In one case, the effluent of the CE capillary is efficiently transferred to a moving, planar SERS substrate via a modification of the ESI sampling technique that is used extensively in MS.¹⁰⁸ In this case, the substrate was a frosted microscope slide onto which silver colloid had been deposited. The separation is deposited as a track of bands on the moving substrate, which acts as a semipermanent record of the separation and is available for performing manipulations (e.g., rinsing or derivatization) without the time constraints imposed by on-column detection. Spectra were demonstrated for low- to submicromolar concentrations of pharmaceutically significant analytes.¹⁰⁸ Moreover, the CE separation was transferred to the substrate with only a minor loss in separation efficiency. In the future, advances in SERS substrate design will probably improve this approach to performing information-rich photonic detection in CE.

24.3.4 Optically Gated Injection

Optically gated injection represents an unusual application of optical methods to CE, which has been applied to study research problems of biomedical interest. Monnig and Jorgenson first developed optically gated injection in order to perform extremely rapid CE separations (less than 2 s).¹¹⁰ To perform an optically gated injection, a sample containing fluorescent analytes is continually introduced into a capillary by electrophoresis. The gating beam is a high-intensity laser beam, which almost completely photobleaches the fluorescent analytes. To perform an injection, the gating beam is briefly blocked, allowing a small plug of fluorescent analytes to pass through the gating beam area. The compounds in this plug are separated before they are detected by an LIF detector as shown in Figure 24.10. Optically gated injections have been used for a number of bioanalytical applications.¹¹¹ This technique has been used with fast CE separations as the second step of two-dimensional separation methods, as well as applied to perform injections for on-line analysis of microdialysis samples.^{8,111} Moore and Jorgenson applied optically gated injections to perform rapid separations of *cis* and *trans* isomers of proline-containing peptides.¹¹² Figure 24.11 shows an example of a separation of *cis* and *trans* glycyl proline from this work.

24.4 Biomedical Applications

Much of the development of CE has been undertaken with biochemical applications in mind, and CE techniques have been applied to a wide range of biomedical problems. The chemical contents of single cells have been analyzed by CE, taking advantage of the technique's small-volume sampling capabilities.^{6,7} Capillary electrophoresis has been applied extensively to the analysis of nucleic acids,^{3–5,113} and applications to study protein conformational changes and protein folding have emerged in recent years.^{114,115}

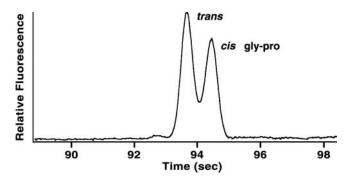

FIGURE 24.11 Separation of fluorescein-labeled *trans* and *cis* gly-pro with optically gated injection (100 ms). The separation distance was 13.7 cm, and the applied field was 508 V/cm. (From Moore, A.W., Jr. and Jorgenson, J.W., *Anal. Chem.*, 67, 3464, 1995. With permission.)

Affinity CE has been developed to study the binding interactions of biological molecules with other chemical species by measuring shifts in electrophoretic mobilities when zones of interacting analytes electrophorese through each other. ^{116,117} Capillary electrophoresis methods have been applied to analyze and characterize enzymes and to quantify enzyme substrates. ^{118–120} Capillary electrophoresis is emerging as an important tool for clinical analysis. ^{121–123} Two specific examples of the application of CE to address biomedical problems are discussed in this section.

24.4.1 Analysis of Substance P Metabolites in Microdialysis Samples

Capillary electrophoresis was used by Lunte and co-workers to separate and detect metabolites of substance P from microdialysis samples collected from rat brains. Substance P is an 11 amino acid neuropeptide, and it is metabolized in the brain by several cytosolic and membrane-bound peptidases. Microdialysis samples were collected from the rat striatum over 15-min intervals throughout the experiments. Substance P (100 μ M) was perfused through the microdialysis probe for the first 6 h of the experiments, and microdialysis samples were collected for an additional 5.5 h after substance P was removed from the perfusing solution. Figure 24.12B shows an electropherogram from a microdialysis sample collected at 120 min during the perfusion of substance P. The peak labels identify the corresponding fragment sequences. The peaks were identified based on co-elution with standard samples.

This application of CE takes advantage of the technique's strengths in the areas of separation and sampling and exposes its primary weakness — detection sensitivity. Resolution of the substance P fragments as shown in Figure 24.12B was accomplished using CD-modified MEKC. A very challenging separation was accomplished by simply adding a cyclodextrin (sulfobutyl ether (IV) β -cyclodextrin) and a surfactant (sodium cholate) to a simple aqueous buffer. The microdialysis samples were collected every 15 min at a flow rate of 0.2 μ l/min, resulting in 3- μ l sample volumes. Fast sampling rates and low probe flow rates are desirable for microdialysis, but they are limited by the sample volume requirements of the analytical methods used to analyze the samples. In principle, hundreds of nl-volume CE injections could be made from a 3- μ l sample. In practice, the minimum sample volume required here was limited by the requirements for the derivatization reaction used to enhance analyte detection and by the volume required to immerse one end of the CE capillary in the sample for injection. Nonetheless, the low sample volume requirements of CE allow researchers to use lower flow rates and to collect samples over shorter time intervals compared to experiments using other analysis methods. 125,126 In addition, multiple injections can be made from a single sample to improve accuracy and reproducibility. Because CE typically uses buffered, aqueous solutions, microdialysates can be injected directly with minimal sample preparation.

Achieving adequate detection sensitivity for these experiments was challenging, however. Detection limits for the substance P fragments ranged from 2.5 to 26 nM, and several enhancement strategies were used to achieve these results. The substance P metabolites were detected by LIF, but these peptides are

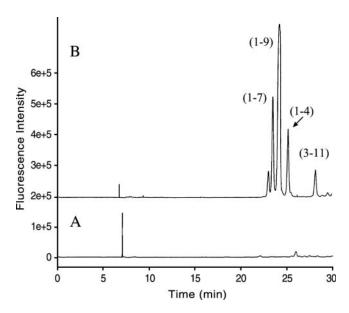

FIGURE 24.12 (A) Blank microdialysis sample prior to introduction of substance P. (B) Brain microdialysis sample 120 min after substance P introduction. (From Freed, A.L. et al., *J. Neurosci. Methods*, 109, 23, 2001. With permission.)

FIGURE 24.13 CEEI assay. The enzyme-substrate zone (E) migrates faster than the inhibitor zone (I) and will overtake it in the capillary later in the experiment. The hashed region behind the enzyme-substrate zone is product formed by the enzyme-catalyzed reaction, which will be detected later by LIF.

either nonfluorescent or weakly fluorescent in their native state. The microdialysis samples were derivatized prior to CE analysis with naphthalene-2,3-dicarboxaldehyde and CN⁻ to form highly fluorescent compounds (λ_{ex} = 442 nm, λ_{em} = 488 nm). A short reaction time was used (2 min) so that the reagent derivatized the amine groups on lysine side chains but did not react extensively with terminal amine groups. This resulted in less interference from other compounds in the dialysate, but it also limited the substance P metabolites detected to those fragments containing the lysine at position 3. In addition, sample stacking by injection of a plug of water preceding the analyte plug was used to lower detection limits. Finally, it was found that the cyclodextrin and sodium cholate added to the buffer enhanced the fluorescence of the labeled analytes by a factor of two to three.

24.4.2 Capillary Electrophoretic Enzyme Inhibition Assays

Whisnant and co-workers have developed an on-column CE method for studying enzyme inhibition. ^{127,128} Figure 24.13 illustrates the basic technique. The capillary is filled with a substrate for the enzyme under study. A zone of inhibitor is first injected into the capillary and an electrophoretic potential is applied for a few seconds. Then a zone of enzyme is injected into the capillary and an electrophoretic potential is applied again. A high concentration of substrate is used to ensure that the enzyme is saturated, and the enzyme zone is actually a zone of enzyme–substrate complex. Because the enzyme–substrate complex has a greater migration rate than the inhibitor zone, the two zones will merge in the capillary, and the enzyme-catalyzed reaction will be inhibited. The two zones will separate again as the experiment continues. The enzyme-catalyzed reaction rate is monitored throughout the experiment based on detection of the reaction product when it migrates past the CE detector. Saevels and co-workers have used a related

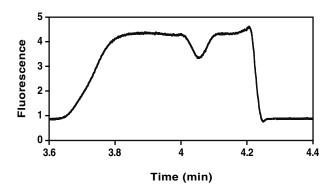

FIGURE 24.14 CEEI assay showing the reversible inhibition of alkaline phosphatase (0.18 nM) by sodium arsenate (125 μM). The sodium arsenate zone was injected first, and then the enzyme was injected after 60 s of electrophoresis. The fluorescence signal is due to product from the enzyme-catalyzed reaction of AttoPhos (0.1 mM).

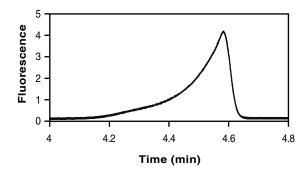

FIGURE 24.15 CEEI assay showing the irreversible inhibition of alkaline phosphatase (0.18 n*M*) by EDTA (4 m*M*). The EDTA zone was injected first, and then the enzyme was injected after 180 s of electrophoresis.

approach to study the inhibition of adenosine deaminase by erythro-9-(2-hydroxyl-3-nonly)adenine. ¹²⁹ In their work the capillary was filled with inhibitor and zones of enzyme and substrate were electrophoretically mixed in the capillary.

Figure 24.14 shows a capillary electrophoretic enzyme inhibition (CEEI) electropherogram for the inhibition of alkaline phosphatase by sodium arsenate. Sodium arsenate is a reversible, competitive inhibitor for this enzyme. A commercial, fluorogenic substrate for alkaline phosphatase, AttoPhos, was used to determine alkaline phosphatase activity. The concentration of fluorescent reaction product detected by LIF indicates the reaction rate for the enzyme-catalyzed reaction as the enzyme traveled down the capillary. The negative peak at 4.05 min indicates inhibition when the zone of $125 \,\mu M$ sodium arsenate overlaps with the zone of enzyme–substrate complex. When the inhibitor is not injected, the electropherogram appears as a flat plateau formed as the enzyme migrates from the injection end of the capillary to the LIF detector. A flat plateau indicates a constant reaction rate throughout the experiment. The enzyme concentration was 0.18 nM; only 1.9 amol of enzyme were injected.

The shape of the electropherogram in Figure 24.14 indicates that sodium arsenate is a reversible inhibitor. The enzyme returns to its original activity when the zones of enzyme–substrate complex and inhibitors separate again after mixing. Figure 24.15 shows a CEEI electropherogram for an irreversible inhibitor of alkaline phosphatase, EDTA, at 4 mM. In this case, the enzyme activity does not recover after the two zones mix, indicating irreversible inhibition. Note that the electropherogram is "reversed" compared to what one might expect. This is a result of the enzyme–substrate complex having a greater migration rate than the reaction product. 127,130 This CEEI technique also showed that EDTA unexpectedly activated alkaline phosphatase at concentrations from 20 to 400 μM . 128

Quantitative analysis of sodium arsenate and sodium vanadate, also a competitive reversible inhibitor of alkaline phosphatase, has been demonstrated using CEEI assays. ¹²⁸ The CEEI data for a range of inhibitor concentrations was analyzed using a Michaelis–Menten-based treatment of competitive enzyme inhibition kinetics to construct a calibration curve for the inhibitors. The K_i values calculated based on this analysis were consistent with values obtained using traditional methods for studying enzyme inhibition kinetics. ¹²⁸ Theophylline, a noncompetitive, reversible inhibitor was quantified using a similar approach. ^{127,128}

25.1 Introduction

Flow cytometry allows the analysis and sorting of particles of biological interest at rates of more than $10^4 \, \rm s^{-1}$, based on the analysis of light scatter and fluorescence. It also permits the quantitative analysis of many cellular constituents based on fluorescence measurements. Measurements at the single-molecule level have been reported. Because of the versatility and richness of information of flow cytometry, it is used in biological and biomedical research, and for clinical data collection. This chapter provides an overview of flow cytometry and its biomedical and clinical applications. For readers interested in further details, we provide references to additional reviews of subtopics. Shapiro¹ provides a comprehensive account of flow cytometry, covering all aspects up to 1995.

25.2 Hardware

Flow cytometers measure multiple optical properties of particles, generally without spatial resolution, from about 20 µm to submicroscopic size at rates of several thousand per second. A typical flow cytometer consists of a fluidic system, the optical components, and analog or digital electronics for data processing, storage, and evaluation (Figure 25.1). Special cytometers also sort particles into different fractions based on optical particle properties. Several sorting mechanisms that have been used are described in this chapter.

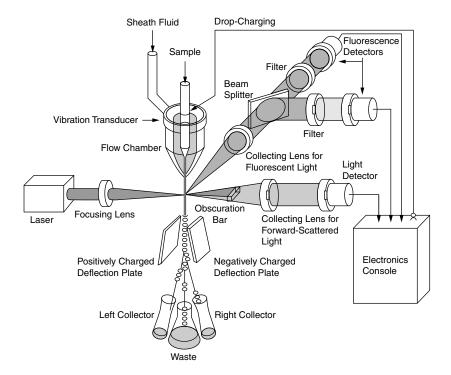

FIGURE 25.1 Components of a typical flow cytometer with droplet cell sorting feature.

25.2.1 Fluidics

In the fluidics system of a cytometer a particle suspension from a tube or well of a microtiter plate is injected into a second fluid stream of aqueous sheath fluid — mostly saline — to create a very narrow, quasi one-dimensional file of particles for intersection with a light beam for optical measurements. Typical stream velocities are 10 m/s. The ratio of sheath fluid volume to sample volume with the size of the observation cuvette determines the diameter of the sample stream and influences the precision of the optical measurements. Typical total stream diameters are on the order of $100 \, \mu m$, sample streams on the order of $10 \, \mu m$. Coefficients of variation better than 2% are quite common for measurements of the DNA content of cell nuclei.

25.2.2 Optics

To perform optical measurements on the particle stream in a cytometer, a light beam, commonly from a laser, is focused on the center of the fluid stream in a cuvette or in a free-flowing stream in air for most cell sorters. Figure 25.2 shows a typical optics diagram for a three-laser sorter. Mercury arc lamps and LEDs are also used as excitation light sources. Cylindrical lenses are used frequently to achieve better uniformity of light intensity for the particle illumination, with a typical beam height of about $20~\mu m$. Research flow cytometers are capable of measuring several light scatter and fluorescence emission intensities.

Many fluorescence measurements on biological systems require a very low limit of detection. Therefore high-numerical aperture lenses are used for the collection of emitted light. Dichroic filters separate scattered and fluorescent light into separate wavelength bands and photomultipliers (PMTs) measure the light intensities in the different bands. With an optimized instrument, photon-noise-limited measurements can be performed, and less than 200 molecules per particle (approximately 10^{-21} mol) of some fluorescent dyes can be detected. Some newer specialized systems use avalanche photodiodes in place of PMTs. Light scatter can be detected with photodiodes.

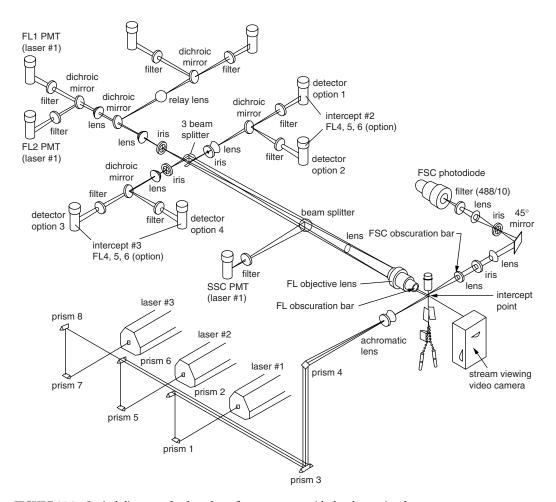

FIGURE 25.2 Optical diagram of a three-laser flow cytometer with droplet sorting feature.

