 2012), but, since cardiac leads can be implanted for decades, verification of long-term durability in humans must await longer term implantation.

More recent approaches to stabilizing polyurethanes to oxidative attack *in situ* have involved the use of surface modifying macromolecules (SMMs) (Santerre et al., 2000), surface modifying end groups (SMEs) (Ward et al., 1995, 1998), and, more recently, self-assembling monolayer end groups (SAMEs) (Ward, 2008). SMMs, typically fluorocarbon-based polymers, are blended with the polyurethanes during processing, and migrate to the surface prior to implantation. SMEs are moieties (typically polysiloxane) bonded to polyurethane as end groups. SAMEs are formed from molecules appended to the backbone of polymers during synthesis. Such molecules consist of three components: a chemically reactive group for conjugation to the polymer as it is being made; typically, a hydrophobic

spacer chain, to provide self-assembly at the surface of the formed article; and a head group from a variety of surface chemistries to provide specific bioactivity. One potential function is to stabilize the polymer against biodegradation (Ward, 2008).

The covalently modified polyurethanes may be used in bulk or as additives to conventional polyurethanes. Both approaches have provided enhanced *in vivo* stability for polyurethane implants; however, the long-term effects of these treatments are not, as yet, known. SMMs have been covalently modified with bioactive agents, such as antioxidants, to provide further degradation resistance (Ernsting et al., 2002).

All of the "barrier" strategies to protecting polyurethanes described above appear to have validity, at least for protecting polyurethanes in the short-term. The long-term (multiyear) benefits of these approaches remain to be seen in light of issues such as surface dynamics, interfacial interactions, and coating durability.

All of these polyurethane modifications, while potentially providing enhanced resistance to biodegradation, still allow susceptibility to attack by biological components, often at slow rates. With poly(carbonate urethanes), for example, superior oxidation resistance has been observed in several studies (Mathur et al., 1997; Tanzi et al., 1997). In other studies, these compositions were shown to be susceptible to oxidation (Christenson et al., 2004). Additionally, in aqueous media *in vitro* and *in vivo*, slow degradation attributable to simple hydrolysis was also detected (Zhang et al., 1997). The body fluid environment provides a relatively stable long-term hydrolytic medium, generally less subject to "respiratory bursts" that strongly enhance oxidative processes. Although phagocytic processes may also produce hydrolytic enzymes, their effects on synthetic polymers are specific and limited (Labow et al., 2002a). Hydrolysis, therefore, may be expected to take place continuously with poly(carbonate urethane) integrity susceptible to a combination of mechanical stress and vigorous oxidizing conditions (Faré et al., 1999; Labow et al., 2002b). Studies of up to three years implantation have indicated detectable degradation (Seifalian et al., 2003). Only long-term implant studies (e.g., five years or greater) would predict the acceptability of poly(carbonate urethanes) or, for that matter, other new polymers having potentially susceptible groups.

Oxidative Degradation Induced by External Environment

Under very limited circumstances, the body can transmit electromagnetic radiation that may affect the integrity of implanted polymers. For example, the cornea and vitreous humor of the eye, as well as superficial skin layers, allow the passage of long-wave (320–400 nanometer) "ultraviolet A" radiation. Absorption of ultraviolet radiation causes electron excitation that can lead to
FIGURE II.4.2.24 Photo-oxidative reactions of aromatic polyurethanes. (A) Formation of quinone-imide from aromatic polyurethane. (From A. J. Coury et al. (1988). *J. Biomater. Appl.,* **3**.) (B) Photolytic cleavage of urethane link. (From S. K. Brauman et al. (1981). *Ann. Biomed. Eng.,* **9**.)

photo-oxidative degradation. This process has been suggested in the breakdown of polypropylene components of intraocular lenses (Altman et al., 1986; Jongebloed and Worst, 1986).

In maxillofacial exo- and very likely endoprostheses, elastomers may undergo undesirable changes in color and physical properties as a consequence of exposure to natural sunlight-frequency radiation (Craig et al., 1980). Photo-oxidation mechanisms involving the aromatic units and the urethane of aromatic poly(ether urethanes) or poly(ester urethanes) are shown in Figure II.4.2.24. Antioxidants and ultraviolet absorbers provide limited protection for these materials.

CONCLUSION

Polymers that are carefully chosen for use in implanted devices generally serve effectively for their intended lifetimes if they are properly processed and device–material–host interactions are adequately addressed. In certain limited circumstances, excessive hydrolytic or oxidative biodegradation occurs. This may be induced by direct attack by the host or by non-biological factors in the environment surrounding the implant. With susceptible polymers, protective measures can be taken to ensure extended efficacy, although new, biodegradation

resistant polymers that are on the horizon may require less protection. Knowledge of biodegradation mechanisms and the employment of appropriate countermeasures such as proper material selection or modification, optimal component design, protection from environmental attack, and careful handling and implantation procedures will promote continued progress in the development of polymers as long-term implantable biomaterials.

CHAPTER II.4.3 THE BIODEGRADATION OF BIODEGRADABLE POLYMERIC BIOMATERIALS

Chien-Chi Lin[1] and Kristi S. Anseth[2]

[1]Department of Biomedical Engineering, Indiana University-Purdue, University at Indianapolis, Indianapolis, IN, USA

[2]Department of Chemical and Biological Engineering, Howard Hughes Medical Institute and University of Colorado, Boulder, CO, USA

INTRODUCTION

The application of biodegradable polymers in medicine can be dated back to the early 1960s when polymers (e.g., poly(glycolic acid) or PGA), that were initially found unstable due to the rapid degradation, were used as suture materials (Morgan, 1969; Dardik et al., 1971; Vert, 1989). Since then, numerous biodegradable biomaterials, both of synthetic and natural origin, have been investigated and continue to play a critical role in clinical applications, as well as laboratory research. While almost all polymers will degrade eventually, only those with therapeutically-relevant degradation rates are considered biodegradable, and are the focus of this section. Among all, synthetic biodegradable polymers are particularly intriguing. In contrast to natural biopolymers, synthetic polymers can be synthesized in a highly controllable and reproducible manner, with defined material properties and user-designed degradability (Middleton and Tipton, 2000). The lack of immunogenicity of synthetic polymers also enhances their potential in clinical applications. The past few decades have seen great advances in the design and applications of synthetic polymeric biodegradable materials (Vert et al., 1992; Anderson and Shive, 1997; Langer and Tirrell, 2004). Through theoretical and experimental investigations, these biodegradable polymers have found numerous applications, particularly in the fields of drug delivery (Siepmann and Gopferich, 2001) and tissue engineering (Freed et al., 1994; Langer and Tirrell, 2004). This chapter discusses the fundamental aspects of biodegradation of synthetic polymeric biomaterials, including: (1) the types of biodegradable chemical bonds that are commonly designed into biomaterials; (2) the degradation modes, mechanisms, and kinetics of biodegradation; and (3) the effect of biodegradation on material properties relevant to their biomedical applications, including drug delivery and tissue engineering.

CHARACTERISTICS OF BIODEGRADABLE POLYMERS

In general, the process of degradation involves a series of cleavage events, leading to polymer chain scission (Gopferich, 1996). Consequently, the molecular weight of the polymer decreases to form lower molecular weight oligomers and monomers, and ultimately results in the loss of mechanical stability of the material. While polymers can be degraded through a variety of mechanisms such as thermal, mechanical, and photodegradation, the most common modes of degradation in a therapeutically-relevant *in vivo* environment are either hydrolytic or enzymatic degradation. The term "biodegradation" is commonly used when degradation involves biological processes, such as body fluids, cellular activities, and enzymatic reactions. The conditions of the biological environment, therefore, determine the rate of polymer degradation to a great extent. For example, the degradation of an implanted polymeric biomaterial may proceed faster in a highly inflammatory environment, due to excessive biological and biochemical activity. The pH and temperature of the local biological environment, enzyme concentrations, and cell infiltration/recruitment to the implant sites all affect the rate of polymer degradation.

In addition to the biological environment, the chemical, physical, and morphological properties of degradable polymers also govern the mode and rate of biodegradation. For example, hydrophobic polymers limit water accessibility, and typically have decreased hydrolytic degradation rates compared to their more hydrophilic counterparts (Gopferich, 1996). Further, amorphous polymers usually degrade faster than semicrystalline polymers. Similarly, polymers with high glass transition temperature (T_g) degrade at slower rates compared to polymers with lower T_g (Pitt et al., 1981a,b; Gopferich, 1996). One must note that biodegradation is a dynamic process, as the polymer properties change with degradation. For instance, the crystallinity of poly(L-lactic acid) or L-PLA increases during degradation, due to a faster degradation rate in the amorphous regions than the crystalline regions of the polymer. This results in a decreased degradation rate over time, due to enhanced polymer crystallinity. On the other hand, the generation of acidic monomers (e.g., lactic acid) can decrease the local pH and result in auto-accelerated degradation of poly(α-hydroxy) esters (Cha and Pitt, 1989; Gopferich, 1996).

Hydrolytically Biodegradable Polymer Bonds

The type of chemical bond in the backbone of a biodegradable polymer plays a major role in dictating the rate of bond cleavage. A brief list of biodegradable polymer bonds is shown in Figure II.4.3.1. In general, anhydride and ortho-ester bonds are among the faster degrading polymer backbone chemical bonds, followed by ester and thioether bonds. The degradation rates of these chemical bonds, however, are largely affected by several factors, such as the presence of hydrophobic functional groups, the altered local pH due to the degradation products, molecular weights of the polymer, and the composition of the copolymer.

Polyanhydrides. The anhydride linkage is among the least hydrolytically stable, so polyanhydrides are typically synthesized from hydrophobic diacids (Rosen et al.,
FIGURE II.4.3.1 Typical repeating units in common biodegradable polymers: (A) polyanhydrides; (B) poly(ortho esters); (C) polyketals; (D) polyacetals; (E) poly(α-hydroxyl esters); (F) poly(β-hydroxyl esters); (G) poly(ε-caprolactone) (an example of specific polymer with degradable ester linkages).
FIGURE II.4.3.2 Conjugation and hydrolysis of a thioether-ester bond. (Adapted from DuBose et al., 2005.)

1983). The hydrophobicity limits water penetration and the fast hydrolysis typically leads to surface erosion, producing di-acid monomers which can be metabolized by the body. Due to the fast degrading anhydride bonds (days to weeks) and the non-toxic acid degradation products, polymers made from polyanhydrides have been used for short-term drug release for more than two decades (Rosen et al., 1983; Leong et al., 1986) (see Chapter II.5.16.C). These unique properties of polyanhydrides result in near zero-order drug release profiles (Tamada and Langer, 1992; Tabata et al., 1993) (surface erosion and bulk degradation are discussed in more detail below).

Poly(ortho esters). Compared to polyanhydrides, poly (ortho esters) are more hydrophobic. They also undergo surface erosion when degrading, albeit with slower degradation rates compared to polyanhydrides (Heller et al., 2002). The degradation of poly(ortho esters) produces esters as initial degradation products, followed by further degradation into acids and alcohols. The use of poly(ortho esters) as controlled release devices can be dated back to the early 1970s (Heller and Barr, 2004). Since the polymer is surface-eroding, the drug release rates are controlled by the rate of polymer erosion, which can be tuned by the polymer composition.

Poly(α-hydroxy esters). Polymers in this category include poly(lactic acid) or PLA, poly(glycolic acid) or PGA, and their copolymers poly(lactic-co-glycolic acid) or PLGA. Poly(α-hydroxy esters) were among the first synthetic polymers with clinical applications (Gilding and Reed, 1979; Reed and Gilding, 1981). For example, PGA has long been used as biodegradable suture material due to its rapid degradation rate. The hydrolysis of poly(α-hydroxy esters) occurs at the ester bonds in the polymer backbone, and is governed by the accessibility of water to those bonds. L-PLA, for example, degrades more slowly than PGA, because of the presence of the hydrophobic methyl side group that hinders water attack to the ester bonds, as well as increasing crystallinity during degradation (Vert et al., 1994). The hydrolysis/

degradation rates of amorphous PLGA are faster than either semicrystalline homopolymers of PLA or PGA, and they can be tuned by adjusting the compositions of the monomers (Gilding and Reed, 1979; Reed and Gilding, 1981; Zhu et al., 1991). It should be noted, however, that PLGA with a 50:50 monomer ratio exhibits the fastest degradation because it has the lowest crystallinity. Further, the acidic degradation products (i.e., lactic acid and glycolic acid) can lower the local pH and accelerate the hydrolytic degradation rate (Cha and Pitt, 1989).

Thioether-ester. An ester bond next to a thioether group is much more susceptible to hydrolytic degradation compared to an unmodified ester bond (Figure II.4.3.2) (DuBose et al., 2005; van de Wetering et al., 2005). Thioether-ester bonds can be formed from addition reactions between unsaturated acrylates and thiols (Elbert et al., 2001; van de Wetering et al., 2005). This so-called "Michael addition" reaction has been used to form degradable hydrogels for controlled release (Elbert et al., 2001) and tissue engineering applications (Elbert and Hubbell, 2001). The degradation rate of the thioether-ester bonds is tuned by altering the neighboring functional groups, such as charge (Jo et al., 2009) and the length of the sulfide containing linker (Schoenmakers et al., 2004).

Modes of Biodegradation

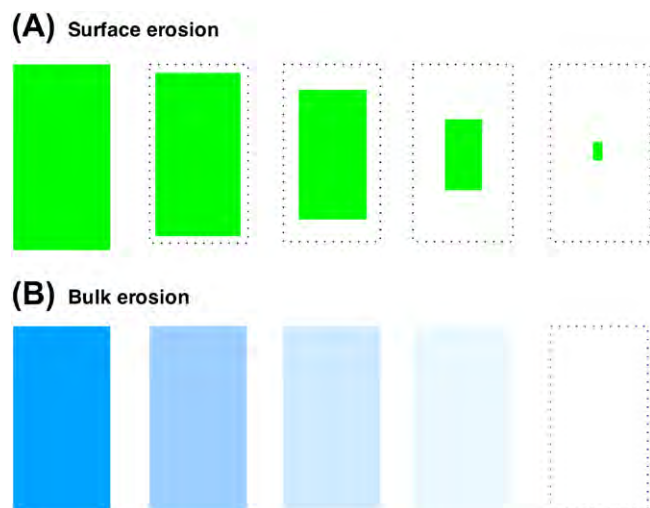
The mode of biodegradation often determines the therapeutic performance of polymeric devices. In general, two types of degradation have been described, including surface erosion and bulk degradation (Figure II.4.3.3) (Gopferich, 1996; Siepmann and Gopferich, 2001). Surface erosion mainly occurs in hydrophobic polymers, such as polyanhydrides (Tamada and Langer, 1992; Tabata et al., 1993) and poly(ortho esters) (Heller et al., 2002; Heller and Barr, 2004), in which the rate of bond cleavage is faster than the rate of water diffusion into the polymer device. Since the degradation process is primarily limited to the surface of the device, the bulk polymer


FIGURE II.4.3.3 Schematics of: (A) surface erosion; and (B) bulk degradation.

structure remains relatively unchanged until the polymer degrades completely (Figure II.4.3.3A). Surface erosion is useful in drug delivery applications, as the release rate of drugs from eroding polymers is independent of diffusion, and is easily altered by changes in the device geometry. Typically, surface eroding systems produce a facile means to achieve zero-order release (Tamada and Langer, 1992; Tabata et al., 1993).

In contrast to surface erosion, bulk degradation occurs when bonds are cleaved throughout the polymeric device (Figure II.4.3.3B). The direct consequence of bulk degradation is the change in molecular weight of the polymer, followed by increasing water content, the libration of soluble monomers and chain fragments, and dramatic changes in mechanical properties. The degradation of poly(α-hydroxy esters), such as PLA, PGA, and PLGA typically belong to this category (Pitt et al., 1981a,b). Since degradation takes place throughout the device, the mechanical properties of the device can decrease dramatically, even at early stages of the degradation process. For controlled release applications, the release rate of the loaded drug is governed by both diffusion and mass loss of the polymer. The prediction of drug release, therefore, requires sophisticated theoretical models (Siepmann and Gopferich, 2001).

In addition to hydrolytic degradation, polymers can also be designed to degrade enzymatically. Since bond cleavage in such polymers is mediated by enzymatic reactions, the mode of degradation is determined by the location and concentration of the enzyme, as well as the kinetics of the enzymatic reaction. Enzymatic degradation, therefore, can be either surface erosion or bulk degradation, and is mainly determined by the accessibility of the enzyme to the interior of the polymer. For example, the degradation of poly(ε-caprolactone) or PCL is greatly accelerated by the presence of lipases, and polymers containing PCL components have been reported to degrade via surface erosion or bulk degradation, depending on

the formulation of the polymer. PCL has been fabricated as polymer blends (Tsuji and Ikada, 1998; Tsuji et al., 1998; Broz et al., 2003), block co-polymers (Allen et al., 2000; Qian et al., 2000; Ahmed and Discher, 2004), and hydrogels (Rice et al., 2006; Rice and Anseth, 2007) for drug delivery and tissue engineering applications.

Polymers containing natural enzyme substrates, typically oligopeptides, can be degraded via cell-secreted enzymes. Such hybrid synthetic–biologic macromolecules are becoming increasingly important in the field of tissue engineering. For example, matrix metalloproteinases (MMPs) are secreted by a variety of cells that trigger the degradation of extracellular matrix (ECM) proteins (Stamenkovic, 2003; Mott and Werb, 2004). This type of enzymatic degradation is extremely important in cell migration, proliferation, angiogenesis, and differentiation in native tissues. Inspired by this natural biological phenomenon, researchers have developed numerous synthetic polymers containing MMP-degradable peptides that are degraded by cell-secreted MMPs (West and Hubbell, 1999; Lutolf et al., 2003; Seliktar et al., 2004; Fairbanks et al., 2009). This mode of degradation is largely determined by the location and concentration of enzymes (which is related to number and proximity of cells), the enzymatic kinetics, and the chemistry and concentration of the substrate. Another approach to synthetic polymers that can be enzymatically degraded involves the incorporation of disulfide (S-S) bonds in the backbone chain. These polymers have been developed for gene delivery and intracellular drug delivery where, upon cellular uptake, S-S bonds are degraded in the intracellular reducing environment by glutathione and thioredoxine reductases.

Role of Water in Biodegradation: Hydrophobic Polymers versus Hydrogels

Regardless of the mode of hydrolytic biodegradation (i.e., surface erosion or bulk degradation), the presence of water is a prerequisite for degradation to occur. Thus, the hydrophilicity of the polymer chains and the transport of water into the device play important roles in determining the rate of biodegradation. The rate of degradation is often governed by the accessibility of the chemical bonds to water, rather than their inherent degradability (Gopferich, 1996). Thus, degradable bonds with hydrophobic side groups will degrade much more slowly than the same chemical bonds with hydrophilic side groups (e.g., hydrophobic PLA versus more hydrophilic PGA). Hydrophobic degradable polymers include polyesters, polyanhydrides, polyphosphazenes, and poly(ortho esters), while hydrophilic degradable polymers often contain low molecular weight segments of poly(ethylene glycol) (PEG), poly(vinyl alcohol) (PVA), poly(acrylic acid) (PAA), poly(hydroxyethyl methacrylate) (pHEMA), and/or poly(N-isopropyl acrylamide) (pNIPAM), although these polymers are not, by themselves, biodegradable. Note that pNIPAM is a

temperature-responsive polymer that is hydrophilic below its lower critical solution temperature or LCST which becomes hydrophobic above its LCST (see Chapter I.2.11).

As has been mentioned, the mode of biodegradation of hydrophobic polymers can be either surface erosion or bulk-degradation, depending on the polymer backbone (Gopferich, 1996; Siepmann and Gopferich, 2001). For example, polyanhydrides usually degrade via a surface erosion mechanism, as the penetration of water into the interior of the polymer is inhibited by the highly hydrophobic polymer. On the other hand, the degradation of polyesters, such as PLA, PGA, and co-polymer PLGA, proceed through bulk-degradation due to the presence of water molecules throughout the polymer. In contrast to hydrophobic polymers where the molarity of water within the polymer is usually much lower than 55.36 M (molarity of pure water at room temperature), hydrophilic polymers usually contain water at much higher concentrations. For example, the concentration of water in hydrogels is usually at a molarity very close to that of pure water, due to the small weight percentage of the polymer in the entire device. As a result, in computational models of hydrophilic polymer hydrolytic degradation, the water concentration is often viewed as constant and combined with the rate constant of polymer bond cleavage.

KINETICS OF BIODEGRADATION

As briefly discussed above, the type of chemical bond determines, to a great extent, the rate of biodegradation. Generally, anhydride and orthoester bonds have higher hydrolytic bond cleavage rates than ester bonds. Other considerations include, but are not limited to: hydrophobicity of the monomer; steric hindrance of the side group; co-polymer compositions; glass transition temperature (T_g); crystallinity of the polymer; and pH of the local environment (Gopferich, 1996).

Hydrolytic Degradation

Surface Erosion. The kinetics of surface-eroding polymers has been well-studied. The hydrolysis of surface-eroding polymers starts at the surface and proceeds gradually to the interior (Figure II.4.3.3A). If a molecule is entrapped in the polymer, the release rates are often correlated directly to the mass loss. To facilitate experimental observation, surface-eroding polymers, such as polyanhydrides, are often fabricated as disks with high aspect ratios (e.g., large diameter compared to the height of the polymer), such that the surface area of the polymer remains roughly constant throughout degradation. Thus, the rate of polymer erosion can be expressed as:

$$\frac{dM}{dt} = -k \qquad (1)$$

where M is the polymer mass at any given time t, and k is the kinetic rate constant of the degradation. Assuming one-dimensional erosion and constant density, Eq. (1) can be rearranged into:

$$\frac{dl}{dt} = -k' \qquad (2)$$

where l is the dimension of the polymer in the direction of degradation front at any given time t, and k' is the adjusted rate constant.

Equation (2) can be easily solved to obtain:

$$l = l_0 - k't \qquad (3)$$

Equation (3) illustrates a linear decrease in polymer thickness as the polymer degrades. This linear relationship is very useful in controlled release applications, as drug release rates can be stringently controlled by the rate of polymer mass loss and approach zero-order release. Equations (1) to (3) dictate the kinetics of surface erosion when the device is fabricated as thin slabs. For other geometries, such as cylinders and spheres, similar equations can be derived accordingly, and once k' is known, multidimensional degradation profiles can be predicted as well.

Bulk Degradation. For hydrolytic bulk degradation, a majority of studies focus on the mechanism of polyester degradation, particularly PLA and its co-polymers with PGA. As an example, the mechanism of polyester biodegradation is discussed in this section. Hydrolysis of polyester is usually described as a random polymer chain scission throughout the polymer, and is auto-accelerated by increasing carboxylic acid end groups. The hydrolysis of ester bonds to produce carboxylic acids can be expressed as:

$$-\frac{d[Ester]}{dt} = k[Ester][H_2O] \qquad (4)$$

Here, $[Ester]$ is the concentration of ester bonds in the polymer; t is the degradation time; k is the kinetic rate constant; and $[H_2O]$ is the concentration of water. As a simplifying assumption for bulk degrading polyesters, the water concentration is often considered constant. Then, Eq. (4) simplifies to:

$$-\frac{d[Ester]}{dt} = k'[Ester] \qquad (5)$$

where k' is a pseudo-first order rate constant. Integrating Eq. (5) yields the following equation:

$$\frac{[Ester]}{[Ester]_0} = e^{-k't} \qquad (6)$$

where $[Ester]_0$ is the initial ester bond concentration.

Since $[Ester]$ is related to the molecular weight (M_n) of the polymer at any time during degradation, Eq. (6) can be expressed as:

$$\frac{M_n}{M_{n0}} = e^{-k't} \qquad (7)$$

It can be seen from Eq. (7) that the molecular weight of the degrading polymer decreases exponentially. It should be noted that Eq. (7) only holds until significant degradation causes the loss of oligomers and carboxylic acids. It has been observed that this relationship is approximately true until the molecular weight of the polymer decreases to below 5000 Da (Pitt et al., 1981b). Substitution of the Mark–Houwink equation ($[\eta] = KMn^{\alpha}$) into Eq. (7) yields:

$$[\eta] = [\eta]_0 \cdot e^{-\alpha k' t} \tag{8}$$

Here, η is the intrinsic viscosity of the polymer, and α is the Mark–Houwink exponent, which depends on the solvent in which the polymer degrades. Equation (8) facilitates the observation of polymer degradation via measuring the change in its intrinsic viscosity.

Equations (4) to (8) only illustrate the basic kinetics of ester bond hydrolysis in bulk-degrading polymers. The prediction of mass loss kinetics in the bulk-degrading polymers, however, often requires more sophisticated mathematical models, as simple cleavage of bonds does not accurately reflect loss of mass from the polymer device. For example, not only monomers, but also oligomers with different molecular weights can be soluble and liberated, leading to difficulties in predicting mass loss from bulk-degrading polymers.

Bulk Degradation in Hydrogels. The degradation of block co-polymer hydrogel networks differs significantly from the degradation of many of the common linear polyesters (Metters et al., 2000a,b, 2001; Martens et al., 2001). For example, the degradation kinetics of networks formed from PLA-*b*-PEG-*b*-PLA precursors (polymerized through acrylate end groups) differs substantially from that of pure PLA degradation. The highly swollen hydrogel network, together with the use of buffered solution, facilitates the removal of relatively low concentrations of acidic degradation products. As a result, the kinetic equation for ester bond cleavage is identical to Eq. (5). For pure polyesters, a significant change in polymer properties occurs at relatively low levels of ester hydrolysis, as a small number of cleavage events leads to a dramatic change in polymer molecular weight, even though the mass loss can be quite small, as significant liberation of monomers and oligomers often occurs at much later

stages of hydrolysis. Likewise, for PLA-*b*-PEG-*b*-PLA hydrogels, the cleavage of a single ester bond within a PLA block of the co-polymer is sufficient to cause microscopic gel structural change. The [*Ester*] in Eq. (5) can be replaced by the [*PLA*], the concentration of PLA blocks in the co-polymer, because hydrolyzing one ester bond per PLA block is sufficient to cause the detachment of the degradable block from the cross-linked network. Equation (5) becomes:

$$-\frac{d[PLA]}{dt} = k'[PLA] \tag{9}$$

Integrating and solving for the [*PLA*] in Eq. (9) gives an exponentially decaying PLA concentration as:

$$[PLA] = [PLA]_0 \cdot e^{-k't} \tag{10}$$

Combining Eq. (10) and the structural information about the PEG-*b*-PLA hydrogel, the cleavage of PLA units can be related to mass loss from the hydrogel. Metters, Bowman, and Anseth have devised statistical kinetic models to predict the degradation behavior of such hydrogels. The following equation describes the probability (P) that any random PLA unit has been hydrolyzed (Metters et al., 2000a,b, 2001):

$$P = 1 - f_{PLA} = 1 - e^{-k't} \tag{11}$$

where f_{PLA} is the fraction of total hydrolyzed PLA units, which is equal to $[PLA]/[PLA]_0$.

As illustrated in Figure II.4.3.4, each PEG chain is attached to the cross-linked network by two PLA units. At any time during gel degradation, each PEG is in one of the three states: (1) completely attached; (2) only one PLA unit hydrolyzed; and (3) both PLA units hydrolyzed. Given the probability of PLA units being hydrolyzed at any time during degradation (P), the fraction (y) of each of the three states can be described as (Metters et al., 2000a,b, 2001):

(1) Fraction with both PLA units intact:

$$y_1 = (1 - P)^2 \tag{12}$$

(2) Fraction with only one PLA unit hydrolyzed:

$$y_2 = 2P(1 - P) \tag{13}$$
FIGURE II.4.3.4 Schematic of a PLA-*b*-PEG-*b*-PLA hydrogel and its hydrolytic degradation process and degradation products.

(3) Fraction with both PLA units hydrolyzed:

$$y_3 = P^2 \tag{14}$$

The mass loss of PEG-*b*-PLA hydrogels involves the loss of PLA-PEG-PLA block co-polymers and/or poly-acrylate kinetic chains. Since multiple PLA units are attached to a single polyacrylate kinetic chain, at least one PLA unit along each cross-link must be hydrolyzed in order for a polyacrylate chain to be released from the degradation gel. The fraction of polyacrylate (F_{PA}) chains to be released from the degradation gel can be described as:

$$F_{PA} = (y_2 + y_3)^N \tag{15}$$

where N is the number of cross-links initially attached to each polyacrylate kinetic chain. Substituting Eqs. (13) and (14) into Eq. (15) yields:

$$F_{PA} = [1 - (1-P)^2]^N \tag{16}$$

To liberate PLA-PEG-PLA blocks, one of the following two situations has to occur: (1) two PLA units, one at each end of the block, need to be hydrolyzed; or (2) one PLA unit is hydrolyzed while the other is attached to an unhydrolyzed PLA unit, which is part of a releaseable polyacrylate chain. Given the probability of PLA unit hydrolysis (P) and the fraction of releaseable polyacrylate chain from the degrading network (F_{PA}), the fraction of PEG units being released from the network is:

$$F_{PEG} = P^2 + F_{PA}\frac{y_2}{2} \tag{17}$$

Equations (16) and (17) give the necessary information about the mass loss from PEG-*b*-PLA hydrogels:

$$\%\ \text{mass loss} = (W_{PA}F_{PA} + W_{PEG}F_{PEG}) \tag{18}$$

Here, W_{PA} and W_{PEG} are the mass percent of the cross-linked network contained in the polyacrylate chains and in the PLA-PEG-PLA segments, respectively.

It should be noted that while the network degradation can be modeled using Eqs (12) to (18), the mass loss behavior will deviate from the prediction once sufficient cross-links are hydrolyzed, causing the entire gel network to be completely water soluble (Metters et al., 2000a,b). To account for this, a "reverse gelation" concept can be implemented.

$$X(t) = [1 - P(t)]^2 \tag{19}$$

At any given time during degradation, $X(t)$ is the fraction of cross-links that remain unhydrolyzed, and $P(t)$ is the fraction of hydrolyzed PLA units. Reverse gelation occurs when $X(t)$ is equal to or less than the gel point conversion (X_c), which is defined as:

$$X_c = \frac{2}{f_{avg}} \tag{20}$$

where f_{avg} is the average functionality of the monomer. For reverse gelation of a cross-linked hydrogel system that degrades via a bulk-degradation mechanism, f_{avg} equals the number of cross-links (N) attached to each kinetic backbone chain. Combining Eqs. (19) and (20) and the information of f_{avg} (= N) yields the critical degradation conversion at which reverse gelation occurs (P_c):

$$P_c = 1 - \left[\frac{2}{N}\right]^{1/2} \tag{21}$$

From the above equations, time (t_c) at which reverse gelation occurs is:

$$t_c = \frac{ln\,(1-P_c)}{-k'} = \frac{ln\left(1 - \left[1 - \frac{2}{N}\right]^{1/2}\right)}{-k'} \tag{22}$$

where N is the weight average number of cross-links per kinetic chain, and k' is the pseudo first-order hydrolysis rate constant. Figure II.4.3.5 shows a theoretical prediction of mass loss profiles of PLA-PEG-PLA hydrogels without (curve A), and with (curve B), reverse gelation (Metters et al., 2000b).

Enzymatic Degradation

Enzymatic Degradation of Synthetic Polymers. Several synthetic polymers are susceptible to enzymatic degradation. For example, amorphous poly(L-lactide) can be degraded by proteinase K, while both amorphous and crystalline poly(ε-caprolactone) can be degraded by lipases of various origins (Liu et al., 2000). Enzymatic degradation of synthetic polymers can be either surface erosion or bulk degradation, depending on the location and stability of the acting enzyme. However, due to the limited water accessibility of most hydrophobic polymers, surface erosion is the dominant degradation mechanism and the kinetics are similar to the hydrolytic surface erosion described in an earlier section of this
FIGURE II.4.3.5 Prediction of mass loss of a PLA-*b*-PEG-*b*-PLA hydrogel versus degradation time. Curve A: without reverse gelation; Curve B: with reverse gelation. Model parameters: W_{PA} = W_{PEG} = 50 wt %; N = 1000 cross-links per backbone chain; and k' = 0.0003 min^{-1}. (From Metters et al. (2000b). *J. Phys. Chem. B*.)

chapter. For hydrophilic polymers permitting the diffusion of the enzyme to the interior of the polymer, the degradation is also mediated by surface erosion mechanism if the rate of enzymatic polymer bond cleavage is faster than the rate of enzyme diffusion.

Bulk degradation of synthetic polymers induced by enzymatic activity may occur under two conditions: (1) the enzyme is able to infiltrate and distribute uniformly throughout the bulk of the polymer; and (2) the rate of enzymatic bond cleavage is slower than the diffusion of the enzyme. Typically, hydrogels containing enzymatic cleavable units in their polymer backbone fall into this category of degradation. Under these assumptions, Michaelis–Menten enzymatic kinetics are commonly used to predict the enzymatic degradation rates of synthetic polymers via bulk degradation mechanism:

$$v_0 = v_{max} \frac{[S]}{K_M + [S]} \qquad (23)$$

Here, v_0 and v_{max} are the initial and maximum reaction rate of degradation, respectively. $[S]$ is the degradable polymeric substrate concentration, and K_M is the Michaelis–Menten constant.

In Eq. (23), v_{max} can also be expressed as:

$$v_{max} = k_{cat}[E] \qquad (24)$$

where k_{cat} is the catalytic constant describing the rate of enzymatic degradation of polymer bonds and $[E]$ is the concentration of enzyme catalytic sites.

As in other enzymatic reactions, both k_{cat} and K_M are important parameters in characterizing the enzymatic degradation of polymers. While k_{cat} represents the sensitivity of an enzyme for a specific polymeric substrate, K_M is the substrate concentration needed to achieve a half-maximum enzyme velocity. Factors affecting these parameters will also determine the rate of polymer degradation.

While simple Michaelis–Menten kinetics can be used to describe enzymatic polymer bond cleavage, they do not provide information regarding the mass loss behavior of the polymers. Sophisticated mathematical models are often required in order to correlate microscopic enzymatic bond cleavage to macroscopic polymer mass loss. For example, to describe the mass loss of cross-linked hydrogels containing enzymatic cleavable substrate (e.g., polycaprolactone), a statistical model (similar to the one described earlier in the hydrolytic degradation of hydrogels) integrating the structural information of the hydrogels was developed (Rice et al., 2006). In this particular example, Eqs. (11) to (14) can be used again except that f_{PLA} is now replaced with f_{CAP}, where CAP represents caprolactone subunits. In addition to the network information, the Michaelis–Menten reaction equations and the first-order decay in active enzyme (e.g., lipase) concentration can be described by the following equations:

$$Lipase + CAP \rightleftharpoons E * S \xrightarrow{k_2} Lipase + D \qquad (25)$$

$$Lipase + CAP \xrightarrow{k_d} Inactive\ Lipase \qquad (26)$$
$$\frac{[Lipase]}{[Lipase]_0} = e^{-k_d t} \qquad (27)$$

Here, $E * S$ is the enzyme–substrate complex, D is the degradation product, CAP is the caprolactone block, k_2 is CAP degradation late constant and k_d is the first order rate constant for deactivation of the lipase.

Time-derivatives of lipase and CAP concentrations can be expressed as (Rice et al., 2006):

$$\frac{d[Lipase]}{dt} = -k_1[CAP][Lipase] + k_{-1}[E * S] + k_2[E * S] - k_d[Lipase] \qquad (28)$$

$$\frac{d[CAP]}{dt} = -k_1[CAP][Lipase] + k_{-1}[E * S] \qquad (29)$$

where k_1 and k_{-1} are the forward and backward enzymatic reaction rate constants for lipase and CAP units, respectively. Solving equations (27) to (29) yields an equation related to the fraction of CAP unit degradation (Rice et al., 2006):

$$\frac{N_{CAP}}{N_{CAP_0}} = exp\left[\frac{k * [Lipase]_0}{k_d}(e^{-k_d t} - 1)\right] \qquad (30)$$

Figure II.4.3.6 illustrates the mass loss profiles as a function of time by solving Eq. (30). It can be seen that the rates of PEG-PCL hydrogel mass loss are functions of several factors, including kinetic parameters ($k*$) and the half-lives of the acting enzyme. One must note that the assumption of bulk degradation will not hold at high enzyme concentrations (i.e., high reaction rates)
FIGURE II.4.3.6 Calculated mass loss profiles for varying values of $k*$ or lipase concentration. Baseline values are shown in solid black line, with $k* = 31.4$ L·mol^{-1}·min^{-1}, lipase concentration = 0.2 mg/mL, and active lipase half-life = 20.4 h (corresponding to $k_d = 5.66 \times 10^{-4}$ min^{-1}). Baseline values for each variable were multiplied by 0.5 (solid gray line), 1.5 (dashed black line), and 2.0 (dashed gray line). $n_0 = 40$ in all calculated profiles. Enzyme was refreshed at 116 hr and 216 hr. (From Rice et al. (2006). *Biomacromolecules*.)

or in thick gels where the diffusion timescale is large. Under these conditions significant surface erosion will occur, which complicates the interpretation of modeling results.

Enzymatic Degradation of Peptide Substrates in Hydrogels. Recently, hydrogels composed of synthetic polymer backbones and enzymatically degradable peptide cross-linkers have been synthesized and studied extensively. These degradable hydrogels are of great importance in controlled release, tissue engineering, and regenerative medicine applications. For example, Hubbell and colleagues pioneered the development of enzymatic degradable hydrogels formed by Michael-type conjugation reactions (West and Hubbell, 1999; Elbert and Hubbell, 2001; Elbert et al., 2001; Lutolf et al., 2003) (also see Chapter I.2.17). The step-growth polymerization mechanism yields cross-linked gel with a regular structure (Figure II.4.3.7), compared to hydrogels formed by chain-growth polymerizations as shown in Figure II.4.3.4. These Michael-type hydrogels are commonly synthesized from the reaction of multi-arm macromers (e.g., PEG) with di-functional peptide linkers and the final networks can be degraded by enzymes (e.g., matrix metalloproteinases). An important application of this type of gel is to encapsulate cells that secrete MMPs to degrade the synthetic matrices through enzymatic action, a degradation process that proceeds only in the presence of encapsulated cells. The cleavage of peptide cross-linkers leads to a decrease in the local gel cross-linking density and the erosion of the polymer chains only in the vicinity of the cells.