High-end research systems offer multiple excitation light sources, either in a colinear arrangement or for more flexibility for the resolution of multiple fluorophors with completely separate spatial optical paths and temporal synchronization.

25.2.3 Electronics

Signals from light detectors are amplified. To allow measurement of small and large signal intensity ranges, linear and logarithmic (typically four decades) ranges are provided on most instruments. Signal subtraction circuitry, linking adjacent spectral fluorescence emission bands, allows for the correction for spectral overlap between fluorescent dyes to express the intensity measurements in relative units of dye concentration rather than light intensities. After baseline subtraction, an analog pulse height or pulse area and a calculated pulse width are provided to an analog-to-digital converter (ADC). The ADC is triggered by a pulse height threshold, based on a Boolean combination of the measurement parameters; after digitization, all of the particle measurements, including those from separate light beams (after temporal synchronization), are stored as a record for the particle in the data matrix. Approaches for the extraction of population information from this data matrix are described in the data analysis section later.

Recently, digital electronics has been used to derive particle measurements from a continuous digitization of detector output through high-speed ADCs. All of the signal calculations on the pulses, including height, area, width, logarithms, and spectral overlap correction, are performed with high-speed digital

signal processors. Calculations of signal parameters are performed with higher accuracy than by analog approximation, and the approach also provides more flexibility for future applications of modern signal signature analysis for flow cytometry.

25.2.4 Cell Sorting with Cloning

As mentioned earlier, several approaches have been used to sort particles in essentially real time, based on the measurements of a flow cytometer. Cell sorting has been reviewed in detail in a recent book chapter.² The most common method for flow cytometric cell sorting uses a piezoelectric actuator, which breaks the stream containing the particles under analysis into droplets. Charging the droplets at the right time with a charge pulse triggered by the results of the optical analysis allows electrostatic deflection into typically four positions, where a collection tube can be placed. Sorting rates of higher than 10⁴ per second can be achieved for the purification of millions of particles (cells) with specific properties in under an hour.

In another setup the particles of interest are deflected into a multiwell plate (typically 96 wells in an 8×12 well arrangement) or onto a plate with cell nutrient under xy control. For cloning, single cells can be deposited there to achieve a cultured cell population that can be traced back to an individual cell. (Figure 25.3).

A University of Cardiff Web site provides good additional information about the hardware of a flow cytometer.

25.3 Data Analysis

Data from flow cytometric measurements are stored in a data matrix, where each row contains the measurement for an individual particle with a column for each of the measurement parameters. One of the measurement parameters can be a time tag for kinetic data evaluation. For most analyses, information on at least 5000 particles is stored and, in many cases, substantially more. At least one byte of data is stored for each of the parameters; in many cases the resolution is higher, e.g., 10 bits per data item. This kind of data file is called a listmode file; the designation comes from the times when data storage was expensive, so, for memory-economy reasons, data were also stored as histogram data (see below). The listmode data matrix is the basis for all subsequent data analysis, but by itself cannot be evaluated easily without computer-based data transformation.

A simple analysis of the data consists of calculating a histogram of the number of particles at each parameter value for all of the parameters. In the simplest implementation, the digital parameter value for each of the particles in the matrix is used as an address for an array (1024 elements long for a 10-bit parameter resolution), and the content of the corresponding array element is incremented by 1 every time the respective value is observed. Data histograms (Figure 25.3A) provide a view of intensity distribution for the subpopulations in a particle ensemble; however, information about the correlation between parameters is lost.

A dotplot (Figure 25.3B) shows the intensity distribution with pairs of two measurement parameters. In a two-dimensional plot, dots are displayed for each particle at *x-y* coordinates corresponding to two parameter values. This plot shows population locations and widths with some relative frequency information from the dot density. Quantitative frequency information is lost because overlapping dots show only as one.

Density and contour plots show quantitative population frequency information with two parameters. Both are based on two-dimensional histograms. A density plot uses a gray scale or colors to represent the *z*-axis (frequency information), whereas a contour plot uses different contour levels to show histogram height or population frequency.

All these data representations show only up to two parameters correlated simultaneously. The listmode data matrix may contain many parameters, for most measurements at least four. Therefore the problem remains to look at subpopulations of the particle ensemble in multidimensional space. A process called

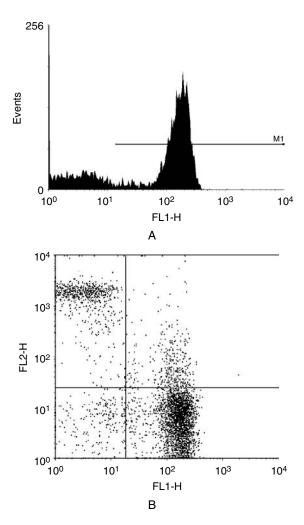

FIGURE 25.3 Histogram (A) and dotplot (B) from a two-color immunofluorescence measurement of mammalian lymphocytes.

gating uses one- or two-dimensional displays to select parameter value sets to include or exclude from additional data displays. In this way properties of particle subpopulations can be determined for all measured parameters. A special case of novel multiparameter "gating" is detailed in Reference 3. Several software packages offer additional features for multiparameter data analysis. Paint-a-GateTM (U.S. Patent 4,845,653)⁴ uses color to highlight populations selected in one display in five more two-dimensional displays in real time. For automated multiparameter analysis, density-based or nearest-neighbor cluster algorithms have been used, among others. Further details on data analysis methods for flow cytometry have been discussed elsewhere.^{5,6}

25.4 Flow Cytometry Measurements

A flow cytometric measurement characterizes one or more populations of a particle suspension with a count value and several optical parameter intensities and their distributions. From the partial count, particle concentrations can be calculated if the sample volume is known. Regardless of the capabilities of the instrumentation to record sample volumes, a known concentration of a reference particle with scatter and fluorescence properties different from the particles of the sample can be added to obtain

concentrations of all the particle populations. However, many applications of flow cytometry only report the relative frequency of a sample particle subset as a fraction of the subset in a superset of the particle sample, e.g., T cells as a percentage of lymphocytes.

The optical parameter intensities are used to derive physical properties of the particles in a sample. Light scatter intensities are related to the size and index of refraction of particles; fluorescence intensities are related to the mass of fluorophors per particle. With calibration of the system, absolute masses of analyte per particle can be determined from fluorescence intensities. However, for most applications relative quantities are reported. Limits of detection for fluorescence measurements with commercial systems are on the order of a few hundred fluorescent molecules per particle; with specialized instrumentation, single-molecule detection has been achieved.

25.5 Biological Applications

25.5.1 Cell Cycle and Cell Proliferation

DNA content (including assessment of aneuploidy and S phase) can be measured with propidium iodide (PI), the Hoechst dyes, or other compounds. Propidium iodide intercalates in the DNA helix and fluoresces strongly orange-red. It has the advantage that it is excited by 488-nm light and can be used on most common flow cytometers. The Hoechst dyes bind to AT pairs in the DNA and enter viable cells without the need for fixation. These dyes are excited using UV light, so they cannot be used on benchtop flow cytometers; however, they may allow dye combinations that are not possible with propidium iodide.⁹

Bromodeoxyuridine (BrdU — a thymidine analog) incorporation for specific cell proliferation can also be measured by immunofluorescence. This is often performed along with DNA staining. Cell cycle and synchronization analysis can be performed allowing quantitative analysis of cell cycle phases. This can be used with or without antibody staining to characterize the transition between cell cycle phases in terms of expression of control proteins.¹⁰

25.5.2 Ca-Flux

Ca²⁺ is the most common signal transduction element in cells, and it is involved in diverse cellular processes. Flow cytometry can be used to measure calcium flux¹¹ and the calcium flux assay can be combined with immunofluorescent stain to identify cell subpopulations by immunofluorescence and measure calcium flux in response to an activating signal.

25.5.3 Cellular Antigen Quantitation

Antigens per cell can be quantitated by standardized fluorescence measurements using flow cytometry. ¹² Quantitative measurements can be used to characterize receptor expression and cellular activation. A number of bead-based methods are available to calibrate flow cytometers and provide quantitative results on density of antigen on cells. ^{13,14}

25.6 Clinical Flow Cytometry Applications

25.6.1 T-Cell Subset Analysis for HIV Disease

No disease has been impacted more by flow cytometry than the human immunodeficiency virus (HIV) infection that causes acquired immune deficiency syndrome (AIDS). Therefore a large part of this section covers applications related to monitoring this disease. Some of the principles discussed previously are further explained for a better understanding of the specific application of flow cytometry.

Contrary to earlier predictions, it was AIDS, not some high-volume oncological phenotype testing, that was responsible for the massive and rapid worldwide mobilization of flow cytometers into clinical immunology laboratories. In 1981, reports appeared from various parts of the United States about young

men who had unusual immunosuppression coupled with opportunistic infections.^{15,16} Soon it was discovered that the hallmark of this new disease, AIDS, was a decrease in numbers of CD4 T-cells (helper cells) in peripheral blood.¹⁷ Next, the causative viral agent for AIDS was isolated: the human immunodeficiency virus (HIV).^{18,19} It was established that the T-helper cell is the primary target for HIV and the CD4 receptor on the surface of these cells is the principal means for viral entry.²⁰ Current cocktails of antiretrovirals can suppress viral replications for years; hence, disease monitoring of patients may be required for decades because no current therapy can completely eliminate HIV from the host.

Throughout the course of disease, T-cell subsets are followed as the best surrogate marker for immune status.²¹ Normal levels of T-helper cells are about 1000 cells/ml of blood (with a range from 600 to 1400); generally, levels below 500 cells/ml indicate that the virus has damaged the immune system.²² The overall level of T cells remains constant until late stages of the disease.²³ For most of disease duration, the CD8 T-cell numbers increase as CD4 T cells diminish.²⁴ An AIDS definition was established based on a CD4 T-cell count of less than 200 cells/ml,²⁵ so accurate and reproducible measurement of T-cell subsets during therapy is an important part of managing treatment for HIV-infected patients.²⁶ T-helper cells often rise following combination antiretroviral therapy;²⁷ however, the rebound levels remain below normal values. Current therapies add years of quality life to patients living with HIV; nevertheless, the virus is never eliminated. Eventually, death from opportunistic infections results.

Fresh whole blood with anticoagulant is required for immunophenotyping T-cell subsets. In evaluating the effectiveness of therapies, viral load and T-cell subset assays are important clinical tools. Currently, clinical flow cytometers handle five or six distinct parameters: forward scatter (FS), side scatter (SS), and three or four fluorescence light (FL) signals: FL1, FL2, FL3, and FL4, respectively. The two light scatters are intrinsic parameters that define morphological features of leukocytes; they are size and granularity, respectively. The FL parameters measure extrinsic cell attributes, such as identification of surface antigens, via fluorescence scattering from fluorochrome-labeled monoclonal antibodies (MAbs).²⁸

Fluorescein isothiocyanate (FITC) is the most universal fluorochrome for immunophenotyping; the second most commonly used dye is R-phycoerythrin (PE). Both dyes can be excited using 488-nm light. Natural and man-made tandem dyes are utilized as third and fourth dyes. Peridinin chlorophyll protein (PerCP) was the first directly conjugated commercially available natural tandem dye. Other dyes are energy-coupled dye (ECD), R-phycoerythrin-CyChrome 5 (PE-Cy5), allophycocyanin (APC), CyChrome 5 (Cy5) and allophycocyanin-CyChrome 7 (APC-Cy7). Currently, simultaneous four-color immunophenotyping is the advanced clinical method. This multicolor application is accomplished by adding a fourth PMT for the detection in the far-red region (Beckman Coulter Corporation, Miami, FL) or by using an additional laser as well as a fourth PMT (BD Biosciences, San Jose, CA). With a red diode laser that excites at 635 nm APC is used as the fourth fluorochrome (see Table 25.1).

For HIV immunophenotyping, single as well as dual laser instruments must produce similar results.^{29,30} Samples are incubated with fluorochrome-labeled MAbs followed by red blood cell lysing.³¹ Various types of leukocyte subsets can then be identified with combinations of intrinsic and extrinsic cell markers.³² The resulting graphic presentation provides not only the relative location of lymphocytes in a dual-parameter dot plot, but also the clustering of monocyte and granulocyte populations. Thus, a three-part leukocyte differential is obtainable.

There is an inherent problem with displays based on intrinsic cell attributes alone. Although the three populations are easy to locate, the light scatter gating protocol does not resolve the interface between populations. For example, there is usually an interface zone between lymphocytes and monocytes where it is possible to find both types of cells (see Figure 25.4). The operator will often set a lymphocyte gate that includes all the lymphocytes but not only lymphocytes or includes only lymphocytes but not all of them. This type of gating strategy is predisposed to optimization of purity and or recovery of lymphocytes, but not both.

In the past decade, steady progress has been made toward the development of more intuitive software for data acquisition and manipulation. A T-gating protocol for simultaneous three-color application was developed in 1992.³³ With this gating method, T cells (CD3) are identified with a bivariate dotplot using heterogeneous parameters, SS (an intrinsic parameter), and CD3 fluorescence (an extrinsic parameter) (see Figure 25.1). From the T-gate, CD4/CD8 cells can be identified by conventional dual-color bivariate

TABLE 25.1 Available MAB–Fluorochrome Conjugates for Single and Dual Laser Immunophenotyping

	Excitation with					
	488	635	Emission	Extinction Coefficient	Quantum	MW
Dye	1st laser	2nd laser	(nm)	$(cm^{-1} M^{-1})$	Yield	(Da)
FITC	X		519	67,000	0.71	389
PE	X		578	1,960,000	0.68	240,000
PerCP	X		675	NA	1	35,000
ECD	x		613	NA	NA	250,000
PE-Cy5	X		675	1,960,000	NA	241,000
APC		x	660	700,000	0.68	104,000
Cy5		x	670	250,000	0.28	792
APC-Cy7		X	767	700,000	NA	105,000

Note: This table includes most of the fluorochromes that are commercially available already conjugated to monoclonal antibodies for immunophenotyping T-cell subsets. Under the column of excitation, the first laser refers to the conventional argon ion source installed on most clinical instruments. The second laser is available as an option on some clinical flow cytometers. NA = not available.

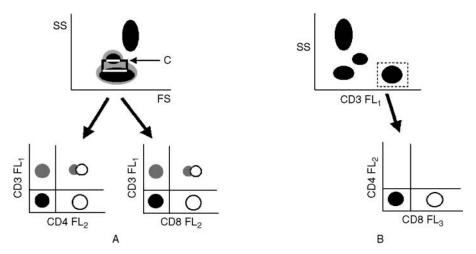

FIGURE 25.4 Gating strategies based on intrinsic and extrinsic cell attributes. Illustrations of homogeneous (A) and heterogeneous (B) gating strategies as they are applied to simultaneous three-color immunophenotyping. (A) is an example of the traditional homogeneous approach to gating, where the two parameters are intrinsic attributes based on cellular morphology. The three regions in the upper part of (A) in descending order are granulocytes, monocytes, and lymphocytes, respectively. Arrow C points to an interface between lymphocytes and monocytes. It is focusing on a common dilemma: how to resolve where the monocyte gate ends and the lymphocyte gate begins. (B) illustrates the advantage of the heterogeneous gating strategy; an extrinsic attribute is harnessed (CD3 FL_1) in combination with an intrinsic one (SS).

quadrant analysis. Heterogeneous protocols can easily be adapted for absolute cell counting. A more recent heterogeneous parameter combination for simplifying CD4 T-cell determinations uses a single tube containing CD45, CD3, CD4, and CD8.³⁴ In this case, the heterogeneous gating strategy combines SS and bright CD45 fluorescence. CD45 is an epitope variably expressed on leukocyte populations in combination with SS; it allows the identification of lymphocytes. This innovative use of heterogeneous gating leads to improved diagnostic tools.³⁵

Absolute cell count (cell concentration) can be obtained by using the single platform technology (SPT). Most clinical flow cytometers are designed to analyze distributions of positive cells within a gate; therefore, CD4/CD8 T cells have been reported as percentage of lymphocytes. However, the most recent guidelines

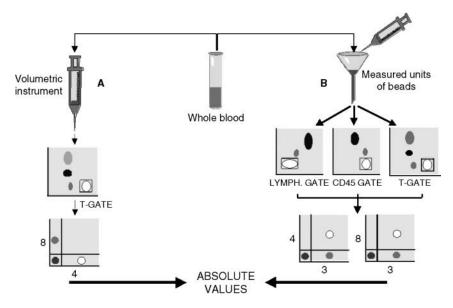

FIGURE 25.5 Various single platform technologies for T-cell subset enumeration. Two SPT approaches are presented for T-cell subset enumeration in (A) and (B). (A) represents a dedicated volumetric instrument where a measured unit of blood is analyzed. (B) illustrates a situation where a known concentration of fluorospheres is added to a known volume of blood. The volume of the mixture is calculated. With the added fluorosphere unit, an accurate T-cell subset count per volume is possible. One homogeneous and two heterogeneous gating strategies are illustrated in the middle of (B).

for immunophenotyping recommend reporting absolute numbers for T-cell subsets.^{36–38} When the absolute count is generated exclusively with a flow cytometer, the process is referred to as a single platform technology. Additional reagents, fluorospheres, are now available to produce absolute and percentage T-cell subsets without data from a hematology instrument.³⁸ SPT is becoming the default protocol for T-cell subset determination (see Figure 25.5). For most clinical instruments, a known number of fluorospheres are added to the whole blood specimen and calculations are made of the ratio between fluorospheres and the volume of sample analyzed with the cells of interest. Precision data have been reported for the single platform method.³⁹ The antigens most often monitored on CD8 T cells are CD57, CD28, and CD38.

Natural killer cells (CD16) decrease with HIV infection, particularly in the later phase of the disease. 40,41 Additional uses of flow cytometry in the detection of HIV infection include evaluation of cell functions such as activation, *in vitro* proliferation, cytotoxic T-lymphocyte responses, detection of various cytokine-producing cells, and measurement of *in situ* HIV antigens and apoptosis. Most of these additional applications are for clinical research use only. In evaluating the effectiveness of HIV therapies, T-cell subsets continue to be the essential clinical surrogate marker for immune status.

In the quest to eradicate the AIDS pandemic, perhaps the next generation of multicolor immunophenotyping instruments will accelerate significant discoveries in cellular immunology, which will in turn lead to long awaited breakthroughs in some overdue fundamental understanding of events in oncology.

25.6.2 Blood Banking

Flow cytometry interrogates the properties of every cell that moves by the laser beam. This feature is exploited in characterizing therapeutic blood products to count an enriched cell population or to validate the effectiveness of removal of unwanted cells.

An example for the first type of application is the enumeration of hematopoietic stem cells by using flow cytometry. 42 Transplantation of hematopoietic progenitor cells is used increasingly in the treatment

of blood disorders, malignancies, and genetic abnormalities. A cell surface molecule, CD34, is present on immature hematopoietic cells and all hematopoietic colony-forming cells.⁴³ The relative frequency of the CD34+ cell population is 1 to 4% of the mononuclear cells in normal bone marrow, and less than 0.1% in normal peripheral blood.⁴⁴ An accurate measure of CD34 cell count is necessary for defining the dose of transplanted stem cells. Cell surface markers (CD34, CD45) and DNA binding dyes are useful to identify stem cells, while the absolute count of CD34 cells is determined by their proportion to a known number of fluorescent beads.⁴⁵

The second category of flow assays identifies the presence of unwanted cells in a purified blood concentrate. Platelet and red blood cell concentrates are regularly used in patient care. Leukocytes could cause graft-vs.-host disease, alloimmunization, and other transfusion-related adverse reactions. Flow cytometry provides a rapid and sensitive method of enumerating "residual" white blood cells in leucoreduced blood products. White blood cells are detected by their binding of a DNA dye; a fluorescent counting bead in the same tube is used as an internal standard for accurate cell counting.⁴⁶

Flow cytometry is a sensitive and rapid research tool for study of platelet disorders.⁴⁷ Conformational changes in platelet glycoproteins, especially GPIIb-IIIa, can be measured using monoclonal antibodies.⁴⁸ These antibodies and multicolor testing strategies are useful to monitor effects of drugs to inhibit platelet activation.⁴⁹

25.6.3 Cancer

Another clinical area in which flow cytometry has contributed to the understanding of disease is cancer diagnosis. Cells from leukemias differ in their molecular, genetic, and immunologic characteristics. Different leukemias have different prognoses and require different therapies. Multiparameter flow cytometry with fluorochrome-labeled monoclonal antibodies has substantially improved diagnosis and classification of the disease, as reviewed in detail by Weir et al.⁵⁰ and Dworzak.⁵¹

In leukemias and other cell proliferation diseases, the analysis of the cellular DNA content (DNA ploidy) has been used to differentiate between healthy and disease-associated cells. High-resolution DNA analysis with precision of close to 1% in DNA content provides information on abnormal DNA content, based on chromosome losses or additions and on the fraction of actively dividing cells (S-phase cells) — a measure for the growth rate of the tumor. More detail on S-phase and ploidy measurements in human cancer tissues can be found in the literature.⁵²

25.7 Clinical Microbiology

Flow cytometry has been demonstrated in many clinical infectious disease applications. Nucleic acid dyes like ethidium bromide have been used to detect bacteria in blood after lysis of blood cells. Identification of bacteria can be performed by immunofluorescence followed by flow cytometric detection. Fungi and parasites can also be measured by flow cytometry. Detection and quantitation of viral antigens and nucleic acids and testing of antimicrobial agents — especially, susceptibility to antibiotics — are other microbiological applications. More detail on these and other applications in clinical microbiology can be found in a recent review with 347 references by Alvarez-Barrientos et al.⁵³ Another reference covers the measurement of microbial susceptibility measurements by flow cytometry.⁵⁴

25.8 Biological and Medical Research

25.8.1 Antigen-Specific T Cells and Immune Function in Infectious Diseases

Quantitative and qualitative measurement of antigen-specific T cells is possible by flow cytometric methods. It offers effective monitoring of immune status during disease and in assessing vaccine efficacy. Single-cell flow assays of antigen-specific T cells include MHC-peptide tetramer staining⁵⁵ and

intracellular cytokine assays.⁵⁶ Each of these assays can provide truly quantitative readouts because they enumerate antigen-specific cells.

Tetrameric complexes of HLA (human leucocyte antigen) molecules can be used to stain antigen-specific T cells in flow cytometric analysis. The enumeration and phenotypical analysis of antigen-specific cellular immune responses against viral, tumor, or transplantation antigens has applications in various experimental and clinical settings.

The intracellular cytokine assay utilizes a three-color combination of fluorochrome-labeled anticytokine, CD69, and CD4 antibodies. CD69 is an early activation antigen whose expression is induced during *in vitro* antigen stimulation. The T cells respond to stimulation by cytokine expression and the secretion of the cytokines is arrested by secretion inhibitors, such as Brefeldin A, inside the cells. The cells are fixed and permeabilized; the frequency of the T cells, which respond to specific stimulation, is determined by the ratio of the cytokine expressing T cells to the total T cell population. This technique allows the detection of functional populations of memory T cells that respond to specific soluble antigens in short-term restimulation assays.

Similar assays are described for detecting antigen specific CD8 T cells, using overlapping peptides as stimulants.⁵⁷ These functional assays assist in delineating the cellular immune response to natural infections or to vaccines.

25.8.2 Measurement of Soluble Analytes Using Multiplex Bead Assays

Flow cytometry can be used as readout for immunoassays. Bead-based, single-analyte flow immunoassays were described for α -fetoprotein assay, β_2 -microglobulin, and for immune complexes. The single assay principle was expanded to the detection of multiple analytes from a single sample, using bead technology.

Beads of different sizes or colors are used for multiplexed immunoassays. McHugh⁶⁰ and Fulwyler et al.⁶¹ used beads of different sizes as carriers for antigens or antibodies. The beads were differentiated by their scatter characteristics and the immunoassay signal was generated through the binding of fluorescent conjugates. Collins used a single bead to measure three different analytes.⁶² Three antibodies were coated to the same bead and the corresponding antigens were detected through binding of monoclonal antibodies, each carrying a different fluorochrome. The three different fluorescent signals were simultaneously detected by using three-color flow cytometry.

Beads can also be identified by one type of fluorescence while the signal is generated by conjugates carrying a second type of fluorescent signal.⁶³ This concept is useful in creating low-complexity bead sets.⁶⁴

Mixing two different fluorescent dyes for the identification of bead populations creates a larger set of distinguishable beads. The immunoassay signal is generated by conjugates coupled to a third type of fluorescent dye. Fulton described such a system, which could differentiate 64 unique bead populations by indexing their position in two-dimensional fluorescent space.⁶⁵

Multiplex beads simplify panel assays. Only a single sample is needed to detect and quantify a number of analytes, an advantage when the sample volume is limited (e.g., pediatric samples, clinical studies, experiments in animal models). The multiple independent measurements within each bead population assure good precision; the wide detection range (at least three orders of magnitude) for fluorescent signal is another advantage. Bead assays are well suited to monitor antibody responses against a panel of antigens from infectious agents. McHugh et al. developed a prototype Hepatitis C virus antibody assay for potential use in the blood bank.⁶⁶

Detection and quantitation of cytokines is a natural area for flow multiplex assays. Figure 25.6 shows a multiplex assay with six cytokines. Oliver, Camilla, and Chen and their co-workers have described multiplex methods to measure panels of secreted cytokines in serum.^{63,64,67} Carson and Vignali demonstrated a multiplex bead assay for simultaneous quantitation of 15 cytokines, using the FlowMetrixTM system.⁶⁸

Pei et al. developed a multiplex bead method to detect antibodies against HLA Class I and Class II antigens.⁶⁹ Pierangeli and co-workers described a flow multiplex assay for the simultaneous detection of

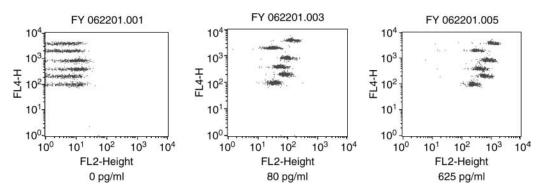

FIGURE 25.6 Multiplex bead immunoassay of 6 human cytokines. Three levels (0, 80, and 625 pg/ml of each of the six cytokines) from a standard curve are shown. The order of the cytokines from top down: IL2, IL4, IL5, IL10, Interferon- γ and tumor necrosis factor- α . (C.-H. Chen and R. Varro, unpublished data.)

IgG and IgM antibodies to cardiolipin and phosphatidylserine.⁷⁰ Lund-Johansen and others⁷¹ applied a bead multiplex assay to assess the level of phosphorylation of different proteins. Monoclonal antibodies were coupled to latex beads, which in turn bound protein kinase substrate proteins. Phosphorylation of the captured proteins was detected with PE-labeled (phycoerythrin) antiphosphotyrosine antibody.⁷

Stall and co-workers constructed a single-tube immunoassay for isotyping of monoclonal antibodies. Seven beads of different red fluorescence intensities were coated with mouse heavy-chain specific antibodies. A mixture of FITC-labeled anti- λ and PE-labeled anti- κ antibodies subsequently identified the heavy and light chain isotype of the captured monoclonal antibody.

Molecular biology techniques are compatible with bead assays. Different amplification strategies were used to demonstrate flow methods to measure HIV viral load.^{73,74} Defoort et al. and Fert developed a flow cytometric reverse transcriptase-polymerase chain reaction (RT-PCR) bead assay to quantitate HIV-1 mRNA.^{75,76}

The multiplex bead method is also compatible with nucleic acid hybridization. Iannone and co-workers describe a multiplex bead method to detect single nucleotide polymorphisms (SNPs). The SNP sites were identified by oligonucleotide ligation (OLA) and subsequent bead capture. Nine SNP markers were simultaneously tested by this method.⁷⁷ Armstrong et al. used direct hybridization to determine the genotypes of eight polymorphic genes in a 32-plex flow assay.⁷⁸ Cai and collaborators developed a sensitive and rapid flow cytometry-based assay for the multiplexed analysis of SNPs based on polymerase-mediated primer extension, or minisequencing, using microspheres as solid supports.⁷⁹

25.8.3 Other Cell Function Assays (Phagocytosis, Oxidative Burst, Basophils)

Flow cytometry is very useful for tracking apoptotic responses. Cellular viability (cytoplasmic membrane permeability) can be monitored using antitubulin antibody. In the early phase of apoptosis the cells lose the asymmetry of their membrane phospholipids. Phosphatidylserine (PS), a negatively charged phospholipid located in the inner leaflet of the plasma membrane, becomes exposed at the cell surface. Annexin V, a calcium and phospholipid-binding protein, binds preferentially to PS, with high affinity. Apoptotic cells are stained by annexin V before the dying cell changes its morphology and hydrolyzes its DNA. Other apoptosis assays include detection of Fas, FasL, caspase enzymes, and other biomolecules. Whole blood flow assays are adaptable for cell function testing. The phagocytic function of granulocytes and monocytes may be measured by detection of ingested fluorescent, opsonized bacteria. One can determine the overall percentage of monocytes and granulocytes showing phagocytosis in general (ingestion of one or more bacteria per cell) and the individual cellular phagocytic activity (number of bacteria per cell).

A variation of this method is used to evaluate the oxidative burst of leucocytes. Unlabeled opsonized bacteria are incubated with heparinized whole blood, and the generated reactive oxidants are detected

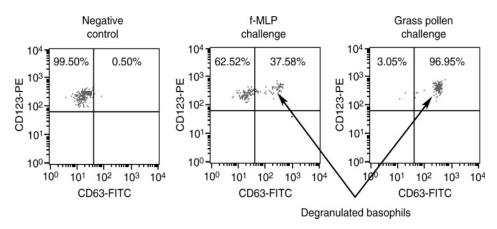

FIGURE 25.7 Basophil degranulation is detected by the rapid appearance of a CD63+ population. (C.-H. Chen and R. Varro, unpublished data.)

by a fluorogenic substrate. Phagocytosis by polymorphonuclear neutrophils and monocytes constitutes an essential arm of host defense against bacterial or fungal infections; a reduction in the rate of oxidative burst may signal inborne defects.^{84,85}

Flow cytometry is an effective method to detect expression levels of receptors on cell surfaces. An example of this type of application is the quantitative determination of low density lipoprotein (LDL) receptor expression on human monocytes. This method is suitable to identify people with the genetically inherited familial hypercholesterolemia (FH) disorder. Individuals homozygous for FH carry mutant forms of the LDL receptor (frequency: 1 in 1,000,000), and have a high risk for atherosclerosis and coronary heart disease. Isolated peripheral blood mononuclear cells (lymphocytes and monocytes) are cultured and the amount of LDL receptors is determined by flow cytometry after staining the cells with a monoclonal antibody against the LDL receptor. This method is useful to identify the genetic defect.