While the degradation kinetics of these gels can also be described by the Michaelis–Menten reaction equations, it should be noted that the kinetic parameters (k_{cat} and K_M) in cross-linked hydrogel systems may differ substantially from those in systems with soluble peptide substrates. Firstly, the presence of PEG chains on both sides of the peptide substrate may create steric hindrance for the enzyme, hence increasing K_M and decreasing the rate of degradation (Lutolf et al., 2003). Further, it was found that k_{cat} is higher when peptide substrates are cross-linked within hydrogels, compared to their soluble counterparts (Lutolf et al., 2003).

INFLUENCE OF BIODEGRADATION ON PROPERTIES OF BIODEGRADABLE POLYMERS AND THEIR APPLICATION

Drug Delivery: Influence of Biodegradation in Diffusion

The benefits of biodegradable polymers, including the versatility of degradation mechanisms and tunable degradation rates, have led to the development of numerous drug delivery and controlled release formulations (Amsden, 1998; Peppas et al., 2000; Anseth et al., 2002; Lin and Metters, 2006; Lin and Anseth, 2009) (Chapter II.5.16). Similar to the mechanisms of biodegradation described earlier, the mode of drug release from biodegradable polymers, in general, can also be categorized into the following mechanisms: surface erosion mediated release; bulk-degradation mediated release; and pendent chain cleavage mediated release.

Drug Release Mediated by Surface Erosion. The release of therapeutics from biodegradable polymers is mediated by surface erosion when: (1) the polymers are degraded via a surface erosion mechanism; and (2) diffusion of the therapeutics is not significant in the release process until degradation occurs. As described earlier, hydrophobic polymers (e.g., polyanhydrides, PCL) with limited water infiltration are typically used as base formulations for release mechanism mediated by surface erosion (Gopferich, 1996). An important characteristic of surface erosion mediated release is that the release profiles correlate well with the mass loss profiles of the degrading polymers. This characteristic is particularly attractive in clinical applications, as the delivery of many drugs requires a controllable and sustained manner. Since the release is mediated by surface erosion, the prediction of the drug release rates is relatively easy, and almost identical to that used to predict polymer erosion. The following empirical equation derived by Hopfenberg and colleagues can be used, and is valid for surface-eroding polymers in slabs, cylindrical, and spherical geometries (Hopfenberg, 1976; Siepmann and Gopferich, 2001):

$$\frac{M_t}{M_\infty} = 1 - \left(1 - \frac{k_0 \cdot t}{c_0 \cdot a}\right)^n \tag{31}$$
FIGURE II.4.3.7 Schematic of cross-linking and enzymatic degradation of hydrogels formed via conjugation reactions.

Here, M_t and M_∞ are the cumulative amounts of drug release at any time and infinite time, respectively; k_0 is the rate constant of polymer erosion; c_0 is the initial drug loading concentration; and a is the half-thickness of a slab or the radius of a cylinder or a sphere. Finally, n is defined as a "shape factor" and is 1, 2 or 3, for a slab, cylindrical or spherical geometry, respectively. It is worth noting that this empirical model assumes that all mass transfer events involved in drug release are considered together in a zero-order process confined to the surface of the device, and that it neglects all edge and end effects. Clearly, when the polymers are in a slab geometry ($n = 1$), the resulting drug release rate is independent of time. On the other hand, the release rates of drugs in polymers with cylindrical or spherical geometry decrease with time, as the surface area of the cylindrical or spherical device decreases with increasing degradation time.

Drug Release Mediated by Bulk Degradation. Compared to surface erosion mediated release, the release of therapeutics from bulk-degrading polymers is more complicated as, in addition to polymer degradation, diffusion of the therapeutics plays an important role and cannot be neglected. Siepmann and Gopferich review the mathematical models, both non-Monte Carlo and Monte Carlo models, that are often used to predict drug release from degradable polymers (Siepmann and Gopferich, 2001). For example, in a non-Monte Carlo approach, the diffusion of any species involved in a poly(ortho ester)-based delivery system that contains an acid-generating species to accelerate hydrolysis can be expressed as (Thombre and Himmelstein, 1985; Joshi and Himmelstein, 1991):

$$\frac{\partial C_i}{\partial t} = \frac{\partial}{\partial x}\left(D_i(x,t) \cdot \frac{\partial C_i}{\partial x}\right) + v_i \tag{32}$$

where i represents any of the multiple components involved in the degradation process, such as water, acidic degradation product, and drug. C_i and D_i are the concentration and diffusion coefficient of the diffusing component, respectively, x is the space variable, and v_i is the sum of the production and degradation rate of species i. During the degradation process, the permeability of the system typically increases, leading to diffusion coefficient (D_i) that varies with the polymer concentration, C_D:

$$D_i = D_i^0 \cdot \exp\left[\frac{\mu(C_D^0 - C_D)}{C_D^0}\right] \tag{33}$$

Here, D_i^0 is the initial diffusion coefficient of species i prior to polymer degradation, C_D^0 is the initial concentration of polymer, and μ is a constant. These partial differential equations can be solved numerically.

Degradable hydrogels are another important area of research where significant efforts have been dedicated to both theoretical modeling and experimental verification. The understanding of network structural evolution during degradation is critical in developing mathematical models for predicting drug release profiles from hydrogel networks. For example, given an experimentally determined volumetric swelling ratio (Q) of a degrading hydrogel, one can easily calculate the average molecular weight between cross-link ($\overline{M}_c$) and the volume fraction of the polymer ($v_{2,s}$). Other parameters important for drug release from these degrading hydrogels can also be derived. An important one is the mesh size of a hydrogel network (ξ) that has been described by Canal and Peppas (Canal and Peppas, 1989; Peppas et al., 2000):

$$\xi = v_{2,s}^{-1/3}(r_0^{-2})^{1/2} = Q^{1/3}(r_0^{-2})^{1/2} \tag{34}$$

where $(r_0^{-2})^{1/2}$ is the root mean squared end-to-end distance of the polymer chains in the unperturbed state.

Under the assumption that the degradation of the polymer bond follows pseudo-first order kinetics, both Q and $\overline{M}_c$ increase exponentially during hydrogel degradation. Consequently, the degrading hydrogel network mesh size will also increase exponentially (Mason et al., 2001):

$$\xi = Q^{1/3}(r_0^{-2})^{1/2} \sim \overline{M}_c^{7/10} = [\overline{M}_c\mid_{t=0} e^{2jk_E' t}]^{7/10} = \eta e^{(7/5)jk_E' t} \tag{35}$$

where η is a constant. For a non-degradable hydrogel, solute diffusivity can be estimated with a model developed by Lustig and Peppas (Lustig and Peppas, 1988):

$$\frac{D_g}{D_0} = \left(1 - \frac{r_s}{\xi}\right) \exp\left(-Y\left(\frac{v_{2,s}}{1 - v_{2,s}}\right)\right) \tag{36}$$

where D_g is the solute diffusivity in the swollen hydrogel, D_0 is the solute diffusivity in water, r_s is the size of the solute, and Y is the ratio of the critical volume required for a successful translational movement of the solute and the average free volume per molecule of solvent. A good approximation for Y for PEG hydrogels is unity.

Clearly, D_g in the above equation is a constant in a non-degrading network. However, for a degradable hydrogel the increasing mesh size (ξ) and decreasing polymer volume fraction ($v_{2,s}$) with network degradation alter the diffusion coefficient (D_g) of a solute in the swollen and degrading hydrogel network. Due to the highly swollen network structure where $v_{2,s}$ is relatively small (<0.1), Eq. (36) can be simplified into (Mason et al., 2001):

$$\frac{D_g}{D_0} = \left(1 - \frac{r_s}{\xi}\right) \exp\left(1 - \frac{r_s}{\eta e^{(7/5)jk_E' t}}\right) \tag{37}$$

From the above equation, one can see that as the network degrades, solute diffusivity increases and approaches D_0.

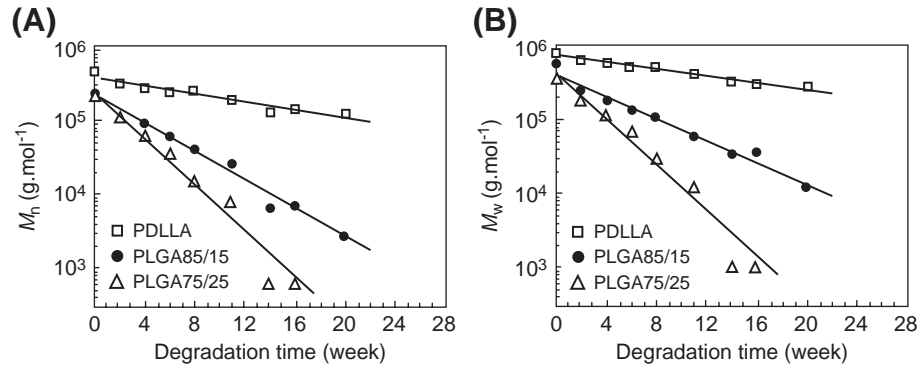
Drug Release Mediated by Pendent Chain Cleavage. The release of a drug conjugated to a polymer network through a cleavable linker (i.e., pro-drug approach) can be modeled by accounting for both the kinetics of linker cleavage and drug diffusion. In general,


FIGURE II.4.3.8 Changes in the: (A) number (M_n) and (B) average molecular weight (M_w) of polymers composing porous scaffolds with different initial copolymer compositions degraded in PBS solution at 37°C. (From Wu & Ding, 2004.)

the following Fickian diffusion equation can be used to describe one-dimensional diffusion of a drug from a hydrogel network:

$$\frac{\partial [P](z,t)}{\partial t} = D_P \frac{\partial^2 [P](z,t)}{\partial z^2} \qquad (38)$$

where $[P]$ is the concentration of the cleaved drug and D_P is its diffusivity, t is the degradation time, and z is the space variable. The rate of product formation $\partial P/\partial t$ can be assumed to be identical to that of the bond cleavage. If the linker is hydrolytically degradable, pseudo-first order degradation kinetics can be incorporated into the above governing equation for highly swollen gels. On the other hand, if the linker is enzymatically degradable, Michaelis–Menton kinetics can be employed.

Tissue Engineering: Influence of Biodegradation on Scaffold Mechanics

Tissue engineering (see Section II.6), as stated by Langer and Vacanti, is: "an interdisciplinary field that applies the principles of engineering and the life sciences toward the development of biological substitutes that restore, maintain or improve tissue functions" (Langer and Vacanti, 1993). Since the conception of tissue engineering, many synthetic biodegradable polymers have lent themselves in the development of "biological substitutes" or "scaffolds" for many biomedical applications, including cartilage and bone regeneration, angiogenesis, nerve regeneration, cardiovascular reconstruction, etc. While in many cases the use of non-degradable scaffolds is favorable (e.g., encapsulation and transplantation of pancreatic islet), degradable polymers are required in numerous applications where the scaffold only serves as a temporary structural support, and degrades gradually as the new tissue is formed. From this perspective, the mechanisms and kinetics of polymer degradation influence greatly the process of tissue regeneration, including cell proliferation and migration.

The most direct effect of polymeric scaffold degradation is the decrease in both the polymer molecular weight and the scaffold mechanical properties, such as

storage and loss moduli. For example, the number (M_n) and average molecular weight (M_w) of bulk-degrading polymers (e.g., PLGA) decrease exponentially with degradation time, and can be expressed as (Wu and Ding, 2004):

$$log\ M = log\ M_0 - kt \qquad (39)$$

Here, M_0 and M are the molecular weights of the degrading polymer prior to and during degradation, respectively; k is the apparent degradation rate constant that can be determined experimentally, and t is the degradation time. Figure II.4.3.8 illustrates the relationship between polymer molecular weight and degradation time (Wu and Ding, 2004).

While these average molecular weights of the degrading polymers are found to decrease monotonically with degradation time, the changes in the moduli of the bulk-degrading polymers are more profound. As observed experimentally, the polymer modulus will increase at early stages of degradation, followed by a plateau phase and finally a dramatic decrease (Wu and Ding, 2004). This behavior is believed to be a result of polymer shrinkage that occurs during the beginning of degradation, which leads to the initial increase, but the changes in properties that are observed during the late stages of degradation are a direct result of the significant decrease in the molecular weight of the polymer molecular chains. In many tissue engineering strategies, biodegradable polymers are processed into highly porous structures to allow cell infiltration. Theoretically, the moduli of degrading polymers can be correlated to their overall porosity (Hou et al., 2003; Zhang et al., 2005; Baker et al., 2009):

$$E_t = E_0(1 - P)^m \qquad (40)$$

$$P = \left(1 - \frac{\rho}{\rho_0}\right) \cdot 100 \qquad (41)$$

where E_t and E_0 are the moduli of the polymer at given time and prior to degradation, respectively. P is the porosity of the degrading polymer, ϱ is the density of

the polymer, and *m* is a characteristic constant for the specific polymer ($1 < m < 3$, e.g., $m = 2.37$ for PLGA (Zhang et al., 2005) and 2.59 for PCL (Hou et al., 2003)). Since the porosity (void volume) of the degrading polymer can be easily measured *in vitro*, the change in the scaffold moduli can also be estimated using these predictions.

In other tissue engineering approaches, biodegradable hydrogels are often used to encapsulate cells and direct tissue regeneration (e.g., encapsulating chondrocytes in hydrogels for cartilage regeneration). For highly swollen hydrogels, the relationships between scaffold degradation and mechanical properties differ significantly from that of hydrophobic porous polymers. For example, the mechanical properties of PEG hydrogels are typically described by rubber elasticity theory and, under certain circumstances (e.g., extremely low temperature), the theory of viscoelasticity (Flory, 1953; Treloar, 1975; Aklonis and MacKnight, 1983; Anseth et al., 1996). In particular, hydrogels in their swollen state usually satisfy the theory of rubber elasticity (Anseth et al., 1996):

$$G_s = \frac{\rho RT}{\overline{M}_c}\left(1 - \frac{2\overline{M}_c}{\overline{M}_n}\right)(v_{2,s})^{1/3} = \frac{\rho RT}{\overline{M}_c}\left(1 - \frac{2\overline{M}_c}{\overline{M}_n}\right)\frac{1}{Q^{1/3}}$$

(42)

Here, G_s is the shear modulus of a swollen gel; ρ is polymer density; R is the gas constant (8.314 Jmol^{-1}K^{-1}); $\overline{M}_n$ is the number-average molecular weight; and T is temperature (K). This relationship correlates the shear modulus of a swollen gel to its cross-linking density ($\overline{M}_c$) and degree of swelling (Q). Clearly, a hydrogel's modulus decreases with an increasing degree of swelling and decreasing gel cross-linking density (i.e., $\overline{M}_c$ is decreased). To simplify the above equation, the Flory–Rehner equation can be substituted into Eq. (42), and assuming a high swelling ratio ($Q > 10$) (Metters et al., 2000a,b; Metters and Lin, 2007):

$$G_s = \frac{\rho RT}{\overline{M}_c}\frac{1}{\left[\beta\left(\overline{M}_c^{3/5}\right)\right]^{1/3}} = \frac{\gamma}{\overline{M}_c^{6/5}}$$

(43)

where β and γ are constants.

For hydrolytically degradable hydrogels (e.g., PLA-*b*-PEG-*b*-PLA hydrogels), $\overline{M}_c$ increases exponentially with time (Anseth et al., 2002). Therefore, Eq. (43) dictates a time-dependent exponentially decreasing modulus for a bulk-degrading hydrogel. Figure II.4.3.9 illustrates the *in vitro* degradation behavior, as well as theoretical verification, of a PLA-*b*-PEG-*b*-PLA hydrogel where the swelling increases and the compressive modulus decreases exponentially with degradation (Anseth et al., 2002). By tailoring the degradation kinetics, these degradable hydrogels have found successful applications in both drug delivery and the regeneration of cartilage (Anseth et al., 2002).
FIGURE II.4.3.9 Changes in material properties during the *in vitro* degradation of a PLA-*b*-PEG-*b*-PLA hydrogel. The solid and dashed lines are exponential curves fit to compressive modulus (●) and volumetric swelling ratio (■) with time constants of $\tau_K = 2000$ min and $\tau_Q = 4200$ min, respectively. (From Anseth et al. 2002.)

SUMMARY

The focus of this chapter has been on developing both a fundamental and quantitative understanding of biodegradation of polymeric biomaterials. Understanding the mechanisms and kinetics of biodegradation is critical in designing biodegradable polymers for many biomedical applications, including matrices for drug delivery and scaffolds for tissue engineering. Designing biodegradable polymeric biomaterials can be challenging, as the design space can be large, with a wide variety of polymer chemistries, degradable moieties, and degradation mechanisms. Further, biodegradation influences numerous material properties, and hence the performance of the final biomedical devices. One important factor that this chapter does not take into account is the complication of the *in vivo* environment. The biodegradation of materials described in this chapter can deviate substantially from *in vitro* observations when placed in a complex and dynamic *in vivo* environment (Chapter II.4.2 addresses key issues in *in vivo* degradation). Nonetheless, understanding the basic principles of biodegradation *in vitro* certainly provides valuable lessons on which biomaterial design is based.

CHAPTER II.4.4 DEGRADATIVE EFFECTS OF THE BIOLOGICAL ENVIRONMENT ON METALS AND CERAMICS

David F. Williams[1] and Rachel L. Williams[2]

[1]Wake Forest Institute of Regeneration Medicine Winston-Salem, North Carolina, USA

[2]Clinical Engineering, Institute of Ageing and Chronic Disease, University of Liverpool, Liverpool, UK

Metallic and ceramic biomaterials continue to be used in many medical device applications. Several of these materials now have more than 40 years' clinical experience, and the factors that control their performance and the mechanisms by which they interact with the human body are well-known and understood. However, since the biological environment to which they are exposed is both very aggressive and very susceptible to material-provoked adverse responses (Williams, 2008), it is important that the potential for degradative effects on these materials is kept clearly in mind as new materials and new applications are introduced.

The environment to which biomaterials are exposed during prolonged use (i.e., the internal milieu of the body) can be described as an aqueous medium containing various anions, cations, organic substances, and dissolved oxygen. The anions are mainly chloride, phosphate, and bicarbonate ions. The principal cations are Na^+, K^+, Ca^{2+}, and Mg^{2+}, but with smaller amounts of many others. Table II.4.4.1 presents the range of values for the anion and cation concentrations in blood plasma and extracellular fluid (Bundy, 1994). This represents an environment with a chloride concentration of approximately a third of that of sea water (Hanawa, 2002). The concentration of dissolved oxygen also influences the aggressive nature of the environment, and in venous blood is approximately a quarter of that in air. The organic substances include low molecular weight species, as well as relatively high molecular weight proteins and lipids. Table II.4.4.2 gives examples of the concentration of various organic components of blood plasma. The protein content of the environment is known to have a significant influence on the corrosive nature of body fluids (Williams, 1985; Khan et al., 1999a; Mueller et al., 2009). The pH in this well-buffered system is around 7.4, although because of inflammation it may change for short periods following surgery to as low as 4 or 5 (Bundy, 1994). The temperature remains constant at around 37°C.

On the basis of existing knowledge of the stability of materials in various environments, we should predict that metals, as a generic group, should be relatively susceptible to corrosion in this biological environment, whereas ceramics should display a varying susceptibility, depending on solubility. This correlates fairly well with experimental

TABLE II.4.4.1	Ionic Concentrations in Blood Plasma and Extracellular Fluid	
Anion, Cation	**Blood Plasma (mM)**	**Extracellular Fluid (mM)**
Cl^-	96–111	112–120
HCO_3^-	16–31	25.3–29.7
HPO_4^{2-}	1–1.5	193–102
SO_4^{2-}	0.35–1	0.4
$H_2PO_4^-$	2	—
Na^+	131–155	141–15
Mg^{2+}	0.7–1.9	1.3
Ca^{2+}	1.9–3	1.4–1.55
K^+	35–5.6	3.5–4

observations and clinical experience, since it is well-known that all but the most corrosion-resistant metals will suffer significant and destructive attack upon prolonged implantation. Also, even the most noble of metals, and those that are most strongly passivated (i.e., naturally protected by their own oxide layer), will still show some degree of interaction. The important passivating implant alloys and their compositions are presented in Table II.4.4.3.

There are some ceramics that have a combination of very strong partially ionic, partially covalent bonds that are sufficiently stable to resist breakdown within this environment, such as the pure simple oxide ceramics, and others in which certain of the bonds are readily destroyed in an aqueous medium so that the material essentially dissolves, for example certain calcium phosphates. Typical implant ceramics and their compositions are presented in Table II.4.4.4.

With these general statements in mind, we have to consider the following questions in relation to the corrosion and degradation of metals and ceramics:

1. Within these groups, how does the susceptibility to corrosion and degradation vary, by what precise mechanisms do the interfacial reactions take place,

and how is material selection (and treatment) governed by this knowledge?
2. Are there variables within this biological environment other than those described above that can influence these processes?
3. What are the consequences of such corrosion and degradation phenomena?

We review each of these questions in this chapter. It is particularly important to bear in mind some general points as these questions are discussed.

1. Material selection cannot be governed solely by considerations of stability, and mechanical and physical properties especially may be of considerable importance. Since corrosion is a surface phenomenon, however, it may be possible to optimize corrosion resistance by attention to, or treatment of, the surface rather than by manipulation of the bulk chemistry (Trepanier et al., 1999, Singh and Dahotre, 2007). This offers the possibility of developing sufficient corrosion resistance in materials of excellent bulk mechanical and physical properties. Thus, noble metals such as gold and platinum are rarely used for structural applications (apart from dental restoration) because of their inferior mechanical properties,

even though they have excellent corrosion resistance; instead, base metal alloys with passivated or protected surfaces offer better all-around properties.

2. Medical devices are not necessarily used in mechanically stress-free conditions, and indeed the vast majority of those using metals or ceramics are structurally loaded. It is well-known that mechanical stress plays a very important role in the corrosion of metals (Gilbert et al., 1993; Jacobs et al., 1998) and the degradation process in ceramics (Piconi and Maccauro, 1999), both potentiating existing effects and initiating others. This has to be taken into consideration.

3. We cannot expect the biological environment to be constant. Within the overall characteristics described earlier, there are variations (with time, location, activity, health status, etc.) in, for example, oxygen levels, availability of free radicals, and cellular activity, all of which may cause variations in the corrosive nature of the environment (Tengvall et al., 1989; Fonseca and Barbosa, 2001). Most important, corrosion is not necessarily a progressive homogeneous reaction with zero-order kinetics. Corrosion processes can be quiescent, but then become activated, or they can be active, but then become passivated and localized, with transient fluctuations in conditions playing a part in these variations.

4. The effects of corrosion or degradation may be twofold. First, and in the conventional metallurgical sense the most obvious, the problem can lead to loss of structural integrity of the material and function. This may be undesirable, as in the case of many long-term prostheses, or desirable, as in devices intended for short-term function (e.g., ceramics for drug delivery systems) or where the material is replaced by tissue during the degradation process, as with ceramic bone substitution. In addition to this, however, and usually of much greater significance with biomaterials, when released into the tissue, the corrosion or degradation products can have a significant and controlling effect on that tissue (Bravo et al., 1990; Jacobs et al., 1998). Indeed, it is likely that the corrosion process is the most important mediator of the tissue response to metallic materials. It is therefore important that we know both the nature of the reaction products and their rate of generation. In this respect it is important to recognize that a very small release of certain metallic ions that cause adverse biological reactions may be more significant than a larger amount of a less stimulating byproduct of corrosion or degradation. The implications of these effects on biocompatibility and the future uses of biomaterials have recently been discussed by Williams (Williams, 2008, 2009).

METALLIC CORROSION

Basic Principles

The most pertinent form of corrosion related to metallic biomaterials is aqueous corrosion. This occurs when electrochemical reactions take place on a metallic surface in an aqueous electrolyte. There are always two reactions that occur: the anodic reaction, which yields metallic ions, for example, involving the oxidation of the metal to its salt:

$$M \rightarrow M(n+) + n(\text{electrons}) \qquad (1)$$

and the cathodic reaction, in which the electrons so generated are consumed. The precise cathodic reaction will depend on the nature of the electrolyte, but two of the most important in aqueous environments are the reduction of hydrogen:

$$2H^+ + 2e^- \rightarrow H_2 \qquad (2)$$

and the reduction of dissolved oxygen:

$$O_2 + 4H^+ + 4e^- \rightarrow 2H_2O \qquad (3)$$

in acidic solutions:

$$O_2 + 2H_2O + 4e^- \rightarrow 4OH^- \qquad (4)$$

or in neutral or basic solutions.

In all corrosion processes, the rate of the anodic or oxidation reaction must equal the rate of the cathodic or reduction reaction. This is a basic principle of electrochemically-based metallic corrosion. It also explains how variations in the local environment can affect the overall rate of corrosion by influencing either the anodic or cathodic reactions. The whole corrosion process can be arrested by preventing either of these reactions.

From a thermodynamic point of view, first consider the anodic dissolution of a pure metal isolated in a solution of its salt. The metal consists of positive ions closely surrounded by free electrons. When the metal is placed in a solution, there will be a net dissolution of metal ions since the Gibbs free energy (ΔG) for the dissolution reaction is less than for the reverse reaction. This leaves the metal with a net negative charge, thus making it harder for the positive ions to leave the surface, and increasing the ΔG for the dissolution reaction. There will come a point when the ΔG for the dissolution reaction will equal the ΔG for the reverse reaction. At this point, a dynamic equilibrium is reached, and a potential difference will be set up across the charged double layer surrounding the metal. The potential difference will be characteristic of the metal and can be measured against a standard reference electrode. When this is done against a standard hydrogen electrode in a 1 N solution of its salt at 25°C, it is defined as the standard electrode potential for that metal (Table II.4.4.5). The position of a metal in the electrochemical series primarily indicates the order with which metals displace each other from compounds, but it also gives a general guide to reactivity in aqueous solutions. Those at the top are the noble, relatively unreactive metals, whereas those at the bottom are the more reactive. This is the first guide to corrosion resistance, but, as we shall see, there are major difficulties related to the use and interpretation of reactions from this simple analysis.

TABLE II.4.4.5	Electrochemical Series
Metal	**Potential (V)**
Gold	1.43
Platinum	1.20
Mercury	0.80
Silver	0.79
Copper	0.34
Hydrogen	0
Lead	−0.13
Tin	−0.14
Molybdenum	−0.20
Nickel	−0.25
Cobalt	−0.28
Cadmium	−0.40
Iron	−0.44
Chromium	−0.73
Zinc	−0.76
Aluminum	−1.33
Titanium	−1.63
Magnesium	−2.03
Sodium	−2.71
Lithium	−3.05

Now consider a system in which the metal is in an aqueous solution that does not contain its ions. In this situation, the electrode potential at equilibrium (i.e., when the rate of the anodic reaction equals the rate of the cathodic reaction) will be shifted from the standard electrode potential and can be defined by the Nernst equation:

$$E = E_0 + (RT / nF \ln(a_{anod} / a_{cath})$$

where E_0 is the standard electrode potential, RT/F is a constant, n is the number of electrons transferred, and a is the activity of the anodic and cathodic reactants. At low concentrations, the activity can be approximated to the concentration. In this situation, there is a net dissolution of the metal and a current will flow. At equilibrium, the rate of the metal dissolution is equal to the rate of the cathodic reaction, and the rate of the reaction is directly proportional to the current density by Faraday's law; therefore:

$$i_{anodic} = i_{cathodic} = i_{corrosion}$$

and the Nernst equation can be rewritten:

$$E = E_0 = \pm \beta \ \ln(i_{corr} / i_0)$$

where β is a constant and i_0 is the exchange current density, which is defined as the anodic (or cathodic) current density at the standard electrode potential. Current density is the current, measured in amperes, normalized to the surface area of the metal.

These conditions represent convenient models for the basic mechanisms of corrosion, but they are hardly realistic. Indeed, in this situation of a homogeneous pure metal existing within an unchanging environment, an equilibrium is reached in which no further net movement

of ions takes place. In other words, the corrosion process takes place only transiently, but is effectively stopped once this equilibrium is reached.

In reality, we usually have neither entirely homogeneous surfaces nor solutions, nor complete isolation of the metal from other parts of the environment, and this equilibrium is easily upset. If the conditions are such that the equilibrium is displaced, the metal is said to be polarized. There are several ways in which this can happen. Two main factors control the behavior of metals in this respect, and determine the extent of corrosion in practice. The first concerns the driving force for continued corrosion (i.e., the reasons why the equilibrium is upset and the nature of the polarization), and the second concerns the ability of the metal to respond to this driving force.

It is self-evident that if either the accumulating positive metal ions in the surrounding media or the accumulating electrons in the metal are removed, the net balance between the dissolution and the replacement of the ions will be disturbed. This will occur in the biological environment surrounding implanted alloys, due to the interaction of the proteins with the metal ions. Metal ions can form complexes with proteins (Steinemann, 1996; Jacobs et al., 1998; Büdinger and Hertl, 2000; Munoz and Mischler, 2007) and these complexes can be transported away from the immediate vicinity. This removes the metal ions from the charged double layer at the interface allowing further release of metal ions to re-establish the equilibrium. Similarly, relative movement between the implant and the tissue, for example, at a bearing surface or on a cyclically loaded implant, will cause mixing at the interface and will modify the composition of the electrolyte, and may modify the surface of the alloy (Khan et al., 1999b). The equilibrium is established precisely because of the imbalance of charge, so that if the charge balance is disturbed, further corrosion will occur to attempt to re-establish the balance. The result will be continued dissolution as the system attempts to achieve this equilibrium, in other words, sustained corrosion. An environment that allows the removal of electrons in contact with the metal or stirring of the electrolyte will achieve this.

The process of galvanic corrosion may be used to demonstrate this effect. Consider a single homogeneous pure metal, A, existing within an electrolyte (Figure II.4.4.1). The metal will develop its own potential, V_A, with respect to the electrolyte. If a different metal electrode, B, is placed into the same electrolyte, but without contacting A, it will develop its own potential V_B. If V_A is not equal to V_B, there will be a difference in the numbers of excess free electrons in each. This is of no consequence if A and B are isolated from each other, but should they be placed in electrical contact, electrons will flow from that metal with the greater potential in an attempt to make the two electrodes equipotential. This upsets the equilibrium and causes continued and accelerated corrosion of the more
FIGURE II.4.4.1 When electrical contact is made between electrodes A and B, electrode B acts as an electron sink, thus upsetting the equilibrium and causing continued dissolution of A.

active metal (anodic dissolution), and protects the less active metal (cathodic protection).

Galvanic corrosion may be seen whenever two different metals are placed in contact in an electrolyte. It has been frequently observed with complex, multicomponent surgical implants such as modular total joint designs consisting of titanium alloy femoral stems and cobalt alloy femoral heads (Jacobs et al., 1998; Virtanen et al., 2008). It is not necessary for the components to be macroscopic, monolithic electrodes for this to happen, and the same effect can be seen when there are different microstructural features within one alloy, such as the multiphase microstructure evident in implants of sensitized stainless steel where the grain boundaries become depleted in chromium and corrode preferentially to the remaining surface (Disegi and Eschbach, 2000). In practice, it is the regional variations in electrode potential over an alloy surface that are responsible for much of the generalized surface corrosion that takes place in metallic components.

Many of the commonly used surgical alloys contain highly reactive metals (i.e., with high negative electrode potentials), such as titanium, aluminum, and chromium. Because of this high reactivity, they will react with oxygen upon initial exposure to the atmosphere. This initial

oxidation leaves an impervious oxide layer firmly adherent to the metal surface; thus all other forms of corrosion may be significantly reduced because the oxide layer acts as a protective barrier, passivating the metal. The manufacturing process for implant alloys may include a passivating step to enhance the oxide layer prior to implantation, for example nitric acid treatment of 316L stainless steel (Fraker and Griffith, 1985; Yoo et al., 2008).

In summary, the basic principles of corrosion determine that:

1. In theory, corrosion resistance can be predicted from standard electrode potentials. This explains the nobility of some metals and the considerable reactivity of others, but is not useful for predicting the occurrence of corrosion of most alloy systems in practice.
2. Irrespective of standard electrode potentials, the corrosion resistance of many materials is determined by their ability to become passivated by an oxide layer that protects the underlying metal.
3. Corrosion processes in practice are influenced by variations in surface microstructural features, and in the environment that disrupt the charge transfer equilibrium.

INFLUENCE OF THE BIOLOGICAL ENVIRONMENT

It is reasonable to assume that the presence of biological macromolecules will not cause a completely new corrosion mechanism. However, they can influence the rate of corrosion by interfering in some way with the anodic or cathodic reactions discussed earlier. Four ways in which this could occur are discussed next.

1. The biological molecules could upset the equilibrium of the corrosion reactions by consuming one or other of the products of the anodic or cathodic reaction. For example, proteins can bind to metal ions and transport them away from the implant surface. This will upset the equilibrium across the charged double layer and allow further dissolution of the metal; in other words, it will decrease ΔG for the dissolution reaction.
2. The stability of the oxide layer depends on the electrode potential and the pH of the solution. Proteins and cells can be electrically active and interact with the charges formed at the interface, and thus affect the electrode potential (Bundy, 1994). Bacteria (Laurent et al., 2001) and inflammatory cells (Fonseca and Barbosa, 2001; Hanawa, 2002; Messer et al., 2009) can alter the pH of the local environment through the generation of acidic metabolic products that can shift the equilibrium.
3. The stability of the oxide layer is also dependent on the availability of oxygen. The adsorption of proteins and cells onto the surface of materials could limit the

diffusion of oxygen to certain regions of the surface. This could cause preferential corrosion of the oxygen-deficient regions and lead to the breakdown of the passive layer. Alternatively, the biomolecule adsorption layer could act as a capacitor, preventing the diffusion of molecules from the surface (Hiromoto et al., 2002).

4. The cathodic reaction often results in the formation of hydrogen, as shown earlier. In a confined locality, the build-up of hydrogen tends to inhibit the cathodic reaction, and thus restricts the corrosion process. If the hydrogen can be eliminated, then the active corrosion can proceed. It is possible that bacteria in the vicinity of an implant could utilize the hydrogen, and thus play a crucial role in the corrosion process.

There is sufficient evidence to support the premise that the presence of proteins and cells can influence the rate of corrosion of some metals (Williams, 1985; Khan et al., 1999a,b; Hanawa, 1999, 2002). Studies have examined these interactions electrochemically, and have found very few differences in many of the parameters measured (e.g., electrode potential, polarization behavior, and current density at a fixed potential). However, analysis of the amount of corrosion through weight loss or chemical analysis of the electrolyte has shown significant effects from the presence of relatively low concentrations of proteins. These effects have varied from several-fold increases for some metals under certain conditions, to slight decreases under other conditions.

It has been shown that proteins adsorb onto metal surfaces and that the amount adsorbed appears to be different in a range of metals (Williams and Williams, 1988; Wälivaara et al., 1992). Similarly, proteins have been shown to bind to metal ions, and it is suggested that they are transported away from the local site as a protein–metal complex and distributed systemically in the body (Jacobs et al., 1998). It is therefore likely that proteins will influence the corrosion reactions that occur when a metal is implanted, although there is no direct evidence to explain the mechanism of the interaction at this time.

CORROSION AND CORROSION CONTROL IN THE BIOLOGICAL ENVIRONMENT

The need to ensure minimal corrosion has been the major determining factor in the selection of metals and alloys for use in the body. Two broad approaches have been adopted. The first has involved the use of noble metals, that is, those metals and their alloys for which the electrochemical series indicates excellent corrosion resistance. Examples are gold, silver, and the platinum group of metals. Because of cost and relatively poor mechanical properties, these are not used for major structural applications, although it should be noted that gold and its alloys are extensively used in dentistry; silver

is sometimes used for its antibacterial activity; and platinum-group metals (Pt, Pd, Ir, Rh) are used in electrodes.

The second approach involves the use of the passivated metals. Of the three elements that are strongly passivated (i.e., aluminum, chromium, and titanium), aluminum cannot be used on its own for biomedical purposes because of toxicity problems; however, it has an important role in several titanium alloys. Chromium is very effectively protected, but cannot be used in bulk. It is, however, widely used in alloys, especially in stainless steels and in the cobalt–chromium-based alloys, where it is normally considered that a level of above 12% gives good corrosion resistance, and about 18% provides excellent resistance. Titanium is the best in this respect, and is used as a pure metal or as the major constituent of alloys (Long and Rack, 1998; Geetha et al., 2009). In alloys the passivating layer promoting the corrosion resistance is predominantly composed of one of these metal oxides. For example, chromium oxide passivates 316L stainless steel and Co–Cr-based alloys, and Ti oxide passivates Ti alloys. The other alloying elements may be present in the surface oxide and this can influence the passivity of the layer (Sittig et al., 1999). Careful pretreatment of the alloys can be used to control the passivity of these alloys (Trepanier et al., 1998; Shih et al., 2000). In particular, production procedures need to be controlled because of their influence on the surface oxides, for example, cleaning (Aronsson et al., 1997) and sterilization (Thierry et al., 2000) procedures.

Although these metals and alloys have been selected for their corrosion resistance, corrosion will still take place when they are implanted in the body. Two important points have to be remembered. First, whether noble or passivated, all metals will suffer a slow removal of ions from the surface, largely because of local and temporal variations in microstructure and environment. This need not necessarily be continuous, and the rate may either increase or decrease with time, but metal ions will be released into that environment. This is particularly important with biomaterials, since it is the effect of these potentially toxic or irritant ions that is the most important consequence of their use. Even with a strongly passivated metal, there will be a finite rate of diffusion of ions through the oxide layer, and possibly dissolution of the layer itself. It is well-known that titanium is steadily released into the tissue from titanium implants (Jacobs et al., 1998; Hanawa et al., 1998). Second, some specific mechanisms of corrosion may be superimposed on this general behavior; some examples are given in the next section.