Human basophils represent a very small portion of circulating leucocytes. They are hypersensitive effector cells of the immune system and play an important role in host defense mechanisms and allergic reactions. The binding of allergens to specific IgE fixed on the basophil membrane via the FceRI receptor triggers cellular activation, degranulation, and the release of potent mediators, including histamine and leukotriene C_4 , 87,88 Multicolor whole blood flow cytometric assays were constructed to detect the degranulation of basophils upon allergen exposure. These assays utilize the appearance of CD63, a member of the tetraspanin superfamily, on activated basophils as a marker for basophil degranulation. So Such an assay is shown (Figure 25.7). In this case the basophil phenotype is defined as HLA-DR negative, CD123 positive cell population, and the degranulation is detected by the expression of CD63. A negative and a positive control are shown together with the effect of a specific allergen challenge.

The cytotoxic activity of human natural killer (NK) cells may be detected by flow cytometry. Fluorescently labeled K562 target cells are incubated with whole blood samples, and the killed target cells are identified by a DNA-stain, which penetrates the dead cells and specifically stains their nuclei. This method can detect altered NK function found in various disorders and can also be used to evaluate the effects of drugs on NK activity. 90-92

25.8.4 Thermodynamic and Kinetic Analysis of Binding Phenomena

Flow cytometry is increasingly used for rapid analysis in drug screening.⁹³ When combined with autosampler pumps and microwell plates, the potential throughput can reach 100,000 samples or more per day.⁹⁴ Sample valve systems allow pressure-free introduction of very small samples, creating a "plug-flow" instrument for rapid sequential flow cytometric sample analysis.⁹⁵

Flow cytometry is uniquely capable of making sensitive and quantitative measurements of molecular interactions. These measurements can be made in real time with subsecond kinetic resolution using

purified biomolecules or living cells.⁹⁶ The role of ligand/receptor binding in signal transduction may be studied in real time using bead-bound receptors⁹⁷ or by studying cell surface receptor interactions and signaling pathways in engineered cells, which contain fusion proteins, carrying fluorescent signals. The use of variants of the green fluorescent protein (GFP) provides valuable *in vivo* methods to explore protein binding, transduction pathways, and binding reactions, exploiting the fluorescence resonance energy transfer (FRET) phenomenon.⁹⁸

Live cell assays may be combined with methodology, which provide information on the longitudinal changes of assay parameters through subsequent generations of cells. Carboxyfluoroscein succinimidyl ester (CFSE) binds to cell membranes and then equally distributes into daughter cells during cell division. After a few days in culture, the amount of cell division may be measured by the decreasing amount of fluorescence of each progeny population. CFSE staining can be combined with calcium flux, mitochondrial activity, pH, and free radical production to measure live cell populations in real time.⁹⁹ Technologies are also available to enhance the detection of antigens expressed at low levels. A signal enhancement method, based on localized DNA amplification was demonstrated by Gusev¹⁰⁰ and substantially improved staining sensitivity of cellular antigens. Enzyme-based amplification of the fluorescent staining is another way to increase signal intensities.¹⁰¹

25.8.5 Molecular and Cellular Biology Research, Genomics, and Proteomics

High-speed sorting of chromosomes, especially at the U.S. National Laboratories in Livermore¹⁰² and Los Alamos,¹⁰³ provided the early material for the human genome project. Chromosomes were prepared from cell division metaphase stages, when they are condensed and stable. After staining with fluorescent or fluorogenic dyes, different chromosomes were separated, based on fluorescence intensity. The nucleic acid base sequence of the chromosomes was determined mostly by restriction enzyme digestion and electrophoresis based sequencing. Based on the ability of specialized flow cytometers to detect single molecules,⁸ it has been proposed to sequence long single nucleic acid strands by identifying bases released by an enzyme cleaving off terminal bases. Even though this proposal has not been implemented yet, a nucleic acid analyzer based on the analysis of single fragment molecules from a restriction enzyme digestion of RNAs has been described.⁸

Other applications of flow cytometry in genomics are the identification of specific nucleic acid sequences in single cells by fluorescence *in situ* hybridization and the fluorescence-based detection of the transfection of cells with genetic material in combination with a marker gene like an enzyme¹⁰³ or a fluorescent protein. One of the earliest applications of flow cytometry is based on monoclonal antibody technology. In the past 20 years, thousands of antibodies have been developed against cellular structures. The reaction of fluorophor-labeled antibodies with cell suspensions, followed by a flow cytometric analysis, measures cell subsets carrying the structures identified by the antibodies. To date, 247 cell surface structures of white blood cells have been characterized with this method; they are tabulated by an international organization as numbered cluster designations. One of the transfer and the fluorescence of the fluore

As mentioned in the previous section on medical applications, these surface markers have helped in our understanding of diseases like AIDS. The characterization of these molecules has also contributed substantially to the knowledge in cell biology. Combined with high-speed cell sorting, these markers provide the basis for large scale isolation of specific cell subsets, which can be further characterized by two-dimensional gel electrophoresis, and mass spectrometry for identifying the complete proteome of different cell types.

25.6 Industrial and Environmental Cytometry

Flow cytometry has found quality control and process monitoring applications in several industrial settings. Examples are the monitoring of industrial cell culture, 108 clone improvement by sorting and

recloning highly productive single cells, 109 and the sorting of transfectants based on expression of coexpressed fluorescent proteins. 110

In agriculture, flow cytometry is used for sperm counting¹¹¹ and sorting.¹¹² Methods for counting microbes in foods like milk have been described.¹¹³ For environmental testing techniques have been proposed for water quality monitoring¹¹⁴ and for measuring bioburden in air.¹¹⁵ Marine biologists are using cytometry to count bacteria and viruses in seawater.¹¹⁶

Overview

X-ray diagnostic imaging is one of the most important tools of modern medicine. Approximately 120,000 x-ray rooms are in use in the United States; an estimated 240 million x-ray procedures are performed in the United States every year. X-ray diagnostic imaging is based on the tissue-differential contrast generated by x-ray and tissue interaction. In Section 26.1 we discuss x-ray-tissue interaction and tissue contrast mechanism. In addition to the traditional coverage of x-ray attenuation-based tissue contrast, we discuss x-ray phase-based tissue contrast, which arises from the very nature of x-ray as a wave. Such coverage is especially appropriate in view of the recent surge of research efforts in x-ray phase imaging. X-ray generation, spectra, and exposure control are discussed in Section 26.2. Section 26.3 discusses projection x-ray imaging (radiography and fluoroscopy), digital imaging detectors and x-ray image intensifiers, and image signal-to-noise ratio analysis of projection imaging. In Section 26.4 we discuss in-line phase-contrast imaging, an emerging x-ray imaging modality with great potential for biomedical applications.

26.1 Biological Tissue-X-Ray Interaction and Tissue Contrast

26.1.1 Attenuation-Based Tissue Contrast

X-rays are ionizing and invisible electromagnetic radiation that, compared to light, have much shorter wavelengths. For x-rays, a simple relation between the energy E and wavelength λ of an x-ray photon exists:

$$\lambda = \frac{12.4}{E(keV)} (\text{Å}) \tag{26.1}$$

For example, in medical diagnostic imaging, x-ray photon energy ranges from approximately 10 to 150 keV, so the wavelengths range from 1.2 to 0.083 Å. The amount of x-ray radiation exposure is often quantified by the amount of ionization generated by x-ray exposure, more specifically, by the electric charge generated per unit mass of air. The unit of x-ray exposure is defined as the Roentgen (R), and $1 R = 2.58 \times 10^{-4}$ coulomb/kg.

Interacting with atomic electrons of biological tissue, x-ray photons can be transmitted, scattered (deflected), or absorbed by tissue. Due to the scatter and absorption the incident x-ray intensity I_0 is attenuated, and the transmitted x-ray intensity I is given by

$$I = I_0 \exp\left(-\frac{\mu}{\rho}\rho t\right) = I_0 \exp(-\mu t)$$
 (26.2)

where μ/ρ , ρ , and μ (product of μ/ρ and ρ) are the mass attenuation coefficient, mass density, and linear attenuation coefficient of the tissue, respectively, and t is the thickness of the tissue. That is, x-ray attenuation depends on tissue's elemental composition (μ/ρ), mass density (ρ), and thickness (t). Apparently, x-ray attenuation increases with increasing μ/ρ , ρ , and t. A biological tissue's mass attenuation coefficient can be calculated as the weighted sum of the coefficients for its constituent elements

$$\left(\frac{\mu}{\rho}\right)_{tissue} = \sum_{i} w_{i} \left(\frac{\mu}{\rho}\right)_{i} \tag{26.3}$$

where $(\mu/\rho)_i$ is the mass attenuation coefficients for the *i*th element and w_i is its weight fraction.

This mixture rule ignores any effect of changes in the atomic wave functions as a result of the molecular, chemical, and crystalline environment; however, the errors are less than a few percent. Different biological tissues have different elemental composition and mass densities and thus their linear attenuation coefficients are different. Along with the difference in tissue thickness, these differences in tissue linear attenuation coefficients result in the attenuation-based tissue contrast according to Equation 26.2.

Obviously bone has larger μ/ρ and ρ than that of soft tissue, and thus attenuates much more x-ray than soft tissue does for comparable thickness. That is why a high contrast exists between bone and tissue in x-ray images. However, μ/ρ and ρ of infiltrating invasive breast carcinoma are only slightly higher than those of glandular breast tissue; the small attenuation difference makes x-ray mammography the most technically challenging among all the radiological imaging tasks. A comprehensive compilation of attenuation can be found in the literature. Table 26.1 provides the mass attenuation coefficients for water from 10 to 150 keV. The data are interpolated from the data of that compilation.

In x-ray diagnostic imaging, it is important to get good tissue contrast while keeping radiation dose as low as achievable. In order to accomplish this, it is important to understand that tissue attenuation-based contrast is x-ray photon energy-dependent because the mass attenuation coefficient μ/ρ of a given tissue depends on x-ray photon energy. In fact, three effects lead to the attenuation for photon energies up to 1 MeV (i.e., below the threshold for the pair production): coherent scattering, incoherent scattering, and photoelectric effects. Consequently, the mass attenuation coefficient μ/ρ has three contributions, one from each of the three:

$$\left(\frac{\mu}{\rho}\right)_{total} = \left(\frac{\mu}{\rho}\right)_{coh} + \left(\frac{\mu}{\rho}\right)_{incoh} + \left(\frac{\mu}{\rho}\right)_{obstocl}$$
(26.4)

Coherent scattering is elastic scattering in which x-ray photon does not lose energy, but is deflected. Incoherent scattering is inelastic scattering; x-ray photon transfers energy to tissue while being deflected. With the photoelectric effect, x-ray photon is absorbed by an atom, and as a result, a bound electron is knocked out from the atom. As Table 26.2 shows, these three effects have different dependence on x-ray photon energy E, atomic number E, and atomic weight E. Radiological techniques utilize these relations

TABLE 26.1 Water Mass Attenuation Coefficients

X-Ray Photon E (keV)	μ/ρ m^2/kg
10	0.5232
20	0.0795
30	0.0376
40	0.0268
50	0.0228
60	0.0207
70	0.0193
80	0.0183
90	0.0175
100	0.0169
110	0.0164
120	0.0159
130	0.0155
140	0.0152
150	0.0149

TABLE 26.2 Dependence of Mass Attenuation Coefficients on X-Ray Photon Energy *E*, Atomic Number *Z*, and Atomic Weight *A*

Mass-Attenuation Coefficients	Dependence on E	Dependence on Z and A
$(\mu/\rho)_{coh}$	$E^{-1.8}$	$Z^{2.8}/A$
$(\mu/\rho)_{incoh}$	$E^{-0.2}$	Z/A
$(\mu/\rho)_{photoel}$	$E^{-3.5}$	$Z^{4.5}/A$

to determine optimal x-ray techniques. More specifically, tissue attenuation contrast in x-ray imaging is specified by the subject contrast (SC):

$$SC = \ln \frac{E_2}{E_1} \tag{26.5}$$

where E_1 and E_2 are the absorbed x-ray energy fluence in the detector for the two tissue projection areas. If μ_1 and μ_2 are the linear attenuation coefficients for the two tissues of thickness t, then the subject contrast between these two tissues for a monoenergetic incident x-ray can be found by using Equation 26.2:

$$SC = \ln \frac{\exp(-\mu_2 t)}{\exp(-\mu_1 t)} = (\mu_1 - \mu_2)t$$
 (26.6)

Note that for polychromatic x-rays the difference $(\mu_1 - \mu_2)$ in this formula should be weighted by the x-ray spectrum. Figure 26.1 shows the subject contrast between a 0.5-mm microcalcification and breast glandular tissue as a function of x-ray photon energy. It shows clearly that the tissue subject contrast decreases rapidly with increasing x-ray photon energy. This is because tissue μ/ρ decreases with increasing x-ray photon energy. Therefore, tissue contrast decreases with increasing x-ray photon energy.

Note that tissue contrast increases with differences in tissue atomic numbers. Therefore, different x-rays are employed for imaging different body parts. For breast imaging, where tissue contrast is low, photons of low energies from 15 to 25 keV are best to keep good tissue contrast and relatively low radiation dose to the breast.³ For chest imaging, where tissue contrast among bone, soft tissue, and air is high, photons of much higher energies (up to 150 keV) are used to keep low dose and reasonable dynamic range.

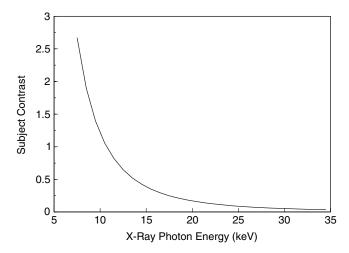

FIGURE 26.1 The subject contrast between a 0.5-mm microcalcification and breast glandular tissue as a function of x-ray photon energy.

In general, the higher the photon energy, the smaller the μ/ρ . However, when photon energy reaches the binding energy of atomic electrons of tissue, photon absorption jumps up because of increasing atom ionization; hence, the mass attenuation μ/ρ jumps up accordingly. The photon energies at which μ/ρ jumps up are called the absorption edges. The existence of absorption edges is of great significance for designing x-ray imaging detector and spectrum-shaping filters (see below.)

26.1.2 Phase-Based Tissue Contrast

In addition to the attenuation, tissue contrast can be realized from the x-ray phase change generated by tissues. Attenuation-based tissue contrast has been utilized in medical imaging for about 100 years, but phase-based tissue contrast was not recognized until quite recently.⁴ X-ray phase change does not arise from new x-ray-tissue interaction; rather, it is a result of coherent x-ray scattering. As was mentioned previously, an x-ray, like light, is an electromagnetic wave. Like any wave field, a coherent x-ray wave field propagating along the z-axis can be described as

$$\psi(x,z) = \sqrt{I(x)} \exp(ikz) \tag{26.7}$$

where x is the coordinate for the transverse direction, $k = 2\pi/\lambda$, λ is the x-ray wavelength, and I(x) is the x-ray intensity. In this case the phase of x-ray wave is kz. When an x-ray scatters from tissue, the phase of the x-ray wave field is changed. This phase change is the result of coherent scattering with small angles and contains diffraction and refraction effects from scattering. The amount of the phase change is determined by biological tissue dielectric susceptibility or, equivalently, by the refractive index of the tissue. The refractive index n for an x-ray is complex and equal to

$$n = 1 - \delta - i\beta \tag{26.8}$$

where δ , the refractive index decrement, is responsible for x-ray phase shift, and β is responsible for x-ray absorption. The δ is given by Wilkins et al.:⁴

$$\delta = \left(\frac{r_e \lambda^2}{2\pi}\right) \sum_{k} N_k (Z_k + f_k^r) \tag{26.9}$$

where r_e , N_k , Z_k , and f_k are the classical electron radius, atomic density, atomic number, and real part of the anomalous atomic scattering factor of the element k, respectively. If the x-ray is away from the absorption edge of tissue, this formula can be simplified to

$$\delta = \left(\frac{r_e \lambda^2}{2\pi}\right) \sum_{k} N_k (Z_k + f_k^r) \cong (4.49 \times 10^{-16}) \lambda^2 N_e$$
 (26.10)

where N_e is the electron density. Although we observe x-ray absorption by body parts everywhere in radiology, we nevertheless often do not realize that human tissue actually refracts x-rays. This is not because tissue δ is too small compared to β ; on the contrary, tissue δ (10^{-6} to 10^{-8}) is about 1000 times greater than β (10^{-9} to 10^{-11}) for x-rays in the 10 to 100 keV range. It is ironic that all x-ray clinical imaging techniques thus far have been designed to image tissue β but not δ . Using this formula for refractive index decrement δ , the amount of x-ray phase change from biological tissue can be calculated as

$$\phi = \frac{2\pi}{\lambda} \int \delta(s) ds \tag{26.11}$$

where s is the distance traveled by the x-ray beam along the vacuum propagation direction.

At this stage of development there are three major modes for phase imaging: x-ray interferometry, diffraction-enhanced imaging, and in-line phase-contrast imaging. The x-ray interferometry images the phase ϕ directly by using a monochromatic x-ray from synchrotron radiation and monochromator crystal.⁵ The diffraction-enhanced imaging⁶ measures the phase gradient $\nabla \phi$ directly by using monochromatic x-ray from synchrotron radiation as well. The in-line phase-contrast imaging measures the Laplacian of phase $\nabla^2 \phi$ directly.⁴ This mode can be implemented with polychromatic x-rays from an x-ray tube. Because x-ray tubes are compact and relatively readily available, we believe that this mode has great potential for clinical applications. The in-line phase-contrast mode is discussed in detail in Section 26.4.

26.2 X-Ray Spectra and Exposure Control

26.2.1 Bremstrahlung and Characteristic Radiation

X-ray attenuation and tissue contrast are x-ray photon energy-dependent, so it is very important to use x-ray photons of appropriate energies to image any given body parts. In order to achieve this, one must first learn how to control the spectrum of x-ray used in imaging. X-ray is usually generated by interaction of electromagnetic fields and charged particles such as electrons. Although an electromagnetic field surrounds a charged particle in a uniform motion of any velocity, it cannot radiate any electromagnetic waves. Only charged particles undergoing acceleration or deceleration can emit x-ray radiation. In medical imaging, the x-ray is usually generated by bombarding a metal target with energetic electrons.

When impacted with a metal target, the incident energetic electrons collide with atomic electrons and nuclei of the metal atoms. In metal the incident electrons slow down and are deflected. The swift deflections are caused primarily by the electrostatic attractive force between nuclei of metal atoms and incident electrons. With these swift deflections, incident electrons undergo huge momentum change, which means huge acceleration; hence, these deflected indent electrons emit x-rays. After repeatedly colliding with the metal atoms, the incident electrons eventually slow down to rest in metal and lose their ability to emit x-rays. X-ray radiation generated by the slowing down of energetic electrons in metal is called bremstrahlung. Bremstrahlung usually consists of x-ray photons of different wavelengths. In other words, bremstrahlung is polychromatic. According to Kramer's law, bremstrahlung intensity $I_{br}(E)$ at photon energy E, is

$$\begin{split} I_{br}(E) &= CZI_{br}(E_o - E), & \text{for } E < E_o, \\ I_{br}(E) &= 0, & \text{for } E > E_o \end{split} \tag{26.12}$$

where Z is the atomic number of the metal target, I_{tube} is the current of incident electrons, and E_o is the kinetic energy of incident electrons. In medical x-ray imaging equipment, incident electrons are accelerated by an applied voltage before impinging on a metal target. That is, for a bremstrahlung E_o in Equation 26.12 equal to eV_o , where V_o is the applied acceleration voltage, e is the electron charge. Kramer's law predicts that below E_o the spectral intensity increases with decreasing E (Figure 26.2). However, due to x-ray attenuation by the metal target, one finds that the output bremstrahlung peaks somewhere around $E_o/2$ (Figure 26.2), depending on the target material and filtration (see below). The total approximate bremstrahlung intensity I_{br-t} can be found by integrating Equation 26.12 over E:

$$I_{br-t} = CZI_{tube}V_o^2 = CZI_{tube}PV_o (26.13)$$

where P is the power loading of tube. Equation 26.13 shows that the total bremstrahlung intensity is approximately proportional to the square of applied acceleration voltage V_o , tube current I_{tube} , and the atomic number Z of the metal target material. Therefore, in order to increase x-ray bremstrahlung intensity, one should apply high acceleration voltage, increase current, and adopt high-Z target material. These three factors are among the most important considerations in the design of x-ray generating devices.

In addition to the bremstrahlung, there is another important mechanism of x-ray generation. When colliding with the atomic electrons of the target, the incident electrons can knock out atomic electrons from their atomic shell and cause the inner shell ionization of metal atoms. X-ray photons can be emitted when the ionized atoms return to their ground states. This kind of x-ray radiation is called the characteristic radiation because the energies of the emitted x-ray photons are discrete and equal to the binding energy differences of atomic shells. Characteristic radiation is named after the relevant inner atomic shells such as K-shell, L-shell, etc.

For example, the K-characteristic radiation results from knocking out of a K-shell electron by an incident electron. Let eV_b be the binding energy of an atomic shell. Obviously, characteristic radiation from this shell can be generated only if $V > V_b$. The larger the $(V - V_b)$, the greater the characteristic radiation. The total

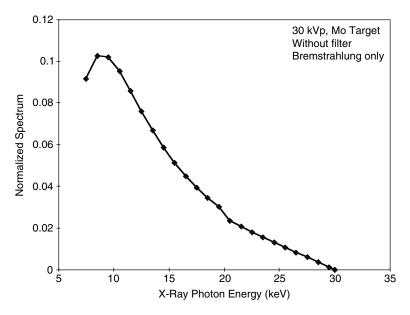

FIGURE 26.2 X-ray bremstrahlung spectrum for an Mo-target at 30 kVp.

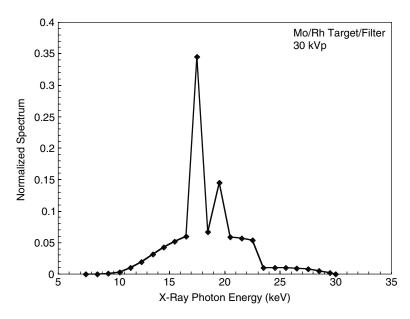

FIGURE 26.3 X-ray spectrum for an Mo-target and Rh-filter at 30 kVp.

output x-ray consists of bremstrahlung and characteristic radiation, and the summed spectrum is shown in Figure 26.3. The spikes in this figure are superposition of these two kinds of x-ray radiation.

For tubes used for general radiography and fluoroscopy, the metal target layer is tungsten (W) alloyed with 5 to 10% of rhenium (Re). However, the target material for mammography is either molybdenum (Mo) or rhodium (Rh). Note that the atomic numbers for W, Mo, and Rh are 74, 42, and 45, respectively. Equation 26.13 shows that a W-target would generate much more bremstrahlung than would an Mo- or Rh-target. The reason for using an Mo- or Rh-target in mammography application is that the K-characteristic radiation photons generated from these targets are in the range of 17 to 23 keV, optimal for breast imaging.

In addition to the metal target material, one can use a filter, a metal sheet, to shape the output x-ray spectrum. During an exposure, low-energy photons are in the bremstrahlung as shown in Figure 26.2. These photons will be absorbed by the patient's body parts before reaching the imaging detector and hence contribute nothing to the imaging. An aluminum filter can reduce the number of low-energy photons, make the x-ray beam more penetrating, and reduce radiation doses to patients. This approach of shaping x-ray spectra is also called beam hardening by filtration. Usually an aluminum filter of 1 mm or more in thickness is used for this purpose. Sometimes, a copper filter of 0.1 mm or more in thickness can be used in fluoroscopy to reduce patient dose significantly.

For mammography, so-called absorption edge filters are used to shape the beam spectrum. As has been explained, the mass attenuation coefficient μ/ρ jumps up at the absorption edge. Using an absorption-edge filter one can selectively attenuate photons with energy higher than the absorption edge, hence shaping the output x-ray spectrum. For example, Mo has an absorption edge at 19.97 keV, and Rh at 23.19 keV. Using an Mo or Rh filter with x-ray tube with an Mo-target, one can generate a larger portion of x-ray photons with the optimal energy range (18 to 23 keV) to achieve better tissue contrast and reduction of radiation dose to breast glandular tissue.⁷⁻⁹

26.2.2 X-Ray Tubes

An x-ray tube is a device that generates x-rays by using the principle previously discussed; it consists of a cathode as the electron emitter, a rotating anode disk as the metal target, and a glass or metal envelope as a structural supporter (Figure 26.4). The glass or metal envelope is used to keep a vacuum of about

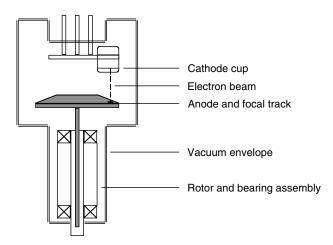

FIGURE 26.4 Schematic of an x-ray tube with a rotating anode.

 5×10^{-7} torr inside the tube. The cathode is composed of a filament (tungsten wire helix of 0.2 to 0.3 mm diameter) and a focusing cup. When heated to around 2400°C by the filament current, the hot filament emits electrons. Except for low tube potentials, the tube current I_A that results from the emitted electrons is almost independent of tube potential and is a function of filament temperature:

$$I_A = CT^2 \exp(-W/kT)A_f \tag{26.14}$$

Here T is the temperature in K, W is the filament's work function (for tungsten W = 4.5 eV), A_f is the area of the filament, k is the Boltzmann constant, and C is a material-dependent constant. Obviously, tube current I_A increases with filament temperature. Usually, the filament current is around 5 A and the tube current ranges from 20 to 1000 mA for radiography. Note that Equation 26.14 is invalid for low tube potentials (<50 kV). When tube potential is low, not all the electrons emitted by filament are drawn to the anode, and the tube current I_A is less than that predicted by Equation 26.14. I_A becomes tube potential-dependent.

This behavior of I_A is often called the space-charge effect. In breast imaging, tube potentials used are relatively low and vary from 25 to 35 kVp. In these cases the achievable I_A is limited by the space-charge effect (especially with small focal spots) and the low I_A imposes a technical challenge for mammography applications.

The tube focusing cup makes the electron beam focus so that the focal spot on the anode surface is kept small. A small focal spot is necessary for achieving a good spatial resolution of x-ray imaging. In projectional x-ray imaging, x-ray focal spot size determines the size of image blur:

$$B = (M - 1)f (26.15)$$

where M is the geometric magnification factor, which is the ratio of the source-detector distance to the source-object distance, and f is the focal spot size. So if M = 2 (as in magnification mammography), B = f. Any fine feature of sizes less than f (at image plane) cannot be recognized. In general, a tube is equipped with two to three focal spot sizes for selection. For tubes used in general radiography, typical focal spot sizes are 1 to 1.2 mm for the large spot sizes and 0.5 to 0.6 mm for small spot sizes. For tubes used in mammography, typical focal spot sizes are 0.3 mm for the large spot and 0.1 mm for the small spot.

The tube anode is a rotating metal alloy disk. In addition to the metal target layer discussed in the previous subsection, the remainder of the anode disk is graphite or molybdenum (Mo). Because about 99% of the energy of incident electrons is transformed into heat at the anode, the anode disk materials should have high melting point and good thermal conductivity. During an exposure, the focal spot is

hotter than the focal track, which is hotter than the anode body because the anode is rotating during an exposure. The anode as a rotor is driven by the stator through magnetic induction, running as an asynchronous motor. The stator driving current is provided by the high-speed starter of the x-ray generator (discussed in detail in the next subsection). The anode rotation speed usually ranges from 1200 to 3600 rpm, and can go as high as 10,800 rpm for the high-speed mode.

Operating "dry" in a vacuum at such a high temperature, the ball bearing must satisfy some exceptional specifications. To extend its life, the anode starts to rotate just before each exposure; after exposure it is brought to rest by a braking circuit of the generator. Note that electron impact time decreases with the velocity ωr , where ω is the anode angular velocity and r is the anode radius. Therefore, the focus spot temperature increases with the input power and x-ray exposure time and decreases with increasing focal spot size, rotation speed, and anode diameter. Because the practical limit of the focal spot temperature is 2500°C (although tungsten's melting point = 3370°C, the highest of all metals), each x-ray tube has its own maximum allowable power loading, which is called the tube power rating. During an exposure, the average power loading P_{load} to an x-ray tube is determined by

$$P_{load} = wVI \tag{26.16}$$

where w is the kV-wave-shape factor, V is the tube kVp (the peak voltage in kV), and I is the tube current in mA.

The kV-wave-shape factor w depends on kV-wave form because the tube kVp is not equal to the average tube potential. For the 3-phase 12-pulse, or high-frequency generators, w = 0.99; for 3-phase, 6-pulse generators, w = 0.95; and for the single-phase generators, w = 0.74. For tube operation, the power loading of an exposure should be lower than the allowed tube power rating, which increases with increasing focal spot size, rotation speed, and anode diameter, but which decreases with exposure time. Power ratings for different exposure times can be determined from the manufacture-supplied tube rating chart or the so-called single-exposure rating chart. For the radiography and fluoroscopy applications, the tube power rating is 100 kW for a 0.1-s exposure with an anode rotation of 10,800 rpm and a focal spot of 1.2 mm. The tube power rating is reduced to 30 kW with a smaller focal spot of 0.6 mm. In addition to the power rating, x-ray tubes are also specified by anode heat capacity, the maximum anode heat load allowed. The heat load H_L generated during an exposure, expressed in heat units (HU; 1 joule = 1.35 HU), is given by

$$H_{L} = 1.35 P_{load} T_{exp} (26.17)$$

where P_{load} is the power loading of the exposure and T_{exp} is the exposure time (in seconds).

Use of large anode mass increases anode heat capacity. For radiography and fluoroscopy (R&F) applications, tube anode heat capacity usually is not less than 400 kHU. Although the power loading is not high for x-ray tubes in computed tomography (CT) applications, the heat loading is high due to long continuous scan time. The anode heat capacity for CT applications can be as high as 6.5 MHU or more. Tube heating during multiple exposures depends also on heat dissipation; in fact, the anode cools by radiating out heat. In order to increase heat dissipation, one can increase anode surface and use the emissive coating. In addition, tube housing is limited by its own maximal allowable heat load. Exceeding the housing maximum heat load can cause failure of the housing or the tube due to the thermal expansion of the insulation oil surrounding the tube. For some applications, like digital subtraction angiography, a tube assembly may be equipped with external oil-to-air or oil-to-water heat exchangers for fast cooling.

26.2.3 X-Ray Generators

In order to generate x-ray and control x-ray exposures one needs to apply controllable high voltage to an x-ray tube. The main function of an x-ray generator is to provide controllable high tube voltages and high tube currents for x-ray generation and exposure control. A generator is specified by the kVp rating

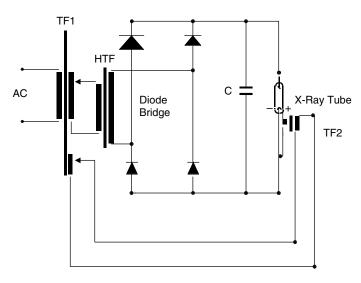

FIGURE 26.5 Circuit schematic of a single-phase x-ray generator.