Pitting Corrosion

The stainless steels used in implantable devices are passivated by the chromium oxide that forms on their surface. It has been shown, however, that in a physiological saline environment, the driving force for repassivation
FIGURE II.4.4.2 This etched metallographic micrograph demonstrates the pitting corrosion of stainless steel.

of the surface is not high (Seah et al., 1998). Thus, if the passive layer is broken down, it may not repassivate and active corrosion can occur.

Localized corrosion can occur as a result of imperfections in the oxide layer, producing small areas where the protective surface is removed (Rondelli and Vicentini, 1999). These localized spots will actively corrode, and pits will form in the surface of the material. This can result in a large degree of localized damage, because the small areas of active corrosion become the anode and the entire remaining surface becomes the cathode. Since the rate of the anodic and cathodic reactions must be equal, it follows that a relatively large amount of metal dissolution will be initiated by a small area of the surface, and large pits may form (Figure II.4.4.2).

Fretting Corrosion

The passive layer may be removed by a mechanical process (Khan et al., 1999b; Okazaki, 2002). This can be a scratch that does not repassivate, resulting in the formation of a pit, or a continuous cyclic process in which any reformed passive layer is removed. This is known as fretting corrosion, and it is suggested that this can contribute to the corrosion observed between a fracture fixation plate and the bone screws attaching the plate to the bone. There are four reasons why fretting can affect the corrosion rate. The first is due to the removal of the oxide film as just discussed. The second is due to plastic deformation of the contact area; this can subject the area to high strain fatigue and may cause fatigue corrosion. The third is due to stirring of the electrolyte, which can increase the limited current density of the cathodic reaction. The fourth, especially seen with titanium, is the influence of fretting on hydrogen absorption, and the consequential hydrogen embrittlement (Rodrigues et al., 2009).

Crevice Corrosion

The area between the head of the bone screw and countersink on the fracture fixation plate can also be influenced by the crevice conditions that the geometry creates (Figure II.4.4.3) (Cook et al., 1987). Porous coated implants may also demonstrate crevice corrosion (Seah et al., 1998). Accelerated corrosion can be initiated in a crevice by restricted diffusion of oxygen into the crevice. Initially, the anodic and cathodic reactions occur uniformly over the surface, including within the crevice. As the crevice becomes depleted of oxygen, the reaction is limited to metal oxidation, balanced by the cathodic reaction on the remainder of the surface. In an aqueous sodium chloride solution, the build-up of metal ions within the crevice causes the influx of chloride ions to balance the charge by forming the metal chloride. In the presence of water, the chloride will dissociate to its insoluble hydroxide and acid. This is a rapidly accelerating process, since the decrease in pH causes further metal oxidation.

Intergranular Corrosion

As mentioned earlier, stainless steels rely on the formation of chromium oxides to passivate the surface. If some areas of the alloy become depleted in chromium, as can happen if carbides are formed at the grain boundaries, the regions adjacent to the grain boundaries become depleted in chromium. The passivity of the surface in these regions is therefore affected, and preferential corrosion can occur (Figure II.4.4.4). Although this problem can easily be overcome by heat treating the alloys (Disegi and Eschbach, 2000), it has been observed on retrieved implants (Walczak et al., 1998) and can cause severe problems, since once initiated it will proceed rapidly and may well cause fracture of the
FIGURE II.4.4.3 Crevice corrosion is evident in the screw hole in this fracture fixation plate.
FIGURE II.4.4.4 Intergranular corrosion is demonstrated on this etched stainless steel specimen.

implant and the release of large quantities of corrosion products into the tissue.

Stress Corrosion Cracking

Stress corrosion cracking is an insidious form of corrosion, since an applied stress and a corrosive environment can work together and cause complete failure of a component, when neither the stress nor the environment would be a problem on their own. The stress level may be very low, possibly only residual, and the corrosion may be initiated at a microscopic crack tip that does not repassivate rapidly. Incremental crack growth may then occur, resulting in fracture of the implant. Industrial uses of stainless steels in saline environments have shown susceptibility to stress corrosion cracking, and therefore

it is a potential source of failure for implanted devices, although to date there has been little evidence that it occurs extensively in clinical practice.

Galvanic Corrosion

If two metals are independently placed within the same solution, each will establish its own electrode potential with respect to the solution. If these two metals are placed in electrical contact, then a potential difference will be established between them, electrons passing from the more anodic to the more cathodic metal. Thus, equilibrium is upset and a continuous process of dissolution from the more anodic metal will take place. This accelerated corrosion process is galvanic corrosion. It is important if two different alloys are used in

FIGURE II.4.4.5 Extensive corrosion on the titanium stem of a modular hip prosthesis.

an implantable device when the more reactive may corrode freely.

Whenever stainless steel is joined to another implant alloy, it will suffer from galvanic corrosion. If both alloys remain within their passive region when coupled in this way, the additional corrosion may be minimal. Some modular orthopedic systems are made of titanium alloys and cobalt-based alloys on the basis that both should remain passive, but evidence of corrosion has been reported (Gilbert et al., 1993). Certainly, as shown in Figure II.4.4.5, titanium stems of modular prostheses can exhibit extensive corrosion. Galvanic corrosion may also take place on a microscopic scale in multiphase alloys where phases are of considerably different electronegativity. In dentistry, some amalgams may show extensive corrosion because of this mechanism.

Intentional Corrosion and Resorption of Implantable Alloys

The vast majority of applications of metallic systems in medical devices are predicated on the assumption that the device will remain in the patient's body for their full life or until it is intentionally removed surgically. As discussed elsewhere in this book, there are some situations where permanence is not required, and indeed could be disadvantageous. Two situations may be mentioned here: the use of temporary supports during tissue healing (as with bone fracture plates), and the use of intravascular stents that support blood vessels after angioplasty procedures. In both of these situations, an intentionally degradable and resorbable material may be considered as an alternative. With bone fracture plates, a range of biodegradable polymers have been used clinically, and there is some good clinical success. With stents, clinical experience is only just beginning, and again attention is being concentrated

on polymers. However, there is increasing interest in the possibility of using magnesium alloys that are known to degrade in the body, and are potentially resorbable.

As reviewed by Staiger et al. (Staiger et al., 2006) and Witte (Witte, 2010), magnesium itself corrodes readily in the body, and magnesium samples can disappear in relatively short times. The rapid loss of strength, and the doubtful biocompatibility of such a rapidly degrading structure, has to be viewed with caution, even though it would appear that the magnesium ions are relatively well-tolerated, magnesium being an essential element in humans. Developments with this element have concentrated on alloying additions that reduce the corrosion rate, without inducing significant cytotoxicity or radically altering the mechanical properties (Xu et al., 2007; Li et al., 2008; Kannan and Raman, 2008). Alloys of Mg–Mn–Zn and Mg–Ca, wherein all alloying additions are also essential elements, figure prominently in these developments. It is a little early to predict the likely clinical success with these alloys.

CERAMIC DEGRADATION

The rate of degradation of ceramics within the body can differ considerably from that of metals, in that they can be either highly corrosion resistant or highly soluble. As a general rule, we should expect to see a very significant resistance to degradation with ceramics and glasses. Since the corrosion process in metals is one of a conversion of a metal to a ceramic structure (i.e., metal to a metal oxide, hydroxide, chloride, etc.) we must intuitively conclude that the ceramic structure represents a lower energy state, in which there would be less driving force for further structural degradation. The interatomic bonds in a ceramic, being largely ionic but partly covalent, are strong directional bonds and large amounts of energy are required for their disruption. As extraction metallurgists

know, it takes a great deal of energy to extract aluminum metal from the ore aluminum oxide, but as we have seen, the reverse process takes place readily by surface oxidation. Thus, we should expect ceramics such as Al_2O_3, ZrO_2, TiO_2, SiO_2, and TiN to be stable under normal conditions (Dalgleish and Rawlings, 1981). This is what is observed in clinical practice. There is limited evidence to show that some of these ceramics (e.g., polycrystalline Al_2O_3 and ZrO_2) do show "aging" phenomena (Piconi and Maccauro, 1999; Marti, 2000), with reductions in some mechanical properties, but the significance of this is unclear. With some variations in structure, there is clear evidence that problems may arise if incorrect structural forms are used. Zirconia is often used in the transformation toughened state; as with most oxide ceramics, the material is inherently brittle but this can be ameliorated by the use of doping elements which cause the formation and retention of a metastable state. This is achieved by the addition of small amounts of the rare earth oxide yttria to the zirconia. The toughening arises from the transformation of crystallographic structure at a crack tip under strain, which causes blunting of the crack and prevents its catastrophic propagation. However, this metastable state can transform under other conditions. Many batches of improperly heat-treated zirconia hip replacement components underwent such changes over a short time after implantation, causing significant structural failure under load (Deville et al., 2005; Chevalier, 2006).

Alternatively, there will be many ceramic structures that, although stable in the air, will dissolve in aqueous environments. Consideration of the classic fully ionic ceramic structure NaCl and its dissolution in water demonstrates this point. It is possible, therefore, on the basis of the chemical structure, to identify ceramics that will dissolve or degrade in the body, and the opportunity exists for the production of structural materials with controlled degradation.

Since any material that degrades in the body will release its constituents into the tissue, it is necessary to select anions and cations that are readily and harmlessly incorporated into metabolic processes, and utilized or eliminated. For this reason, it is compounds of sodium, and especially calcium, including calcium phosphates and calcium carbonates, that are primarily used.

The degradation of such compounds will depend on chemical composition and microstructure (Bohner, 2000). For example, tricalcium phosphate $[Ca_3(PO_4)_2]$ is degraded fairly rapidly, while calcium hydroxyapatite $[Ca_{10}(PO_4)_6(OH)_2]$ is relatively stable. Within this general behavior, however, porosity will influence the rates so that a fully dense material will degrade slowly, while a microporous material will be susceptible to more rapid degradation.

In general, dissolution rates of these ceramics *in vivo* can be predicted from behavior in simple aqueous solution. However, there will be some differences in detail within the body, especially with variations in degradation rate seen at different implantation sites. It is possible that cellular activity, either by phagocytosis or the release of free radicals, could be responsible for such variations.

In between the extremes of stability and intentional degradability lie a small group of materials in which there may be limited activity. This is particularly seen with a number of glasses and glass ceramics, based on Ca, Si, Na, P, and O, in which there is selective dissolution on the surface involving the release of Ca and P, but in which the reaction then ceases because of the stable SiO_2-rich layer that remains on the surface. This is of considerable interest because of the ability of such surfaces to bond to bone, and this subject is dealt with elsewhere in this book.

On the basis of this behavior, bioceramics are normally classified under three headings:

- Inert or "nearly inert" ceramics
- Resorbable ceramics
- Ceramics of controlled surface reactivity.

This area is discussed in detail in other chapters within this book.

SUMMARY

This chapter has attempted to demonstrate that metals are inherently susceptible to corrosion, and that the greatest care is needed in using them within the human body. In general, ceramics have much less tendency to degrade, but care still has to be taken over aging phenomena. The human body is very aggressive toward all of these materials.

CHAPTER II.4.5 PATHOLOGICAL CALCIFICATION OF BIOMATERIALS

Frederick J. Schoen[1] and Robert J. Levy[2]

[1]Professor of Pathology and Health Sciences and Technology (HST), Harvard Medical School, Executive Vice Chairman, Department of Pathology, Brigham and Women's Hospital, Boston, MA, USA

[2]Abramson Pediatric Research Center, The Children's Hospital of Philadelphia, University of Pennsylvania, Philadelphia, PA, USA

INTRODUCTION

Formation of nodular deposits of calcium phosphate or other calcium-containing compounds may occur on biomaterials and prosthetic devices used in the circulatory system and at other sites. This process, known as *calcification* or *mineralization*, has been encountered in association with both synthetic and biologically derived biomaterials in diverse clinical and experimental settings, including chemically-treated tissue (*bioprosthetic*) and homograft cardiac valve substitutes (Mitchell et al., 1998; Schoen and Levy, 1999, 2005), blood pumps used as cardiac assist devices (Schoen and Edwards, 2001), breast implants (Peters et al., 1998; Legrand et al., 2005), intrauterine contraceptive devices (Patai et al., 1998), urological stents (Vanderbrink et al., 2008), intraocular lenses (Neuhann et al., 2008; Nakanome et al., 2008; Rimmer et al., 2010), and scleral buckling materials (Brockhurst et al., 1993; Yu et al., 2005). Vascular access grafts for hemodialysis and synthetic vascular replacements composed of Dacron® or expanded polytetrafluoroethylene (e-PTFE) also calcify in some patients (Tomizawa et al., 1998; Schlieper et al., 2008). Calcification can lead to important clinical complications, such as stiffening and/or tearing of tissue heart valve substitutes, encrustation with blockage of a urinary stent or clouding of intraocular lenses (Table II.4.5.1).

Deposition of mineral salts of calcium (as calcium phosphates, especially calcium hydroxyapatite) occurs normally in bones and teeth, and is a critical determinant of their strength (called *physiologic* mineralization). Mineralization of skeletal tissues is both controlled and restricted to specific anatomic sites. The mature mineral phase of bone is a poorly crystalline calcium phosphate known as calcium hydroxyapatite, which has the chemical formula $Ca_{10}(PO_4)_6(HO)_2$. Mineralization of some implant biomaterials is desirable for proper function, e.g., osteoinductive materials used for orthopedic or dental applications (Habibovic and de Groot, 2007), and materials used to engineer skeletal and dental tissues (Kretlow and Mikos, 2007; Bueno and Glowacki, 2009). However, severe consequences can occur if mineralization occurs in regions that do not normally calcify (*pathologic* or *ectopic* mineralization) (Kirsch, 2008).

Since the biomaterials used in medical devices outside of the musculoskeletal and dental systems are not intended to calcify, calcification of these biomaterials is pathologic. The mature mineral phase of biomaterial-related and other forms of pathologic calcifications is a poorly crystalline calcium phosphate that closely resembles the calcium hydroxyapatite present in bones and teeth. Indeed, as we will see later, biomaterials-related calcification shares many features with other conditions of pathologic calcification and physiologic mineralization. Pathologic calcification of natural structures is also a common feature of important disease processes; for example, in native arteries and heart valves, calcification occurs as an important feature of the serious diseases atherosclerosis and calcific aortic stenosis, respectively (Mitchell and Schoen, 2010; Schoen and Mitchell, 2010).

Pathologic calcification is further classified as either *dystrophic* or *metastatic*, depending on its setting (Kumar et al., 2010). In dystrophic calcification the deposition of calcium salts (usually calcium phosphates) occurs in damaged or diseased tissues or related to biomaterials; moreover, dystrophic calcification usually occurs in the setting of normal systemic calcium metabolism (generally defined by a normal product of the serum levels of calcium and phosphorus). In contrast, metastatic calcification comprises the deposition of calcium salts in otherwise normal tissues in individuals who have deranged mineral metabolism, usually with markedly elevated blood calcium or phosphorus levels. Conditions favoring dystrophic and metastatic calcification can act synergistically. Thus, the rate and extent of dystrophic mineralization within abnormal tissues are accelerated when calcium and/or phosphorus serum levels are high, for example, in kidney failure or calcium supplementation (Umana et al., 2003; Peacock, 2010), and in osteoporosis (Hofbauer et al., 2007; Hjortnaes et al., 2010). Moreover, the ability to form physiologic mineral (e.g.,

TABLE II.4.5.1	Representative Prostheses and Devices with Clinical Consequences Due to Biomaterials Calcification	
Configuration	**Biomaterial**	**Clinical Consequence**
Cardiac valve prostheses	Glutaraldehyde-pretreated porcine aortic valve or bovine pericardium, and allograft aortic/pulmonary valves	Valve obstruction or incompetency
Cardiac ventricular assist bladders	Polyurethane	Dysfunction by stiffening or cracking
Vascular grafts	Dacron® grafts and aortic allografts	Graft obstruction or stiffening
Soft contact lens	Hydrogels	Opacification
Intrauterine contraceptive devices	Silicone rubber, polyurethane or copper	Birth control failure by dysfunction or expulsion
Urinary prostheses	Silicone rubber or polyurethane	Incontinence and/or infection

in bone) is regulated through adjustment of enhancing and inhibiting substances, many of which circulate in the blood (Weissen-Planz et al., 2008). In young individuals (especially into early adulthood) the balance appropriately favors bone formation; moreover, the biochemical environment that favors physiologic bone formation in children also promotes calcification of biomaterials (Bass and Chan, 2006; Peacock, 2010).

The cells and extracellular matrix of dead tissues are the principal sites of pathologic calcification. Calcification of an implant biomaterial can occur within the tissue (*intrinsic* calcification) or at the surface, usually associated with attached cells and proteins (*extrinsic* calcification) or in the implant fibrous capsule. An important instance of extrinsic calcification is that associated with prosthetic valve infection (prosthetic valve endocarditis) or thrombi.

THE SPECTRUM OF PATHOLOGIC BIOMATERIALS AND MEDICAL DEVICE CALCIFICATION

Tissue Heart Valves

Calcific degeneration of glutaraldehyde-pretreated porcine bioprosthetic and bovine pericardial heart valves (Figure II.4.5.1) is a clinically significant and well-characterized dysfunction of a medical device due to biomaterials calcification (Schoen and Levy, 1999, 2005). The predominant pathologic process is intrinsic calcification of the valve cusps, largely initiated in the deep cells and the tissue from which the valve was fabricated and often involving collagen. Calcification leads to valve failure most commonly by causing cuspal tears, less frequently by cuspal stiffening, and rarely by inducing distant emboli. Overall, approximately half of porcine bioprostheses fail within 12–15 years. Calcification is more rapid and aggressive in the young; to exemplify, the rate of failure of bioprostheses is approximately 10% in 10 years in elderly recipients, but is nearly uniform in less than four years in most adolescent and preadolescent children (Chan et al., 2006).

In some young individuals with congenital cardiac defects or acquired aortic valve disease, human *allograft/homograft* aortic (or pulmonary) valves surrounded by a sleeve of aorta (or pulmonary artery) are used. Allograft valves are valves removed from a person who has died and transplanted to another individual; the tissue is usually cryopreserved, but not chemically cross-linked. Allograft vascular segments (without a valve) can be used to replace a large blood vessel. Allograft vascular tissue, whether containing an aortic valve or nonvalved, can undergo severe calcification, particularly in the wall; calcification can lead to allograft valve dysfunction or deterioration (Mitchell et al., 1998).

> Calcific degeneration of glutaraldehyde-pretreated porcine bioprosthetic and bovine pericardial heart valves (Figure II.4.5.1) is a clinically significant and well-characterized dysfunction of a medical device due to biomaterials calcification (Schoen and Levy, 1999, 2005). The predominant pathologic process is intrinsic calcification of the valve cusps, largely initiated in the deep cells and the tissue from which the valve was fabricated and often involving collagen. Calcification leads to valve failure most commonly by causing cuspal tears, less frequently by cuspal stiffening, and rarely by inducing distant emboli. Overall, approximately half of porcine bioprostheses fail within 12–15 years.

Polymeric Heart Valves and Bladders in Blood Pumps

Calcification has also complicated the use of heart valves and artificial mitral valve *chordae tendineae* composed of polymers (e.g., polyurethane) (Fukunaga et al., 2010; Hilbert et al., 1987; Schoen et al., 1992a; Schoen and Levy, 1999; Wang et al., 2010) and the flexing bladder surfaces of blood pumps used as ventricular assist systems or total artificial hearts (Schoen and Edwards, 2001) (Figure II.4.5.2). Massive deposition of mineral leading to failure has been noted in experimental animals, but a lesser degree of calcification has been encountered following extended human implantation. Mineral deposits can result in deterioration of pump or valve
FIGURE II.4.5.1 Calcification of a pericardial bioprosthetic heart valve, implanted in a person for many years. (A) Gross photograph, demonstrating marked thickening of cusps by nodular calcific deposits; (B) radiograph of another long-term valve, demonstrating predominant deposits at commissures; (C) photomicrograph demonstrating calcific nodule deeply embedded within cuspal tissue; von Kossa stain (calcium phosphates black) 100×.
FIGURE II.4.5.2 Calcification of an experimental polymeric (polyurethane) heart valve. (A) Gross photograph of valve; (B) photomicrograph calcified material at surface of polymer (polymer at bottom of photo); and calcification of the flexing bladder of a ventricular assist pump removed from a person after 257 days. (C) Gross photograph. Calcific masses are noted by arrows. (D) photomicrograph (B) and (D) von Kossa stain (calcium phosphates black) 100×.

performance through loss of bladder pliability or the initiation of tears. Blood pump calcification, regardless of the type of polyurethane used, generally predominates along the flexing margins of the diaphragm, emphasizing the important potentiating role of mechanical factors in this system (Coleman et al., 1981; Harasaki et al., 1987; Kantrowitz et al., 1995).

Calcific deposits associated with polymeric heart valve or blood pump components can occur either within the adherent layer of deposited thrombus, proteins, and cells (*pseudointima*) on the blood-contacting surface (extrinsic mineralization) or is below the surface (intrinsic calcification) (Joshi et al., 1996). In some cases, calcific deposits are associated with microscopic surface defects, originating either during bladder fabrication or resulting from cracking during function.

Breast Implants

Calcification of silicone-gel breast implant capsules occurs as discrete calcified plaques at the interface of the inner fibrous capsule with the implant surface (Peters and Smith, 1998; Gumus, 2009). Capsular calcification has also been encountered with breast implants in patients with silicone envelopes filled with saline. Calcification could interfere with effective tumor detection and diagnosis, which could potentially delay treatment, particularly in patients who have breast implants following reconstructive surgery for breast cancer. In a study of breast implants removed predominantly

for capsular contraction, 16% overall demonstrated calcific deposits, including 26% of implants inserted for 11–20 years, and all those inserted for more than 23 years (Peters and Smith, 1995). Another study demonstrated calcification associated with virtually all implants examined after more than 20 years (Legrand et al., 2005).

Ivalon® (polyvinyl alcohol) sponge prostheses, used quite extensively during the 1950s, were also frequently associated with calcification. In Japan, where augmentation mammoplasty was frequently performed using injection of foreign material (liquid paraffin from approximately 1950 until 1964, and primarily liquid silicone injections thereafter), the incidence of calcification has been much higher. One study showed calcification in 45% of breast augmentations which were done by injection (Koide and Katayama, 1979).

Intrauterine Contraceptive Devices

Intrauterine contraceptive devices (IUDs) are composed of plastic or metal, and placed in a woman's uterus chronically to prevent implantation of a fertilized egg. Device dysfunction due to calcific deposits can be manifested as contraceptive failure or device expulsion. For example, accumulation of calcific plaque could prevent the release of the active contraception-preventing agent – either ionic copper from copper-containing IUDs or an active agent from hormone-releasing IUD systems. Studies of explanted IUDs using transmission and electron

microscopy coupled with X-ray microprobe analysis have shown that surface calcium deposition is virtually ubiquitous, but highly variable among patients (Khan and Wikinson, 1985; Patai et al., 1998).

Urinary Stents and Prostheses

Mineral crusts form on the surfaces of urinary stents and nephrostomy tubes, which are used extensively in urology to alleviate urinary obstruction or incontinence (Goldfarb et al., 1989; Vanderbrink et al., 2008). Observed in both male and female urethral implants and artificial ureters, this calcification can lead to obstruction and device failure. The mineral crust typically consists of either calcium oxalate or calcium phosphate mineral such as hydroxyapatite or struvite, an ammonium- and magnesium-containing phosphate mineral derived from urine. There is some evidence that encrustation may both result from and predispose to bacterial infection.

Intraocular and Soft Contact Lenses and Scleral Buckles

Calcium phosphate deposits can opacify intraocular and soft contact lenses, typically composed of poly-2-hydroxyethyl-methacrylate (HEMA) (Bucher et al., 1995; Nakanome et al., 2008; Neuhann et al., 2008; Rimmer et al., 2010). Calcium from tear fluid is considered to be the source of the deposits found on HEMA contact lens, and calcification may be potentiated in patients with systemic and ocular conditions associated with elevated tear calcium levels (Klintworth et al., 1977). Encircling scleral bands, used in surgery for retinal detachment, and composed of silicone or hydrogel materials, also calcify (Lane et al., 2001).

ASSESSMENT OF BIOMATERIALS CALCIFICATION

Calcific deposits are investigated using morphologic and chemical techniques (Table II.4.5.2). Morphologic techniques facilitate detection and characterization of the microscopic and ultrastructural sites and distribution of calcific deposits, and their relationship or tissue or biomaterials structural details. Such analyses directly yield important qualitative (but not quantitative) information. In contrast, chemical techniques, which require destruction of the tissue specimen, permit identification and quantitation of both bulk elemental composition and determination of crystalline mineral phases. However, such techniques generally cannot relate the location of the mineral to the details of the underlying tissue structure. The most comprehensive studies use several analytical modalities to simultaneously characterize both morphologic and chemical aspects of calcification. Moreover, newer techniques are available for non-destructive and potentially non-invasive characterizing of calcification, both in specimens (microcomputer tomography (micro CT)) (Ford-Hutchinson, 2003; Neues and Epple, 2008), and *in vivo* using molecular imaging (Aikawa et al., 2007). Micro CT has been used extensively in studies of bone regenerative biomaterials (Jiang et al., 2009). Molecular imaging, which probes *biomarkers* of particular targets or pathways of the cellular and molecular mechanisms of calcification, is particularly exciting in this context to enable the visualization of the ongoing and dynamic process of calcification, potentially quantitatively and repetitively in living organisms (New and Aikawa, 2011).

Morphologic Evaluation

Morphologic assessment of calcification is done by means of several readily available and well-established

TABLE II.4.5.2	Methods for Assessing Calcification	
Technique	**Sample Preparation**	**Analytical Results**
Morphologic Procedures		
Gross examination	Gross specimen	Overall morphology
Radiographs	Gross specimen	Calcific deposit distribution
Micro-computed tomography	Gross specimen	Three-dimensional reconstruction of calcific deposit morphology, localization, and quantification
Light microscopy – von Kossa or alizarin red stains	Formalin or glutaraldehyde fixed	Microscopic phosphate or calcium distribution, respectively
Transmission electron microscopy	Glutaraldehyde fixed	Mineral ultrastructure
Scanning electron microscopy with electron microprobe	Glutaraldehyde fixed	Elemental localization and quantitation
Electron energy loss spectroscopy	Glutaraldehyde fixed or rapidly frozen	Elemental localization and quantitation (high sensitivity)
Chemical Procedures		
Atomic absorption	Ash or acid hydrolyzate	Bulk calcium
Colorimetric phosphate analysis	Ash or acid hydrolyzate	Bulk phosphorus
X-ray diffraction	Powder	Nature of crystal phase
Infrared spectroscopy	Powder	Carbonate mineral phase

techniques that range from macroscopic (gross) examination and radiographs (X-rays) of explanted prostheses to sophisticated electron energy loss spectroscopy. Each technique has advantages and limitations; several techniques are often used in combination to obtain an understanding of the structure, composition, and mechanism of each type of calcification.

Careful visual examination of the specimen, often under a dissecting (low power) microscope, and radiography assess distribution of mineral. Specimen radiography typically involves placing the explanted prosthesis on an X-ray film plate and exposing to an X-ray beam in a special device used for small samples (e.g., we use the Faxitron, Hewlett-Packard, McMinnville, CA with an energy level of 35 keV for 1 minute for valves). Deposits of mineral appear as bright densities which have locally blocked the beam from exposing the film (see Figure II.4.5.1B).

Light microscopy of calcified tissues is widely used. Identification of mineral is facilitated through the use of either calcium- or phosphorus-specific stains, such as alizarin red (which stains calcium) or von Kossa (which stains phosphates brown-black) (Figure II.4.5.2B and Figure II.4.5.3). These histologic stains are readily available, can be easily applied to tissue sections embedded in either paraffin or plastic, and are most useful for confirming and characterizing suspected calcified areas which have been noted by routine hematoxylin and eosin

staining techniques. Sectioning of calcified tissue which has been embedded in paraffin often leads to considerable artifacts due to fragmentation; embedding of tissue with calcific deposits in a harder medium such as glycolmethacrylate polymer can yield superior section quality.

Electron microscopic techniques, which involve the bombardment of the specimen with a highly focused electron beam in a vacuum, have much to offer in the determination of early sites of calcific deposits. In transmission electron microscopy (TEM), the beam traverses an ultra-thin section ($0.05\ \mu m$) (Figure II.4.5.4); observation of the ultrastructure (submicron tissue features) of calcification by TEM facilitates the understanding of the mechanisms by which calcific crystals form. Scanning electron microscopy (SEM) images the specimen
FIGURE II.4.5.3 Light microscopic appearance of calcification of experimental porcine aortic heart valve tissue. Note cell-based orientation of initial deposits (arrows). (B) 21-day implant demonstrating collagen calcification. Bar = $2\ \mu m$. Ultrathin sections stained with uranyl acetate and lead citrate. (Figure (A) reproduced with permission from Schoen, F. J. et al. (1985), p.521.)

surface, and can be coupled with elemental localization by energy-dispersive X-ray analysis (EDXA), allowing a semi-quantitative evaluation of the local progression of calcium and phosphate deposition in a site-specific manner. Electron energy loss spectroscopy (EELS) couples transmission electron microscopy with highly sensitive elemental analyses to provide a most powerful localization of incipient nucleation sites and early mineralization (Webb et al., 1991). In general, the more highly sensitive and sophisticated morphologic techniques require more demanding and expensive preparation of specimens to avoid unwanted artifacts. Forethought about, and careful planning of, specimen handling optimizes the yield provided by the array of available techniques, and allows multiple approaches to be used on specimens from a particular experiment.

Chemical Assessment

Quantitation of calcium and phosphorus in biomaterial calcifications permits characterization of the progression of deposition, comparison of severity of deposition among specimens, and determination of the effectiveness of preventive measures (Levy et al., 1983a, 1985a; Schoen et al., 1985, 1986, 1987; Schoen and Levy, 1999). However, such techniques destroy the specimen (and hence obliterate any spatial information) during preparation. Calcium has been quantitated by atomic absorption spectroscopy of acid-hydrolyzed or ashed samples. Phosphorus is usually quantitated as phosphate, using a molybdate complexation technique with spectrophotometric detection. The specific crystalline form of the mineral phase can be determined by X-ray diffraction. Carbonate-containing mineral phases may also be analyzed by infrared spectroscopy.

MECHANISMS OF BIOMATERIALS CALCIFICATION

Regulation of Pathologic Calcification

The determinants of biomaterial mineralization include factors related to: (1) host metabolism; (2) implant structure and chemistry; and (3) mechanical factors. Natural cofactors and inhibitors may also play a role (see below). The most important host metabolic factor relates to young age, with more rapid calcification taking place in immature patients or experimental animals (Levy et al., 1983a). Although the relationship is well-established, the mechanisms accounting for this effect are uncertain. An important implant factor for bioprosthetic tissue is pretreatment with glutaraldehyde, done to preserve the tissue (Golomb et al., 1987; Grabenwoger et al., 1996). It has been hypothesized that the cross-linking agent glutaraldehyde stabilizes and perhaps modifies phosphorous-rich calcifiable structures in the bioprosthetic tissue. These sites seem to be capable of mineralization

upon implantation when exposed to the comparatively high calcium levels of extracellular fluid. Calcification of the two principal types of tissue used in bioprostheses – glutaraldehyde-pretreated porcine aortic valve or glutaraldehyde-pretreated bovine pericardium – is similar in extent, morphology, and mechanisms (Schoen and Levy, 2009).

> The determinants of biomaterial mineralization include factors related to: (1) host metabolism; (2) implant structure and chemistry; and (3) mechanical factors. Natural cofactors and inhibitors may also play a role.

Calcification has typically been considered a passive, unregulated, and degenerative process. However, the observations of matrix vesicles, hydroxyapatite mineral, and bone-related morphogenetic and non-collagenous proteins in situations of pathological calcification has suggested that the mechanisms responsible for pathologic calcification may be regulated, similarly to physiologic mineralization of bone and other hard tissues, and that some of the mechanisms regulating these paradoxically different processes may be shared (Johnson et al., 2006; Demer and Tintut, 2008; Persy and D'Haese, 2009). In normal blood vessels and valves, inhibitory mechanisms outweigh procalcification inductive mechanisms; in contrast, in bone and pathologic tissues, inductive mechanisms dominate. Naturally-occurring inhibitors to crystal nucleation and growth (of which at least 11 have been identified), may also play a role in biomaterial and other cardiovascular calcification (Weissen-Plenz et al., 2008). Specific inhibitors in this context include osteopontin (Steitz et al., 2002) and phosphocitrate (Tew et al., 1980). Naturally-occurring mineralization cofactors, such as inorganic phosphate (Jono et al., 2000), bone morphogenic protein (a member of the transforming growth factor (TGF) beta family) (Bostrom et al., 1993), pro-inflammatory lipids (Demer, 2002), and other substances (e.g., cytokines) may also play a role in pathologic calcification. The non-collagenous proteins osteopontin, TGF-beta1, and tenascin-C involved in bone matrix formation and tissue remodeling have been demonstrated in clinical calcified bioprosthetic heart valves, natural valves, and atherosclerosis, suggesting that they play a regulatory role in these forms of pathologic calcification in humans (Srivasta et al., 1997; Bini et al., 1999; Jian et al., 2001, 2003), but a direct relationship has not yet been demonstrated.

Mechanical factors also regulate calcification. Both intrinsic and extrinsic mineralization of a biomaterial is generally enhanced at the sites of intense mechanical deformations generated by motion, such as the points of flexion in heart valves (Thubrikar et al., 1983). The mechanisms underlying mechanical potentiation of calcification associated with biomaterials are incompletely understood, but the effect mimics the well-known Wolf's

TABLE II.4.5.3	Experimental Models of Calcification	
Type	**System**	**Typical Duration**
Calcification of bioprosthetic or other tissue heart valve	*In vitro* incubation of tissue fragment or flexing valves	Days to weeks
	Rat subdermal implant of tissue fragment	3 weeks
	Calf or sheep orthotopic valve replacement	3–5 months
	Rat or sheep descending aorta	1–5 months
Calcification of polyurethane	Rat subdermal implant of material sample	1–2 months
	Calf or sheep artificial heart implant	5 months
	Trileaflet polymeric valve implant in calf or sheep	5 months
Calcification of hydrogel	Rat subdermal implant of material sample	3 weeks
Calcification of collagen	Rat subdermal implant of material sample	3 weeks
Urinary encrustation	*In vitro* incubation	Hours to days
	In vivo bladder implants (rats and rabbits)	10 weeks

law in bone, in which formation and adaptation occurs in response to the mechanical forces that it experiences (Chen et al., 2010). Moreover, the enhancement is seen in systems where static but not dynamic mechanical strain is applied (Levy, 1983a), and in systems where live stem cells are subjected to a spectrum of mechanical environments (Yip et al., 2009).

Experimental Models for Biomaterials Calcification

Animal models have been developed for the investigation of the calcification of bioprosthetic heart valves, aortic homografts, cardiac assist devices, and trileaflet polymeric valves (Table II.4.5.3). The most widely used experimental models used to investigate the pathophysiology of bioprosthetic tissue calcification, and as a preclinical screen of new or modified materials and design configurations, include tricuspid or mitral replacements or conduit-mounted valves in sheep or calves, and isolated tissue (i.e., not in a valve) samples implanted subcutaneously in mice, rabbits or rats (Levy et al., 1983a; Schoen et al., 1985, 1986). In both circulatory and non-circulatory models, bioprosthetic tissue calcifies progressively with a morphology similar to that observed in clinical specimens, but with markedly accelerated kinetics. *In vitro* models of biomaterials calcification have been investigated, but have not been useful in studying mechanisms or preventive strategies (Schoen et al., 1992a; Mako and Vesely, 1997).

Compared with the several years normally required for calcification of clinical bioprostheses, valve replacements in sheep or calves calcify extensively in three to six months (Schoen et al., 1985, 1986, 1994). However, expense, technical complexity, and stringent housing and management procedures pose important limitations to all the circulatory models using large animals. In addition, implantation in the heart requires the use of complex surgical procedures utilizing cardiopulmonary bypass, as well as a high level of surgical expertise and postoperative care. These limitations stimulated the development of subdermal (synonym *subcutaneous* – under the skin) implant models. Subdermal bioprosthetic implants in

rats, rabbits, and mice provide the following useful features: (1) calcification occurs at a markedly accelerated rate in a morphology comparable to that seen in circulatory explants; (2) the model is economical so that many specimens can be studied with a given set of experimental conditions, thereby allowing quantitative characterization and statistical comparisons; and (3) specimens are easily and quickly retrieved from the experimental animals, facilitating the careful manipulation and rapid processing required for detailed analyses (Levy et al., 1983; Schoen et al., 1985, 1986).

Thus, the subcutaneous model is a technically convenient and economically advantageous vehicle for investigating host and implant determinants and mechanisms of mineralization, as well as for screening potential strategies for its inhibition (*anticalcification*). Promising approaches may be investigated further in a large animal valve implant model. Large animal implants as valve replacements are also used: (1) to elucidate further the processes accounting for clinical failures; (2) to evaluate the performance of design and biomaterials modifications in valve development studies; (3) to assess the importance of blood–surface interactions; and (4) to provide data required for approval by regulatory agencies (Schoen, 1992b and 1994). Polyurethane calcification has also been studied with subdermal implants in rats (Joshi et al., 1996).