(the maximum kVp allowed), and the kV-ripple and power rating (the maximum power loading allowed for a 0.1-s exposure.) Here the kVp means the peak tube voltage in kV. The tube voltage is not a strict constant during an exposure, but with ripples around a mean value.

The amount of the kV-ripple is usually specified as a percentage of the peak voltage. As mentioned earlier, tube voltage determines the highest energy of the output x-ray photons. Therefore, in addition to tube kVp and tube current, the amount of kV-ripple affects x-ray radiation output and x-ray spectra. Small kV-ripple is desirable for x-ray exposure reproducibility, consistency of image quality, and radiation dose reduction. In general, the higher the kVp, the more penetrating the x-ray beam, but the lower the image contrast. Therefore, the tube kVp used varies depending on the body parts to image. Typically, one uses 125 to 150 kVp for chest x-rays, 110 to 130 kVp for computed tomography, 75 to 85 kVp for abdomen exams, 65 to 75 kVp for skull exams, and 24 to 35 kVp for mammography. Therefore, typical x-ray generator kVp ratings are 150 kVp for R&F generators and 45 kVp for mammography generators. The typical power ratings are 60 to 100 kW for digital subtraction angiography (DSA) generators, 50 to 60 kW for the R&F generators, and about 5 kW for mammography generators.

The heart of an x-ray generator is a high-power and high-voltage circuit. A basic single-phase generator is shown in Figure 26.5. The autotransformer TF1, which is fed by the line AC power, functions as the kVp control. The low-input AC voltage is transformed into high AC voltage by using the high-voltage transformer HTF. The diode bridge rectifies (in the full-wave) the high-voltage AC. The step-down transformer TF2 provides filament current control. The kV-ripple can go as high as 100% with a single-phase generator; however, if the line supply is replaced by a three-phase line supply, then the rectified sine waves from different phases can be interleaved; hence, kV-ripple can be reduced to 13 to 25% (for the 6-pulse interleaving) and 5 to 10% (for the 12-pulse interleaving.) Note that hat tube kVp generated by single- or three-phase generators depends on the input line regulation as well, and the kVp reproducibility is easily compromised by unstable line supply condition. The other drawback of single- or three-phase generators is the slow response for tube kVp control.

For medical imaging equipment, compactness is crucial. The high-voltage transformers of single- and three-phase generators are especially bulky in size and weight. However, note that the induced voltage, U, of a transformer is proportional to the product of A, n, and f, where f is the transformer operating frequency, A is the core cross section of transformer, and n is the number of turns. It is clear that increase of operating frequency f allows reduction in f and f and f and f are generator operating at a high frequency can be much smaller in size and lighter in weight. This is why high-frequency generators operating at

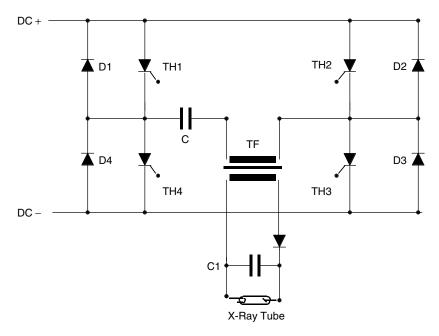

FIGURE 26.6 Circuit schematic of a high frequency inverter.

a high frequency of a few to tens (or even up to about 100) kilohertz have proliferated in recent years. They reduce the size and weight by 50 to 80% compared to single- and three-phase generators, and they reduce manufacturing costs as well. Moreover, high-frequency generators provide fast response and greatly reduced kV ripples.

High-frequency generators are based on converter technology. The key is to convert the conventional AC power of 60 Hz and a few hundred volts to a high-frequency (HF) power supply of tens of kilohertz. This task is assumed by the HF inverter. The conventional AC power is first rectified and filtered to a DC power; the DC power is then inverted to HF pulses. Figure 26.6 shows a basic DC to HF inverter. Four thyristors, TH1 to TH4, work as controlled switches. A thyristor works like a diode with a control gate. The trigger pulses are applied to the gate of a thyristor control switching on and off the current flowing through the thyristor. The high-voltage transformer TF couples the x-ray tube as a load to the inverter and provides high voltage to the tube. The HF pulses are generated by a series RLC resonant circuit.

In this case, coupling capacitor C, inductance L of transformer TF, and the tube load consist of a series RLC resonant circuit controlled by "switches" TH1 to TH4. The RLC resonant circuit works as follows. When thyristors TH1 and TH3 are gated on, they work like two closed switches. The DC voltage is then applied to the RLC circuit. As is well known, capacitor C tends to oppose voltage changes and inductor L tends to resist current change because capacitor C stores electric energy and inductor L stores magnetic energy and energy transfer takes time. The interchange of the stored electric for magnetic energy and vice versa results in a current oscillation in the thyristors and RLC circuit. Due to energy dissipation on the load R, the oscillating current is really a dampened sinusoidal current. The frequency of the oscillating current is called the resonant frequency f_{res} , and is given by

$$f_{res} = \frac{1}{2\pi\sqrt{LC}} \tag{26.18}$$

During the negative half of the sinusoidal cycle, current flows through the antiparallel diodes D1 and D3, instead of thyristors TH1 and TH3, because thyristors do not allow a reverse current. Note that dampening the load makes the second peak smaller than the first in the cycle. However, when the full sinusoidal cycle is completed, the RLC resonator cannot start its second cycle because thyristors TH1

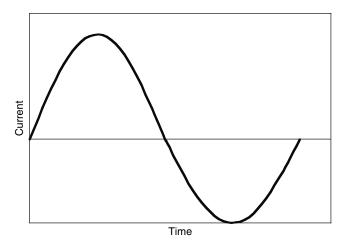

FIGURE 26.7 Current pulse waveform in a high-frequency inverter.

and TH3 have already been switched off (self-communication) during the reversing half cycle. Therefore, only a single current pulse is generated (Figure 26.7) for each pair of trigger pulses to the gates of TH1 and TH3. To degauss the transformer core, TH2 and TH4 take turns generating the next current pulse in a similar way. The difference is that the polarity of the applied DC power is reversed this time; hence, the RLC resonance process leads to a "reversed" current pulse. The frequency at which the two trigger pulse pairs are applied is called the driving frequency f_{d^*} . The higher the driving frequency, the denser the current pulse train.

The secondary coil of the transformer TF couples a rectifying circuit with the RLC circuit. The rectifying circuit consists of a diode bridge and a capacitor C_l for filtering. Because tube voltage is equal to the voltage across C_b , C_l is called the load capacitor. The rectifying circuit converts the high-frequency current pulses into charge pockets stored in C_l . At the beginning of an exposure, the driving frequency f_d is very high in order to charge C_l rapidly and build up the desired tube voltage. The voltage of load capacitor C_l can be measured by a precision resistor voltage divider. Once the desired tube voltage is established, a feedback signal will be sent to a voltage frequency converter V/F, the output of which controls the driving frequency f_d of the gate trigger pulse circuit. The f_d will then be reduced to deliver just enough charge pockets to C_l for compensating the discharge consumed by the tube current. Therefore, although the resonant frequency f_{res} is fixed by coupling capacitor C and inductance L through Equation 26.18, the driving frequency f_d varies during exposures. However, the maximum driving frequency allowed is the resonance frequency f_{res} .

Using the closed-loop servo control described previously, tube voltage control is very fast and accurate, and the kV-ripple ranges from 2 to 15%, depending on the power rating. For a given resonant frequency f_{res} , the ripple decreases with increasing power. Therefore, in order to keep uniform kV-ripple, an x-ray generator may need to use different coupling capacitors when the tube focal spot is switched, because the power rating with the small focal spot is much lower than that with the large focal spot.

Another advantage of high-frequency generators is that they can use single-phase or three-phase line supply because the inverter circuits of the generators are powered by DC power. The inverter circuit described earlier can also provide power for the filament. In a filament inverter, the filament transformer is step down in voltage (step up in current) and the secondary coil of the transformer is coupled directly with the tube filament without rectifying circuitry. A precision resistor in series with the x-ray tube senses the tube current in real time, and the sensed signal is used as the feedback signal to control the driving frequency of the filament inverter. In this way tube current control is much faster and more accurate than that with single- or three-phase generators.

In addition to providing high voltage and power to the tube, an x-ray generator should also provide the means for x-ray exposure control. It is clear from Equation 26.13 that the exposure rate is proportional

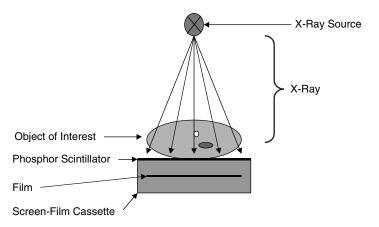

FIGURE 26.8 Schematic of projection radiograph.

to tube current, and the total exposure is proportional to the integral of I_{tube} over exposure time, which is called the total mAs (mA × seconds) of the exposure. All x-ray generators include an mAs switch to control the total mAs delivered during an exposure. A simple electronic timer (for a constant the mA during exposure) can be the mAs switch circuitry or a current integrator (for a falling I_{tube} during exposure). However, modern x-ray generators use the automatic exposure control (AEC) circuitry as the mAs switch.

With AEC, exposures are turned off once a preset amount of exposure incident on the image receptor is reached. In this way AEC ensures that the imaging detector always receives almost the same amount of radiation exposure regardless of object attenuation. A typical AEC circuit consists of an x-ray sensor, a current integrator, and a comparator. The x-ray sensor generates a sensing current proportional to the exposure rate incident on image receptor. The current integrator measures the total exposure to the image receptor. Finally, the comparator sends out the exposure termination signal when the output of current integrator reaches the preset exposure value. The radiation sensor can be an ionization chamber that transforms x-ray to electric current. A fluorescent screen coupled with a photodiode can also function as the radiation sensor for AEC. In this case a fluorescent screen transforms the x-rays to light and a photodiode works as a light sensor.

26.3 Projection X-Ray Imaging

26.3.1 Conventional Radiography

Projection radiography is the most conventional technique used in radiological imaging. It uses an x-ray beam to generate a two-dimensional transmission image of patient anatomy. As shown in Figure 26.8, during x-ray exposure the x-ray beam passes through the body of the patient and is recorded by a two-dimensional detector. On the passage, the x-ray radiation is attenuated by absorption and scattering within the body; the x-ray gets diffracted as well. Different anatomical structure, as well as different body thickness, attenuates and diffracts the x-ray beam differently. However, in this section we discuss only attenuation-based projection radiography; phase-contrast imaging is discussed in Section 26.4.

The conventional projection radiograph is a spatially modulated attenuation pattern of the anatomical structure. In other words, a projection radiograph is a two-dimensional "x-ray shadow image" of the three-dimensional anatomy of the patient. More exactly, a projection radiograph is a two-dimensional map of I(x, y):

$$I(x,y) = I_o \exp\left(-\int \mu(x,y;s)ds\right)$$
 (26.19)

where I_o is the incident x-ray intensity, I(x, y, s) is the detected intensity at position (x, y, s), and s is the distance along the ray direction from the x-ray focal spot to point (x, y). The integral in Equation 26.19 gives the projection sum of the linear attenuation coefficients along the ray path. This projection image is different from the images from the tomography (longitudinal and computed tomography), where an image of a tissue slice is a two-dimensional map of the tissue linear attenuation coefficients' map $\mu(x, y; s)$ of the slice at s. Due to space limitations, tomography will not be covered in this chapter.

The x-ray detectors can be screen–film combinations or digital imaging detectors. Film was the first radiographic detector used in medicine, and to date it has been widely used in medical imaging. In fact, the function of a radiographic film is not only limited to a detector; it simultaneously plays a role as display device and archiving medium.

Unexposed film is a thin sheet of inert plastic coated with emulsion on one or both sides. The film is insensitive to x-ray energies used in medical practice; therefore, the x-ray images are, in most cases, detected with a screen–film combination. Here the term screen, also called intensifying screen, refers to a luminescent screen that contains densely packed luminescent materials. The luminescent substances should be highly efficient for x-ray absorption and conversion of x-ray to light and should have light emission spectra matching the film's spectral sensitivity.

At present, most intensifying screens use gadolinium oxysulfide (Gd_2O_2S) as the luminescent material. The Gd_2O_2S -based intensifying screens convert each x-ray photon of 30 keV to about 1500 green light photons. A piece of film is placed in direct contact with a piece of intensifying screen in a cassette. During x-ray exposure, the x-ray photons exiting from the patient first interact with a Gd_2O_2S -based intensifying screen. The screen will convert the x-ray to green light, and the green light exposes the film. With a subsequent chemical development process, the original radiographic image of the patient is captured permanently on the film.

26.3.2 Digital Radiography

In recent years radiology has undergone a revolutionary change from screen-film-based radiology to digital radiology, which uses optoelectronic detectors to record images. A digital image detector detects transmitted x-ray pixel by pixel (the field of a single detector element). Thus, the digital image appears as an array of pixels. Figure 26.9 shows an example of how a simple one-dimensional image would appear in analog and digital format. To decrease the information loss from discontinuities in the image due to pixel averaging, the detector element size must be significantly smaller than the important features within the image. Although the digital image can be captured with a large dynamic range, interpretation of the radiograph requires that the image be depicted on screen or in hard-copy format. The information in these representations of the image is usually truncated to 8-bit data from 12- or 14-bit data. This is not necessarily a problem because features of interest are often within a smaller grayscale range than the entire dynamic range of the detector; however, high-fidelity electronic display and hard-copy printing devices are necessary to preserve diagnostic quality.

Various optoelectronic detectors have been developed and successfully applied in clinical practice. Three types of detectors are used in the majority of digital imaging systems; charge-coupled device (CCD)

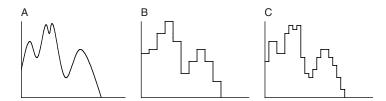

FIGURE 26.9 Analog image information is recorded as a sequence of individual pixel values as opposed to a continually changing function. The digital value at a pixel can be thought of as the average of the analog value across the area of the pixel. The analog image (A) can lose resolution as it is converted to a digital signal (B). To improve resolution, the detector element size, i.e., pixel size, can be decreased (C).

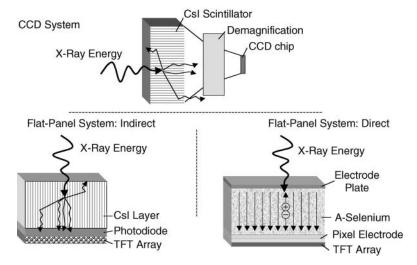

FIGURE 26.10 Digital radiography detectors have two main types: the CCD system and the TFT flat-panel system. The CCD system converts the x-rays to visible light at a CsI scintillator screen before the signal is demagnified and detected at the CCD. One type of flat-panel system, the indirect system, also converts the x-ray signal to visible light before it is converted to charge by photodiodes at the detector. The direct flat-panel system converts the x-rays directly to charge in a layer of amorphous selenium. The charges are drawn to the detector by an applied electric field.

detector systems, flat-panel thin-film transistor (TFT) detector systems (Figure 26.10), and the photo stimulable phosphor imaging plate detector systems. Each detector type has its advantages and disadvantages; certainly they are most effective when applied to particular tasks. Before we describe and compare these detectors in detail, let us discuss the specification parameters for digital imaging detectors. These parameters include field coverage, detector sensitivity and quantum efficiency, spatial resolution, noise factors, and dynamic range.

The image size requirements are important factors in selecting a detector. Stereotactic breast biopsy imaging, for example, requires relatively small images to be acquired; thus, for this application, a single CCD detector including a demagnification step would be acceptable because minimal demagnification would be necessary. For larger images, a higher degree of demagnification is necessary to map to the CCD, possibly decreasing image resolution to an unacceptable level. CCDs are combined into detector arrays for use in larger-size imaging applications. Another alternative, full-field TFT arrays, which are manufactured in standard film sizes, may have better performance potential for larger image fields.