Pathophysiology of Bioprosthetic Heart Valve Calcification

Data from valve explants from patients and subdermal and circulatory experiments in animal models using bioprosthetic heart valve tissue have elucidated the pathophysiology of this important clinical problem, and enhanced our understanding of pathologic calcification in general (Figure II.4.5.4). The similarities of calcification in the different experimental models and clinical bioprostheses suggest a common pathophysiology, independent of implant site. Calcification appears to depend on exposure of a susceptible substrate to extracellular fluid; mechanical factors and local implant-related or

(A)

(B)
FIGURE II.4.5.5 Extended hypothetical model for the calcification of bioprosthetic tissue. (A) Overall model, which considers host factors, implant factors, and mechanical damage, and relates initial sites of mineral nucleation to increased intracellular calcium in residual cells and cell fragments in bioprosthetic tissue. The ultimate result of calcification is valve failure, with tearing or stenosis. The key contributory role of existing phosphorus in membrane phospholipids and nucleic acids in determining the initial sites of crystal nucleation is emphasized, and a possible role for the independent mineralization of collagen is acknowledged. Mechanical deformation probably contributes to both nucleation and growth of calcific crystals. (B) Events at the cell membrane and other calcium-binding structures. There is a substantial physiologic (normal) gradient of free calcium across the cell membrane (10^{-3} M outside, 10^{-7} M inside) which is maintained as an energy-dependent process. With cell death or membrane dysfunction, calcium phosphate formation can be initiated at the membranous cellular structures. ((A) Reproduced by permission from Schoen, F. J. & Levy, R. J. (2005). Calcification of tissue heart valve substitutes: Progress toward understanding and prevention. *Ann. Thorac. Surg.*, **79**, 1072–1080. (B) Reproduced by permission from Schoen, F. J. et al. (1988). Biomaterials-associated calcification: Pathology, mechanisms, and strategies for prevention. *J. Appl. Biomater.*, **22**, 11–36.)

circulating substances may play regulatory roles. However, since the morphology and extent of calcification in subcutaneous implants is analogous to that observed in clinical and experimental circulatory implants, despite the lack of dynamic mechanical activity characteristic of the circulatory environment, it is clear that dynamic stress promotes, but is not prerequisite for, calcification of bioprosthetic tissue. Interestingly, in the subcutaneous model, calcification is enhanced in areas of tissue folds, bends, and areas of shear, suggesting that static mechanical deformation also potentiates mineralization (Levy et al., 1983a). Although these data suggest that local tissue disruption mediates the mechanical effect, the precise mechanisms by which mechanical factors influence calcification are uncertain.

Although a potential role for inflammatory and immune processes has been postulated by some investigators (Love, 1993; Human and Zilla, 2001a,b), no definite role has been demonstrated for circulating cells, and many lines of evidence suggest that neither nonspecific inflammation nor specific immunologic responses appear to favor bioprosthetic tissue calcification. Proponents of an immunological mechanism for failure cite that: (1) experimental animals can be sensitized to both fresh and cross-linked bioprosthetic valve tissues; (2) antibodies

to valve components can be detected in some patients following valve dysfunction; and (3) some failed tissue valves have brisk mononuclear inflammation, no causal immunologic basis has been demonstrated for bioprosthetic valve calcification. However, calcification in either circulatory or subcutaneous locations is not usually associated with inflammation. Moreover, in experiments in which valve cusps were enclosed in filter chambers that prevent host cell contact with tissue, but allow free diffusion of extracellular fluid and implantation of valve tissue in congenitally athymic ("nude") mice who have essentially no T-cell function, calcification morphology and extent are unchanged (Levy et al., 1983a,b). Clinical and experimental data detecting antibodies to valve tissue after failure may reflect a secondary response to valve damage, rather than a cause of failure.

Glutaraldehyde pretreatment of tissues or severe anoxia/hypoxia/ischemia leading to cell death in natural tissues or tissue-based biomaterials engenders cell injury. Consistent with a dystrophic mechanism, the initial calcification sites in bioprosthetic tissue are predominantly dead cells and cell membrane fragments (Levy et al., 1983a; Schoen et al., 1985, 1986; Schoen and Levy, 1999) (see Figure II.4.5.4). In non-functional cells or cells which have been rendered non-viable by

glutaraldehyde fixation, the normal cellular handling of calcium ions is disrupted. Normally, plasma calcium concentration is 1 mg/ml (approximately 10^{-3} M); since the membranes of healthy cells pump calcium out, the concentration of calcium in the cytoplasm is 1000–10,000 times lower (approximately 10^{-7} M). The cell membranes and other intercellular structures are high in phosphorus (as phospholipids, especially phosphatidyl serine, which can bind calcium); they can serve as nucleators. Mitochondria are also enriched in calcium. Other initiators under various circumstances include collagen and elastic fibers of the extracellular matrix, denatured proteins, phosphoproteins, fatty acids, blood platelets and, in the case of infection, bacteria. We have previously hypothesized that cells calcify after glutaraldehyde pretreatment because this cross-linking agent stabilizes all the phosphorous stores, but the normal mechanisms for elimination of calcium from the cells are not available in glutaraldehyde-pretreated tissue (Schoen et al., 1986). Initial calcification deposits eventually enlarge and coalesce, resulting in grossly mineralized nodules that cause prostheses to malfunction.

Calcification of the adjacent aortic wall portion of glutaraldehyde-pretreated porcine aortic valves, and valvular allografts and vascular segments, is also observed clinically and experimentally. Mineral deposition occurs throughout the vascular cross-section, but is accentuated in the dense bands at the inner and outer media, and cells and elastin (itself not a prominent site of mineralization in cusps) are the major sites. In non-stented porcine aortic valves which have greater portions of aortic wall exposed to blood than in currently used stented valves, calcification of the aortic wall could stiffen the root, altering hemodynamic efficiency, causing nodular calcific obstruction, potentiating wall rupture or providing a nidus for emboli. Some anticalcification agents (see later), including 2-amino-oleic acid (AOA) and ethanol, prevent experimental cuspal but not aortic wall calcification (Chen et al., 1994a,b).

Calcification of Collagen and Elastin

Calcification of the extracellular matrix structural proteins collagen and elastin has been observed in clinical and experimental implants of bioprosthetic and homograft valvular and vascular tissue, and has been studied using a rat subdermal model. Collagen-containing implants are widely used in various surgical applications, such as tendon prostheses and surgical absorptive sponges, but their usefulness is compromised owing to calcium phosphate deposits and the resultant stiffening. Cross-linking by either glutaraldehyde or formaldehyde promotes the calcification of collagen sponge implants made of purified collagen, but the extent of calcification does not correlate with the degree of cross-linking (Levy et al., 1986). Elastin calcification has also been studied (Vyavahare et al., 1999; Lee et al., 2006).

PREVENTION OF CALCIFICATION

Three strategies have been investigated for preventing calcification of biomaterial implants: (1) systemic therapy with anticalcification agents; (2) local therapy with implantable drug delivery devices; and (3) biomaterial modifications, whether by removal of a calcifiable component, addition of an exogenous agent or chemical alteration. The subcutaneous model has been widely used to screen potential strategies for calcification inhibition (*anticalcification* or *antimineralization*). Promising approaches have been investigated further in a large animal valve implant model. However, strategies that appeared efficacious in subcutaneous implants have not always proven favorable when used on valves implanted into the circulation (see below).

Analogous to any new or modified drug or device, a potential antimineralization treatment must be effective and safe. The treatment should not impede valve performance such as hemodynamics. Investigations of an anticalcification strategy must demonstrate not only the effectiveness of the therapy, but also the absence of adverse effects (Schoen et al., 1992b). Adverse effects in this setting could include systemic or local toxicity, tendency toward thrombosis on infection, and induction of immunological effects or structural degradation, with either immediate loss of mechanical properties or premature deterioration and failure. Indeed, there are several examples whereby an antimineralization treatment contributed to unacceptable degradation of the tissue (Jones et al., 1989; Gott et al., 1992; Schoen, 1998). The treatment should not impede normal valve performance, such as hemodynamics and durability. As summarized in more detail in Table II.4.5.4, a rational approach for preventing bioprosthetic calcification must integrate safety and efficacy considerations with the scientific basis for

TABLE II.4.5.4	Criteria for Efficacy and Safety of Antimineralization Treatments
Efficacy	
• Effective and sustained calcification inhibition	
Safety	
• Adequate valve performance (i.e., unimpaired hemodynamics and durability)	
• Does not cause adverse blood–surface interactions (e.g., hemolysis, platelet adhesion, coagulation protein activation, complement activation, inflammatory cell activation, binding of vital serum factors)	
• Does not enhance local or systemic inflammation (e.g., foreign body reaction, immunologic reactivity, hypersensitivity)	
• Does not cause local or systemic toxicity	
• Does not potentiate inflection	

(Modified from Schoen F.J. et al. (1992). Antimineralization treatments for bioprosthetic heart valves. Assessment of efficacy and safety. *J. Thorac. Cardiovasc. Surg.*, **104**,1285–1288.)

TABLE II.4.5.5	Preclinical Efficacy and Safety Testing of Antimineralization Treatments
Type of Study	**Information Derived**
Subcutaneous implantation in rats	• Initial efficacy screen • Mechanisms • Dose–response • Toxicity
Biomechanical evaluation	• Hemodynamics • Accelerated wear
Morphologic studies of unimplanted valves	• Structural degradation assessed by light and transmission electron microscopy • Scanning electron microscopy
Circulatory implants in large animals	• Device configuration, surgical technique, *in vivo* hemodynamics, explant valve pathology • Durability, thrombi, thromboembolism, hemolysis, cardiac and systemic pathology

TABLE II.4.5.6	Prototypical Agents for Mechanism-Based Prevention of Calcification in Bioprosthetic Heart Valves
Mechanisms	**Strategy/Agent**
Inhibition of hydroxyapatite formation	Ethane hydroxybisphosphonate (EHBP)
Inhibition of calcium uptake	2-Alpha-amino-oleic acid (AOA™)
Inhibition of Ca-P crystal growth; inhibition of alkaline phosphate; chemical modification of elastin	Ferric/aluminum chloride exposure
Phospholipid extraction	Sodium dodecyl sulfate (SDS)
Phospholipid extraction and collagen conformation modification	Ethanol exposure
Eliminate glutaraldehyde potentiation of calcification: • amino acid neutralization of glutaraldehyde residues • polyepoxide (polyglycidal ether), acyl azide, carbodiimide, cyanimide and glycerol cross-linking • dye-mediated photooxidation	Modification of (alternatives to) glutaraldehyde fixation

AOA™ (2-α-amino-oleic acid) is a trademark of Biomedical Designs, Inc., of Atlanta, GA, USA.

inhibition of calcium phosphate crystal formation. This will of necessity involve the steps summarized in Table II.4.5.5, before appropriate clinical trials can be undertaken (Schoen et al., 1992b; Vyavahare et al., 1997a).

Experimental studies using bioprosthetic tissue implanted subcutaneously in rats have clearly demonstrated that adequate doses of systemic agents used to treat clinical metabolic bone disease can prevent its calcification (Levy et al., 1987). However, systemic therapy with anticalcification agents may be efficacious, but is unlikely to be safe. Sufficient doses of systemic agents used to treat clinical metabolic bone disease, including calcium chelators (e.g., diphosphonates such as ethane hydroxybisphosphonate (EHBP)), can prevent the calcification of bioprosthetic tissue implanted subcutaneously in rats. However, because they also interfere with physiologic calcification (i.e., bone growth), systemic drug administration is associated with many side-effects in calcium metabolism, and animals receiving doses sufficient to prevent bioprosthetic tissue calcification suffer growth retardation. Thus, the principal disadvantage of the systemic use of anticalcification agents for preventing pathologic calcification is the consequent inhibition of bone formation and body growth. To avoid this difficulty, approaches for preventing the calcification of bioprosthetic heart valves have been based on co-implants of a drug delivery system adjacent to the prosthesis, in which the effective drug concentration would be confined to the site where it is needed (i.e., the implant), and systemic side-effects would be prevented (Levy et al., 1985b). A localized anticalcification effect would be particularly attractive in young people. Studies incorporating EHBP in nondegradable polymers, such as ethylene-vinyl acetate (EVA), polydimethylsiloxane (silicone), silastic, and polyurethanes have shown the effectiveness of this strategy in animal models. This approach, however, has been difficult to implement clinically.

The approach which is most likely to yield an improved clinical valve in the short-term involves modification of the substrate, either by removing or altering a calcifiable component or binding an inhibitor. Forefront strategies should also consider: (1) a possible synergism provided by multiple anticalcification agents and approaches used simultaneously; (2) new materials; and (3) the possibility of tissue-engineered heart valve replacements. The agents most widely studied, for efficacy, mechanisms, lack of adverse effects, and potential clinical utility are summarized below and in Table II.4.5.6. Combination therapies using multiple agents may provide synergy of beneficial effects (Levy et al., 2003), potentially permitting simultaneous prevention of calcification in both cusps and aortic wall, particularly beneficial in stentless aortic valves.

Inhibitors of Hydroxyapatite Formation

Bisphosphonates. Ethane hydroxybisphosphonate (EHBP) has been approved by the FDA for human use to inhibit pathologic calcification, and to treat hypercalcemia of malignancy. Compounds of this type probably inhibit calcification by poisoning the growth of calcific crystals. Either cuspal pretreatment or systemic or local therapy of the host with diphosphonate compounds inhibits experimental bioprosthetic valve calcification (Levy et al., 1985, 1987; Johnston et al., 1993). Recently,

controlled clinical trials which have orally administered bisphosphonates have demonstrated the ability to stabilize osteoporosis. These agents, such as Alendronate (Phosphomax®, Merck, Inc.) are hypothesized to act by stabilizing bone mineral.

Trivalent Metal Ions. Pretreatment of bioprosthetic tissue with iron and aluminum (e.g., $FeCl_3$ and $AlCl_3$) inhibits calcification of subdermal implants with glutaraldehyde-pretreated porcine cusps or pericardium (Webb et al., 1991; Carpentier et al., 1997). Such compounds are hypothesized to act through complexation of the cation (Fe or Al) with phosphate, thereby preventing calcium phosphate formation. Both ferric ion and the trivalent aluminum ion inhibit alkaline phosphatase, an important enzyme used in bone formation. This may be related to their mechanism for preventing initiation of calcification. Furthermore, research from our laboratories has demonstrated that aluminum chloride prevents elastin calcification through a permanent structural alteration of the elastin molecule. These compounds are also active when released from polymeric controlled-release implants.

Calcium Diffusion Inhibitor

Amino-oleic Acid. 2-alpha-amino-oleic acid (AOA™, Biomedical Designs, Inc., Atlanta, GA) bonds covalently to bioprosthetic tissue through an amino linkage to residual aldehyde functions, and inhibits calcium flux through bioprosthetic cusps (Chen et al., 1991, 1994a). AOA™ is effective in mitigating cusp, but not aortic wall, calcification in rat subdermal and cardiovascular implants. This compound is used in FDA-approved porcine aortic valves (Fyfe and Schoen, 1999; Celiento et al., 2012; El-Hamamsy et al., 2011).

Removal/Modification of Calcifiable Material

Surfactants. Incubation of bioprosthetic tissue with sodium dodecyl sulfate (SDS) and other detergents extracts the majority of acidic phospholipids (Hirsch et al., 1993); this is associated with reduced mineralization, probably resulting from suppression of the initial cell-membrane oriented calcification (Figure II.4.5.6). This compound is used in an FDA-approved porcine valve (David et al., 1998; Bottio et al., 2003).

Ethanol. Ethanol preincubation of glutaraldehyde-cross-linked porcine aortic valve bioprostheses prevents calcification of the valve cusps in both rat subdermal implants, and sheep mitral valve replacements (Vyavahare et al., 1997b, 1998). Eighty percent ethanol pretreatment: (1) extracts almost all phospholipids and cholesterol from glutaraldehyde-cross-linked cusps; (2) causes a permanent alteration in collagen conformation as assessed by Attenuated Total Reflectance-Fourier Transform Infrared Spectroscopy (ATR-FTIR); (3) affects cuspal interactions
FIGURE II.4.5.6 Reduction of calcification of bioprosthetic tissue by preincubation in 1% SDS demonstrated in a rat subcutaneous model of glutaraldehyde cross-linked porcine aortic valve. These results support the concept that phospholipid extraction is an important but perhaps not the only mechanism of SDS efficacy. (Reproduced by permission from Schoen, F. J., Levy, R. J. & Piehler, H. R. (1992). Pathological considerations in replacement cardiac valves. *Cardiovasc. Pathol.*, **1**, 29–52.)

with water and lipids; and (4) enhances cuspal resistance to collagenase. Ethanol is in clinical use as a porcine valve cuspal pretreatment in both Europe and the United States, and use in combination with aluminum treatment of the aortic wall of a stentless valve is under consideration.

Decellularization. Since the initial mineralization sites are devitalized connective cells of bioprosthetic tissue, these cells may be removed from the tissue, with the intent of making the bioprosthetic matrix less prone to calcification (Courtman et al., 1994; Wilson et al., 1995).

Use of Tissue Fixatives Other than Glutaraldehyde, and Modification of Glutaraldehyde Fixation

Since previous studies have demonstrated that conventional glutaraldehyde fixation is conducive to calcification of bioprosthetic tissue, several studies have investigated modifications of, and alternatives to, conventional glutaraldehyde pretreatment. For example, and paradoxically, fixation of bioprosthetic tissue by extraordinarily high concentrations of glutaraldehyde (5–10× those normally used) appear to inhibit calcification (Zilla et al., 1997, 2000); moreover, residual glutaraldehyde residues in bioprosthetic tissue can be neutralized ("detoxified") by treatment with lysine or diamine, this inhibits calcification of subdermal implants (Grabenwoger et al., 1992; Zilla et al., 2000, 2005; Trantina-Yates et al., 2003).

Nevertheless, there is presently no mechanistic explanation for these glutaraldehyde-related observations. Non-glutaraldehyde cross-linking of bioprosthetic tissue with epoxides, carbodiimides, acylazides, and other compounds reduces their calcification in rat subdermal implant studies (Xi et al., 1992; Myers et al., 1995), and with triglycidylamine (TGA), an epoxy cross-linker

(Connolly et al., 2011) and photooxidative preservative in large animal implants in sheep (Moore and Phillips, 1997).

Alternative Materials

Polyurethane trileaflet valves have been fabricated and investigated as a possible alternative to bioprostheses or mechanical valve prostheses (Ghanbari et al., 2009). Despite versatile properties, such as superior abrasion resistance, hydrolytic stability, high flexural endurance, excellent physical strength, and acceptable blood compatibility, the use of polymers has been hampered by calcification, thrombosis, tearing, and biodegradation. Although the exact mechanism of polyurethane calcification is as yet unclear, it is believed that several physical, chemical, and biologic factors (directly or indirectly) play an important role in initiating this pathologic disease process (Schoen et al., 1992c; Joshi et al., 1996; Hyde et al., 1999).

CONCLUSIONS

Calcification of biomaterial implants is an important pathologic process affecting a variety of tissue-derived biomaterials, as well as synthetic polymers in various functional configurations. The pathophysiology has been partially characterized with a number of useful animal models; a key common feature is the involvement of devitalized cells and cellular debris. Clinically useful preventive approaches based on either modifying biomaterials or local drug administration appear to be promising in some contexts.

CHAPTER II.5.1 INTRODUCTION: APPLICATIONS OF BIOMATERIALS

Frederick J. Schoen[1] and Jack E. Lemons[2]
[1]Professor of Pathology and Health Sciences and Technology (HST), Harvard Medical School, Executive Vice Chairman, Department of Pathology, Brigham and Women's Hospital, Boston, MA, USA

[2]University Professor, Schools of Dentistry, Medicine and Engineering, University of Alabama at Birmingham, Birmingham, AL, USA

Most students of biomaterials have a strong interest in medical or dental applications. Biomaterials are used for the construction of components in an extensive array of devices across a wide range of medical disciplines. When considering the applications of biomaterials as a section focus, a primary consideration is on outcomes of treatments. Outcomes are evaluated in terms of the discipline and the specific biomaterial properties needed for a highly specific application to improve outcomes of patients with specific clinical problems. For example, a total joint replacement has very different considerations than a tooth root replacement, although both anchor in bone for function. Similarly, requirements for a heart valve are very different compared to a vessel replacement or an endovascular stent, although all have extensive blood contact and some biomaterial properties are in common.

The following chapters in Part II present a broad spectrum of biomaterials applications and the key properties needed for specific physiological environments. The Cardiovascular section starts with Nonthrombogenic Biomaterials (II.5.2) by Sefton and Cardiovascular Medical Devices (II.5.3). Subsections A–D describe Valves (II.5.3A), Endovascular Stents, Vascular grafts, and Stent Grafts (II.5.3B), Other Cardiovascular Devices (II.5.3C), all by Schoen and Padera, and Implantable Cardiac Assist Devices and IABPs (II.5.3D) by Simon, Borovetz and Wagner. The emphasis shifts to artificial cells (II.5.4) by Chang, and Extracorporeal Artificial Organs (II.5.5) by Ritchie. Two chapters with musculoskeletal emphasis are Orthopedic and Dental Applications (II.5.6 and II.5.7) by Hallab and Jacobs, and Lemons and Misch, respectively. Adhesives and Sealants (II.5.8) are presented by Watts. Ophthalmologic Applications (II.5.9) and subdivisions on contact lenses (II.5.9A), IOLs (II.5.9B), Corneal Inlays (II.5.9C), Glaucoma Drains (II.5.9D), and

Retinal Prostheses (II.5.9E) are presented by Steinert and Jain; Jacob; Patel; Cunanan; Cunanan; and Humayun et al. respectively. Chapters follow on Bioelectrodes (II.5.10), Cochlear Prostheses (II.5.11) and Stimulating Electrodes (II.5.12) implants, Biosensors (II.5.13), Burn Dressings and Skin Substitutes (II.5.14), and Sutures (II.5.15) by Venugopalan and Ideker; Spelman; Peckhan, Ackermann, and Moss; LaFleur and Yager; Helm, Orgill B., Ogawa and Orgill D.; and Taylor and Shalaby, respectively. Chapters on applications are extended in the next series on Drug Delivery Systems (II.5.16), with subsections on Injected Nanocarriers PEGylation, Targeting, Polymer–Drug Conjugates, Liposomes, Polymeric Micelles, Dendrimers, Nucleic Acid Delivery, and Polymeric and Albuminated Drug Nanoparticles, collectively by Hoffman, and Gombotz; Pun; Stayton, Ghosn, and Wilson J. The drug delivery systems (DDS) chapters continue with Injected Degradable Depot DDS (II.5.16C), Implants and Inserts (II.5.16D), Smart DDS (II.5.16E), Transdermal DDS (II.5.16F), and Oral DDS (II.5.16G) by Gombotz; Wright and Kleiner; Hoffman; Cleary; and Wilson C., respectively. This section closes with chapters on Diagnostic Applications (II.5.17) by Domingo, Hawkins, Peck, and Weigl, and Silicones (II.5.18) by Curtis and Colas.

A central theme is the generation and use of design criteria based on desired functionality, potentially deleterious biomaterials–tissue interaction mechanisms, pathologies of the underlying conditions for which the implant is needed, and the basic properties of the various biomaterials available or needing to be developed. It should not be surprising that considerable research and development has led to clinically used devices with active mechanical, electrical, biologic or mass exchange functions.

Biomaterials applications and surgical implant technology assume a key role in current clinical practice. In 2000, it was estimated that approximately 20 million individuals had an implanted medical device. The number is growing, but is difficult to assess precisely. A recent article in *The Wall Street Journal* (July 18, 2011) summarized the five most frequently implanted medical devices in the US: artificial eye lenses (>2.5 million per year); tympanostomy ear tubes (>0.75 million per year); coronary arterial stents (>0.5 million per year); prosthetic knee joints (>0.5 million per year); and metal screws, pins, plates,

and rods (>450,000 per year). The economic impact is massive; in 2000 costs associated with prostheses and organ replacement therapies exceeded $300 billion US per year, and comprised >1% of the US gross domestic product (GDP) and nearly 8% of total healthcare spending worldwide (Lysaght and O'Loughlin, 2000). Thus, medical devices contribute to the expense associated with modern healthcare in the United States, which is presently in excess of 17% of GDP, continues to grow, and has become a significant public policy issue. For the widely used artificial eye lenses, at 2.5 million surgeries performed annually at a rate of about $3200 to $4500 per eye, the total expenditure is estimated at between $8 billion and $10 billion per year. The use of health technology assessment tools can assist those in leadership positions in making rational decisions as to which new technologies to adopt, based on evaluation of clinical effectiveness, cost-effectiveness, and risk to patients.

Most implants serve their recipients well for extended periods by alleviating the conditions for which they were implanted. Considerable effort is expended in understanding biomaterials–tissue interactions and eliminating patient–device complications (the clinically important manifestations of biomaterials–tissue interactions). Moreover, many patients receive substantial and extended benefit, despite complications. For example, heart valve disease is a serious medical problem affecting over 30,000 people per year in the United States. Patients with aortic stenosis (the most common form of heart valve disease) have a 50% chance of dying within approximately three years without surgery. Surgical replacement of a diseased valve leads to an expected survival of 70% at 10 years, a substantial improvement over the natural course. However, of these patients whose longevity and quality of life have clearly been enhanced, approximately 60% will suffer a serious valve-related complication within 10 years after the operation. Thus, long-term failure of biomaterials leading to a clinically significant event does not preclude clinical success, for a significant duration and overall.

The range of tolerable risk of adverse effects varies directly with the medical benefit obtained by the therapy. Benefit and risk go hand-in-hand, and clinical decisions are made to maximize the ratio of benefit to risk. The tolerable benefit–risk ratio may depend on the type of implant and the medical problem it is used to correct. Thus, more risk can be tolerated with a heart assist device (a life-sustaining implant) than with a prosthetic hip joint (an implant that relieves pain and disability and enhances function), and much more risk than with a breast implant (an implant with predominantly cosmetic benefit). As an example, total hip arthroplasties (THAs) with metal-on-metal (MoM) or more correctly cobalt alloy-on-cobalt alloy articulating surfaces, have been used clinically since the 1950s. Applications of recent generation THAs exceed hundreds of thousands. Very recently, metallic debris products in larger quantities have been associated with adverse foreign-body reactions, need for revisions, and a recall action of one design/product; for updated information on this topic, students are referred to the US Food and Drug Administration (FDA) web site (http://www.fda.gov/MedicalDevices/ProductsandMedical-Procedures/ImplantsandProsthetics/MetalonMetalHipImplants/default.htm), the American Academy of Orthopaedic Surgeons website (AAOS.org) and/or the American Society for Testing and Materials website (ASTM.org). An ASTM symposium Standard Technical Publication (STP) on this topic should be available in late 2012.

In summary, this section explores the most widely used applications of materials in medicine, biology, and artificial organs. The progress made in many of these areas has been substantial. In most cases, the individual chapters describe a device category from the perspective of the clinical need, the armamentarium of devices available to the practitioner, the results and complications, and the challenges to the field that limit success.

CHAPTER II.5.2 NONTHROMBOGENIC MATERIALS AND STRATEGIES: CASE STUDY

Michael V. Sefton[1], Cynthia H. Gemmell[1], and Maud B. Gorbet[2]

[1]Department of Chemical Engineering and Applied Chemistry, Institute of Biomaterials and Biomedical Engineering, University of Toronto, Canada

[2]Department of Systems Design Engineering, University of Waterloo, Canada

ISO Standard 10993-4, *Biological Evaluation of Medical Devices Part 4: The Effects on Blood* (ISO/ AAMI 1995), which manufacturers of medical devices need to use as guidance to register their products, includes thrombosis and coagulation among the tests that need to be done. However, specific test methods are not detailed. With a view to clarifying this question, a series of plasma-modified tubes (along with an unmodified control and other commercially available tubing) were prepared, surface characterized, and exposed to heparinized whole blood (1 U/mL heparin) for one hour at 37°C (Sefton et al., 2001). The surface modifications included several different plasma vapors (H_2O, CF_4, and fluorine). The 1.5 mm

ID (internal diameter) tubing was incubated with whole blood on a rocking platform to gently agitate the blood and keep the cells from overtly settling. This system does not probe the effect of shear on cell activation; rather the agitation and long incubation time are thought sufficient to create "well-mixed" conditions.

Some of the results from this study are shown in Figure II.5.2.1 and Table II.5.2.1. One of the conclusions from this study is that the materials with the lowest levels of platelet and leukocyte activation (microparticle formation, CD11b upregulation) were the unmodified materials (polyethylene, Pellethane™, a polyurethane), and

that the surface modifications tested here had either no effect or only made things worse from the perspective of platelet and leukocyte activation. The scanning electron micrographs showing little cellular deposit on the polyethylene or Pellethane™ were consistent with the flow cytometry findings. Except for those materials that were worse, the other materials expressed similar levels of activation for platelets, leukocytes, and the other markers tested; i.e., the majority of the "inert" materials (in the absence of bioactive components like heparin) appear to have a similar non-specific effect on blood.

FIGURE II.5.2.1 Cell activation results after 60 min contact with whole blood (1 unit/mL heparin) at 37°C. Flow cytometry results are mean ±SD. (a) Platelet microparticle levels (percentage of platelet events); (b) Leukocyte CD11b up-regulation (expressed relative to the maximum upregulation obtained with a phorbol ester). (c) Scanning Electron Micrographs of biomaterial surfaces following exposure to blood. Scale bar is 10 μm. PE: Polyethylene; Pell: Pellethane.

TABLE II.5.2.1	Most Biomaterials are the Same	
Parameter	**EDTA* Control (or Equivalent)**	**Value for Most Materials**
Platelet count loss (%)	0 (by definition)	25–35
P-selectin (% positive)	6.4	~8–9
Platelet–leukocyte aggregates (fluorescent intensity)	46	~200–250
CD11b upregulation (% of maximum)	15	~50–60
L-selectin shedding	11	~70–90

Most materials, despite very different non-specific chemical modifications, resulted in similar levels of platelet and leukocyte activation. These were higher than the corresponding negative control values. The similarity of CD11b upregulation values is seen in Figure II.5.2.1b, while the presence of exceptions that were more activating is seen in the microparticle results in Figure II.5.2.1a.

*Ethylenediaminetetraacetic acid.

The results from this study contrast sharply with other studies (many of them cited in this chapter) showing large differences in blood interactions between different biomaterials. This highlights the lack of consensus about blood–materials interactions. Reasons for this lack of consensus are discussed in Chapter II.3.5.

CHAPTER II.5.3 INTRODUCTION TO CARDIOVASCULAR MEDICAL DEVICES

Frederick J. Schoen
Professor of Pathology and Health Sciences and Technology (HST), Harvard Medical School, Executive Vice Chairman, Department of Pathology, Brigham and Women's Hospital, Boston, MA, USA

The past several decades have witnessed a virtual explosion in the number and scope of innovative surgical and interventional diagnostic and therapeutic procedures performed on patients with cardiovascular diseases. Data from the National Center for Health Statistics and the American Heart Association indicate that approximately seven million major cardiac and vascular operations are done annually in the United States. Concurrent with and integral to the broad application of these surgical and interventional procedures is the use of various prostheses and medical devices. Data from 2006 (reported in 2009) show 641,000 percutaneous coronary interventions (almost all using endovascular bare-metal and drug-eluting stents), 253,000 coronary artery bypass graft procedures, 104,000 cardiac valve procedures (using approximately 85,000 substitute heart valves, pacemakers (418,000), implanted cardioverter-defibrillators (114,000) and their leads, and many cardiac assist devices, vascular grafts, umbrellas, patches, and others (Lloyd-Jones et al., 2009).

Thus, cardiovascular prostheses and medical devices, and their constituent biomaterials, are of critical importance to interventional cardiologists, and cardiac and vascular surgeons. The number and complexity of devices permit choices among surgical or catheter-based interventional options that optimize short- and long-term patient management. The recognition and understanding of complications of these devices, many of them related to the biomaterials that comprise them, has led to iterative efforts to improve their performance and safety through biomaterials and device research and development that has led to improvements which have been translated into improved patient care. The nature, frequency, and pathologic anatomy of their complications, as well as the responsible blood–tissue–biomaterials interaction mechanisms have been published for widely used devices used for many years, but are less well-appreciated for recently introduced or modified devices, and those currently in development (Schoen, 2001; Schoen and Edwards, 2001).

This section, composed of 4 sub-chapters, summarizes key considerations in cardiovascular medical devices, including the underlying pathology of the conditions they are designed and used to treat, relevant biomaterials research, and the most important complications that need to be circumvented. The first chapter (II.5.3.A) summarizes cardiac valve prostheses, which have been used extensively and for approximately a half century, are clinically important; their outcomes and pathological descriptions of complications encountered with many different types of valve prostheses are well-known. The second chapter (II.5.3.B) discusses devices used for vascular repair and replacement (including vascular grafts and endovascular stents [and stent grafts]). The third chapter (II.5.3.C) discusses pacemakers and implantable cardioverter-defibrillators, cardiac assist and replacement devices and miscellaneous cardiovascular devices, including percutaneous catheter-based techniques to treat cardiovascular disease in a minimally invasive manner, such as septal defect closure devices, filters to prevent pulmonary embolism and left atrial occlusion devices, and devices to minimize the consequences of a dilated, failing heart. Finally, in the fourth chapter (II.5.3.D), specific biomaterials and engineering design issues related to implantable cardiac assist devices and artificial hearts, a complex and evolving set of technologies, are discussed.

A. SUBSTITUTE HEART VALVES

Frederick J. Schoen and Robert F. Padera, Jr
Department of Pathology, Brigham and Women's Hospital and Harvard Medical School, Boston, MA, USA

INTRODUCTION

Used extensively for approximately half a century, cardiac valve prostheses are a clinically important achievement of biomaterials science and biomedical engineering. Indeed, the prestigious 2007 Lasker Award for Clinical Medical Research was granted to Drs. Albert Starr and Alain Carpentier to recognize the importance of cardiac valve replacement as a major clinical success (Chaikof, 2007; Lifton, 2007). Starr performed the first successful valve replacement in the heart by implanting a caged-ball mechanical valve prosthesis in the mitral position (Starr, 2007); the history of cardiac valve replacement is discussed in more detail in Chapter III.2.9 of this book. Carpentier fabricated a "bioprosthesis," combining chemically-treated biologic tissue and a mechanical structure to create a tissue-based (although non-living) heart valve replacement (Carpentier, 2007). Relevant outcome data and pathological descriptions of complications of many different types of valve prostheses are well-known (Vongpatanasin et al., 1996; Schoen, 2001; Bonow et al., 2006).

In this chapter we review the past history, present status, and future directions of cardiac valve replacement, focusing on biomaterials challenges and opportunities in substitute heart valves, a widely used medical device.

> Used extensively for approximately half a century, cardiac valve prostheses are a clinically important achievement of biomaterials science and biomedical engineering.

HEART VALVE FUNCTION AND DYSFUNCTION

The four valves play a critical role in ensuring unidirectional forward blood flow through the heart. The tricuspid valve allows one-way flow from the right atrium to the right ventricle, and correspondingly, the pulmonary valve from the right ventricle to the pulmonary artery, the mitral valve from the left atrium to the left ventricle, and the aortic valve from the left ventricle to the aorta. The heart valves open and close with each cardiac cycle, approximately once per second, which equates to approximately 40 million times per year and 3 billion times in a 75-year lifetime. Detailed insights about the biomechanical function of the natural heart valves have recently emerged (Sacks and Yoganathan, 2007; Sacks et al., 2009).

Disorders of heart valves can cause stenosis (i.e., obstruction to flow) or regurgitation (i.e., reverse flow across the valve) (Sharma et al., 2008; Schoen and Mitchell, 2010). Sometimes, both stenosis and regurgitation are present in the same valve. Some disease processes such as infective endocarditis (infection of a heart valve) can cause rapid (in days) destruction of the affected valve, and can lead to abrupt heart failure and death, while others such as calcific aortic stenosis can take many decades to develop clinical manifestations. Progress has been made in recent years toward elucidating a conceptual framework that integrates the dynamic functional structure of heart valves from macro- to micro- to ultra-structure, the biomechanical properties, and the pathobiological behavior of the cardiac valves (Schoen, 2008, 2012).

There are several major forms of valvular heart disease (Figure A.1); most involve the aortic and/or the mitral valve. The most common type of valve disease and most frequent indication for valve replacement overall is calcific aortic stenosis – obstruction at the aortic valve secondary to age-related calcification of the cusps of a valve that was previously anatomically normal (Figure A.1A) (Carabello and Paulus, 2009). Although the precise mechanisms are not yet completely understood, calcific aortic stenosis occurs owing to formation of calcific nodules in the valve cusps, which does not allow them to fully open. This causes pressure overload of the left ventricle that induces hypertrophy (enlargement of the mass) of the walls of this chamber (Rajamannan et al., 2011). This condition takes decades to develop, and typically produces symptoms in approximately the 7th–8th decades of life. Although the normal aortic valve has three cusps, 1–2% of all individuals are born with a bicuspid aortic valve (i.e., with only two cusps), a condition called congenital bicuspid aortic valve. A congenitally bicuspid valve generally works well initially and into adulthood, but persons who have this condition develop valve dysfunction
FIGURE A.1 Types of heart valve disease. (A) Severe degenerative calcification of a previously anatomically normal tricuspid aortic valve, the predominant cause of aortic stenosis, and the leading form of valvular heart disease. (B) Chronic rheumatic heart disease, manifest as mitral stenosis, viewed from the left atrium. (C) Myxomatous degeneration of the mitral valve, demonstrating hooding with prolapse of the posterior mitral leaflet into the left atrium (arrow). ((A), (B): Reproduced by permission from Schoen, F. J. & Edwards, W. D. (2001). Valvular heart disease: General priciples and stenosis. In: Cardiovascular Pathology, 3rd edn, Silver, M. D., Gotlieb, A. I. & Schoen, F. J. (eds.). Saunders: Philadelphia.)

and thereby symptoms at younger ages – approximately 10 years earlier than in a patient having a valve with three cusps. Aortic regurgitation (also known as insufficiency) is a less frequent (but nevertheless important) problem, most often caused by dilation of the aortic root. This prevents complete and effective closure of the cusps, allowing backflow across the valve and leading to volume overload of the left ventricle (Goldbarg, 2008). Mitral stenosis (Figure A.1B) has a single predominant cause – chronic rheumatic heart disease – which leads to scarring and stiffening of the mitral leaflets. This condition usually occurs many years following an episode of acute rheumatic fever secondary to streptococcal pharyngitis (a common form of childhood throat infection) (Chandrashekhar et al., 2009). However, mitral regurgitation results from many different conditions; the most frequent is myxomatous valve degeneration (also known as floppy mitral valve), in which the strength of the mitral valve tissue is deficient, thereby causing the valve leaflets to deform excessively (Carabello, 2008) (Figure A.1C). Conditions in which the left ventricle is abnormally dilated and/or scarred, and consequently the valve is not supported properly and infective endocarditis (i.e., infection of the valve) are among the other major causes. Diseases of the right-sided valves (tricuspid

and pulmonic) are much less common than those of the left-sided valves. However, in children with congenital heart disease, there is a need for valves in the pulmonary position (in addition to left-sided valves); replacement of valves in congenital anomalies accounts for approximately 5% of valve replacements (Barnett and Ad, 2009). The major clinical complication of valvular heart disease is cardiac failure secondary to changes in the myocardium induced by pressure or volume overload of the chambers, either upstream or downstream of the diseased valve.

HEART VALVE REPLACEMENT AND REPAIR

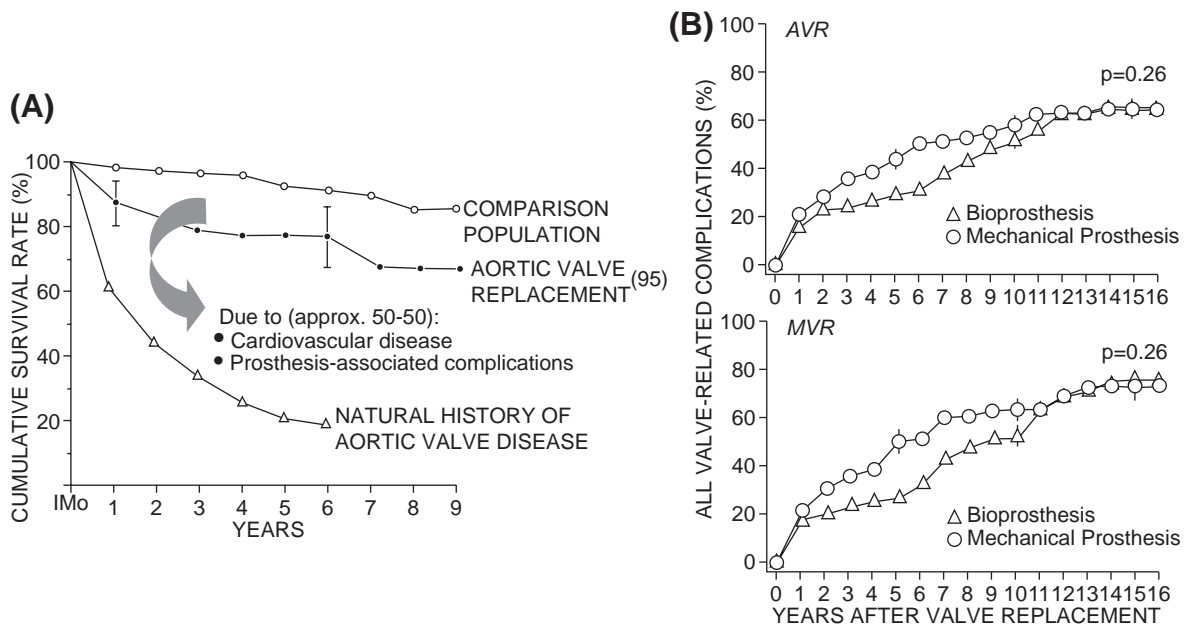
Heart valve disease is common and serious, and individuals with its various forms have significant mortality and morbidity. For example, the mortality of non-surgically treated critical aortic stenosis, the most deleterious functional abnormality, is approximately 50% at 2–3 years following the onset of symptoms; this natural history is more severe than that of many cancers. Each year in the United States, 20,000 individuals die directly of valvular heart disase; aortic valve disease accounts for approximately 60% of these (Barnett and Ad, 2009). Valve replacement is a highly beneficial


FIGURE A.2 Outcome following cardiac valve replacement. (A) Survival curves for patients with untreated aortic valve stenosis (natural history of valve disease) and aortic valve stenosis corrected by valve replacement, as compared with an age-matched control population without a history of aortic valve stenosis. The numbers presented in this figure for survival following valve replacement nearly four decades ago remain accurate today. This reflects the fact that improvements in valve substitutes and patient management have been balanced by a progressive trend toward operations on older and sicker patients with associated medical illnesses. (Reproduced by permission from Roberts, L. et al. (1976). Long-term survival following aortic valve replacement. Am. Heart J. 91: 311–317.) (B) Frequency of valve related complications for mechanical and tissue valves following mitral valve replacement (MVR) and aortic valve replacement (AVR). (Reproduced by permission from Hammermeister, K. et al. (2000). Outcomes 15 years after valve replacement with a mechanical versus a bioprosthetic valve: Final report of the Veterans Affairs Randomized Trial. J. Am. Coll. Cardiol. 36: 1152–1158.)

therapy for such patients; survival following valve replacement is 50–70%, and serious complication-free survival is approximately 30–50% at 10–15 years (Rahimtoola, 2003). Operative mortalities for aortic and mitral valve replacement are 3% and 6% respectively. While valve replacement thus provides a substantial improvement over the natural history of disease, patients with artificial valves still do not fare as well as similarly aged individuals without valve disease; complications related to the device are a major reason for this difference (Figure A.2).

The surgical treatments available for valvular heart disease include replacement of the valve with a prosthesis and repair of the existing abnormal valve tissue to make it functional (Fedak et al., 2008). Reconstructive/repair procedures to eliminate mitral insufficiency and to minimize the severity of rheumatic mitral stenosis are now highly effective and commonplace. A recent survey of practice in the US showed that 69% of mitral valve operations for mitral regurgitation, and 46% of mitral valve operations overall, compared with only 3% of aortic valve operations, currently use repair rather than replacement (Gammie et al., 2009). Whenever possible, repair of a valve is preferable over replacement; advantages of repair relate to the elimination of both the risk of prosthesis-related complications and the need for chronic anticoagulation (which will be discussed later) that is required in many patients with substitute valves, particularly mechanical valves.

Surgical valve repair is often accompanied by stabilization of the annulus (valve ring) with or without implantation of a prosthetic annuloplasty ring. Regrettably, repair is usually not possible for most forms of aortic valve disease.

When repair is not possible, severe symptomatic valvular heart disease is treated by surgical valve replacement, which comprises excision of part or all of the diseased valve, and replacement by a functional substitute. From a design standpoint, the ideal replacement valve would be nonthrombogenic, non-hemolytic, infection resistant, chemically inert, durable, and easily inserted. It would open fully and close quickly and completely, heal appropriately in place, and not be noticed by the patient (for example, it would be noise-free) (Harken et al., 1962; Sapirstein, 2001). Additional criteria for valve design also emphasize the patient's point of view (Rahimtoola, 2010).

The evolution of prosthetic heart valves and related cardiovascular surgical technology was enabled during the first half of the 20th century, by multiple key developments including cardiac catheterization, innovative surgical techniques, the cardiopulmonary bypass, and the anticoagulant heparin (Chaikoff, 2007). In the late 1950s, stimulated by collaborations established between surgeons and biomedical engineers, innovative procedures and device technology which matured in the surgical research laboratory were translated to clinical practice. These developments fostered new opportunities to replace dysfunctional cardiovascular components

with biologic or synthetic prostheses. A key step in modern valve replacement technology was the Hufnagel ball valve, designed to be implanted rapidly into the descending thoracic aorta with the use of proximal and distal fixation rings (Butany et al., 2002). However, with this valve regurgitant flow from the lower body was prevented, but cardiac work was only partially relieved and coronary flow was not improved. Subsequently, Albert Starr and his colleagues, along with a mechanical engineer, Lowell Edwards, fabricated a valve consisting of a stainless steel cage, a heat-cured Silastic ball, and a base surrounded by a Teflon fabric sewing cuff, the latter component permitting the surgeon to suture the valve in place orthotopically (i.e., in the anatomically appropriate location within the heart). The three generic components described above: 1) moving part (either synthetic or biologic); 2) superstructure to guide the motion of the moving occluder; and 3) sewing cuff (anchored at the anastomotic site); comprise the key parts of all previous and present heart valve prostheses.

The achievements of Starr and Carpentier provided the foundation on which the clinical success of heart valve replacement is built. Biomedical engineering technological developments have contributed to markedly improved materials and designs for mechanical and biological valves. Today, more than 80,000 valve replacement procedures are performed each year in the United States, and more than 275,000 per year are done worldwide. Moreover, devices and techniques for minimally invasive and percutaneous (catheter-based) valve replacement and repair and other interventional techniques are undergoing rapid innovation and development, and there has been exciting progress toward the creation of a living tissue-engineered heart valve replacement (Kidane, 2008).

> … devices and techniques for minimally invasive and percutaneous (catheter-based) valve replacement and repair and other interventional techniques are undergoing rapid innovation and development, and there has been exciting progress toward the creation of a living tissue-engineered heart valve replacement.

MECHANICAL AND TISSUE VALVE REPLACEMENT DEVICES: TYPES AND COMPLICATIONS

Hundreds of designs of substitute heart valve replacement devices have been explored experimentally and in patients; most have been abandoned owing to design and material deficiencies that manifest in complications which became apparent only in clinical use (Dewall, 2000; Edmunds, 2001). Today's cardiac valvular substitutes are of two generic types, mechanical valves and biological tissue valves. The choice of which valve to use in a particular patient is often difficult (El Oakley, 2008; Rahimtoola, 2010).

Mechanical prosthetic heart valves (Figure A.3) are composed of non-physiologic biomaterials that employ rigid, mobile occluders in a metallic cage (cobalt-chrome or titanium alloy), as in the Bjork-Shiley, Medtronic-Hall, and OmniScience valves or two carbon hemidisks in a carbon housing, as in the St. Jude Medical, CarboMedics CPHV, and the Medical Carbon Research Institute or On-X prostheses. Today, all mechanical valve occluders are fabricated from pyrolytic carbon. As described in Chapter I.2.8, pyrolytic carbon has high strength, fatigue and wear resistance, and exceptional biocompatibility, including thromboresistance. The opening and closing of a prosthetic valve is purely passive, with the moving parts (occluder or disc(s)) responding to changes in pressure and blood flow within the chambers of the heart and great vessels. Patients receiving mechanical valves must be treated with lifelong anticoagulation to reduce the risk of thrombosis and thromboembolic events (see below).

Tissue valves (Figure A.4) resemble natural valves more than do mechanical prostheses. The term "bioprostheses" describes a special type of tissue valve composed of three cusps of tissue derived from animals – most frequently either a porcine (pig) aortic valve or bovine (cow) pericardium – each treated with glutaraldehyde. Glutaraldehyde fixation preserves the tissue and decreases its (already relatively low) immunological reactivity, and kills the cells within the valve tissue. No immunosuppression is generally used for these xenografts as is required for whole organ transplants (e.g., kidney, liver or heart). However, since these valves no longer contain viable cells, the cusps themselves cannot remodel or respond to injury as normal tissue does. Bioprosthetic valve cusps are mounted on a metal or plastic stent with three posts (or struts) to simulate the geometry of a native semilunar valve. As with mechanical valves, the base ring is covered by a Dacron or Teflon covered sewing cuff to facilitate surgical implantation and healing. Commonly used bioprosthetic valves are the Hancock porcine, Carpentier-Edwards porcine, and Carpentier-Edwards pericardial tissue valves.

Also used occasionally are tissue valves derived from human cadaveric aortic or pulmonary valves, with or without the associated vascular conduit (called allografts or homografts). These valves have good hemodynamic profiles, a low incidence of thromboembolic complications without chronic anticoagulation, and a low re-infection rate following an original valve replacement for endocarditis (O'Brien, 2001). Several decades ago, when the use of valve allografts began, they were sterilized and/or preserved with chemicals or irradiation; such valves suffered a high rate of leaflet calcification and rupture. Subsequent technical developments have led to the current practice, allografts that are cryopreserved rather than chemically preserved. Freezing is performed with protection from ice crystal formation using dimethyl-sulfoxide. The valves are subsequently stored until use at −196°C in liquid nitrogen. Contemporary allograft valves yield

Churchill Livingstone: New York.)

freedom from degeneration and tissue failure equal to or better than those of conventional porcine bioprosthetic valves, but their use is limited by availability, difficulty in obtaining the proper size, and a more complex surgical procedure for implantation.

The reliability of a valve prosthesis and its interactions with the host and local tissues play a major role in patient outcome. Four categories of valve-related complications (Figure A.5) are most important: thrombosis and thromboembolism; infection; structural dysfunction (i.e., failure or degeneration of the biomaterials comprising a prosthesis); and non-structural dysfunction (i.e., miscellaneous complications and modes of failure not encompassed in the previous groups). The major advantages of tissue valves compared to mechanical prostheses are their pseudo-anatomic central flow and relative nonthrombogenicity; consequently, patients with tissue valves usually do not require anticoagulant therapy unless they have atrial fibrillation or another specific propensity to thrombose the valve. As reflected in overall heart valve replacement industry data, innovations in tissue valve technologies and design have stimulated this segment of the market to grow disproportionately in the last decade by expanding indications for tissue valve use (Fann et al., 2001), and as will be noted later in this chapter, potentially enhanced durability. Thus, there has been a trend toward an increasing fraction of tissue valves implanted relative to mechanical valves (see later).

> The reliability of valve prosthesis and its interactions with host tissue play a major role in patient outcome. Thromboembolic complications are the major cause of mortality and morbidity after cardiac valve replacement with mechanical valves. In contrast, structural dysfunction has been a frequent cause of failure of the most widely used bioprostheses.

Thromboembolic complications are the major cause of mortality and morbidity after cardiac valve replacement with mechanical valves. As discussed in Chapter II.2.6, no synthetic or modified biological surface produced by man is as resistant to thrombosis (*thromboresistant*) as normal unperturbed endothelium. As in the cardiovascular system in general, Virchow's triad (surface thrombogenicity, hypercoagulability, and locally static blood flow) largely predicts the relative propensity of a device to thrombus formation and location of thrombotic deposits with cardiovascular prostheses (Bennett et al., 2009). Exposure of blood to an artificial surface can induce thrombosis, embolization, and consumption of platelets and plasma coagulation factors, as well as the systemic effects of activated coagulation, complement products, and platelets. Thus, patients who have received mechanical substitute heart valves require lifetime therapeutic anticoagulation with warfarin derivatives, which induces a risk of hemorrhage, potentially serious and in some cases fatal (Vahanian, 2008). Thrombotic deposits

Pathological considerations in replacement cardiac valves. Cardiovasc. Pathol. 1: 29.)

forming on valve prostheses can immobilize the occluder or shed emboli to downstream arterial beds (Figures A.5A–C).

Prosthetic valve infection (endocarditis) occurs in 3–6% of recipients of substitute valves (Figure A.5D). When endocarditis was the reason for the original valve replacement, the risk is markedly increased. Rates of infection of bioprostheses and mechanical valves are similar. However, since mechanical valve biomaterials cannot themselves become infected, endocarditis on mechanical valves is localized to the prosthesis–tissue junction at the sewing ring, with accompanying tissue destruction in this area (Piper, 2001). While bioprosthetic valve endocarditis can also be localized to the

host tissue–prosthesis junction, biological tissue, despite being chemically fixed, can support growth of bacteria and other microorganisms, and thus the cusps are involved in some cases. The most frequent portals of entry include the mouth via dental procedures, urologic infections and interventions, and indwelling catheters; all comprise breaches of a natural mucosal membrane that may release organisms into the blood. Prosthetic valve endocarditis can occur either early (less than 60 days post-operatively) or late (can be years). The microbial etiology of early prosthetic valve endocarditis is dominated by the staphylococcal species *S. epidermidis* and *S. aureus*, even though prophylactic antibiotic regimens used routinely at the time of implantation are targeted against these microorganisms. The clinical course of early prosthetic valve endocarditis tends to be fulminant. The most common organisms in late prosthetic valve endocarditis are *S. epidermidis*, *S. aureus*, *Streptococcus viridans*, and *enterococci*. Prosthetic valve endocarditis usually necessitates surgical reintervention.

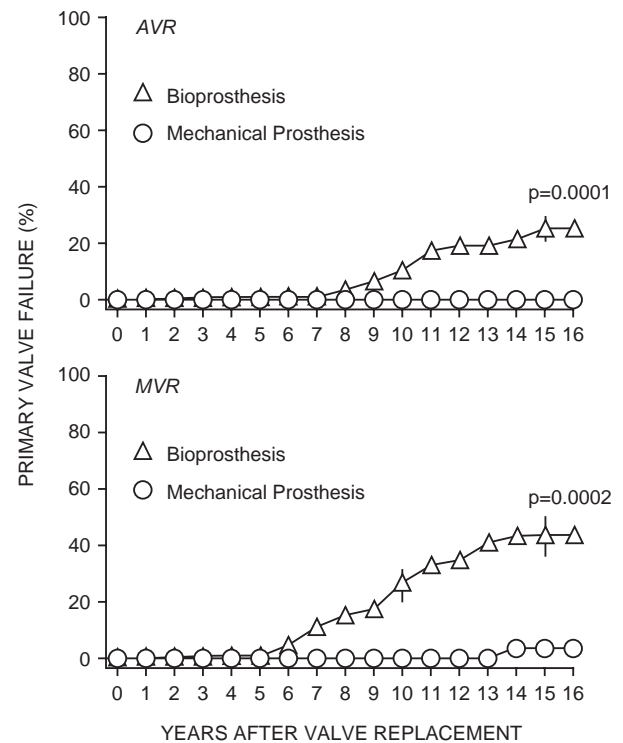
Prosthetic valve dysfunction owing to materials degradation can necessitate reoperation or cause prosthesis-associated death. Many valve models have been withdrawn from clinical use because of poor durability. Durability considerations vary widely for mechanical valves and bioprostheses, for specific types of each, for different models of a particular prosthesis utilizing different materials or having different design features, and even for the same model prosthesis placed in the aortic rather than the mitral site. Fractures of metallic or carbon components of mechanical valve prostheses are fortunately rare, but are usually catastrophic and life-threatening (Figure A.5E). Contemporary single-leaflet or bileaflet tilting disk valves with pyrolytic carbon occluders and either metallic struts or carbon housing have generally favorable durability. Fractures related to past design defects are noteworthy in two valve cohorts. In one instance, the Bjork-Shiley single leaflet tilting disk valve was redesigned with the intention of enhancing disk opening and relieving obstruction and thromboembolic complications that occurred with the original and widely used model. The resultant Bjork-Shiley 60° and 70° convexoconcave tilting disk valves suffered fractures of the welded metallic outlet strut and separation from the valve, leading to frequently fatal disk escape. Over 80,000 valves of this model were implanted, and at least 600 fractured in this manner. The underlying problem was due to the unanticipated consequence of disk closure at a higher velocity and force, causing over-rotation and an excessively hard contact with the metallic outlet strut. When the outlet strut stresses exceeded its endurance limit fatigue fracture occurred, most frequently in the region of the welds anchoring this strut to the housing. In another instance, fractures of carbon valve components (hemi-disk or housing) occurred in implanted Edwards (previously Hemex)-Duromedics bileaflet tilting disk valves. At least 37 valves of this type failed in this manner. Studies


FIGURE A.6 Frequency of primary valve failure (nonthrombotic valve obstruction or central valvular regurgitation) for mechanical and tissue valves following mitral valve replacement (MVR) and aortic valve replacement (AVR). Cuspal mineralization is the major responsible pathologic mechanism with regurgitation through tears the most frequent failure mode. (Reproduced by permission from Hammermeister, K. et al. (2000). Outcomes 15 years after valve replacement with a mechanical versus a bioprosthetic valve: Final report of the Veterans Affairs Randomized Trial. J. Am. Coll. Cardiol. 36: 1152–1158.)

of these explants suggest that valve fracture with leaflet escape resulted from variable combinations of five factors: (1) microporosity in the pyrolytic carbon coating in the leaflets; (2) cavitation bubbles impacting on the carbon surfaces during function; (3) unusual combinations of dimensional tolerances; (4) poor shock-absorbing qualities of the annular tissues in some patients (perhaps due to calcification-induced rigidity); and (5) structural defects in the valve prosthesis induced by fabrication or surgical mishandling. Fractures of carbon components have been encountered only rarely with other carbon bileaflet tilting disk valves, such as the St. Jude Medical valve.

In contrast structural dysfunction is frequent, and is the major cause of failure of the most widely used bioprostheses (Figure A.5F). Bioprosthetic valve structural tissue failure usually results in progressive symptomatic deterioration, which requires reoperation (Schoen and Levy, 2005). Within 15 years following implantation, 30–50% of porcine aortic valves implanted as either mitral or aortic valve replacements require replacement because of primary tissue failure (Figure A.6). Cuspal mineralization is the major responsible pathologic mechanism,

with regurgitation through tears the most frequent failure mode in porcine valves (see Chapter II.4.5). Bovine pericardial valves also suffer design-related tearing, and/or calcification. Calcification is markedly accelerated in younger patients, with children and adolescents having an especially accelerated course.

Within the group of complications causing non-structural failure are those that relate to healing of the valve in the site of implantation, either too little or too much. Inadequate healing can cause paravalvular leaks, which permit reverse flow usually through a relatively small hole at the junction of prosthesis and host tissue when the valve is closed. Paravalvular leaks may be clinically inconsequential, may cause hemolysis (see below), or can cause heart failure through regurgitation. In contrast, over-exuberant healing, called tissue overgrowth (or pannus), can block occluder motion or lead to secondary thrombus. Hemolysis (destruction of red blood cells) is unusual with contemporary valves, but paravalvular leaks or dysfunction owing to materials degeneration may induce clinically important hemolysis through mechanical destruction of red blood cell membranes by the high shear stresses that are engendered by blood being forced at high velocity through small spaces.

Various incremental improvements to valve prostheses are being investigated in preclinical studies and clinical research and implementation. For example, methods are being actively studied, and some are being used clinically to prevent calcification of bioprosthetic valves (see Chapter II.4.5). The confidence engendered by early data that these methods may have extended the durable lifetime of bioprosthetic valves has led to a dramatic resurgence of their use, particularly in the USA (Figure A.7). Indeed, in the AHRQ database for 2005, bioprostheses were used in 50% of aortic and 40% of mitral valve replacements, respectively (Barnett and Ad, 2009). Tissue valve use continues to expand; in the database of

FIGURE A.7 Percentage use of bioprosthetic valves relative to mechanical valves from 1997 through 2006. Bioprosthetic valve use increased progressively during 10 years. Asterisk indicates $P < 0.000001$. (Reproduced by permission from Brown, J. M., O'Brien, S. M., Wu, C. et al. (2009). Isolated aortic valve replacement in North America comprising 108,687 patients in 10 years: Changes in risks, valve types, and outcomes in the Society of Thoracic Surgeons National Database. J. Thorac. Cardiovasc. Surg. 137: 82–90.)

the Society for Thoracic Surgeons, contemporary utilization of bioprosthetic tissue valves is estimated to be about 80% of all aortic and 69% of all mitral substitute heart valves used (Brown et al., 2009; Gammie, 2009). As bioprosthetic valve structural degeneration is accelerated in younger patients, the trend toward increasing use of bioprostheses (relative to mechanical valves) is especially high in older recipients.

Other approaches to provide improved valves include modifications of bioprosthetic valve stent design and tissue mounting techniques to reduce cuspal stresses, tissue treatment modifying or alternative to conventional glutaraldehyde pretreatment to enhance durability and post-implantation biocompatibility, non-stented porcine valves, minimally cross-linked autologous pericardial valves, and flexible trileaflet polymeric (polyurethane) prostheses (Kidane, 2009).

TRANSCATHETER VALVE REPLACEMENT

The surgically implanted bioprosthetic and mechanical valves discussed above are excellent therapies for valvular heart disease, and have a long and proven track record of success. However, some patients with valvular heart disease are currently unable to receive these valves due to other significant medical conditions (called co-morbidities) that create a prohibitively high surgical risk with unacceptable operative mortality. These patients would benefit from a less invasive approach, which would carry very low procedural mortality compared to the traditional surgical one, and might provide significant benefit in treating the valvular disease. Percutaneous balloon valvuloplasty (where a balloon threaded via a catheter to the inside of the aortic valve is expanded under pressure, thereby stretching the valve tissue and fracturing calcific deposits) alone provides insufficient benefit. New catheter-based interventional techniques for inserting foldable prosthetic valves within stenotic aortic and pulmonary valves, and for emulating surgical repair of regurgitant mitral valves, are in various stages of preclinical development, clinical testing, and clinical use (Vassiliades et al., 2005; Block, 2006) (Figure A.8). Percutaneous implantation of a heart valve that can be mounted on an expandable stent, delivered percutaneously through standard catheter-based techniques, and implanted within a diseased valve annulus, has been demonstrated to be feasible. Such valves are expanded in-vivo either by a balloon or are self-expanding (see Figure A.8). Percutaneous valve replacement is most likely to be used in patients with severe aortic stenosis deemed otherwise inoperable, and in congenital heart disease where percutaneous pulmonary valve replacement may find a distinct niche to obviate the morbidity of reoperation to replace malfunctioning pulmonary conduits. In patients with repaired congenital heart disease, complications of an obligatory right ventricle to pulmonary artery conduit are frequent, and the opportunity for palliation to

FIGURE A.8 Percutaneous valve replacement technology. (A) The Edwards-SAPIEN™ balloon-expandable aortic valve replacement designed for percutaneous implantation, constructed from bovine pericardium attached to a stainless steel stent. A fabric sealing cuff covers the ventricular aspect to prevent leaks between the prosthesis and surrounding tissues. The valve is mechanically crimped onto a valvuloplasty balloon catheter and expanded within the aortic annulus to displace and exclude the stenotic native from the circulation. (B) Corevalve™ aortic bioprosthesis, constructed of bovine pericardium attached to a self-expanding nickel-titanium alloy (nitinol) stent. The ventricular portion has a high radial force to compress the native valve. The midportion is tapered to avoid interference with the coronary arteries. The aortic portion is flared to provide additional fixation against the wall of the ascending aorta. Nitinol can be made soft at cold temperatures, allowing the stent to be tightly compressed within a delivery sheath. Once positioned within the native valve the sheath is withdrawn, allowing the stent to assume its predetermined shape. There is adequate radial force to compress the native valve. (C) The Melody™ pulmonary valve is constructed from a bovine jugular venous valve attached with sutures to a platinum-iridium alloy stent. The relatively delicate venous valve functions well in the pulmonary circulation, but is too fragile for use in the systemic. Although often referred to as a pulmonary valve, its maximum expanded diameter of 22 mm largely limits its use to surgically-constructed right ventricular to pulmonary artery conduits in the pediatric population. ((A) and (B) reproduced by permission from Schoen, F. J. & Webb, J. G. (2008). Prosthetics and the Heart. In: Atlas of Cardiovascular Pathology for the Clinician, McManus, B. M. & Braunwald, E. (eds.), pp. 241–256. Current Medicine: Philadelphia, PA).

delay or prevent surgery is attractive in many cases. For aortic valve disease, the excellent clinical success with surgical aortic valve replacement presently restricts the use of percutaneous valve replacement to non-surgical candidates or as a bridge to valve replacement in patients in whom surgery needs to be delayed.

> New catheter-based interventional techniques for inserting foldable prosthetic valves within stenotic aortic and pulmonary valves, and for emulating surgical repair of regurgitant mitral valves, are in various stages of preclinical development, clinical testing, and early clinical use.

The devices used as percutaneous valve replacements have an outer stent-like structure which contains leaflets. The stent holds open a valve annulus or segment of a prosthetic conduit, and resists the tendency of a vessel, valve annulus or diseased native leaflets to recoil following balloon dilation, supports the valve leaflets, and provides the means for seating the prosthesis in the annulus or vessel. The types of tissues used for the valve component include bovine, equine or porcine pericardium, and bovine jugular venous valves. The stents can be made from self-expandable or shape-memory materials such as nickel-titanium alloys (e.g., Nitinol) or from balloon-expandable materials such as stainless steel, platinum-iridium or other alloys. The delivery strategy involves collapsing the device and placing it within a catheter-based sheath; for balloon expandable devices, they must be collapsed over a balloon. The catheter containing the device can be inserted through a local incision into the femoral artery (or vein as appropriate to the target site) using essentially the same technique for deployment of coronary artery stents and other endovascular and cardiac devices. In the case of aortic stenosis, the catheter containing the valve device is passed from the femoral artery retrograde up the aorta to the aortic valve, and deployed between the cusps of the calcified aortic valve, pushing the diseased cusps as far as possible out of the way. Alternatively, the device can be deployed in an antegrade fashion using a minimally invasive surgical approach through the apex of the left ventricle. This transapical approach is favored in patients with significant atherosclerotic disease of the femoral artery or aorta, since manipulation of catheters through such sites can dislodge atherosclerotic debris, leading to emboli. For children with failed right ventricular to pulmonary artery devices used to correct certain types of congenital heart defects, the valve is threaded from the femoral vein to the inferior vena cava through the right side of the heart.

Several catheter-based devices are currently in various stages of development and clinical use in the aortic and pulmonary position (Chiam, 2009; Lurz, 2009; Ye, 2009; Zajarias, 2009). The two transcatheter aortic valves with the largest clinical experience are the Edwards SAPIEN device and the CoreValve ReValving system. The FDA approved SAPIEN device is composed of a balloon expandable stainless steel stent which houses a bovine pericardial trileaflet valve. The stent has a low profile and is designed to be placed in the subcoronary position (Figure A.8A). There is a polymer skirt circumferentially attached to the stent to reduce paravalvular leaks.

The CoreValve device, which at the time of this writing, has achieved the CE Mark in Europe but not FDA approval, is composed of a self-expandable Nitinol stent which houses a porcine pericardial trileaflet valve (Figure A.8B). These devices have been used in approximately 40000 patients worldwide since the first human experience was reported in, and further use is expected grow rapidly (Rodés-Cabau, 2012). The FDA approved Medtronic Melody transcatheter pulmonary valve is composed of a balloon expandable platinum-iridium alloy stent which houses a segment of bovine jugular vein containing its native venous valve (Figure A.8C) (Lurz et al., 2009). The Melody was designed to be used in patients with congenital heart disease, usually children or young adults, who have received surgically implanted right ventricular outflow tract conduits that are failing, either due to stenosis or regurgitation. Catheter-based valves may also play a role in the treatment of surgically implanted bioprosthetic valves that are failing due to stenosis or regurgitation, in a so-called "valve-in-valve" application in which a new prosthesis is inserted directly into a prior one.

ENGINEERED HEART VALVES

Recent scientific and technological progress has stimulated the goal of generating a "tissue-engineered" heart valve, a living valve replacement that would obviate the complications of conventional valve replacement, adapt to changing environmental conditions in the recipient, and potentially grow with a growing patient (Breuer et al., 2004; Vesely, 2005; Mendelson and Schoen, 2006; Sacks et al., 2009). Innovative work toward this objective is active in many laboratories, and may eventually lead to clinical application, though many challenges exist. The clinical need, opportunities, progress, and challenges of heart valve tissue engineering are described in detail in Chapter II.6.10.

B. ENDOVASCULAR STENTS, VASCULAR GRAFTS, AND STENT GRAFTS

Frederick J. Schoen and Robert F. Padera, Jr.
Department of Pathology, Brigham and Women's Hospital and Harvard Medical School, Boston, MA, USA

INTRODUCTION

Considerable progress on the impact of atherosclerosis-related disease has been made over the last several decades in the United States and elsewhere. Between 1963 (the peak year) and 2000 there was an approximately 50% decrease in the death rate from the consequences of coronary artery atherosclerosis and a 70% decrease in death from strokes. From 1995–2005 alone, death rates from cardiovascular disease declined more than 25%. Three factors have contributed to this impressive improvement: (1) prevention of atherosclerosis through changes in lifestyle, including reduced cigarette smoking, altered dietary habits with reduced consumption of cholesterol and saturated animal fats, and control of hypertension; (2) improved methods of treatment of myocardial infarction and other complications of atherosclerosis-related disease, especially coronary artery bypass graft surgery, and manipulation of atherosclerotic blood vessels through catheters placed into blood vessels in the groin and threaded up to the heart (a collection of procedures called percutaneous coronary intervention (PCI), which includes percutaneous transluminal coronary angioplasty and placement of stents (see below)); and (3) prevention of recurrence in patients who have previously suffered serious atherosclerosis-related clinical events.

> Vascular pathologies – and their downstream sequelae – are responsible for more morbidity and mortality than any other category of human disease (Mitchell and Schoen, 2010). Cardiovascular disease overall accounted for one-third of the nearly 2.5 million deaths in the United States in 2006; coronary heart disease alone caused about one of every five deaths (Lloyd-Jones, 2009).

This chapter summarizes the major types of treatments and related challenges and opportunities to manage the

two principal mechanisms causing clinically-important vascular disease states:

- Narrowing (stenosis) or complete obstruction of vessel lumina;
- Weakening of vessel walls.

Most vascular disease occurs through the process of *atherosclerosis*, a slowly progressive disease in which asymmetric focal thickenings (also called *atheroma* or *plaques*) form in and obstruct small arteries or weaken larger arteries, beginning in childhood and typically causing symptoms in middle age or later life (Mitchell and Schoen, 2010). The characteristic lesion of atherosclerosis is the atheroma or plaque that forms through thickening of the inner layer of the vessel wall (called the *intima*). Plaque formation occurs by a mechanism involving smooth muscle cell proliferation, production of collagen, and accumulation of lipids in the arterial wall (Libby, 2005). Vascular pathology caused by atherosclerosis is shown in Figure B.1.

Atherosclerosis primarily affects the large elastic arteries, and large and medium-sized muscular arteries of the systemic circulation, particularly near branches and sharp curvatures. Although veins are usually spared from atherosclerosis, venous bypass grafts interposed within branches of the arterial system (such as saphenous vein grafts) frequently develop intimal thickening, and ultimately atherosclerotic obstructions. Moreover, some arteries used as arterial grafts, such as the internal mammary artery, are largely spared. The principal sites of involvement of atherosclerosis are the abdominal aorta, coronary arteries, popliteal arteries, descending thoracic aorta, and internal carotid arteries.

In small arteries, atherosclerotic plaques can grow sufficiently large to occlude lumens, and thereby compromise blood flow to downstream organs, leading to ischemia, a pathologic condition caused by inadequate blood flow, and the resulting tissue damage. Obstruction, which can occur either progressively (e.g., by atherosclerosis) or precipitously (e.g., by thrombosis or embolism), diminishes flow (*perfusion*) to the downstream tissue. Thus, if a coronary artery is blocked, the perfusion via coronary flow may be inadequate to meet the metabolic needs of the downstream heart muscle (myocardium), leading to a physiologic condition called *ischemia*. If the blockage is severe and prolonged, then
FIGURE B.1 Atherosclerosis. (A) and (B) Gross views of atherosclerosis in the aorta. (A) Mild atherosclerosis composed of fibrous plaques, one of which is denoted by the arrow. (B) Severe disease with diffuse and complicated lesions (with wall destruction and superimposed thrombosis). (C) Histologic features of atherosclerotic plaque in the coronary artery, demonstrating fibrous cap (F), and a central necrotic (largely lipid) core (C). The lumen (L) has been moderately compromised. An uninvolved portion of the arterial wall is designated by an arrow. In this section, collagen has been stained blue (Masson's trichrome stain). (Reproduced by permission from Mitchell, R. N. & Schoen, F. J. (2010). Blood vessels. In: Robbins/Cotran Pathologic Basis of Disease, 8th ed., Kumar, V., Fausto, N., Abbas, A. et al. (eds.), p. 487. W.B. Saunders: Philadelphia, PA.)

tissue dies and the result is a heart attack (*myocardial infarction*); if in a cerebral artery neurons die, and the result is a stroke (*cerebrovascular accident*).

In the aorta and other large vessels, where plaque does not typically cause obstruction, advanced atherosclerosis can weaken the arterial wall, resulting in an aneurysm or dissection, either of which can rupture. An *aneurysm* is a localized abnormal dilation of a blood vessel that forms as a result of destruction and weakening of the vascular wall beneath an atherosclerotic plaque. The most frequent type of aneurysm is the abdominal aortic aneurysm (AAA), a dilation of the distal aorta immediately before it bifurcates into the iliac arteries to provide the blood supply to the legs (Sakalihasan, 2005); aneurysms located in the chest, either as ascending or descending thoracic aortic aneurysms (TAA), can also occur. Another type of arterial disease is a *dissection*, which arises when blood enters the wall of the artery to form a hematoma dissecting between its layers. This is often due to conditions such as hypertension or intrinsic genetic deficiency of the quality of the collagen of the arterial wall, which weakens its mechanical properties (Prêtre, 1997). Approximately 45,000 people die annually in the United States from diseases of the aorta and its branches.

> Mechanical therapies to prevent and treat the complications of vascular disease in general and atherosclerotic obstructions in particular include endovascular manipulation such as balloon angioplasty and stents, vascular bypass, vascular replacement using grafts, and various combinations of these approaches.