Detector sensitivity, that is, how well the detector converts the x-ray signal into charge, is another factor. Sensitivity is directly related to the efficiency of this conversion, the so-called quantum efficiency. The x-ray quanta interact with the detector material primarily according to the photoelectric effect, wherein one or more photons are produced as the x-ray quanta loses energy to an atom (high Z) of the detector. The quantum efficiency, η , is related to the attenuation properties of the detector material as well as to detector thickness. In other words, efficiency is dependent on an x-ray's effectiveness at giving up energy to a detector atom, as well as on the likelihood of the x-ray encountering a detector atom to donate this energy to, a quantity proportional to the thickness of the detector material.

The attenuation properties are determined by the composition of the detector material as well as by the energy of the incident x-rays. In general, higher-energy x-rays can penetrate more deeply into detector material (the attenuation coefficient is smaller for high energies), whereas low-energy x-rays penetrate more shallowly (the attenuation coefficient is larger for low energies). Another factor affecting quantum efficiency is the "fill factor" of the detector, i.e., the area of active detector material per total detector element area. As the fill factor approaches 100%, less undetected radiation must be used for an image of adequate intensity and thus the total radiation dose is minimized.

The spatial resolution of the detector plate is dependent on characteristics of the detector as well as on external factors. Significant detector characteristics affecting resolution are the size of the active portion of each detector element (the effective aperture size), the distance between detector elements (the spatial sampling interval), and lateral spreading effects due to limitations of the detector material or information transfer from the detector to the computer. External factors influencing spatial resolution include relative motion between the detector and the x-ray source or the patient, and unsharpness resulting from the magnification of the image due to the spreading of the x-ray beam. Different resolutions are necessary for different types of imaging, depending upon the size and spacing of significant features.

Another factor affecting the sharpness of an image is noise. All x-ray images are statistical in nature. In other words, because x-rays arrive at the detector in quantum packets of energy, the image will inherently contain some degree of graininess, or quantum noise. Ideal image acquisition systems are called quantum noise limited because no other sources of noise exist. The x-ray image signal must be significantly stronger than the noise or it will not be discernable and thus not useful. The signal-to-noise ratio (SNR) is a quantity that indicates the relationship between the useful signal and other noise.

The detective quantum efficiency (DQE) describes the effectiveness of transferring the SNR of the incoming x-ray signal to the digital output, that is, adding as little extra noise in the process as possible. The mathematical formula for DQE and a detailed DQE analysis are the subject of the next subsection. Ideally, the DQE is equal to the quantum efficiency, η , but detectors add noise from different sources depending on their particular characteristics. Some detectors, for example, are sensitive to visible light as well as x-rays and therefore light leakage into the detector casing may increase noise. Other detectors are very sensitive to heat and must be operated at low temperatures to reduce so-called thermal noise. Background noise can often become insignificant if the incident image signal is intensified; however, a challenging balance exists between minimizing radiation dose and achieving reasonable SNR at the outcome.

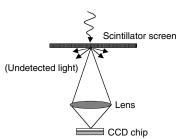

The dynamic range of a detector describes the range of signal levels at which the detector can accurately record an image, considering intrinsic noise factors. The range must be adequate to measure the most and the least radio-opaque regions of the image and everywhere in between. The dynamic range is limited at low levels because the signal can become washed out by noise. At high levels, detector elements can become saturated and leak onto adjacent elements, blurring the final image. Although most digital detectors are capable of acquiring images with a significantly reduced x-ray dose compared to their screen–film counterparts, many sources of noise must be controlled to maintain adequate imaging ability at these low signal levels.

A common type of digital detector is the CCD (see Figure 26.10). Systems utilizing the CCD as the detector element have had a few variants in the decades since its advent. The CCD is manufactured as a 2- to 5-cm square chip tiled with 256×256 to 2048×2048 sensitive detectors that correspond to pixels in the digital image. CCD detectors utilize an indirect conversion system, incorporating a step to convert x-rays to light before the detection step. Incident x-rays are converted to visible light at a scintillation screen. Although so-called unstructured and structured scintillators are used, structured scintillators like crystalline cesium iodide have better resolution capabilities. Cesium iodide forms needle-like crystals that act like optical fibers to direct scattered light to the photodiode with improved spatial resolution. ¹²

Although other scintillator materials are used, light produced by phosphor materials in unstructured screens is more likely to spread to adjacent pixels, reducing resolution properties. Because the CCD is smaller than what most imaging applications demand, image demagnification or various types of detector field expansion must take place. The detector field can be expanded by combining several CCDs into a detector array to obtain an image with a single exposure. The detector field can also be expanded by scanning a single CCD or a smaller CCD array throughout the image field to obtain piecewise images that are combined at the end of the imaging process. ¹⁰ Image demagnification can be accomplished with a system of lenses or with tapered optical fibers (Figure 26.11). The efficiency of lens coupling is limited by the sampled light signal that hits the collecting optics, and the image is susceptible to distortion due to lens defects. ¹¹ Consequently, only a fraction of the signal emitted by the phosphor plate is transmitted

Optical Lens Coupling:

Fiber Optic Coupling:

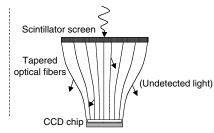

FIGURE 26.11 The CCD detector receives the visible light image after demagnification by a lens system or tapered optical fiber system. The lens system transmits only a portion of the light from the CsI screen, leading to a reduced SNR at the detector (and thus a reduced DQE). The tapered optical fiber system is also inefficient, leaking some light as the reflection angle changes along the length of the fiber.

through the lens system to reach the detector. The SNR of this type of system is highest when little demagnification is necessary.

Optical fiber tapers are not completely efficient or distortion-free. Visible light output from the phosphor plate can leak from the optical fibers due to the changing reflection angle within the optical column, and bundling of multiple tapered fibers can produce image distortion (Figure 26.11). The inefficiency of the lens and fiber-optics systems causes the DQE of CCD detectors to be lower than systems not requiring demagnification. Systems that require very little demagnification have the highest DQE. The advantages to CCD detectors are that they have extremely low intrinsic noise factors, so a high degree of detector capability can be achieved despite inefficiencies due to demagnification. In addition, the CCD has a broad dynamic range and a highly linear response to the incident signal.¹¹

The second broad system category is the flat-panel system, which utilizes a thin film transistor array as the detector (Figure 26.10). Within this category, there are two types of systems: those that convert x-rays directly to electric charge that can be read out by a computer as a digital signal (direct conversion), and those that include an intermediate conversion from x-ray photons to visible light photons (indirect conversion).

The indirect conversion detector has a few steps of signal modification before the analog image is converted to digital. The first modification occurs at a scintillation screen, where a phosphor, usually crystalline cesium iodide (CsI), absorbs the x-rays and re-emits energy in the visible spectrum, according to the photoelectric effect. High-energy x-ray quanta incident on the plate are each converted to several visible light quanta, resulting in an intensification of signal known as quantum gain. ¹¹ The thicker the phosphor layer, the greater the likelihood that all of the x-rays will interact with phosphor to create photons and maximize quantum gain.

However, the light emitted from the phosphor is not necessarily emitted in the same direction in which the incident x-ray was traveling. Consequently, this conversion adds a scatter, or blurring, effect to the original signal that is directly related to the distance the light photons need to travel before detection, i.e., the thickness of the phosphor. Thus, the thickness of the layer must be determined by compromising these effects (Figure 26.12). The ideal thickness would maximize intensity while minimizing distortion of the signal at the output.¹¹ CsI crystals are actually grown on the surface of microelectronic detector plates to improve the detector's spatial resolution and efficiency. At the exit face of the scintillator screen, the visible light is detected by an array of amorphous silicon photodiodes that transmit a proportional quantity of charge to transistors, where it is stored until readout (Figure 26.13A).

The direct digital system is constructed as a layer of amorphous selenium sandwiched between a single electrode plate at the entry face and pixel-sized TFTs at the exit face. A voltage at the electrode plate during image acquisition creates an electric field within the selenium that maximizes image quality. The incident x-ray signal passes unaltered through the electrode plate and is absorbed in the selenium layer.

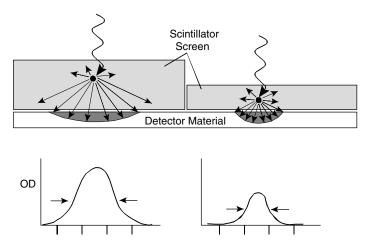

FIGURE 26.12 The ideal scintillator screen would maximize intensity (increase thickness), while minimizing image distortion or wash-out due to scattering (decrease thickness).

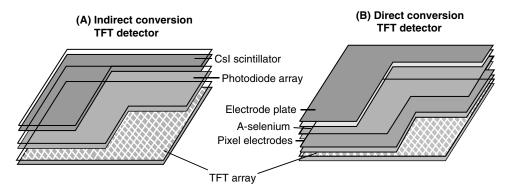

FIGURE 26.13 The indirect conversion flat-panel detector (A) has three layers: a CsI scintillator plate, an array of pixel-sized photodiodes, and a layer of a-silicon thin film transistors. The direct conversion flat-panel detector (B) has four layers: an electrode plate, an amorphous selenium semiconductor layer, an array of pixel electrodes, and a layer of a-silicon thin film transistors.

The x-ray energy liberates electrons within the selenium layer which are drawn by the electric field straight to the pixel electrodes at the exit face. This design results in very little image scatter and a fill factor theoretically approaching 100% because the electric field funnels charge into the transistors and thus loses minimal signal from the area between active portions of detector elements (Figure 26.13B).

For direct or indirect conversion, information is retrieved in the same manner — through an active matrix readout method. The information in the TFTs is read row by row. An electric pulse is applied to the gate of the transistors one row at a time, allowing the charge stored at the drain to be measured at the source (Figure 26.14). The charge at each column location is amplified and multiplexed row by row until all of the transistors have been read out, at which point the information is compiled into a complete digital image file. ¹³ An indexed 12- or 14-bit numerical value — in base 10, a number from zero to several thousand — is stored in the file for each pixel in the image.

The third category system is computed radiography (CR), which utilizes the photostimulable phosphor imaging plate (also known as the storage phosphor) as the detector device. Photostimulable phosphor imaging plates are the most popular large-area electronically readable detectors currently available. CR (a misnomer) is based on the photostimulable phosphors. These phosphors are made up of barium fluorohalide family compounds (BaFX, where X is I, Br, or Cl) doped with bivalent europium ions that

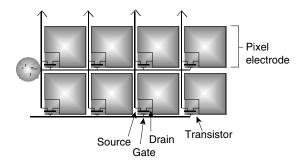

FIGURE 26.14 Information is read from the detector through an active matrix readout method. An electric pulse is sent along a row (starburst), allowing the stored charge to be read at each pixel column location (arrows). The entire array is read out row by row and multiplexed into a digital image file.

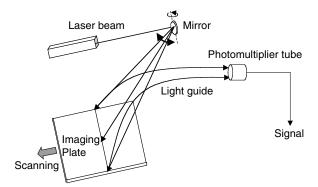

FIGURE 26.15 Schematic of the laser scanner for reading exposed photostimulable phosphor plates.

provide the luminescence centers. Incident x-ray makes electron–hole pairs in the crystal. Some of the halogen ion vacancies trap electrons to create the metastable F-centers. These trapped electrons create a latent image.¹⁴

To retrieve the latent image, one places the exposed phosphor plate into a laser scanner. A red He-Ne laser beam raster scans the exposed phosphor and the trapped electrons are released from the traps. Undertaking atomic energy level transitions, these released electrons migrate to europium ions to release the stored energy as luminescence blue light. A photomultiplier tube collects the emitted blue light as signals to form the image (Figure 26.15). Note that the storage plate is reusable after erasure by intensive illumination. Obviously, the spatial resolutions depend on the spatial sampling frequency of the scan laser.

The major advantage of the storage plates is that they can be used exactly like conventional portable cassettes, but with latent images in traps rather than on film. The storage plates are available in different sizes matching the standard field of views (FOVs) and with large enough dynamic ranges for radiography. For these reasons, storage plates have been widely used in emergency and bedside radiography since their debut in the early 1990s. More than 10,000 CR units have been installed in the United States to date.

This technology also has several disadvantages. First, the laser light scattering in the phosphor reduces the spatial resolution. Spatial resolutions are approximately 1.5 lp/mm at 50% MTF; the limiting resolution is approximately 3.5 line pairs (lp)/mm. Second, the DQE(f) is low due to the low efficiency of collecting the signal light and the granularity noise involved, especially at high spatial frequency. The DQE is about 15% for low spatial frequencies and decreases rapidly with increasing spatial frequency. This DQE is lower than that of screen–film-based radiography; therefore, the radiation doses to the patient are more than 50% higher than those with conventional radiography. Third, the work throughput of radiography with phosphors is lower than that of conventional radiography.

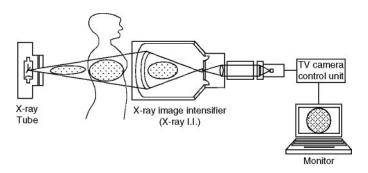

FIGURE 26.16 The flow chart for fluoroscopic image formation.

26.3.3 Image Intensifier TV Chain and Fluoroscopy

Another important modality of projection x-ray imaging is fluoroscopy, in which exposures are continuous and acquired images are displayed on a TV monitor, usually on 30 frames per second. Therefore, fluoroscopy images body parts in real time. This real-time imaging capability makes fluoroscopy extremely useful for diagnostic imaging, therapeutic imaging (cardiac angioplasty, interventional procedures), and image guidance for surgical procedures.

The key device for fluoroscopy is the image intensifier-TV chain. The flow chart for fluoroscopic image formation is shown in Figure 26.16. As a projection imaging modality, a continuous x-ray exposure is projected on body parts of interest and the transmitted x-ray from these body parts is detected first by an image intensifier. An image intensifier comprises a vacuum bottle with an x-ray transparent input window and a glass or fiber-optic output window through which the output image is displayed. Figure 26.17 is a schematic drawing of an image intensifier (I.I.). Because the transmitted x-ray is incident upon a scintillation layer (commonly of CsI:Na) of the I.I., an x-ray photon is absorbed via the photoelectric effect (discussed in Section 26.1). The absorbed energy is eventually converted to low-energy secondary electrons and these electrons then recombine under emission of light. The wavelengths of the light depend on the scintillator and doping material used in the I.I.

For the commonly used CsI:Na scintillator the peak wavelength of light is about 420 nm. Each absorbed x-ray photon of 30 keV would produce about 1500 light photons. These photons then reach the semi-transparent photocathode of I.I., which is made up of antimony and various alkali metals such as cesium. For example, cesium antimonide (Cs₃Sb) is commonly used for photocathodes. In order to increase I.I. efficiency, the light sensitivity of the photocathode is matched to wavelength of the scintillation light. Again, through the photoelectric effect mentioned in Section 26.1, the light photons kick out electrons from the photocathode.

Thus far, the detected x-ray has completed conversion to photoelectrons. The spatial distribution of the photoelectrons is just a "contact print" of the light image in the input phosphor of I.I. Obviously,

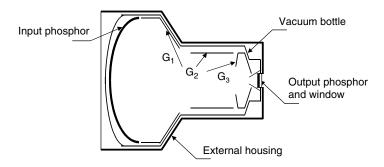

FIGURE 26.17 Schematic of the image intensifier (I.I.).

the thicker the input phosphor (e.g., CsI scintillator layer), the more light is generated and, hence, more electrons are converted. However, an increase in thickness also leads to an increase in lateral diffusion of light inside the layer and consequently reduces its spatial resolution. Usually, the thickness of CsI layer varies from 300 to 450 μ m; typically, each impinging x-ray photon of 30 keV generates about 200 electrons. The x-ray attenuation-based image detected by the input phosphor converts to a photoelectronic image.