ANGIOPLASTY AND STENTS

Percutaneous cardiovascular interventions (PCI), including balloon dilation of an artery blocked by atherosclerotic plaque and/or thrombotic deposits (called percutaneous transluminal coronary angioplasty (PTCA)) and endovascular stents are used to restore blood flow through a diseased portion of the coronary circulation, and are shown in Figure B.2 (Landau, 1994; Daemen et al, 2007, 2 parts). In PTCA, a procedure developed and implemented first

(A)

(B)
FIGURE B.2 Balloon angioplasty and endovascular stenting. (A) Catheter-based interventions for opening occluded coronary arteries: 1, Percutaneous transluminal coronary angioplasty (PTCA); and successively, 2, 3, and 4, balloon-expandable stent placement. A balloon-tipped catheter is positioned in the coronary artery narrowing and inflated (1). The stent is positioned at the site of the coronary narrowing (2). When the balloon is inflated, the stent expands and presses against the arterial wall (3). The balloon is deflated and removed. The stent remains permanently in place, helping to keep the artery open (4). Within a few weeks, new tissue will grow over the stent struts and cover them. (B) Metallic stents on expanded balloons. ((A) Reproduced by permission from Michaels, A. D. & Chatterjee, K. (2003). Circulation 106: e187; (B) Reproduced by permission from Al Suwaidi, J., Berger, P. B. & Holmes, D. R. (2000). Coronary artery stents. JAMA 284: 1828.)

by Andreas Gruntzig in the late 1970s, a long catheter is passed from the femoral artery up the aorta to the openings (called *ostia*) of the coronary arteries that arise from the aorta immediately distal to the aortic valve cusps. Using radio-opaque dye and fluoroscopy, areas of stenosis can be identified. In PTCA a deflated balloon is passed over a guidewire to a site of stenosis, where the balloon is inflated using progressive and substantial expansile force (~10 atm). Enlargement of the lumen and increased blood flow induced by PTCA occurs by plaque reduction via compression, embolization or redistribution of the plaque contents, and by overall mechanical expansion of the vessel wall (Virmani, 1994). Although early angioplasty balloons were made from polyvinyl chloride and polyethylene, current balloons are composed of nylon or polyethylene teraphthalate. Short-term failure of this procedure (i.e., closure of the treated vessel within hours to days) can occur via several mechanisms, including elastic recoil of the vessel wall, acute thrombosis at the site of angioplasty, and acute dissection or blood within the vessel wall itself in the area of angioplasty. Nevertheless, the "Achilles heel" of PTCA is the development of progressive, proliferative restenosis which occurs in 30–50% of patients, most frequently within the first 4–6 months (Haudenschild, 1993). The usual process causing restenosis after PTCA is fibrous tissue formation in the lumen owing to excessive medial smooth muscle proliferation as an exaggerated response to angioplasty-induced injury, similar to features of atherosclerosis itself, and to stent and vascular graft healing (see below). Systemic pharmacologic therapies, by themselves, have not effectively mitigated restenosis after PTCA.

Stents mitigate at least some of the negative consequences of PTCA. Developed in the late 1980s, stents are expandable tubes of metallic mesh that splint open the vessel wall at the site of balloon angioplasty or vascular injury. Today, virtually all patients undergoing PCI will also receive a stent. Stents preserve luminal patency, and provide a larger and more regular lumen by acting as a scaffold to support the disrupted vascular wall and thereby reduce the impact of postangioplasty restenosis (Daemen et al, 2007a, 2007b). Stenting may also be done in the peripheral vasculature, such as the femoro-popliteal system (Schillinger and Minar, 2009; Yustein et al, 2009). Bare metal stents are short tubular segments of metal mesh composed of balloon-expandable 316L stainless steel or nitinol that range from 2.5 to 4.0 mm in diameter. Other metals and polymers are being investigated.

Stents can have complications, particularly thrombosis, occurring early or late, and late restenosis (Figure B.3). Early thrombosis, occurring in 1 to 3% of patients within 7 to 10 days of the procedure (see Figure B.3A) has largely been overcome by aggressive multidrug treatment with antiplatelet agents such as clopidogrel, aspirin, and glycoprotein IIb/IIIa inhibitors. The major long-term complication of bare metal stenting with devices is instent restenosis (Figure B.3B), which occurs in 50% of
FIGURE B.3 Major complications of endovascular stenting. (A) Early thrombosis (T) associated with a metallic coronary artery stent. (B) Late proliferative restenosis with fibrous tissue (R). Stent wire cross sections are black in this histologic section. Filling the lumen inside of the stent. (Reproduced by permission from Schoen, F. J. & Edwards W. D. (2001). Pathology of cardiovascular interventions. In: Cardiovascular Pathology, 3rd edn, Silver, M. D., Gotlieb, A. I. & Schoen, F. J. (eds.). Churchill Livingstone: New York.)

patients within six months (Virmani, 1999). The causes of stent thrombosis and restenosis are complex, and are largely due to stent–tissue interactions, including inflammation, which may potentially interfere with healing and re-endothelialization (Nakazawa, 2009). Damage to the endothelial lining and stretching of the vessel wall stimulate adherence and accumulation of platelets, fibrin, and leukocytes (white blood cells). Stent wires may eventually become completely embedded in an endothelium-lined layer of intimal fibrosis composed of smooth muscle cells in a matrix of collagen, which is essentially scar. This tissue may thicken secondary to the release of growth factors, chemotactic factors, and inflammatory mediators from platelets and other inflammatory cells that result in increased migration and proliferation of smooth muscle cells, and increased production of extracellular matrix molecules, narrowing the lumen and resulting in restenosis.
FIGURE B.4 Patient outcomes after standard bare metal stenting compared with those following drug eluting stent placement. (A) Actuarial rate of event-free survival. (B) Survival free from major adverse coronary events (sirolimus-eluting stent, solid line, bare metal stent dashed line). ((A) Reproduced by permission from Moses, J. W. et al. (2003). Sirolimus-eluting stents versus standard stents in patients with stenosis in a native coronary artery. N. Engl. J. Med. 349: 1315; (B) Reproduced by permission from Fajadet, J. et al. (2005). Maintenance of long-term clinical benefit with sirolimus-eluting coronary stents. Circulation 111: 1040.)

Stent technologies have undergone a relatively rapid evolution, with three distinct key stages of biomaterials development: (1) bare metal stents (BMS); (2) polymer-coated drug-eluting stents (DES); both used extensively in contemporary clinical interventional cardiology, and more recently; (3) completely resorbable/biodegradable stents (RBS), which are presently in clinical trials. Stent development has focused on mitigation of in-stent thrombosis and flexibility and ease of implantation, thereby allowing the treatment of a greater number and variety of diseased sites that occur within a particular patient and among patients. The choice of stent is based on several factors, including the characteristics of a given plaque, such as its diameter, length, and location within the coronary arterial anatomy, and the experience of the interventional cardiologist with a particular type of stent.

The most effective approach to reduce the incidence of in-stent restenosis occurring with BMS is the use of DES (Figure B.4) (Serruys, 2006; Daemen, 2007a, 2007b; Kukreja, 2008; Pedon, 2008; Moore, 2009; Moses, 2003). In DES, the drugs are embedded in a polymer matrix (such as a mixture of poly-n-butyl methacrylate and polyethylene-vinyl acetate (EVA) or a gelatin-chondroitin sulfate coacervate film) that is coated onto the stent wires. The drugs used most widely are rapamycin (sirolimus) (Sousa et al, 2003) and paclitaxel (Ong and Serruys, 2005) in the Cypher (Cordis) and Taxus (Boston Scientific) stents, respectively. Rapamycin, a drug used for immunosuppression in solid organ transplant recipients, inhibits proliferation, migration, and growth of smooth muscle cells and extracellular matrix synthesis. Paclitaxel, a drug used in chemotherapeutic regimens for several types of cancer, also has similar anti-smooth muscle cell activities. The drugs are released by diffusion and/or polymer degradation over varying periods of time that can be controlled by engineering the specifics of the polymer-drug system. At the time of this writing, it is estimated that more than six million people worldwide have received DES, including about three million in the United States. Indeed, stents are the most common device used to treat heart disease currently, and their insertion has become one of the most common medical procedures of any kind.

> The most effective approach to reduce the rate of in-stent restenosis encountered with bare metal stents is the use of polymer-coated drug-eluting stents.

Although DES inhibits in-stent restenosis (Moses, 2003), data from recent studies suggest a small but significant increased risk of late (>1 year post-implantation) stent thrombosis causing myocardial infarction and/or sudden death in patients who have DES. Although animal studies and some clinical data suggest that late stent thrombosis may be related to DES-induced inhibition of stent endothelialization, the significance and causes of late stent thrombosis are controversial (Holmes et al., 2007). The risk of late stent thrombosis does not seem to negate the overall advantages in patient outcomes of DES over BMS.

In contrast to both BMS and DES, which are permanent implants, RBS ultimately resorb to effect removal of foreign material that may potentiate a thrombotic event. RBS may permit more versatility in subsequent therapies, and do not interfere with the diagnostic evaluation by non-invasive imaging such as cardiac magnetic resonance and CT. Several RBS variants are in development or in clinical trials. The key challenges are to enhance biocompatibility, control the kinetics of degradation needed to maintain sufficient mechanical strength

to limit recoil, and minimize inflammation (Ramcharitar, 2008). Recent studies have used several innovative features, including: (1) an everolimus eluting poly-L-lactide stent; (2) a novel locking mechanism to overcome recoil; (3) a combination of an antiproliferative drug with endothelial progenitor cell capturing antibodies to facilitate endothelialization; (4) dual drug eluting stents having an antiproliferative drug and polymeric salicyclic acid to limit inflammation; and (5) a metal RBS composed of magnesium (Ramcharitar et al, 2007; Sharkawi et al, 2007; Brown et al, 2009).

VASCULAR GRAFTS

Vascular grafts are used to bypass an obstructed vessel or to replace a segment of vessel that has formed an aneurysm or dissection. To ensure a high likelihood of clinical success and long-term patency, vascular grafts must be 1) resistant to thrombosis, smooth muscle cell-caused intimal thickening, fatigue, and aneurysm development, 2) have material compliance properties similar to the normal and diseased vessels to which they will be anastomosed, and 3) have a sufficient level of suturability. Although animal studies strongly suggest that this combination of specifications is achievable, translation to clinical practice remains a challenge, particularly in grafts <6–8 mm diameter.

The concept of using synthetic material as a conduit in the vascular system dates back to the early 1900s, when animal experiments were carried out using aluminum, silver, glass, and lucite tubes as vascular replacements. Fabrics such as Vinyon N, a nylon fabric used in parachutes, were employed in the mid-1950s as vascular conduits that could be fashioned from commercially available textiles. Current synthetic vascular grafts, such as those shown in Figure B.5, are typically fabricated from polyethylene terephthalate (Dacron®) or expanded polytetrafluoroethylene (ePTFE®), with the Dacron® grafts being used for larger vessel applications and the ePTFE® used to bypass smaller vessels (<8 mm diameter). These grafts can be made porous to enhance healing, but may be impregnated with connective tissue proteins (such as gelatin or albumin) to aid clotting, reduce the blood loss through the pores implantation and stimulate tissue ingrowth, and with antibiotics to

reduce the risk of infection. Loosely woven or porous synthetic grafts that are not impregnated need to be preclotted with the patient's own blood before implantation, in order to minimize hemorrhaging through the graft interstices. Modern techniques for peripheral and coronary bypass differ little from the first leg vascular bypass (1948) or the first successful coronary artery bypass (1967). The expanded polytetrafluoroethylene (ePTFE) material used in Scribner's first chronic-use prosthetic blood vessel (1961) is largely identical to the graft used currently. Functional, lasting hemodialysis access for patients with kidney failure is a particularly challenging application for vascular grafts in which many "solutions" exist, but none is ideal (Scott, 2007). There is considerable ongoing research and development to make more sophisticated, safe, and effective vascular substitute materials (de Mel et al, 2008; Aper et al, 2009; Ravi et al, 2009).

> Synthetic fabric grafts perform well in large-diameter, high-flow, low-resistance locations such as the aorta and the iliac and proximal femoral arteries, with grafts used for aortofemoral bypass having 5–10 year patency rates of 90% (Clagett, 2002). In contrast, synthetic small-diameter vascular grafts (<6 to 8 mm in diameter) generally perform less well, with five-year patency less than 50%.

In general, the longer the interposition or bypass graft, and the smaller the diameter of the recipient vessel (with a corresponding increase in resistance to flow), the less favorable are both short- and long-term patency rates. For this reason, a major superficial vein in the leg, the saphenous vein, is typically removed surgically (from the patient needing the bypass) and moved to the site needed to bypass blockages in the coronary circulation (for coronary artery bypass grafting) or in the extremities (e.g., for femoropopliteal bypass grafting) when an adequate length of disease-free vein segment can be harvested for the necessary application. Other natural vessels such as the internal mammary artery may be used to bypass blockages in the coronary circulation.

When a synthetic graft is implanted, the luminal surface of the graft becomes coated with an adsorbed layer of plasma proteins, primarily fibrinogen. This layer
FIGURE B.5 Vascular grafts. (A) Dacron aortic interposition graft (Terumo). (B) Dacron aorto-iliac graft (Terumo). (C) ePTFE small vessel grafts (Gore).

develops over time into a platelet-fibrin aggregate (not covered by endothelium), termed a *pseudointima*. When endothelial cells cover this layer, simulating the inner layer of a native blood vessel and serving as a nonthrombogenic surface, the entire tissue thickness is termed a *neointima*. A neointima is generally considered more favorable than a pseudointima. Healing of a vascular graft by neointima is generally incomplete over its internal surface, despite long intervals following implantation

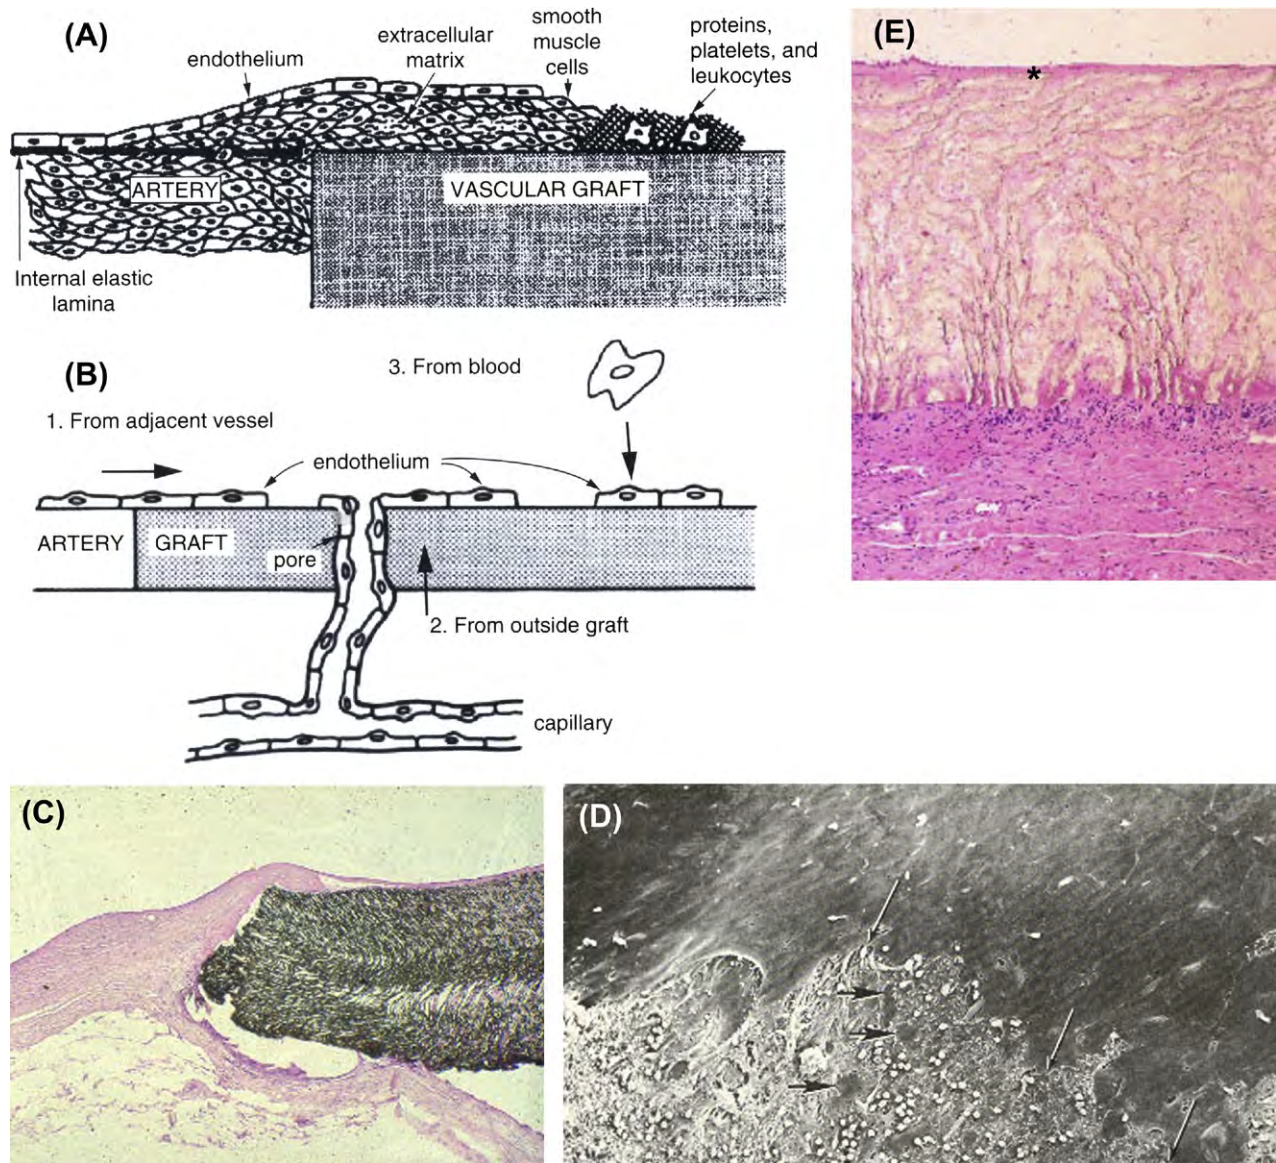
(Figure B.6). Tissue lining the inner wall of a vascular graft or other biomaterial implanted in blood has three possible sources: (1) overgrowth from the host vessel across anastomotic sites; (2) tissue ingrowth through sufficiently large interstices; and (3) deposition of functional endothelial cells and/or multipotential stem cells from the circulating blood (see Figures B.6A and B.6B). Experience suggests that humans have a limited ability to endothelialize vascular grafts from the circulation, resulting


FIGURE B.6 Vascular graft healing at the anastomosis (site where the vascular graft is sutured to the native artery). (A) Schematic diagram of pannus formation, the major mode of graft healing with currently available vascular grafts. Smooth muscle cells migrate from the media to the intima of the adjacent artery, and extend over and proliferate on the graft surface; this smooth muscle cell layer is covered by a proliferating layer of endothelial cells, forming an endothelialized (neointimal) layer. (B) Possible sources of endothelium on the blood-contacting surface of a microporous knit or velour Dacron vascular graft. (C) Low-power photomicrograph of histologic section of ePTFE graft anastomosis, demonstrating thin overgrowth of tissue from adjacent normal artery (similar to (A)). (D) Scanning electron micrograph at the limit of endothelial coverage shown schematically in (A) (native artery toward upper right, graft center lower left). (E) Graft center at a distance from the anastomosis of ePTFE graft, showing a thin layer of non-endothelialized thrombus (a pseudointima) at asterisk. ((A) and (B) Reproduced by permission from Schoen, F. J. (1989). Interventional and Surgical Cardiovascular Pathology: Clinical Correlations and Basic Principles. WB Saunders: Philadelphia, PA. (C) and (E) Reproduced by permission from Schoen, F. J. & Edwards W. D. (2001). Pathology of cardiovascular interventions. In: Cardiovascular Pathology, 3rd edn, Silver, M. D., Gotlieb, A. I. & Schoen, F. J. (eds.). Churchill Livingstone: New York. (D) Reproduced by permission from

in confluent endothelium covering only a 10–15 mm zone adjacent to the anastomosis (i.e., the sutured connection of the graft to the native artery). Thus, except adjacent to an anastomosis, a compacted platelet-fibrin pseudointima comprises the inner lining of clinical fabric grafts, even after long-term implantation (see Figure B.6C–E). Firm adherence of such linings to the underlying graft is difficult to achieve, and dislodgment of the lining leading to distal embolization or formation of a flap obstructing flow may occur. In a graft with interstices large enough to permit ingrowth of fibrovascular tissue, endothelial cells may originate from capillaries extending from outside to inside the graft and migrate to the luminal surface at a large distance from the anastomosis. However, since most porous knit clinical vascular grafts have insufficient porosity for tissue ingrowth, although they can bleed through and are therefore pre-clotted to avoid hemorrhage, existing grafts and other fabrics used as cardiovascular implants heal primarily by ingrowth of endothelium and smooth muscle cells from the cut edges of the adjacent artery or other tissue. The ability of grafts to heal over anastomoses depends on largely poorly-understood factors related to the graft material, local hemodynamics, potential other aspects of the host, and species; for example, sheep tend to heal grafts better than humans (Figure B.7). Also, circulating endothelial progenitor cells (EPC) derived from the bone marrow with the ability to differentiate into mature endothelial cells are thought to be recruited into the peripheral blood in situations of vascular repair or angiogenesis (Sata 2006; Tilki et al, 2009). EPC are believed to exert their function using two main strategies: activating the local endothelial cells and/or differentiating into mature endothelial cells themselves that integrate into the damaged vessel. To do this, EPC must home to "angiogenic active" sites, adhere to the activated/damaged endothelial cells or to the extracellular matrix, and participate in the endothelial activation/repair process. However, the role of EPC in typicl graft healing is lokely small. However, harnessing this mechanism represents a potential therapeutic opportunity.

An implanted graft also becomes encapsulated in the surrounding connective tissue and elicits a typical foreign-body reaction. The tissue covering the graft on its exterior surface, separating it from normal tissue, consists of a layer of inflammatory cells including giant cells adjacent to the material, covered by collagen, fibroblasts, blood vessels, and other cellular and extracellular connective tissue elements. This foreign-body capsule extends from the outside graft surface to the surrounding undisturbed body tissues. Graft interstices may be filled with fibrin or connective tissue elements, including cells and extracellular matrix and, where ingrowth has occurred, blood vessels.

The major complications of vascular grafts are thrombosis/thromboembolism, infection, a fluid collection outside the graft separating it from surrounding tissues
FIGURE B.7 Gross appearance of opened composite graft (2 pieces, each a different graft material, sewn together at the midpoint, denoted by arrow,) implanted in a sheep as a bypass conduit adjacent to a surgically constricted (by a ligating suture, now removed) descending thoracic aorta and removed after six months. One graft segment (left) has partial neointima formation extending over the graft; the other (right) has minimal neointima formation. The graft segment on the right has porosity sealed with albumin and the one on the left is gelatin sealed. The aortic constriction is indicated by an asterisk. (Reprinted by permission from Kadoba, K. et al. (1992). Experimental comparison of albumin-sealed and gelatin-sealed knitted Dacron conduits. J. Thorac. Cardiovasc. Surg. 103: 1059.)

(called a *seroma*), an extravascular hematoma resulting from a defect in the graft or a disrupted anastomosis and that communicates with the intravascular space (called a *pseudoaneurysm*), intimal hyperplasia (similar to the process of restenosis caused by SMC proliferation and scarring), and structural degeneration of the component biomaterials. Small diameter blood vessel grafts (<6-8 mm) have an especially high attrition rate (Figure B.8). In general, tissue grafts perform better than synthetic grafts (see Figure B.8A). Failure of synthetic small-diameter vascular prostheses is most frequently due to occlusion by thrombus formation (see Figure B.8B and B.8C) or generalized or anastomotic growth of fibrous tissue (called anastomotic fibrous hyperplasia, similar to intimal hyperplasia, above). As in any cardiovascular site "Virchow's triad" of surface thrombogenicity, hypercoagulability of the patient's blood, and locally static or low blood flow largely predict the propensity towards thrombus formation (see Figure B.8D and B.8E). Virchow's triad predicts thrombosis in small-diameter synthetic grafts where there can be low flow states due to poor flow out of the end of the graft (termed *run-off*), usually owing to atherosclerotic obstructions beyond the site of anastomosis. In larger vessels with higher blood flow such as the aorta, the surface thrombogenicity of the graft is usually overcome by brisk flow to minimize macroscopic thrombus formation. Contributing factors to anastomotic hyperplasia include: (1) surface thrombogenesis; (2) delayed or incomplete endothelialization of the fabric; (3) disturbed flow across the anastomosis; and (4) mechanical factors, especially compliance mismatch, at the junction of implant and host tissues. In vein grafts, intimal hyperplasia is often diffuse along the

graft length, leading to progressive luminal reduction of the entire graft. In contrast, synthetic vascular prostheses tend to develop intimal hyperplasia predominantly at or near anastomoses, particularly at the distal site.

Prophylactic systemic antibiotics at the time of surgery limit infection of implanted vascular prostheses. Early infections typically are related to the surgical procedure or to perioperative complications such as wound infection. Late infections usually occur secondary to seeding of the synthetic material by microorganisms from the blood in patients with low-grade bacteremia, often secondary to dental or gastrointestinal procedures. Since the anastomotic suture line is often involved in vascular graft infection, an infected vascular graft usually has a partially disrupted connection to the natural artery. Thus, rupture with hemorrhage at the graft site (i.e., a pseudoaneurysm, as described above) may bring the patient to clinical attention. Surgical removal of an infected graft is usually necessary to manage the infection. So far as we know from a clinical perspective, all graft materials or fabric textures are approximately equally susceptible to infection.

Progressive deterioration of a synthetic vascular graft can cause mechanical failure at the anastomotic site or in the body of the prosthesis, leading to aneurysm or pseudoaneurysm formation. The causes of delayed failure of a synthetic prosthesis include chemical, thermal or mechanical damage to polymeric yarn materials during manufacture, fabric defects induced during manufacture (e.g., dropped stitches), damage by vascular clamps during the insertion procedure and, rarely, postoperative degradation of graft material by mechanisms that are poorly-understood.

In view of the complications associated with vascular grafts, current research has focused on improvement of synthetic vascular grafts and on alternatives such as tissue-engineered blood vessels (see below). Attempts have been made to covalently modify the luminal surface of the grafts with various biologically active compounds in order to: (1) prevent coagulation; (2) prevent platelet adhesion/aggregation; (3) promote fibrinolysis; (4) inhibit smooth muscle cell adhesion/proliferation; and (5) promote endothelial cell adhesion and proliferation. Endothelialization of the entire graft would improve the thrombo-resistance of the graft, and may also help prevent bacterial attachment to the graft and subsequent infection.

STENT GRAFTS

Aortic aneurysms and dissections have been traditionally treated with open surgical procedures involving a large thoracic or abdominal incision and the replacement of the diseased portion of aorta by a synthetic graft. It is thus not surprising that, although such procedures are very effective, aortic aneurysm and dissection repair and aorto-bifemoral bypass grafting can have significant associated complications in certain patient populations, and the recovery time can be long. In 1999, aortic stent grafts for the treatment of abdominal aortic aneurysms that could be placed via catheter rather than open surgery became commercially available (Greenhalgh and Powell, 2008).

Stent grafts are composed of a synthetic fabric tube reinforced by a stent, whose struts facilitate rapid and stable expansion during insertion. This type of implant combines the features of stents and vascular grafts, and can be deployed endovascularly via a catheter (Figure B.9). The stent portion is manufactured from stainless steel, cobalt chromium alloy or nickel alloys (Nitinol) (Soor, 2008). The graft portion, usually polyester or ePTFE, can be located either on the luminal or abluminal
FIGURE B.9 Stent grafts. (A)–(D) Configuration of various commercially available stent graft devices showing composite metal and fabric portions (see original source for specific models and manufacturers). (A) and (B) are modular bifurcated stent graft composed of a nitinol exoskeleton and polyester or ePTFE linings. The stent-graft shown in (A) relies on radial force to fix the device into place. The stent-graft shown in (B) has proximal barbs to anchor the graft at its proximal end. The stent-graft shown in (C) is a unibody device made of polytetrafluoroethylene graft and a cobalt chromium alloy stent inside the graft. The stent graft shown in (D) is formed from several segments with a stainless steel stent on the outside of the graft. (E) High power photomicrograph of the cross-section of a well-healed experimental stent graft device explanted from a dog aorta. The lumen is widely patent, and the fabric and metal components are visible. (F) high and (G) low power photomicrographs of the cross sections of stent graft showing interaction with the vascular wall, and demonstrating mild intimal thickening. Nature Clinical Practice Cardiovascular Medicine 4, 206; (E)–(G) Courtesy Jagdish Butany, MD, University of Toronto.)
FIGURE B.10 Use of stent grafts in vascular disease. (A) Deployed endovascular stent graft in abdominal aortic aneurysm, with the proximal end immediately distal to the renal arteries and bifurcated into the iliac arteries bilaterally. (B) Endovascular stent graft in dissection. Left panel demonstrates the typical features of a thoracic dissection with flow in both the true and the expanded false lumen resulting from a major proximal entry tear. Right panel shows a stent graft placed to scaffold the dissected aorta and to seal the entry to the false lumen, resulting in reconstruction of the true lumen with subsequent false lumen thrombosis. The thrombosed segment of the original vessel eventually scars shut. ((B) Reproduced by permission from Nienader, C. A. et al. (2009). Randomized comparison of strategies for Type B aortic dissection. Circulation 120: 2519.)

(outside) aspect of the metallic stent, and is intended to provide a mechanical barrier to prevent intravascular pressure from being transmitted to the weakened wall of the aneurysm, thus excluding the aneurysm from the flow of blood. Once in place, a stent graft acts as an artificial lumen for blood to flow through, not into the surrounding aneurysm sac. The stent graft seals tightly upstream and downstream of the aneurysm or dissection. Fixation in some models is enhanced by hooks or barbs. Endovascular stent grafting can be used to treat some AAAs, as well as some thoracic aortic aneurysms and dissections. In the case of AAA or TAA, deployment of a stent graft and exclusion of blood from the aneurysm immediately takes the pressure off the aneurysm wall. In the case of a dissection, the stent portion holds the vessel open, and compresses and squeezes blood out of the false lumen in the wall of the artery. Stent grafts are deployed in a similar manner to stents in the coronary circulation, either as self-expanding Nitinol-based units or over an inflatable balloon. A stent graft used for a given application is selected by diameter, length, and geometry of the lesion, and location of side branches or branch points.

Endovascular aneurysm repair (EVAR) surgery is done via a catheter introduced in the peripheral vasculature, threaded to the diseased portion of aorta, and a stent graft deployed. EVAR has many advantages over conventional surgery, chief among which are lower operative complication and mortality rates. This is particularly important when determining treatment options for elderly and high-risk patients with concurrent medical conditions. Many

models have been introduced, and the range of vascular problems amenable to this therapy has been expanding with generally favorable results (Matsumoto, 2008; Matsumura et al, 2008; Svensson et al, 2008; Espinosa et al, 2009). Figure B.10 shows the concept for repair of both an abdominal aortic aneurysm and a thoracic aortic dissection. Considerable development of new devices is underway (Desai et al, 2010).

Although open surgery is avoided with EVAR, endovascular repair is a complex interventional procedure accompanied by potential procedural and device-related complications. The major device-related problem is leakage of blood through or around the graft (called an *endoleak*), which occurs in approximately 20% of stent graft recipients. First-generation devices have also suffered from problems such as stroke at the time of insertion, ascending aortic dissection or aortic penetration from struts, vascular injury, graft collapse, graft material failure, continued aneurysm expansion or rupture, migration of the device from the location of original deployment, and kinking.

Stents and stent grafts have been especially successful in treating sub-totally occluded short (5–10 cm) segments of the iliac artery that can cause significant chronic lower extremity ischemia, and in the treatment of stenosis of the renal arteries, the smaller arteries of the lower extremity (femoral, popliteal and tibial arteries), the carotid arteries, the celiac artery, and the superior mesenteric artery. However, stents and stent grafts in these sites suffer mechanical failure at a greater rate

than those in the coronary circulation. Failure modes related to the stent graft biomaterials include fracture of the stent struts, fabric erosion by external calcific deposits, and fatigue fracture of the stent wires (Jacobs et al, 2003; Chuter, 2009; Diehm et al, 2009).

ENGINEERED VASCULAR GRAFTS

Engineered blood vessels are described in detail in Chapter II.6.9 of this book. Therefore, only a brief overview is included here. Conventional vascular grafts lined *in vitro* with autologous endothelial cells have been used in patients needing bypass of obstructed leg arteries, but who had no suitable saphenous vein available. Patency of endothelialized grafts was good, and explants are purported to show an endothelium following years of implantation (Deutsch et al, 2009).

Several approaches to fully-engineered vascular grafts have been pursued. Bell and colleagues postulated that cell-seeded living grafts could be grown *in vitro*. Vessel "equivalents" composed of collagen and cultured bovine fibroblasts, smooth muscle cells, and endothelial cells have been investigated, but despite reinforcement with a Dacron mesh such grafts have been unable to withstand burst strengths for *in vivo* applications (Weinberg and Bell, 1986). An approcah used by several groups has used vascular cells applied onto tubular resorbable polymer scaffolds matured *in vitro* in a bioreactor prior to *in vivo* implantation (Gong and Niklason, 2006). Shin'oka and colleagues applied the cell-scaffold-bioreactor approach clinically with successful use of cell-seeded polymers to repair congenital defects in the low-pressure pulmonary outflow tracts of pediatric patients. However, none of these approaches have yielded sufficient mechanical strength to warrant application of an engineered graft to adult arterial bypass. Exposure to pulsatile physical forces during *in vitro* bioreactor maturation generally enhances graft properties; pulsed grafts are thicker, have greater suture retention, higher cell and collagen density than nonpulsed engineered grafts, and have a histological appearance similar to that of native arteries (Solan et al, 2009). Another approach to vascular graft engineering utilizes naturally derived matrices with or without cell repopulation prior to implantation (Kaushall et al, 2001). Vascular grafts fabricated from small intestine submucosa used experimentally in dogs were reported to be completely endothelialized and histologically similar to arteries (Lantz et al, 1993).

Another approach to vascular engineering extends the concept of Sparks' silicone mandril-grown graft used clinically in the 1970s, in which a collagenous tube was formed as the fibrous capsule reactive to an implanted foreign-body (silicone mandril) adjacent to a diseased vessel; the mandril was subsequently removed, yielding an autologous tissue tube (Sparks, 1973). However, owing to the variability of the quality of tissue generated in older patients in areas of circulatory insufficiency, such vascular replacements frequently developed aneurysms when used clinically. Grafts grown as the reactive tissue that forms around silicone tubing inserted into the peritoneal cavity of rats, rabbits, and dogs, everted (so that mesothelial cells became the blood-contacting surface), and grafted into the carotid artery of the same animal remained patent for up to four months (Hoenig et al, 2005).

Other investigators have fabricated mechanically-sound engineered tissue vascular grafts by constructing a cohesive cellular sheet of smooth muscle cells, rolling this sheet to form the vessel media, analogous to a "jelly roll," and wrapping a sheet of human fibroblasts around the media to serve as an adventitia, and seeding endothelial cells in the lumen (L'Heureux et al, 1998). Cell-sheet technology seems to yield high cell density, which ensures synthesis and deposition of the proper amount of extracellular matrix. The technique involves rolling a monolayer of living fibroblast cells into a tubular tissue construct. The matured construct formed by the fused cell layers was then decellularized. A second concentric layer was fabricated by rolling a second monolayer of living fibroblast cells around the outside of the first tube. Finally, the tissue-engineered vascular tube biofabricated from two concentric acellular and cellular layers is seeded with autologous endothelial cells. Cell-sheet technology has been used to generate clinical arteriovenous fistulas for hemodialysis access and for other tissues (Elloumi-Hannachi, 2010). Recently, McAllister and co-workers reported a six-month follow-up for the first 10 patients implanted with a fully biological tissue-engineered graft used as access for hemodialysis, developed with cell-sheet tissue-engineering technology (McAllister et al, 2009).

C. OTHER CARDIOVASCULAR DEVICES

Robert F. Padera, Jr. and Frederick J. Schoen
Department of Pathology, Brigham and Women's Hospital and Harvard Medical School, Boston, MA, USA

INTRODUCTION

There are many life-saving and live-sustaining medical devices in clinical use and development to treat a wide variety of cardiovascular conditions; these devices are the subject of the current chapter. The treatment of arrhythmias by pacemakers and implantable cardioverter-defibrillators has been one of the major successes in modern medicine. Mechanical circulatory support devices, from cardiopulmonary bypass machines first introduced in the 1950s to the latest generation of ventricular assist devices, have both enabled development of advanced surgical procedures such as valve replacement and coronary artery bypass grafting (discussed in the previous sections), and have provided new tools in the armamentarium of heart failure therapies. Many devices take advantage of the development of percutaneous catheter-based techniques to treat cardiovascular disease in a minimally invasive manner, such as septal defect closure devices, filters to prevent pulmonary embolism and left atrial occlusion devices, and devices to minimize the consequences of a dilated, failing heart.

PACEMAKERS AND ICDS (FOR CARDIAC ARRHYTHMIAS)

The normal cardiac electrical cycle (Figure C.1A) begins with an impulse initiated by the sinoatrial (SA) node, the heart's natural pacemaker, which is located in the right atrium near the junction with the superior vena cava. The impulse spreads through the muscle of both left and right atrial walls, causing depolarization of the cardiac myocytes that result in atrial contraction. The impulse arrives at the atrioventricular (AV) node, which is in the posterior right atrium enclosed by the ostium of the coronary sinus, located in the septal leaflet of the tricuspid valve and the membranous portion of the interatrial septum (called the triangle of Koch). After a short delay within the AV node, the impulse passes to the bundle of His, and into the left and right bundle branches, located in the intraventricular septum. The impulse spreads through the right and left ventricular myocardium, causing a wave of myocyte depolarization and thereby coordinated ventricular contraction. The SA and AV nodes and the bundles of His and its right and left bundle branches are composed of cardiac muscle cells specialized for conduction.

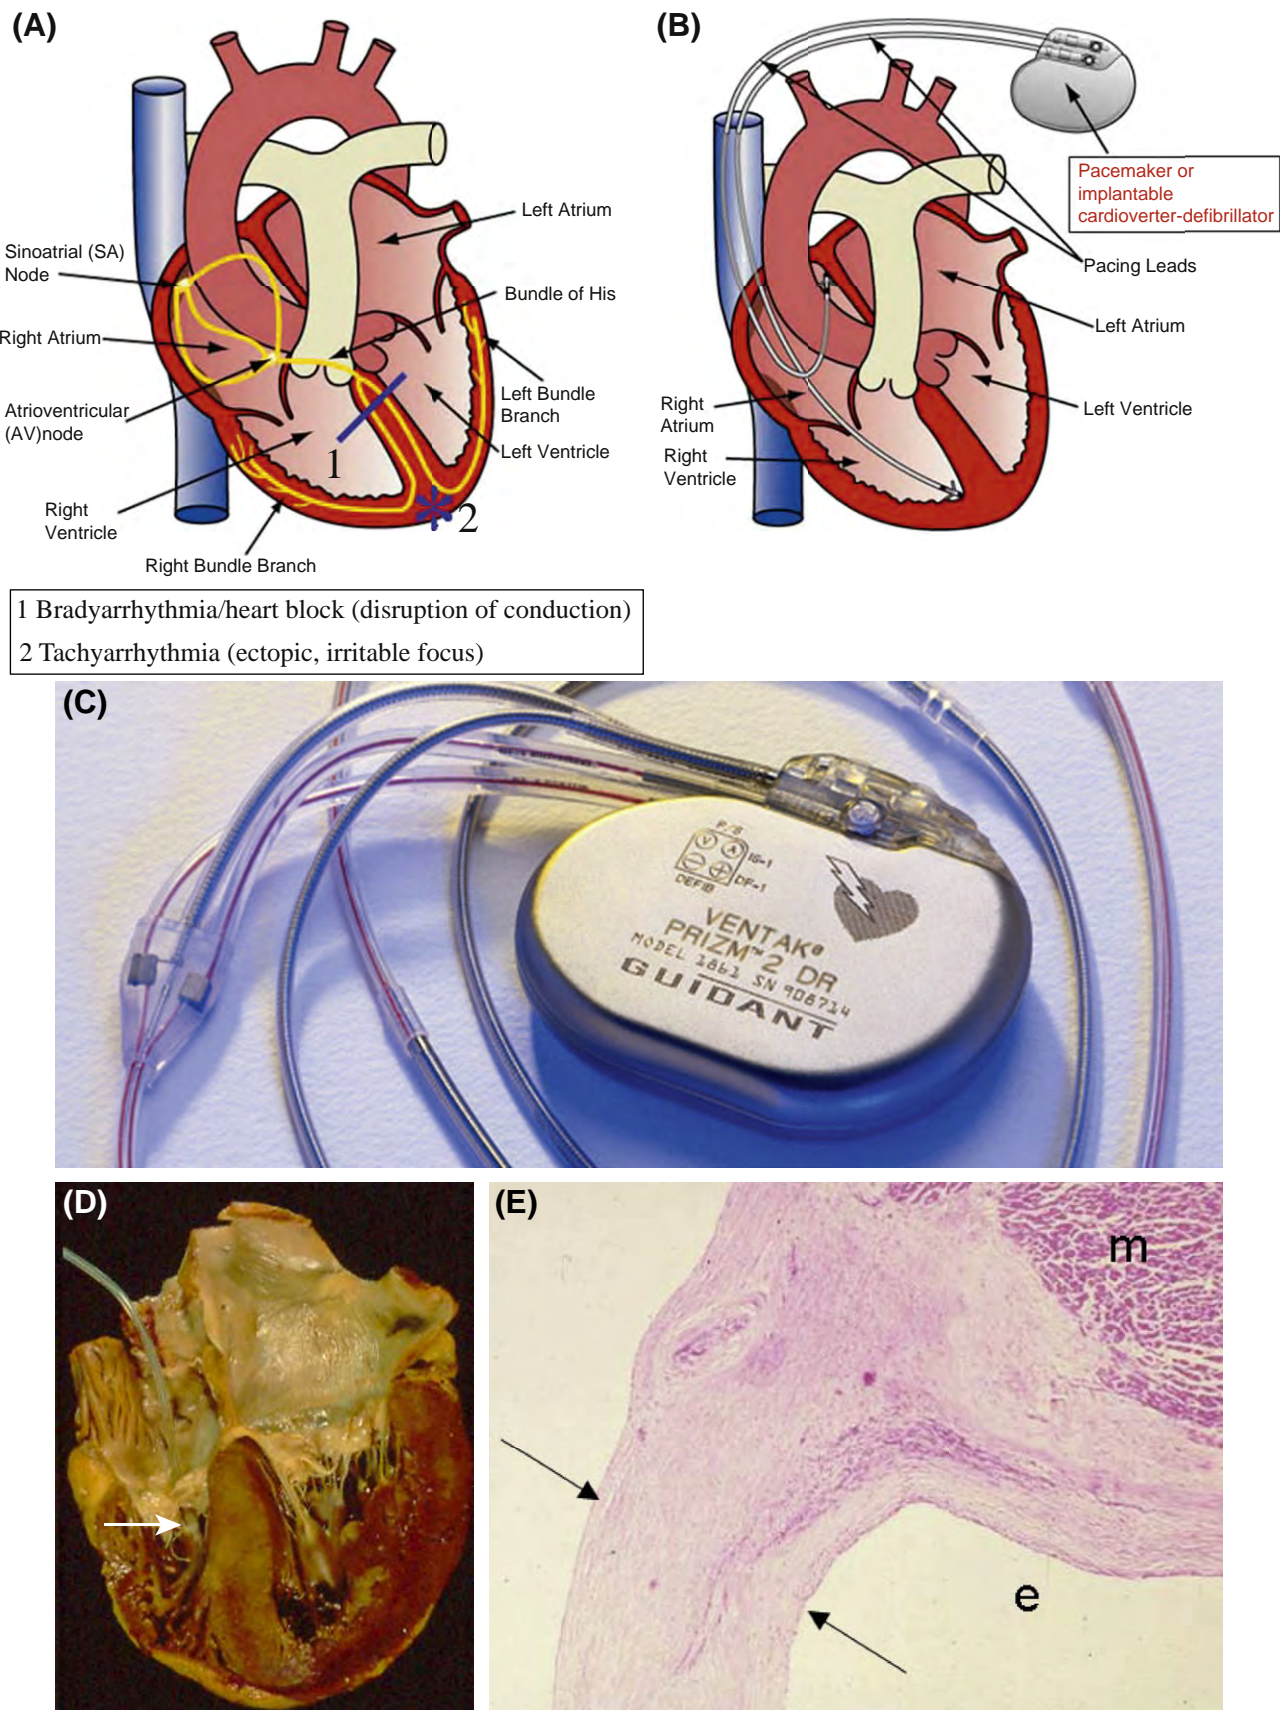
Cardiac arrhythmias (Huikuri et al., 2001) reflect disturbances of either impulse initiation or impulse conduction. Foci of impulse-generating (automatic) cells outside the SA node, called ectopic foci, may initiate cardiac impulses that generate suboptimal ventricular


FIGURE C.1 (A) The normal cardiac electrical cycle showing schematically both conduction blocks and ectopic foci of impulse generation. (B) Schematic demonstrating ICD lead placement in right ventricle. (C) Guidant Prizm II DR ICD, introduced to the US market in 2000, and withdrawn in 2005. (D) Transvenous pacing lead placed in right ventricle demonstrating fibrosis of the distal portion of the lead (arrow). (E) Fibrous capsule surrounding pacemaker electrode in right ventricle (see FIGURE C.1D). Low power photomicrograph demonstrating space previously occupied by electrode (e), fibrous tissue separating electrode from blood in the right ventricular chamber (between arrows) and extending around enlectrode to separate it from myocardium (m), potentially creating a barrier to conduction of the pacing impulse. ((E) Reproduced with permission from Schoen, F. J. & Edwards, W. D. (2001). Pathology of cardiovascular interventions, including endovascular therapies, revascularization, vascular replacement, cardiac assist/replacement, arrhythmia control and repaired congenital heart disease. contractions. These arrhythmias are usually fast, i.e., tachyarrhythmias, that can result in ventricular fibrillation, which can be fatal. Intrinsic SA node dysfunction can also account for disturbances of impulse initiation. In contrast, disturbances of impulse conduction mainly consist of conduction blocks or re-entry. Conduction blocks constitute a failure of propagation of the usual impulse through the specialized muscle as a result of a disease process (such as ischemia or inflammation) or certain drugs. Blocks can be complete (no impulse propagation) or incomplete (impulse propagates more slowly than normal), and can be permanent or transient. Re-entry is said to occur when a cardiac impulse traverses a loop of cardiac fibers and re-excites previously excited tissue without a second impulse from the SA node. For patients in whom these cardiac arrhythmias cannot be controlled pharmacologically by antiarrhythmic drugs, two therapeutic options are available: (1) electrical therapy to control the cardiac rhythm, such as direct current cardioversion or implantable devices such as pacemakers and implantable cardioverter-defibrillators; and (2) interventional/surgical therapy to remove the affected tissue or interrupt the abnormal pathway, such as endocardial resection, cryoablation or radiofrequency ablation.

Cardiac Pacemakers

Cardiac pacemakers are medical devices that provide impulses to the conduction system to initiate contraction. The first cardiac pacemaker was implanted (Atlee and Bernstein, 2001) in 1958, and since then cardiac pacing has become a well-established therapeutic tool. The first pacemakers were large (40–200 cm^3) by today's standards (9–45 cm^3), and contained few of the features that are standard in current devices. Over a million patients in the United States currently have pacemakers (Figure C.1B and C.1C), and over 250,000 new permanent pacemakers are implanted each year; pacemaker placement, revision or removal is a commonly performed procedure. Most cardiac pacemakers are implanted in patients older than 60 years, but they are also used in children, including infants, when necessary. The most common indications for permanent cardiac pacing are various types of conduction block. Some conduction blocks lead to bradycardia (abnormally low heart rate), while others, predominantly in the left or right bundles, will result in ventricular dyssynchrony and inefficient ventricular contraction in the setting of a normal heart rate. These conduction blocks can result in decreased cardiac output and the signs and symptoms of congestive heart failure, but can be well treated by cardiac pacing.

Modern cardiac pacing (Kusumoto and Goldschlager, 2002), either temporary or permanent, is achieved by a system of interconnected components consisting of: (1) a pulse generator which includes a power source and circuitry to initiate the electric stimulus and to sense cardiac electrical activity; (2) one or more electrically insulated conductors leading from the pulse generator to the heart, with a bipolar electrode at the distal end of each; and (3) a tissue or blood and tissue interface between electrode and adjacent stimulatable myocardial cells. The pacemaker delivers a small current (2–4 mA) to the myocardium via the electrodes, resulting in depolarization and contraction of the heart.

Temporary pacing is most frequently used for patients with acute myocardial infarction that is complicated by cardiac conduction system disturbances that could progress to complete heart block. Leads for temporary cardiac pacing are generally directed transvenously into the apex of the right ventricle, and the pulse generator is located outside the body. In the context of cardiac surgery when the epicardium is already exposed, temporary pacing is achieved by placing insulated wires with bare ends to the epicardial surfaces of the atria or ventricles with the leads emerging transthoracically from the anterior chest to permit easy withdrawal. Ultimately, the temporary pacemaker is either replaced by a permanent device or discontinued.

Permanent cardiac pacing involves long-term implantation of both pulse generator and electrode leads. The generator is placed in a tissue pocket beneath the skin on the left anterior chest with the leads advanced transvenously through the left subclavian vein to terminate at the endocardial surface of the heart. The tips of the electrodes are typically placed within the right atrium and/or right ventricle, depending on the pacing modality.

A single chamber pacemaker delivers a stimulus based on a programmed timing interval. The pacemaker also senses intrinsic cardiac activity, and can be inhibited from providing unnecessary or inappropriate stimuli. This "demand" pacing is valuable in a patient whose problem is intermittent. A dual chamber pacemaker with electrodes in both the atrium and ventricle delivers the sequential atrial and ventricular signals to approximate the timing of the normal heartbeat. This device also senses intrinsic atrial and ventricular depolarizations, and delivers stimuli at the appropriate time to maintain proper synchrony of the chambers.

Patients with ventricular conduction delays, such as left bundle branch block, may suffer from heart failure due to dyssynchrony of ventricular contraction, where the right and left ventricles do not contract simultaneously. Cardiac resynchronization therapy (CRT) via biventricular pacing is a recently implemented intervention in which pacing electrodes are placed in the right atrium, right ventricle, and coronary sinus. The coronary sinus electrode stimulates the lateral wall of the left ventricle to allow for simultaneous excitation of the right and left ventricles, and for more uniform contraction of the entire left ventricle. CRT has been shown to significantly improve cardiac function in these patients (McAlister et al., 2007).

Permanent implantable pacemakers are powered by lithium-iodide batteries with a finite lifespan of 5–8 years,

requiring removal and reimplantation of a new device when the battery is exhausted. In fact, that first patient to receive an implantable pacemaker in 1958 required 22 different pulse generators until his death in 2001 at the age of 86. Improving battery technology to allow for longer lifespan would minimize the number of reimplantations that a patient would require, and the complications that arise from these procedures.

The interface between the electrode and depolarizable myocardial tissue is of critical importance in the proper functioning of the pacemaker (Figure C.1D). Typically, a layer of nonexcitable fibrous tissue induced by the electrode forms around the tip of the electrode, which is undesirable as it increases the strength of the threshold pacing stimulus required to initiate myocyte depolarization (Figure C.1E). Strategies to reduce this fibrosis include improved lead designs, and the use of slow local release of corticosteroids to minimize the thickness of fibrous tissue formed after lead implantation (Mond and Grenz, 2004). The practical point is that, if the pulse generator output is not set sufficiently high in the early post-implantation phase, loss of pacing with potentially fatal consequences can result. By contrast, maintaining output at such high levels once thresholds have stabilized greatly shortens battery life. Thus, pacemakers with adjustable variations in output have been developed.

An ideal endocardial pacing lead should provide stable fixation immediately from the time of implantation, achieve and maintain a minimal threshold for stimulation, maximize sensing, and function reliably for many years. Electrode fixation to the endocardium may be active or passive. In active fixation, the electrode is designed to grasp the endocardial surface to achieve immediate fixation at implantation. A very effective aid to passive fixation is the addition of projecting "tines" or fins, in the region of the electrode tip. A different approach to improving fixation has been the development of electrodes with porous metal surfaces to foster tissue ingrowth. An endocardial pacemaker lead may require a special design if it is implanted at a particular site. One example is the J-shaped atrial lead, which is curved to facilitate placing the electrode tip in the right atrial appendage, inherently the most stable site for fixation.

Implantable Cardioverter-Defibrillators (ICDs)

The first implantable cardioverter-defibrillator was placed in 1980; currently more than 100,000 ICDs are implanted annually in the United States. The goal of ICDs is to prevent sudden death in patients with certain life-threatening arrhythmias by resetting the heart's electrical activity and stimulating a normal cardiac rhythm. ICDs have been shown to revert sustained ventricular tachycardia (abnormally high ventricular rate) and ventricular fibrillation (uncoordinated electrical/myocardial

activity) in multiple prospective clinical trials. Benefit in overall mortality has been well-documented (The Antiarrhythmics versus Implantable Defibrillators (AVID) Investigators, 1997).

An ICD consists of similar components to a pacemaker, namely a pulse generator and leads for tachydysrhythmia detection and therapy. The pulse generator is a self-powered, self-contained computer with one or two 3.2 V lithium-silver vanadium oxide batteries used to power all components of the system, including aluminum electrolytic storage capacitors. The devices have a service life of 3–5 years, at which point they require removal and implantation of a new device. The lead is generally placed in the right ventricle through a transvenous approach. The ICD constantly monitors the ventricular rate, and when the rate exceeds a certain value, provides therapy. Current devices will initially provide a short burst of rapid ventricular pacing that terminates some types of ventricular tachyarrhythmias without providing a large shock. This approach can terminate up to 96% of episodes of ventricular tachycardia without the need for a shock. If this pacing fails to break the arrhythmia, the ICD delivers a shock of 10–30 Joules between the electrode in the right ventricle and the surface of the pulse generator to terminate the dysrhythmic episode. These devices also keep a running record of arrhythmias and treatment results. ICDs are indicated in patients at high risk for ventricular arrhythmias (primary prevention), and in patients who have already had an episode of aborted sudden cardiac death (secondary prevention).

Complications of Pacemakers and ICDs

These devices share many of the same complications, many of them requiring device removal and replacement. Like many cardiovascular devices, these are life sustaining technologies, and the implications of device failure can be fatal due to a lack of appropriate cardiac pacing (for pacemakers) or inability to sense or deliver appropriate therapy for a lethal arrhythmia (for ICDs). While normal device end-of-service from a depleted battery may not be technically considered a device malfunction, it certainly requires device replacement, and may happen prematurely due to increased fibrosis at the lead–tissue interface requiring a higher stimulus threshold. Failures of the hardware, including the battery/capacitor and charge circuit, connectors and leads are the most common device malfunctions, with software problems being less prevalent. Some mechanical failures include electrode dislodgment, lead fractures, electrode corrosion, and insulation failure. Complications related to leads may be related to the body of the lead, as distinct from the lead-device pack interface or the electrodes. Several devices and components have been recalled in recent years for these modes of failure (Amin and Ellenbogen, 2010). Lead improvements over the years have included

helical coil and multifilament designs, to decrease electrical resistance and enhance flexibility and durability (Haqqani and Mond, 2009). In the past, many reports appeared on interference with pacemaker function by devices ranging from electric razors, toothbrushes, and microwave ovens at home, to electrosurgical and diathermy apparatus in hospitals. Fortunately, recent generations of cardiac pacemakers have been greatly improved with regard to their resistance to electromagnetic interference.

Many complications relate to the interaction of the device biomaterials with the host tissue. These include infection, thrombosis, and thromboembolism, myocardial penetration or perforation, pressure necrosis of the skin overlying the pulse generator, and migration or rotation of the pulse generator. Infection is a dreaded complication of implantable devices in general, and is this is certainly true for pacemakers and ICDs (Uslan, 2008). The infection may originate in the subcutaneous pocket and track along the lead, which acts as a contaminated foreign-body. Alternatively, it may occur by implantation of bacteria on traumatized endocardium or thrombus contiguous with the lead. The most common organisms responsible for these infections are coagulase-negative *Staphylococcus* species such as *S. epidermidis*. Septicemia may develop, and septic pulmonary emboli may occur. The fundamental therapeutic principle in device-related endocarditis is treatment of the infection with antibiotics, followed by removal of at least the lead and, when the pacemaker pocket is involved, the entire pacing system (Baddour et al., 2010).

ICDs contain more extensive hardware than pacemakers, and this may contribute an increased relative frequency of complications. Several additional considerations are specific to ICDs. The consequences of repeated defibrillations can cause the following effects: (1) direct effect of repeated discharges on the myocardium and vascular structures; and (2) possible thrombogenic potential of the indwelling intravascular electrodes. Another major complication of ICDs from the standpoint of the patient, other than the inability to sense or terminate an arrhythmia leading to sudden death, is an inappropriate shock. In addition to being startling and quite painful at the time of the shock, patients receiving multiple inappropriate shocks have been known to develop post-traumatic stress disorder symptoms.

As mentioned above, the leads are designed to optimize their interactions with the adjacent myocardium; this can be problematic when a complication arises in which the leads must be removed. Some leads can be removed by prolonged gentle traction, but many require additional tools and techniques to free them from the venous wall, through which the body of the lead travels, and from the myocardium, to which they are often tenaciously adherent (Smith and Love, 2008). Recourse to cardiotomy with cardiopulmonary bypass may be needed if the lead is densely incarcerated in fibrous tissue.

CARDIAC ASSIST AND REPLACEMENT DEVICES (FOR HEART FAILURE)

Heart Failure and Treatment Options

Congestive heart failure (Jessup and Brozena, 2003) is a deficiency of the pumping function of the heart, and is an extremely common condition, affecting approximately 5.8 million Americans. Each year in the US, congestive heart failure is the principal cause of death in 60,000 individuals, a contributing factor in over 280,000 deaths, and the primary discharge diagnosis in over 1.1 million hospitalizations, all increases over previous years. Cardiac transplantation is a potential solution for some of these patients (Mancini and Lietz, 2010). However, the increasing discrepancy between the number of acceptable donor hearts (only 2500 per year) and the large number of patients who might benefit from cardiac transplantation (estimated at greater than 100,000 per year) has prompted efforts towards the development of mechanical devices to augment or replace cardiac function (Baughman and Jarcho, 2007; Boilson et al., 2010; Krishnamani et al., 2010).

Congestive heart failure is the final common pathway of many cardiac conditions, including valvular heart disease, coronary artery atherosclerosis with resultant ischemic heart disease, and diseases that affect the cardiac muscle directly (termed cardiomyopathies). Heart failure can occur precipitously, as in myocardial infarction or viral myocarditis, or it can be a slow, progressive worsening of exercise tolerance and shortness of breath over many months or years owing to ongoing deterioration of the heart muscle. It can manifest itself in the postoperative period after both cardiac surgery (e.g., valve replacement, cardiac transplantation) and non-cardiac surgery (e.g., abdominal aortic aneurysm repair).

As one might expect, therefore, the natural history of heart failure depends on the cause and progression of the underlying disease process. For example, patients with heart failure after cardiac surgery (called postcardiotomy shock) often recover the vast majority of their cardiac function after a short period of time if they are otherwise sustained by mechanical circulatory support. In contrast, patients with dilated cardiomyopathy, one of the most common indications for cardiac transplantation, often need long-term mechanical support; studies have shown that at least 50% of such individuals would die in 3–5 years from their disease without it. One must take these clinical considerations into account when designing mechanical support systems, as different devices may best serve patients with different problems (DiGiorgi et al., 2003).

Cardiopulmonary Bypass

First used in 1953 by Dr. John H. Gibbon, cardiopulmonary bypass devices pump blood external to the body,

and thereby permit complex cardiac surgical procedures to be done safely and effectively. Bypass machines are useful in extracorporeal membrane oxygenation (ECMO) to assist in the transport of oxygen and carbon dioxide for patients (especially neonates and infants) with pulmonary diseases such as the respiratory distress syndrome (Alpard and Zwischenberger, 2002).

The basic operating principles of the current heart-lung machines are quite straightforward, and have changed little in the past half century. Deoxygenated blood returning from the systemic circulation into the right atrium is withdrawn by gravity siphon into a cardiotomy reservoir, and is then pumped into an oxygenator. The most common type of oxygenator is a membrane oxygenator, where oxygen is passed through the tube side of a shell-and-tube type device, while the blood passes through the shell side. Oxygen and carbon dioxide are exchanged via diffusion through synthetic membranes (usually polypropylene or silicone) with high permeability to these respiratory gases. The oxygenated blood is then passed through a heat exchanger to adjust the temperature of the blood, and the blood is returned to the systemic circulation via the aorta. At the beginning of the procedure, the patient is anticoagulated with heparin to reduce the risk of thrombosis within the device; as the patient is weaned from bypass, the anticoagulation can be quickly reversed by the use of a drug called protamine. During an operation, the heat exchanger lowers the temperature of the blood and therefore the core body temperature, decreasing the metabolic requirements of the body and protecting the organs (including the heart) against ischemic damage. At the end of the operation, the blood can be warmed to normal physiologic temperature as the patient is weaned from the bypass machine. A specially trained perfusionist controls the operation of the heart-lung machine, allowing the surgeon and anesthesiologist to concentrate on their respective tasks. This device, therefore, provides the function of both the heart (maintaining systemic blood flow and pressure) and the lungs (oxygenating blood and removing carbon dioxide), allowing the heart to be effectively stopped for delicate surgical procedures that would be more difficult or impossible to perform on a beating, moving heart.

Many improvements to the original design of cardiopulmonary bypass machines have been made since their inception. One of the problems with the original heart-lung machines was the trauma that they would cause to the blood cells. Hemolysis of red blood cells would lead to functional anemia and loss of oxygen carrying capacity of the blood; damage to platelets would lead to thrombocytopenia (low numbers of or dysfunctional platelets), resulting in bleeding problems. The problem of blood cell damage has been largely overcome with advanced pump designs and the use of the membrane oxygenators. Roller pumps and centrifugal pumps are commonly used, because they cause a lower degree of hemolysis and shear forces; it is important in the design of these pumps to determine the optimum balance between pumping function and hemolysis/shear stress to the formed blood elements. Bubble oxygenators, which directly pass bubbles of oxygen gas through the blood, cause more hemolysis, protein denaturation, and platelet dysfunction than membrane oxygenators, and are currently less frequently used. In addition, newer devices allow blood that has escaped the circulation within the sterile operating field around the heart to be processed and returned to the patient, reducing the need for blood transfusion during the procedure.

Cardiopulmonary bypass can result in many pathophysiologic changes, including complement activation from the prolonged interaction of blood with synthetic surfaces, platelet and neutrophil activation and aggregation, changes in systemic vascular resistance, and expression of other proinflammatory mediators (Levy and Tanaka, 2003). When these changes are severe, the use of the heart-lung machine can result in complications including confusion, renal insufficiency, pulmonary dysfunction, low-grade hepatic dysfunction, and increased susceptibility to infection. Together, these manifestations are termed the postperfusion syndrome. The last decade has seen the development of mini-extracorporeal circuit (MECC) cardiopulmonary bypass systems (Curtis et al., 2010) with a goal of providing cardiopulmonary bypass with a reduction in this harmful systemic inflammatory response. The MECC has a greatly reduced tubing length, smaller priming volumes, reduction in the blood–air interface, and fewer components than the standard bypass systems, and it utilizes heparin-coating components and centrifugal blood pumps. These systems show a reduction in post-operative cytokine levels, organ damage, post-operative complications, and the need for blood transfusions, compared to standard circuits (Vohra et al., 2009).

Intra-Aortic Balloon Pumps

Since the original use of the intra-aortic balloon pump (IABP) in 1968 by Kantrowitz, the basic design and function of the current device has remained relatively similar during the ensuing decades, but the indications for IABP have increased; an estimated 42,000 patients received IABPs in the US in 2002 (Lee and Makkar, 2006). The typical patient is critically ill with acute cardiogenic shock, mechanical complications of myocardial infarction such as ventricular septal or papillary muscle rupture, unrelenting ventricular arrhythmias or advanced heart failure. Also, patients undergoing high-risk cardiac surgical procedures or percutaneous revascularization may benefit from the use of devices in the peri-procedure period. IABPs (Figure C.2) are catheter-based polyethylene or polyurethane balloons with volumes of 25–50 ml, although smaller devices are used in the pediatric population. Helium is most often used as the inflating gas;

FIGURE C.2 Percutaneous intra-aortic balloon pump. Left: Balloon deflated for insertion. Right: Balloon inflated. (Courtesy S. Volvek, Datascope Corp., Oakland, NJ.)

blood to the myocardium. In addition, left ventricular afterload (the pressure the myocardium must attain to pump blood into the aorta) is decreased, reducing the workload and therefore the oxygen requirement of the myocardium. The combination of these two hemodynamic factors therefore improves the balance between myocardial oxygen supply and demand, and results in improved cardiac performance. The device also directly improves systemic circulation to a modest degree (approximately 10%).

IABP therapy permits the heart to rest and recover enough function to support adequate circulation after the device has been removed, usually after only a few days. The major contraindications for IABP use include severe peripheral vascular disease including aneurysms, aortic valve regurgitation, and aortic dissection (owing to the need to thread the balloon through peripheral arteries and the aorta). Complications, which occur in approximately 7% of patients with IABPs in a recent registry study, include limb ischemia from insertion site problems, bleeding, thrombosis with embolization, aortic dissection, balloon rupture, and sepsis.

Ventricular Assist Devices and Total Artificial Hearts

Ventricular assist devices are used primarily in three settings: (1) for potentially reversible heart failure, in which cardiac function is likely to recover with cardiac rest (e.g., postcardiotomy shock); (2) for end-stage cardiac failure not likely to recover, and where mechanical support will provide a bridge to transplantation; and (3) for long-term cardiac support for patients with end-stage congestive heart failure that are not transplant candidates (so-called "destination therapy") (Christiansen et al., 2008). LVADs are also being investigated as a "bridge-to-recovery" in patients with congestive heart failure to induce ventricular changes that might improve cardiac function and eventually allow device removal. Research in this area focuses on the mechanisms of cardiac recovery, identification of patients who could achieve recovery, and specifics such as the timing and duration of therapy (Maybaum et al., 2008; Birks, 2010).

Ventricular assist devices, first successfully employed by DeBakey in 1963, can replace ventricular function for extended periods, in contrast to the short-term duration of cardiopulmonary bypass or IABP use. The earliest devices used for bridge-to-transplant or destination therapy (Hunt and Frazier, 1998) were large, pulsatile systems, with the inflow cannula of the device generally connected to the left ventricular apex, and the outflow cannula connected to the ascending aorta. The pump itself would either be implanted in the peritoneal cavity with a driveline traversing the skin to provide power and controller functions or would remain extracorporeal with the inflow and outflow cannulae each traversing the skin. Over the past decade there has been a seismic

its low viscosity allows for rapid inflation and deflation, and it is rapidly dissolved in the bloodstream in the event of inadvertent balloon rupture.

IABPs (Baskett et al., 2002; De Sousa et al., 2010) are generally positioned under fluoroscopic guidance in the descending thoracic aorta after percutaneous insertion via the femoral artery. They are timed to inflate during diastole (ventricular filling) and deflate during systole (ventricular contraction), using the patient's electrocardiogram or arterial pressure curve for synchronization. This is counter-pulsation (Trost and Hillis, 2006), which is out of phase with the patient's heartbeat, and causes volume displacement of blood proximally and distally within the aorta. Several beneficial effects serve to improve cardiac function. Coronary blood flow (the majority of which occurs in diastole) is increased by the rise in diastolic pressure, delivering more oxygenated

FIGURE C.3 Diagrams of pulsatile (A) and continuous flow (B) left ventricular assist devices, and total artificial heart (C). ((A), (B) Reproduced with permission from Slaughter, M. S. et al. (2009). Advanced heart failure treated with continuous-flow left ventricular assist device. N. Engl. J. Med. 361: 2241–2251; (C) Reproduced with permission from Copeland, J. G. et al. (2004). Cardiac replacement with a total artificial heart as a bridge to transplantation. N. Engl. J. Med. 351: 859–867.)

shift away from these pulsatile devices to so-called "continuous flow" devices, both for bridge-to-transplant and destination therapy (Figure C.3A and C.3B) (Slaughter et al., 2009). These devices, which are comprised of axial or centrifugal pumps along with similar inflow and outflow cannulae and drivelines to the pulsatile systems, are much smaller, more easily implanted, and provide continuous flow for augmentation of cardiac output. In contrast to VADs, where the native heart remains in place, a total artificial heart is composed of two pumping chambers which together replace the entire heart and provide both right and left ventricular function, analogous to heart transplantation (Figure C.3C). Percutaneous VADs, which can be quickly deployed in a manner similar to IABPs, have been developed for short-term applications such as acute cardiogenic shock, and support for high-risk interventional procedures (Sarkar and Kini, 2010).

The major complications of cardiac assist devices, as they have been since the inception of this therapy, are hemorrhage, thrombosis/thromboembolism, infection and device component failure, including the pump and

electrical systems (Figure C.4). Hemorrhage continues to be a problem in device recipients, with many predisposing factors including: (1) anticoagulation therapy and its management along with coagulopathy secondary to liver dysfunction and poor nutritional status; (2) contact of the blood with the device, resulting in intrinsic platelet dysfunction and acquired von Willebrand disease; and (3) the extensive nature of the required surgery. In the absence of adequate anticoagulation, and despite the development of minimally thrombogenic blood-contacting surfaces and appropriate blood flow characteristics, thrombi can form in areas of disturbed blood flow such as connections of conduits and other components to each other and to the natural heart. These thrombi can detach and lead to catastrophic embolic events such as ischemic stroke. Infectious complications have been a major limiting factor in the prolonged use of cardiac assist devices (Padera, 2006). Infection can occur within the device, but may also be associated with the percutaneous pneumatic or electrical lines. These infections are a significant cause of morbidity and mortality, and are often resistant to antibiotic therapy and host defenses.

MISCELLANEOUS CARDIOVASCULAR DEVICES

Closure Devices: Patent Ductus Arteriosus, Patent Foramen Ovale, Atrial, and Ventricular Septal Defects

In prenatal life, the circulation is different than it is in postnatal life (Schoen, 1999). The lungs of the fetus are not expanding, and oxygenation of fetal blood is provided via the placenta and maternal circulation. This requires two important shunts that need to close immediately after birth. The foramen ovale, a hole in the fetal intra-atrial septum, allows oxygenated blood returning to the right atrium from the placenta to preferentially pass into the left atrium. This blood passes through the mitral valve into the left ventricle, and is pumped out through the aorta into the systemic circulation. The ductus arteriosus, present between the pulmonary artery and aorta, allows deoxygenated blood pumped from the right ventricle to bypass the lungs and directly re-enter the systemic circulation, as the prenatal pulmonary circulation has a high vascular resistance (owing to the non-expanded lungs). After birth, these functional shunts should close to completely separate the right and left circulations; failure to do so results in a patent foramen ovale (PFO) or patent ductus arteriosus (PDA) that can allow inappropriate shunting of blood in the postnatal circulation. In addition, atrial septal defects (ASDs) or ventricular septal defects (VSDs) can also result from abnormal formation of the atrial septum or ventricular septum. While these defects can be

closed via an open surgical procedure (sutures and/or fabric patches for PFO, ASD or VSD, ligation for PDA), efforts have been made to allow closure of these defects using a minimally invasive approach (Hornung et al., 2002). The decision to close a PFO, ASD, VSD or PDA depends on the size of the shunt and the symptoms of the patient.

The first catheter-based closure of a PDA was performed in 1967 by Porstmann using an Ivalon plug to occlude flow through the ductus arteriosus. Of the many PDA closure devices that have been developed over the years, most are metal-based devices that work by causing thrombosis of the PDA with subsequent organization and fibrosis, permanently preventing flow through the residual ductus arteriosus. Two of the more commonly used devices are the Gianturco coil (a stainless steel coil containing polyester fibers to promote thrombosis), and the Amplatzer duct occluder (a conical device consisting of Nitinol wires and a polyester fiber patch to promote thrombosis and tissue integration).

Mills and King reported the first transcatheter closure of an ASD in 1976 using a double umbrella device that covered the opening both from the right and left atrial sides. Their occlusion device consisted of a skeleton of ePTFE coated wire supporting an occluder of Dacron fabric delivered through a catheter. Improvements over the years include better device fixation methods and smaller caliber introducers. Several designs of PFO/ASD closure devices are currently in use (Kim et al., 2007). The Amplatzer device (AGA Medical Corp., Golden Valley, MN) consists of double Nitinol discs filled with polyester patches connected by a small waist; the waist sits within the defect to connect the discs, which sit on either side of and are selected to be larger than the defect. The StarFLEX (NMT Medical, Boston, MA) device is a double umbrella device with metallic arms covered in polyester fabric; the two umbrellas are connected centrally. The Helex (W. L. Gore and Associates, Flagstaff, AZ) is a single Nitinol wire in a helical configuration which is covered by an expanded polytetrafluoroethylene patch. These devices are shown in Figure C.5. Advantages of nonsurgical closure devices such as these include a shorter hospital stay, more rapid recovery, and no residual thoracotomy scar. With the experience gained in the transcatheter closure of PFOs and ASDs, this interventional technology is being extended to the closure of some VSDs, particularly in patients thought to be poor operative risks.

Several types of complications have been reported for closure devices. The most straightforward is the failure to fully close the defect, resulting in residual shunting. These devices work to close the defects at least in part via thrombosis; if the thrombosis extends beyond the defect on the device, thromboemboli may result. Inadequate fixation of the device within the defect or a device-defect size mismatch can result in device embolization.

Fractures of various device components, air embolism at the time of device deployment, infection, device erosion through adjacent tissues with perforation, and development of new arrhythmias have also been reported. A number of devices are in development, with the trends being defect-specific design and minimization of the amount of foreign material left in the patient, including the use of biodegradable components (Majunke and Sievert, 2007).

Inferior Vena Cava Filters: Deep Venous Thrombosis and Pulmonary Embolus

Venous thromboembolic disease is a significant cause of morbidity and mortality, largely due to the complication of pulmonary embolism (PE). The most common scenario is for a thrombus to form in the deep venous system of the lower extremities (so-called deep venous thrombus or DVT), become detached from the wall of the vein, travel through the inferior vena cava to the right side of the heart, and lodge as an embolus in one of the large branches of the pulmonary artery. First-line therapy for patients with DVT or PE involves anticoagulation with warfarin and/or low molecular weight heparin. However, when anticoagulation is contraindicated due to active or threatened bleeding or when there is recurrent DVT/PE despite adequate anticoagulation, placement of an inferior vena cava (IVC) filter is often indicated (Crowther, 2007).

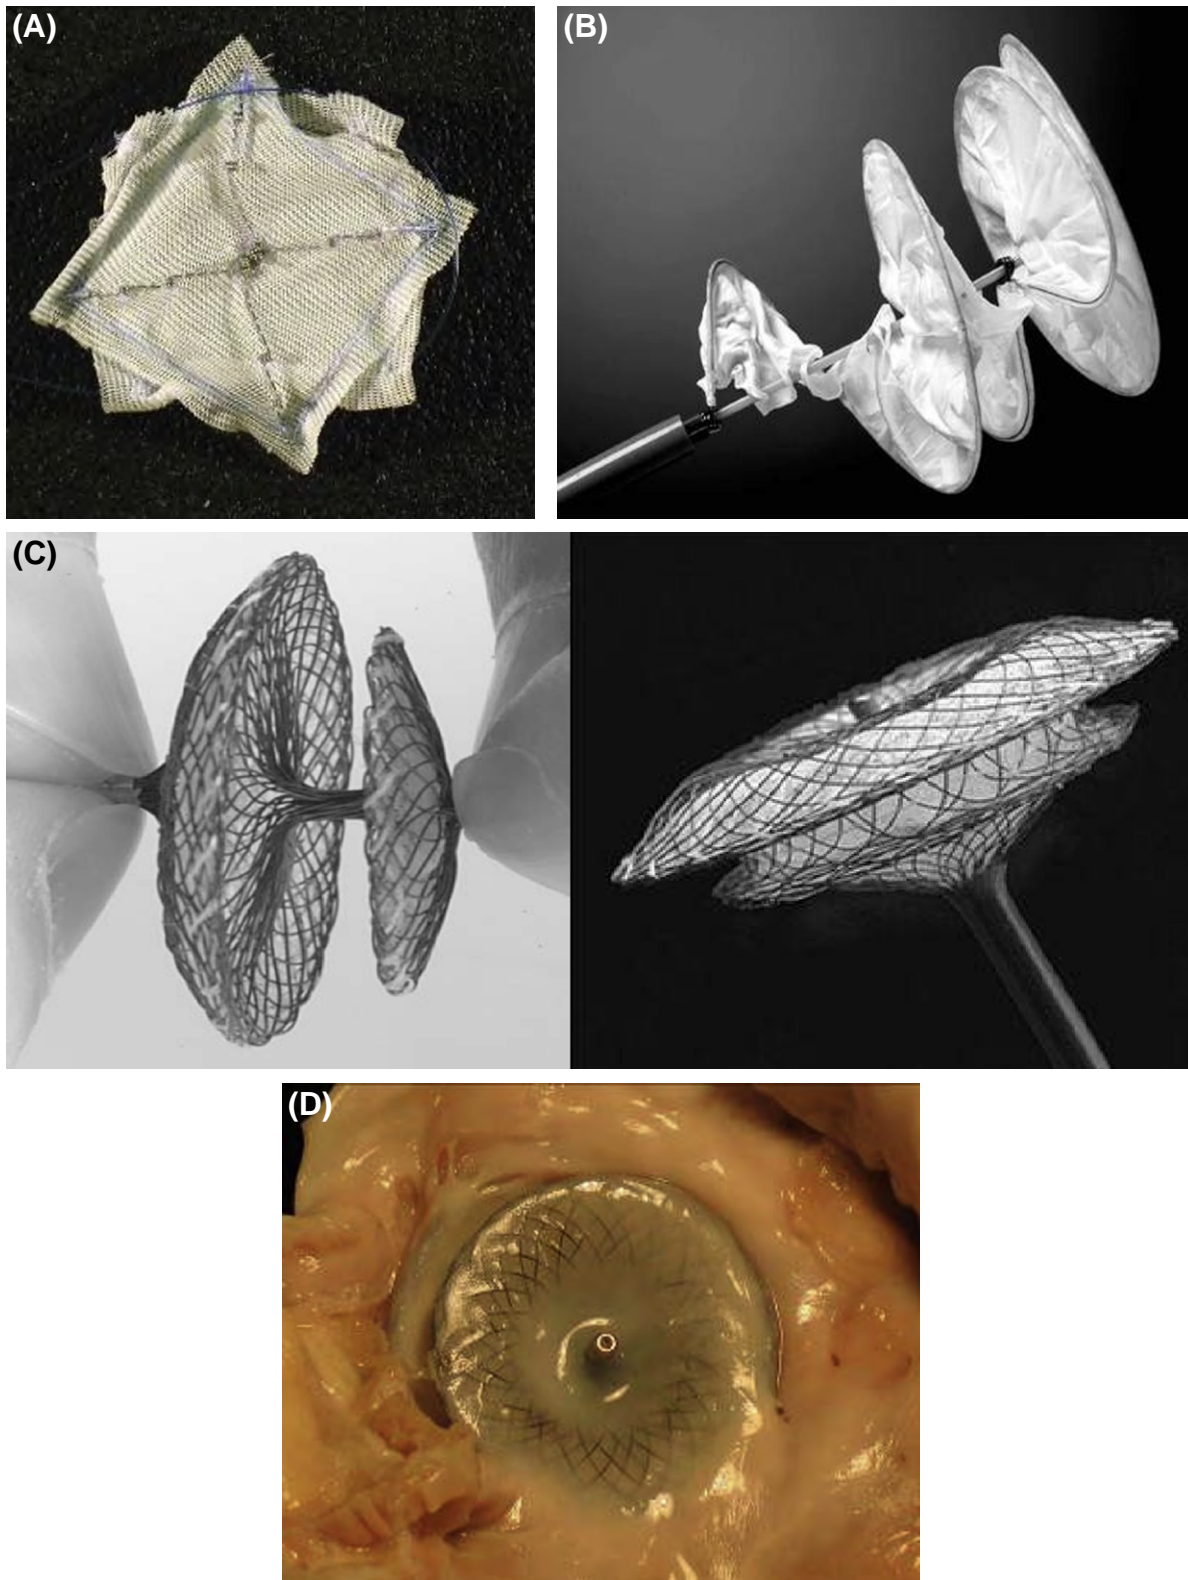
The concept of placing a barrier to catch DVTs destined for the pulmonary circulation dates back to Trousseau in the 1860s, but such filters did not become clinical reality until the late 1960s (Greenfield and Michna, 1988). Prior to the development of these devices, surgical ligation of the IVC during an open abdominal operation was performed. Interventional radiologists began to place filters using a minimally invasive percutaneous approach in the 1980s, and currently about 50,000 devices are implanted in the US annually. Five types of permanent IVC filters are commonly used in current clinical practice whose common design elements include metallic wires in a configuration to catch emboli in the bloodstream, a mechanism to anchor the device securely to the wall of the IVC, and an ability to be deployed through a catheter percutaneously. These devices (Streiff, 2000) include the two Greenfield-style filters (one titanium and one stainless steel), the Bird's nest filter (stainless steel), the Simon nitinol filter (nickel-titanium allow with thermal memory properties), and the Vena Tech filter (alloy of cobalt, chromium, iron, nickel, molybdenum, magnesium, carbon, and beryllium). Retrievable IVC filters (Figure C.6) have been developed which can be left in place indefinitely or removed after a period of time percutaneously. Contraindications for anticoagulation (and thus the indications for the device) are often temporary, so retrievable IVC filters will allow device removal after safe and adequate anticoagulation is


FIGURE C.5 (A) CardioSEAL septal repair device. Helex septal occluder device. (C) (B) Amplatzer ASO occluder device, constructed of woven nitinol with a fabric core. Implantation requires an adequate rim of tissue around the defect to secure the device and prevent migration or embolism of the device. Tissue ingrowth into the interstices of the fabric typically provides effective sealing within a few months following implantation. Amplatzer™ occluders specifically designed for closure of defects of the atrial or ventricular septum, patent ductus and patent foramen ovale are available. possible for the patient, thereby reducing the possibility of developing device-related complications (Tschoe et al., 2009).

Complications of these devices include thrombosis at the insertion site, thrombi forming on the filter itself, thrombosis and obstruction of the IVC, migration or tilting of the device, filter fracture, and penetration of the IVC wall. Current research involves creating devices: (1) with a lower profile to make insertion easier and reduce insertion site thrombosis; (2) that could be converted into a stent when no longer needed; and (3) that could degrade and potentially release therapeutics. Research is also ongoing to evolve the existing devices with the goal of catching potentially lethal emboli while maintaining adequate vena caval blood flow. As these devices have become safer and more effective, the indications for their use have expanded

and clinical trials are ongoing to determine their most appropriate use.

Left Atrial Appendage Occlusion Devices

Atrial fibrillation (AF) affects more than three million individuals in the US, making it the most common cardiac arrhythmia. Instead of orderly atrial contraction initiated by the SA node, rapid disorganized electrical activity in the atria causes these upper chambers of the heart to quiver or fibrillate, resulting in poor contractile function and irregular flow within the chamber. As would be predicted by Virchow's triad, thrombosis may occur due to these flow abnormalities within the atria, especially within the atrial appendage. Atrial appendage thrombi are thought to be the source of thromboemboli, explaining why patients with AF are at a five-fold greater risk for embolic stroke than people in sinus rhythm. Anticoagulation with warfarin is effective in reducing the risk of atrial thrombosis and stroke, but this therapy has many drawbacks including a narrow therapeutic window, variability in metabolism of the drug, interactions with other drugs and metabolites, need for frequent monitoring by blood drawing, poor patient compliance and, most importantly, the risk of life-threatening bleeding. An approach for reducing the risk of thromboembolic stroke in patients with AF is to remove or ligate the left atrial appendage, first proposed in the 1930s and first performed in 1949, via a surgical approach. Nonsurgical approaches to close the left atrial appendage have been developed, and include several devices that can be deployed percutaneously to occlude the opening to the appendage and isolate it from the blood in the left atrium (Maisel, 2009). The Watchman (Figure C.7) left atrial appendage system (Atritech Inc., Plymouth, MN) is a percutaneously deployed parachute-shaped device consisting of a Nitinol cage with a polytetrafluoroethylene membrane on its surface, and fixation barbs along the perimeter which allow it to anchor in the atrial appendage. This device has been shown to be non-inferior to standard warfarin therapy in a recent clinical trial (Holmes et al., 2009). Other devices that have been used or are in development include the Amplatzer (AGA Medical Corp., Golden Valley, MN) cardiac plug, the PLAATO (ev3 Endovascular, Plymouth, MN) system (which is no longer available), and the biodegradable Transcatheter Patch (Custom Medical Devices, Athens, Greece), along with several epicardial clip systems (Singh and Holmes, 2010).

Cardiac Support Devices

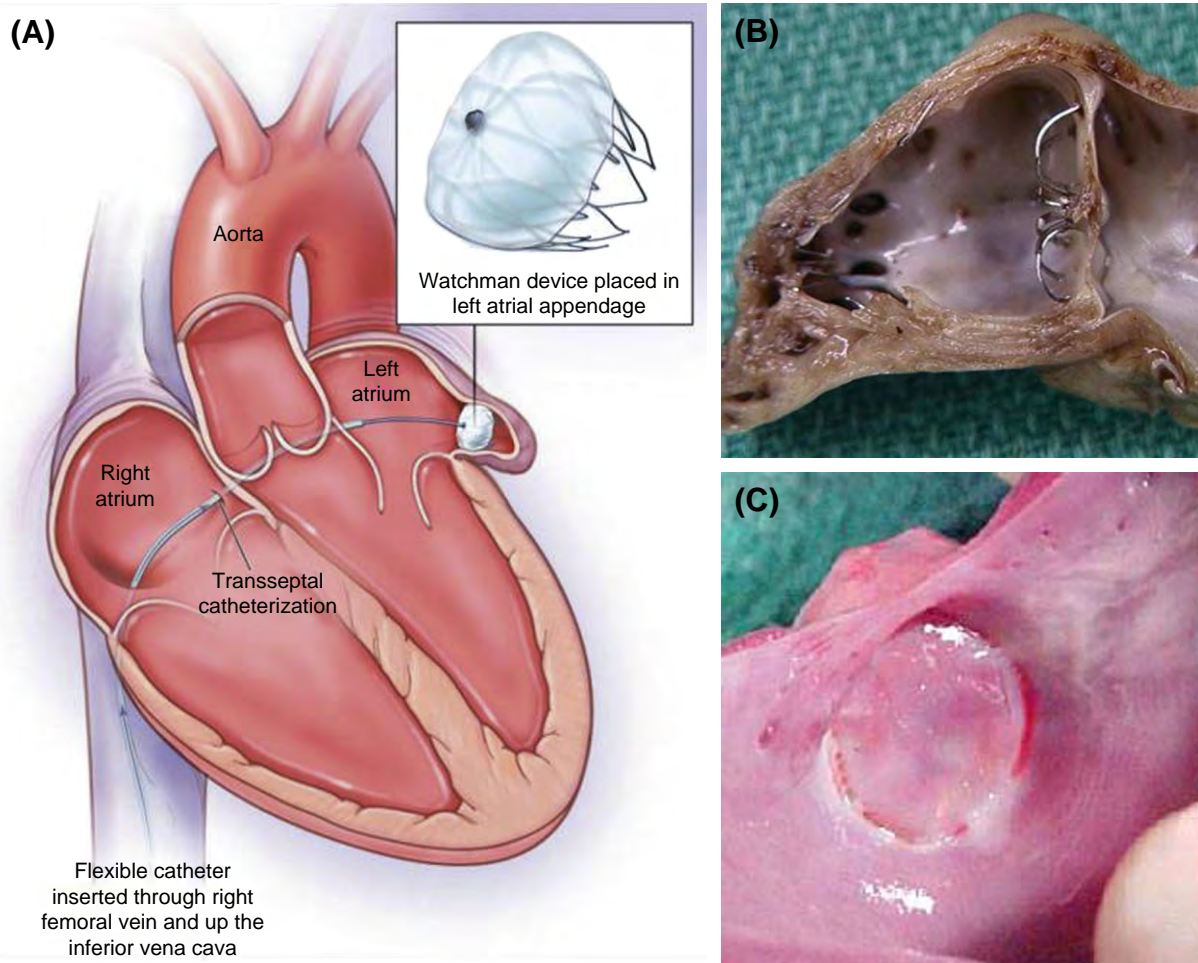
Patients with chronic congestive heart failure and a low ejection fraction show evidence of left ventricular remodeling, resulting in a dilated, spherical-shaped ventricle rather than the normal elliptical configuration. While this anatomic shape change has long been known to be


FIGURE C.7 The Watchman left atrial appendage occluder device. (A) Diagrammatic. (B) Left atrial appendage occlusion device in an animal model 45 days after implantation (Watchman™, Atritech Inc.) (Onalan, O. & Crystal, E. (2007). Left atrial appendage exclusion for stroke prevention in patients with nonrheumatic atrial fibrillation. Stroke 38: 624–630). The appendage is thought to be a major source of stasis and thrombus formation in the setting of atrial fibrillation. Surgical removal or exclusion of the appendage may reduce the risk of thromboembolic stroke. Percutaneous occlusion can be achieved by implantation of a catheter delivered device using a femoral vein and transseptal approach to the left atrium. ((A) Reproduced with permission from Maisel, W. H. (2009). Left atrial appendage occlusion – closure or just the beginning? N. Engl. J. Med. 360: 2601–2603; (B) Reproduced from Schoen, F. J. & Webb, J. G. Prosthetics and the Heart. In: Atlas of Cardiovascular Pathology for the Clinician, McManus, B. M. & Braunwald, E. (eds.), pp. 241–256. Current Medicine: Philadelphia, PA.)

a marker of heart failure, recent evidence suggests that it may actually contribute to disease progression, and that therapies aimed at reducing wall stress and myocyte stretch may halt or reverse the detrimental remodeling process, resulting in improved cardiac function (Sabbah, 2003). The CorCap Cardiac Support Device (Acorn Cardiovascular, St. Paul, MN) is a mesh-like device that is surgically implanted around the heart to provide diastolic support to the ventricles, thereby reducing wall stress (Figure C.8A) (Starling and Jessup, 2004). It is composed of a polyester knit with an open weave construction, such that it will stretch more in the apex-to-base direction than in the circumferential direction, prompting the failing heart to return to a more natural elliptical configuration. The device was shown to be safe in a recent clinical trial, and effective in promoting reverse remodeling characterized by reduced left ventricular volumes and a more elliptical left ventricular shape, along with

improvements in patients functional status and quality of life (Starling et al., 2007). The Myosplint device (Figure C.8B) used another approach, with three transventricular tension members preventing further remodeling of the left ventricle.

CONCLUSION

Cardiovascular medical devices have been used for more than half a century for myriad applications that save, prolong, and enhance the quality of life for countless individuals. Still, complications from these devices can cause significant morbidity and mortality for individual patients, even years after implantation. Ongoing research aims to improve existing devices, reduce the frequency and severity of complications, and develop novel approaches to the treatment of cardiovascular disease in this exciting field truly at the interface of medicine and technology.

CLINICAL NEED AND APPLICATIONS

Heart failure results in over 250,000 deaths per year in the United States. There are approximately 550,000 new cases diagnosed annually, and those diagnosed with this condition have a mortality rate of 70% to 80% at eight years (Thom et al., 2006). When the severity of heart failure is graded, those in the sickest class (New York Heart Association class IV) have an even poorer prognosis, with a survival rate of only about 25% at two years (Schocken et al., 1992). Despite survival improvements with medical therapies, survival with advanced disease is still reported to be 20% at five years (Ammar et al., 2007). For these end-stage patients, heart transplantation has become an effective treatment. Actuarial survival rates for heart transplant patients are 85% at one year, 80% at two years, and 75% at five years (Ammar et al., 2007).

The success of heart transplantation is limited, however, by an inadequate and stagnant donor supply. Although 35,000–64,000 patients could potentially benefit from heart transplantation annually (Funk, 1991), only about 2200–2300 cardiac transplants are performed in the US annually. There has not been a significant change in cardiac transplant volume over the ten years from 1998–2007 (US Department of Health and Human Services, 2008). While waiting for scarce donor organs to become available, approximately 10% of individuals listed for heart transplantation die annually (Ammar et al., 2007). To address the need to support the circulation in patients with end-stage heart failure, a wide variety of mechanical devices have been developed over the past several decades. Current devices that are in clinical use will be discussed in this chapter, as will circulatory support devices that may enter the market in the near future. In the vast majority of cases these devices do not physically replace the heart (as would a total artificial heart); rather they function as ventricular assist devices (VADs), providing flow assistance to one side of the heart.

Roles for Ventricular Assist Devices

As a bridge to cardiac transplantation, VADs have provided circulatory support to end-stage heart failure patients who otherwise would have a low likelihood of surviving until a donor organ became available. Nearly 70% of patients undergoing VAD support have survived until heart transplantation (Mehta et al., 1995), with more recent devices having a 79% survival to transplant (Pagani et al., 2009). Recent data have shown that six months after VAD implantation there was 17% mortality, with 51% receiving a heart transplant (Kirklin et al., 2008). Patients undergoing VAD "bridging" generally do not undergo further deterioration in their condition and, in fact, demonstrate markedly improved end-organ function, and an improvement in their health status due to improved perfusion (Frazier et al., 1994). Ironically, the success of VAD bridging has been implicated in intensifying the donor shortage by including recipients who would otherwise not have survived until transplantation (Massad et al., 1996). A second result of this trend is the need for increasingly extended periods of VAD support prior to organ availability.

With the increasingly broad and positive experience of supporting patients until transplantation with VADs, the concept of using VADs as a permanent source of circulatory support or as a "destination therapy" has been advanced. A number of factors led to the consideration and investigation of permanent support: the limited donor organ supply; a significant patient population that fails to meet age and medical eligibility requirements for transplant listing; and improved quality of life with recent portable VAD designs. This has now been approved for one device in the US after the Randomized Evaluation of Mechanical Assistance for the Treatment of Congestive Heart Failure (REMATCH) trial (Rose et al., 2001) demonstrated survival benefit for patients deemed not to be cardiac transplant candidates compared to medical therapy with a two year survival of 23% versus 8%, respectively. Major concerns regarding this option are primarily the complications that remain associated with VAD support. As one might expect, biomaterial performance, device reliability, and biocompatibility are central to the perceived limits of utilizing VADs as alternatives to transplant in end-stage heart failure patients. In the REMATCH trial such complications included: bleeding (42%); infection (28% at three months, with 25% dying of sepsis); stroke (24% with neurological event); and peripheral thromboembolism (Rose et al., 2001), although complications appear to be decreasing with experience (Long et al., 2005).

The improvement in end-organ function generally associated with extended circulatory support has lead investigators to evaluate whether the heart muscle itself may undergo recovery from the disease process of heart failure during the support period. A variety of recent studies in VAD-supported patients have shown a reduction in the inflammatory mediators associated with heart failure, as well as decreased myocyte necrosis and apoptosis, improved myocyte contractility, and indications of improved function in the left ventricle (Mann et al., 1998). These reports have lead to the investigation of

VAD support as a "bridge to recovery," where patients undergo device explantation without heart transplant due to sufficient recovery of myocardial function while mechanically supported. The attractiveness in bridging to recovery lies in freedom from transplantation and immunosuppressive therapy for the patient and an increased donor organ supply for the community. Early clinical experience with this procedure indicates that, although success can be achieved, patients must be carefully screened for this procedure and the majority of VAD patients are unlikely to meet selection criteria (Loebe et al., 1999). Small studies have reported an incidence of myocardial recovery sufficient for VAD removal in 5–10% of adult patients (Simon, 2005). A multicenter prospective study funded by the National Institutes of Health is currently underway to investigate myocardial recovery during VAD support.

VENTRICULAR ASSIST DEVICE DESIGN AND BLOOD-CONTACTING MATERIALS

Six currently available devices are approved by the FDA for the provision of circulatory support while patients await a donor heart. All but one of these works as a VAD (the other is a total artificial heart). The general flow path of a VAD can be seen in Figure D.1. The inflow conduit of the device is connected to the apex of the left ventricle. Blood from the patient's ventricle enters the VAD conduit and flows into a pumping sac. For pulsatile pumps, a unidirectional valve in the inflow conduit prevents flow reversal during pump activation. A valve
FIGURE D.1 ThermoCardiosystems HeartMate VAD demonstrating anatomical placement and blood flow. (Reprinted from Arabia, F. A., Smith, R. G., Rose, D. S., Arzouman, D. A., Sethi, G. K. and Copeland, J. G. (1996). *ASAIO J.* 42, M542–M546.)

is not necessary for the growing number of rotary, continuous flow pumps. The pumping sac in pulsatile pumps can be triggered to compress by several methods: sensing pump filling, compressing at a constant frequency or by triggering off the patient's electrocardiogram. Upon compression the inflow valve is closed and the outflow valve opens, permitting blood flow through the outflow conduit toward the patient's ascending aorta. The VAD thus "unloads" the left ventricle of the heart and provides the necessary work to periodically propel blood into the arterial tree.

This pulsatile or first generation design is giving way to continuous flow (second and third generation) pumps (Olsen, 1999). Rotary blood pumps have a number of advantages over pulsatile VADs. A continuous flow pump requires no bladder to create a stroke volume comparable to the native ventricle, rather flow is accomplished with an impeller, in either an axial flow (straight through) or centrifugal (center to tangential edge) configuration. The rotary pumps are significantly smaller (on the order of an AA cell battery in certain designs), have fewer moving parts, and are free from valves and cyclic actuators. The major sources of wear are the bearings which are blood- or plasma-immersed in second generation designs. Third generation designs have reduced mechanical wear further by suspending the impellers magnetically. This innovative design is felt to increase overall reliability and durability. Lower overall masses and volumes of implanted materials make these second and third generation systems applicable to patients generally excluded from current implantable pulsatile VADs, e.g., smaller women and children. Also, with the smaller pump size, less of a pocket needs to be created in the body for implantation, and this may reduce bleeding and infection rates. Without valves and the compression of a pumping sac, the rotary pumps are also much quieter than current pulsatile flow generating devices.

Although free from some of the shortcomings of VADs that generate pulsatile flow, rotary pumps introduce some unique biocompatibility concerns. The high revolutions per minute (RPM) required of rotors to generate ~5 liters per minute flow rates in these pumps (~5000–10,000 RPM) subjects blood elements to high peak shear stresses not encountered physiologically. Although these stresses are of very short duration, concerns arise regarding hemolysis and platelet activation due to this exposure. Biocompatibility testing with rotary blood pumps invariably involves assessment of hemolytic indices, evaluation of thrombotic deposition and, in animal studies, assessment of potential end-organ embolic damage. To minimize the occurrence of shear-related blood trauma associated with regions of flow turbulence or stagnation in these pumps, fluid flow over turbine blade designs is often visualized during pumping or computationally modeled (Kerrigan et al., 1996; Burgreen et al., 1999). A second hemodynamic concern regards the reduced pulsatility of blood flow that occurs when a continuous flow, rotary pump

is connected to empty the left ventricle and pump blood to the aorta. The chronic effects of diminished pulsatility on long-term patient health are not known, although the routine use of continuous flow pumps for cardiopulmonary bypass, acute circulatory support, and extracorporeal membrane oxygenation (ECMO) have not lead to major physiologic complications, and large animal implants appear to tolerate this type of circulation for periods beyond six months. Data on this topic was reviewed by Saito (2004).

The mechanical requirements inherent to small rotary blood pumps have resulted in the selection of metals, primarily titanium alloys, as the material of choice for impellers, flow straighteners, and pump housings. In some current rotary systems inflow and outflow cannulae do not differ remarkably in design and materials selection from those used with pulsatile VADs, while in others the departure is significant, illustrated by designs wherein the pump is moved into the ventricle (Westaby et al., 1998; Wampler et al., 1999; Frazier et al., 2002). Design and control concerns arise in association with the inflow orifice of rotary pumps. When ventricular pressures are reduced, the ventricular septum has the potential to be drawn into or around the inflow orifice, obstructing flow and potentially damaging the ventricular wall (Amin et al., 1998). Such concerns do not arise with the passive filling, pulsatile flow generating VADs currently used clinically.

The design of inflow and outflow pump bearings (which support the spinning rotor and resist axial and radial thrust loads) represents a major challenge for rotary blood pump designers. The bearings used in this setting must effectively dissipate heat, exhibit acceptably low wear, support radial and axial loads, and be readily machined to very high tolerances. Bearing designs currently under investigation utilize magnetic suspension, blood lubrication or lubrication provided by a purge fluid. Since sliding contact may occur during transients in pressure and flow, starts and stops, and unexpected patient acceleration and deceleration, it is important that bearing materials be wear-resistant. With blood or plasma contact, it is also important that these bearings exhibit appropriate blood biocompatibility. Current reported materials that have been evaluated for rotary pump bearings include zirconium-niobium alloy (Zr-2.5Nb), titanium-zirconium-niobium alloy (Ti-13Zr-13Nb), as well as carbon coating techniques (Golding et al., 1998).

First Generation Blood Pumps

As described above, these pumps were some of the first designed and provide pulsatile flow via compression of a pumping sac. Such designs can either replace the patient's heart (as would a total artificial heart) or work as a ventricular assist device (VAD). Clinically, VADs are used much more frequently, although one total artificial heart (TAH) is approved by the FDA (CardioWest™

Temporary Total Artificial Heart, Syncardia Systems, Inc.). TAH design began in the early to mid-1980s with the first implants of the Jarvik-7 total artificial heart intended for permanent support (DeVries et al., 1984). Medical complications such as infection and thromboembolism, as well as manufacturing concerns, lead to the discontinuation of TAH use as permanent support. Also at this time the success of immunosuppressive therapies was being reported, raising heart transplantation to the role of preferred therapy for end-stage heart failure. The TAH was subsequently utilized in the bridge to transplant role (Guy, 1998) for which it is now approved (Arabia et al., 1999; Copeland et al., 2004).

In the 1990s several VADs received FDA approval for use as a bridge to cardiac transplantation, including the Thoratec PVAD™, HeartMate XVE (both Thoratec Corporation, Pleasanton, CA), and Novacor Left Ventricular Assist System (World Heart Inc, Salt Lake City, UT). The Novacor device has since been removed from the market by World Heart in favor of developing the third generation Levacor™ VAD. The Thoratec PVAD™ (Thoratec Corporation, Pleasanton, CA) is based upon the Pierce-Donachy VAD originally developed in the mid-1970s at Pennsylvania State University, and currently has been implanted in over 4000 patients. In Figure D.2 the interface of this VAD with the circulatory system is presented. Of particular note is the paracorporeal nature of this device. Both inflow and outflow conduits cross the skin, and the
FIGURE D.2 Thoratec VADs utilized for bi-ventricular support. The right ventricular assist device (RVAD) draws blood from the right atrium, while the left ventricular assist device (LVAD) is connected to the apex of the left ventricle. Both pumping sacs rest outside of the body with inflow and outflow conduits crossing the skin. (Reprinted from Hunt, S. A. and Frazier, O. H. (1998). *Circulation* 97, 2079–2090.)

pumping sac rests on the lower abdomen. One advantage of this type of design is the potential to implant smaller patients. Also of note is the potential for this device to be used in a bi-ventricular support mode with two devices implanted in tandem, as shown in Figure D.2. Although it has been found that the majority of patients experiencing end-stage heart failure require only left ventricular assistance (Kormos et al., 1996), for those who require support of the right ventricle, the Thoratec pump can be placed in conjunction with another Thoratec pump or other VAD supporting the left ventricle.

The Thoratec VAD has the potential to draw blood from cannulae designed to interface with the ventricle or atrium, with the former being more commonly utilized for extended left ventricular support. The inflow cannula and the pumping sac are composed of Thoralon™, a proprietary polyurethane elastomer blended with a surface modifying agent. The surface modifying agent is designed to increase the potential for surface molecular rearrangement and reduce thrombogenicity (Farrar et al., 1988). The outflow cannula is composed proximally of Thoralon™ polyurethane that fuses distally with a Dacron graft, to allow suturing to the ascending aorta. The Dacron graft is preclotted with patient blood and thrombin or cryoprecipitate and thrombin prior to implantation to seal the graft pores. Where the cannulae cross the skin polyester velour is present on external surfaces of the Thoralon™ to encourage tissue integration. The opposing valves controlling flow into the pumping sac are tilting disc mechanical valves (Bjork-Shiley Monostrut). Compression of the full pumping sac produces a stroke volume of approximately 65 mL and is accomplished pneumatically, requiring connection to a controller providing positive and negative air pressure. A portable pneumatic system allows for reasonable mobility and the potential for discharge to home.

The HeartMate XVE, including the inflow and outflow conduits as well as the pumping sac, resides entirely within the patient, as seen in Figure D.1. An older pneumatic model utilized an external air pump to compress the pumping sac in a fashion akin to that of the Thoratec device, while the currently available vented electric design uses an integral electric motor powered by an external battery pack. The HeartMate XVE has been one of the most widely utilized VAD design to date, with more than 4500 patients having been implanted worldwide.

The inflow from the apex of the left ventricle in the Heartmate XVE design occurs through a titanium alloy (Ti-6Al-4V) cannula attached to a low-porosity Dacron graft. The blood- and tissue-contacting surfaces of the titanium cannula are surface coated with sintered titanium microspheres 50–75 μm in diameter, as seen in Figure D.3A. The Dacron portion of the inflow conduit houses a 25 mm porcine xenograft valve (Medtronic).

The outflow conduit is also a valved Dacron conduit with an identical opposing valve at the exit of the pumping sac. The pumping sac is comprised on one side of a titanium alloy surface with sintered titanium microspheres. On the opposing side the flexible pusher plate diaphragm is made of Biomer polyurethane that has been textured on its blood-contacting surface with surface integral fibrils approximately 18 μm in diameter and 300 μm in length, as seen in Figure D.3B (Menconi et al., 1995). The maximum stroke volume of the pumping sac is 83 mL.

The implication of having textured surfaces contacting the blood in the HeartMate VAD is that these
FIGURE D.3 (A) Blood-contacting surface of the rigid housing in the HeartMate VAD with sintered titanium microspheres (spheres are 50–75 μm in diameter). (B) Integrally textured polyurethane surface of the flexible diaphragm (fibrils are approximately 18 μm in diameter). (Reprinted from Menconi, M. J., Pockwinse, S., Owen, T. A., Dasse, K. A., Stein, G. S. and Lian, J. B. (1995). *J Cell Biochem* 57, 557–573.)

surfaces rapidly clot upon device placement. While this may seem like a negative scenario for the interior surfaces of a VAD, the concept behind the design is that while clots rapidly form on these surfaces, these thrombi are densely adherent and do not appear to embolize into the bloodstream in a clinically relevant manner. Over time additional blood cell interaction occurs, similar to an inflammatory reaction (see Chapter II.2.2). A heterogeneous surface containing platelets, monocytes, macrophages, foreign-body giant cells, lymphocytes, and multipotent circulating cells is deposited. It is postulated that multipotent circulating cells differentiate into fibroblasts, myofibroblasts, and in some cases endothelial cells, which are reported to populate the surface (Frazier et al. 1993; Rafii et al., 1995; Spanier et al., 1999). The fibroblastic cells may then secrete extracellular matrix components such as collagen, which is routinely found on textured VAD surfaces following extended implants. Unlike the inflammatory response associated with porous cardiovascular biomaterial surfaces, the cells populating the interior HeartMate VAD surface are likely derived entirely from the passing blood. Cellular migration from

tissue onto these surfaces in the timeframe that the cellular deposits are observed is considered unlikely. The blood-contacting biological interface that develops from the initial surface coagulum after approximately one week is referred to as the pseudointimal layer (Figure D.4), and has been shown not to grow in thickness exceeding 150 μm over periods of implantation in the order of one year (Menconi, 1995).

Second Generation Blood Pumps

Second generation blood pumps are generally rotary pumps with bearings immersed in blood or plasma. They deliver diminished pulsatile or continuous blood flow. These include those described by Butler et al. (1997) seen in Figure D.5, DeBakey (1997) illustrated in cross-section in Figure D.6 (Westaby et al., 1998; Wampler et al., 1999). While the HeartMate II® (Thoratec Corp.), Jarvik 2000® (Jarvik Heart, Inc.), HeartAssist 5™ (MicroMed Cardiovascular Inc.), INCOR® (Berlin Heart GmbH) and the Synergy® (CircuLite, Inc.) utilize a rotary pump design, the EVAHEART (EVAHEART MEDICAL USA) and the CorAide™ (Arrow International, Inc.) are centrifugal pumps. These pumps are not completely implantable, having a percutaneous line for power transmission, pump monitoring, and speed (RPM) control. Most, if not all of these pumps have now entered clinical trials including one, HeartMate II, approved by the FDA for bridge-to-cardiac transplantation based upon favorable trial completion (Miller et al., 2008). Clinical trials have focused on bridge-to-cardiac transplantation, although HeartMate II is completing a destination therapy trial. In addition to these long-term implantable pumps, continuous-flow technology has allowed for the development of shorter duration, less invasive assist devices utilized in emergency situations (such as organ perfusion during cardiogenic shock) or to provide support during high risk surgical procedures. Examples of these devices are the
FIGURE D.4 Pseudointima developed on the interior textured surfaces of the HeartMate VAD after an implantation period of 243 days. Impella® 2.5 & 5.0 (ABIOMED, Inc.) and the Tandem-Heart® (Cardiac Assist Inc.).

Third Generation Blood Pumps

Third generation pumps are characterized by magnetically or hydrodynamically suspended impellers. Similar to second generation pumps, they can deliver continuous or diminished pulsatile blood flow. Examples are the Dura-Heart™ (Terumo Heart, Inc.), HeartWare® HVAD™ (HeartWare International, Inc.) [Figure D.7] and the short-term Thoratec® Centrimag® (Thoratec Corp).
Complications and VAD Biocompatibility Issues. Complications associated with the implantation and operation of VADs include those that may be related to biomaterial-centered processes discussed earlier in this text, including thromboembolism, infection, and bleeding. It is worth noting, however, that the mechanisms behind these complications vary among patients and are multifactorial. Many of the processes contributing to the complication may be independent of the biomaterial implant. Of particular relevance here is the health status of the patient at the time of device implantation. Patients in end-stage heart failure suffer from a variety of conditions secondary to the poor perfusion of their organs. They undergo a variety of invasive treatments and monitoring that precede VAD insertion, and have

often spent extended periods sedentary in the hospital environment.

Independent of VAD implantation end-stage heart failure patients are at risk of infection due to poor perfusion, compromised immune function, extended exposure to nosocomial infections, and invasive monitoring devices. Thromboembolism can occur in this patient group as a result of ventricular arrhythmia and ventricular mural thrombi, poor distal hemodynamics, and systemic vascular disease. Bleeding risks are elevated as a result of compromised liver function secondary to poor organ perfusion, and invasive monitoring and therapy short of VAD implantation. With these considerations in mind, there is certainly a relationship between the extensive biomaterial surface implantation of a VAD and the above complications. For first generation pumps blood-contacting surface areas range from 400–500 cm^2; and while second and third generation pumps have reduced this contact area, these devices still represent a substantial biomaterial implantation for an extended period. The major complications will be discussed below.

Thromboembolism

Thromboembolic rates for VAD support vary widely among the specific devices studied and the reporting centers. Rates can vary simply due to the average implant

period of the VAD, the health of the patients selected for support, and the patient medical management routine. Thromboembolism can be defined in a conservative manner to include only obvious neurologic events (strokes) lasting for more than 24 hours that are coupled with imaging evidence of a recent cerebral infarction, and which cannot be explained as originating from a source other than the VAD. Alternatively, the definition can be liberalized to include suspected neurologic events such as blurred vision, weakness on one side, compromised field of view, and other events that are transient in nature ("transient ischemic attacks;" with symptoms resolving within 24 hours), that may or may not be followed up with diagnostic imaging, and that may potentially be explained by some other risk factor. It is also possible to investigate peripheral embolization with imaging techniques that would not likely be employed in the majority of clinical centers (Schmid et al., 1998). Finally, although not generally included in reported thromboembolic rates, tissue infarcts attributable to VAD support can be quantified at the time of autopsy in patients who die while on the device. With these limitations to reported thromboembolic rates in mind, historically reported rates for first generation pumps have been 5–30% (Mehta et al., 1995; DeRose et al., 1997; El-Banayosy et al., 1999a). Interest in standardizing definitions, and therefore the reported incidence of adverse events, has resulted in the formation of the Interagency Registry for Mechanically Assisted Circulatory Support (INTERMACS), which is an NIH-sponsored registry of US FDA approved mechanical circulatory support devices. While this only includes FDA-approved devices, it has been mandated that all implanting centers participate in order to receive reimbursement from the Centers for Medicare and Medicaid Services. INTERMACS recently reported 199 neurologic events, 14 arterial non-neurologic events, and 33 venous thrombotic events in a total of 483 patients over an approximately two-year period (Holman et al., 2009). In this report, neurologic events were the leading cause of death (11%), which further emphasizes the how persistent the problem of thromboembolism is for blood pumps.

To explain the principle mechanisms of thromboembolism in VAD patients one need recall the mechanisms of thrombosis on artificial surfaces discussed in Chapter II.2.6 and consider the role of flow on this thrombotic process as discussed in Chapter II.2.6 (Hanson & Tucker). Low pump volumetric outputs have been directly associated with thrombotic deposition on the valves of first generation pumps (Wagner et al., 1993). This design was subsequently altered to reduce the potential for low blood velocities to develop within the pumping sac and valve system. With all VAD designs, excessively low volumetric flow is considered to be a risk factor for thromboembolism.

The hemostatic system is affected with the implantation of all types of VADs. With the HeartMate pulsatile device it has been shown that platelets, coagulation, and fibrinolysis are all activated early in the implant period, at two hours after the operation (Livingston et al., 1996). This activation is in excess of the marked elevations resulting from the extensive biomaterial contact involved in cardiopulmonary bypass for the implant surgery. The textured, prothrombotic surfaces of this VAD likely contribute to this effect. Longer-term elevations in hemostatic markers have also been reported for all VAD designs. Ongoing elevations in platelet activation, coagulation, and fibrinolysis suggest that the device surfaces remain active during the implant period in bridge to transplantation patients (Spanier et al., 1996; Dewald et al., 1997; Wilhelm et al., 1999).