A photoelectronic image is not convenient for projection on a television camera for display, but is relatively easily "intensified." Therefore, one needs to amplify the photoelectronic image first and then convert the amplified photoelectronic image into a visible image for the TV camera. This amplification is done through electron acceleration by applied high voltage; an output phosphor (output screen) is employed to convert the amplified photoelectron image into a visible image, which is an intensified original x-ray attenuation-based image. For the amplification, a high voltage is applied between the photocathode (V = 0) and the output phosphor (V = 25 to 35 kV; see Figure 26.17). In this way each electron gains in energy by about 30 keV.

A common output phosphor is the P20 phosphor, which is a mixture of zinc cadmium sulphide doped with silver ($Zn_{0.6}Cd_{0.4}S:Ag$) and 15,16 emits green light of 520 and 540 nm. Impinging on the output phosphor, each of the accelerated electrons causes the emission of about 1000 green light photons. Because each absorbed x-ray photon of 30 keV generates about 200 electrons from photocathode as mentioned earlier, each absorbed x-ray photon of 30 keV will generate 2 \times 10⁵ green light photons at the output window. Comparing this figure to the intensifying screens (Gd_2O_2S -based screens) used in conventional radiography (Section 26.3), the light photon gain from an I.I. is about 100 to 200 times higher.

To further increase the light output luminance (flux intensity), demagnification technique is employed. The ratio of the input phosphor entrance size to the output phosphor size is called the demagnification ratio. The diameter of output phosphor is about 1.5 to 3.5 cm, much smaller than that of the I.I. entrance fields, which varies from 15 to 40 cm. The luminance of the output phosphors is the light flux density, so the luminance is proportional to the square of the demagnification ratio. Therefore, demagnification brings about 100-fold increase in output light luminance. Combining the I.I. intrinsic gain and demagnification gain, we can define the gain of an I.I. as the conversion factor. This factor specifies how much output light luminance is per unit exposure rate in units of mR/s. Modern I.I. have conversion factors more than 200 Nit/(mR/s)(for 112-in. I.I.), and when the conversion factor degrades to below 100, the image intensifier should be replaced; otherwise, poor image quality and high radiation doses to the patient and operator may result.

In addition to image intensification, an image intensifier should also provide images without much blurring and distortion. The function of electron optics of an I.I. is to ensure that the photoelectrons emitted by the photocathode are focused on the output phosphor with tolerable distortion. Three additional electrodes (G1, G2, and G3 in Figure 26.17) inserted between photocathode and output screen implement the electron optics. These five pieces form the so-called pentrode structure of electron optics. The G3 electrode allows one to zoom image by reducing the input screen portion projected onto the output phosphor. For example, by increasing G3 voltage, we can make a smaller portion of input phosphor project onto the output phosphor and the demagnification ratio reduces. Because the size of output phosphor is fixed during adjusting G3 voltage, reduction of the demagnification ratio magnifies the images.

Therefore image intensifiers of any given size always have magnification modes corresponding to smaller entrance sizes. For example, it is common that a 12-in. I.I. has magnification modes for 9-in. and 6-in. sizes. The G2 electrode is the focusing electrode. When fluoroscopy images show losing spatial resolution (say resolution <1 lp/mm for 12-in. I.I.), we usually recommend that G2 voltage (and the TV camera focusing) be checked. The G1 electrode adjusts the resolution uniformity.

Once the x-ray attenuation images have been converted to visible light images at output phosphor, a TV camera is used to generate the video signals for display on a TV monitor (Figure 26.16). The TV camera is optically coupled to the output screen of the I.I. by the so-called conjugate lens. Obviously the CCD device discussed in detail earlier is a good choice for a TV camera; however, the vacuum camera

tube is commonly used instead. A camera tube is a vacuum tube of about 1 in. external diameter, consisting of a target plate made of light-sensitive photoconductive materials, e.g., antimony trisulphide (Sb_2S_3) , an electron gun, electron scanning, and focusing coils. A green light image from I.I. output phosphor is projected by the lens onto the target of camera tube. The target is photoconductive, so one light photon creates a mobile electron–hole pair.

Hence, the local electric resistances of the target are changed according to the illumination intensities received locally. The higher the intensity, the lower the local resistance. In this way, the projected image forms a map of the resistance changes on the target. When an electron beam scans the target line by line (512 or 1024 lines), the electron beam picks up (senses) the resistance changes and converts them into electric current changes. The signal current (the displacement current) ranges from about 100 nA for an average image brightness to 2000 nA for a very bright image. The signal current changes with the illumination intensity as

$$I_s = cE^{\gamma} + I_d \tag{26.20}$$

where I_s is the signal current, I_d is the dark current, and c is a constant. E is the illumination intensity and γ determines how fast the signal current changes with E. Therefore, γ determines the signal transfer characteristics and has important effects on the image contrast scale and the dynamic range. While the beam scans the target line by line, the video signal changes accordingly. The camera tube functions as a signal current source and feeds the video amplifier. The video signal (voltage signal) is mixed with the TV synchronization signals to form the composite video signal and then is amplified. The amplified complete video signal is sent to a TV monitor for image display.

The most commonly used TV camera is the vidicon tube, which uses antimony trisulphide (Sb_2S_3) as the target photoconductive material. Vidicon tube has γ of 0.7; hence, it has a good dynamic range. By the way, the video amplifier for fluoroscopy is linear, and the TV monitor has γ of about 2. The overall system γ is thus about 1.4. In addition to γ , other important parameters of a TV camera are the lag, sensitivity, noise, resolution, and burn resistance. The definition of lag requires explanation. Lag is the inertia that is the residual signal percentage after 20 scans. It is the most important parameter and essentially determines if the camera device can be used in an imaging task. Vidicon has a relatively large lag of 8 to 16%; it cannot be used for angiography and image-guided interventional procedures. However, it has the advantage of reduction of noise (by integration of image frames) for fluoroscopy. The target material mainly decides the lag of a camera tube. For example, plumbicon (PbO target) has a lag of 1% and saticon (SeAsTe target) has a lag of 6%. The CCD camera has a very low lag as well. These camera tubes are used in angiography and interventional procedures. Note that all TV cameras (including CCD) other than vidicon have unit γ .

Another important aspect of fluoroscopy is automatic exposure control (AEC). Because different anatomical structures may have quite different attenuation, the x-ray factors (kVp and mA) should be adjusted accordingly in real time to keep comparable image brightness and reduce undue radiation exposure to the patient. To achieve this, one must have the means to sense the exposure rate of x-ray incident on I.I. entrance and to keep it constant during fluoroscopy by adjusting the x-ray factors (kV and mA) through a feedback control of the x-ray generator. The target I.I. entrance exposure should be set on a balance of good image quality and reduction of radiation doses to patients and medical staff. According to our experiences from clinical applications, target I.I. entrance exposure rates should be set so that the low contrast resolution (discussed in Section 26.3.4 in terms of SNR) is about 2.5 to 3.5% for features of about 1 cm in size. In our experience the I.I. entrance exposure rates should be set at approximately 1.2 to 2.4 mR/min for a 12-in. I.I., and scaled inversely with the square of the ratio of I.I. sizes. For example, the I.I. entrance exposure rates should be about 2.4 to 4.8 mR/min for a 9-in. I.I.

The photocathode current of I.I. and video signal from a TV camera can be used as the sensing signal AEC of fluoroscopy. With AEC, low x-ray factors (low kVp and mA) are used for imaging small and easily penetrated body parts; consequently, the x-ray exposure rate to the patient is relatively low as well. As the attenuation of imaged body parts increases, AEC automatically drives x-ray factors (kVp

and mA) up in an amount just enough to maintain comparable image brightness. In this way constant average image brightness is achieved and inadequate radiation exposure to patients and medical staff is avoided. Of course, for the sake of radiation protection, the maximum exposure rate is limited. As increasing attenuation drives AEC to the maximal exposure rate, one must increase the video amplifier's gain to keep image brightness approximately constant. This video gain adjustment is implemented by the automatic gain control (AGC) circuitry. Note that the maximal exposure rate at patient skin entrance should not exceed 10 R/min according to U.S. federal regulations. If the x-ray system has a high-level control and special means of its activation, then the maximum exposure rate at the patient skin entrance should not exceed 20 R/min when high-level control is activated, also according to U.S. federal regulations.

26.3.4 Signal-to-Noise Ratio Analysis

In radiological imaging, x-ray quantum efficiency and corresponding imaging characteristics such as SNR, noise power spectrum (NPS), and DQE are crucial to design considerations and performance evaluations such as lesion detectability and patient radiation dose. The following modeling of SNR, NPS, and DQE provides a comprehensive summary of theoretical and of practical aspects of radiological imaging apparatus. Here we use the optically coupled CCD system described in the previous subsection as an example for analysis. This concept can be applied to many other radiological imaging systems.

In an optically coupled CCD x-ray imaging system (no image intensifier in the imaging chain), the transfer of light from an x-ray intensifying screen to a CCD imager can be accomplished by directed contact of these components. However, currently available CCDs require a demagnifying optical coupler (either a lens or fiber taper) between the intensifying screen and the detector to image an area larger than the size of the detector. In the quantum transfer of image data between an intensifying screen and imager, the optical coupling component represents a weak link in the cascaded imaging chain. Thus, in the 1960s and 1970s, image intensifiers were considered integral components for achieving quantum noise limitation in electronic imaging systems. To determine whether this assumption holds for newer electronic detectors, we derived an equation for analyzing the SNR for these systems.

The noise in an optically coupled CCD system is composed of quantum noise (x-ray quantum noise and secondary quantum noise generated through the cascaded process) and additive noise (noise related to the detector or to the detector electronics). Although each noise component can be analyzed separately using existing mathematical methods,¹⁷ we have derived an SNR equation encompassing the combined effects of quantum and additive noise.¹⁸ This equation was derived based on the principle of cascaded imaging analysis and other SNR models.¹⁷ Although it can be applied to many imaging systems, it is particularly convenient for analyzing performance or optimizing design tradeoffs for optically coupled CCD x-ray imaging systems. The details and derivation of this equation can be found in Reference 18.

$$SNR = C(\eta N_i)^{1/2} \left[1 + \frac{1}{g_1 g_2} + \frac{1}{g_1 g_2 g_3} + \frac{N_a^2}{\left(g_1 g_2 g_3\right)^2 \eta N_i} \right]^{-1/2}$$
(26.21)

where η is the quantum efficiency of the intensifying screen or other scintillator used in the imaging chain. It is assumed that all the statistical processes of absorption, photon transport within the screen, and photoemission can be described and characterized by one number: the quantum efficiency η . Also, N_i is the x-ray photon flux, which is the number of x-ray photons per pixel at the entrance of the intensifying screen; N_a is the total additive noise of the overall imaging chain; g_1 is the x-ray-to-light conversion ratio, or quantum gain of the intensifying screen; g_2 is the optical coupling efficiency of the lens, fiber taper, or other coupler; g_3 is the quantum efficiency of the CCD or other electronic detector; and C is the subject contrast. The product of $g_1g_2g_3$ is the overall quantum efficiency, or total quantum gain of the system; its unit is the number of electrons produced in the CCD per x-ray photon absorbed in the scintillator (electrons per x-ray photon).

The quantum efficiency of a Min-R medium mammographic screen has been estimated at $\eta=0.65.^{19}$ Assuming a typical mammographic screen entrance exposure of 12 mR and an average x-ray photon energy of 20 keV, the number of x-ray photons per pixel at the entrance of the intensifying screen for a detector having a 0.048 × 0.048 mm pixel size is $\eta N_i=1600$ x-ray photons/pixel. Therefore, the number of absorbed x-ray photons per pixel is $\eta N_i=1040$ x-ray photons/pixel. For this analysis, a contrast (*C*) of 1 was assumed. For a system using a cooled CCD, the total additive noise N_a is usually less than 15 electrons; for TV tubes, N_a is usually larger than 500 electrons. The x-ray-to-light conversion ratio (g_1) of a high-resolution mammography intensifying screen is reported at 400 to 600 in the forward direction. Conservative estimates of g_3 are (1) 0.35 for a front-illuminated CCD; (2) 0.60 for a back-illuminated CCD such as the Tektronix (TK2048EB); and (3) 0.20 for a TV tube. From our previous work, we have estimated the optical coupling efficiency of a lens to be:

$$g_2 = \frac{0.75}{4F^2(1+M)^2 + 1} \tag{26.22}$$

where F is the F-number (the ratio of the focal length to the effective diameter) of the lens and M is the demagnification ratio. For example, for an F/0.8 (F = 0.8) lens working at a demagnification factor of 2, $g_2 = 3.1\%$.

Equation 26.21 can be used to illustrate the dominant noise component in a cascaded electronic imaging system. For example, if the total quantum gain, $g_1g_2g_3$, of the imaging chain is small or the additive noise, N_a , is large, the value of the denominator is larger than 1. Then the SNR of the system is dominated by one of the cascaded stages or by additive noise. While $g_1g_2g_3$ is small, the additive noise, N_a , will affect the performance of the system significantly. As $g_1g_2g_3$ becomes large, the value of the denominator approaches 1 and the equation reduces to SNR = $C/\eta N_i$, representing a perfect x-ray quantum noise limited, additive noise-free imaging system.

To illustrate an example application of Equation 26.21, we use parameters typical for lens-coupled TV camera systems, which were extensively investigated in the 1960s and 1970s. Substituting $g_1g_2g_3 = (500)(0.031)(0.2) = 3.1$ and $N_a = 500$ into Equation 26.21, we have:

$$SNR = \frac{C(\eta N_i)^{1/2}}{(1.32 + 25)^{1/2}} = 0.2C(\eta N_i)^{1/2}$$
 (26.23)

This example illustrates that the lens-coupled TV system is not x-ray quantum noise limited and that it is the additive noise (N_a) , not the total quantum gain $(g_1g_2g_3)$, that dominates the SNR.

The introduction of the I.I., as discussed earlier, provided a solution to the additive noise problem by boosting the image signal and increasing quantum gain. The value for $g_1g_2g_3$ may approach 400; therefore, the SNR of an I.I. TV system can be expressed as:

$$SNR = \frac{C(\eta N_i)^{1/2}}{(1 + 0.004)^{1/2}} = 0.99C(\eta N_i)^{1/2}$$
 (26.24)

The I.I. TV system is absolutely x-ray quantum noise limited and both analog and digital I.I. TV systems are used currently in many clinical procedures. However, electro-optical devices such as image intensifiers have limitations that reduce spatial resolution and contrast sensitivity. Mammography, which requires high spatial resolution and high contrast sensitivity, cannot be performed using a conventional I.I. TV system. Examining Equations 26.21 through 26.24 more closely, it is theoretically intuitive that x-ray quantum noise limitation might be achieved **without** an image intensifier if the additive noise level were greatly reduced. Modern CCD receptors, with additive noise as low as 15 electrons, are suitable

TABLE 26.3 Total Quantum Gain and Additive Noise and Their Impact on SNR

	Lens-TV	I.ITV	Lens-CCD
Additive noise N_a	500 Electrons	500 Electrons	15 Electrons
Quantum gain $g_1g_2g_3$ SNR	3.1 Electrons/x-ray $0.2C(\eta N_i)^{1/2}$	400 Electrons/x-ray $0.99C(\eta N_i)^{1/2}$	9.3 Electrons/x-ray $0.95C(\eta N_i)^{1/2}$

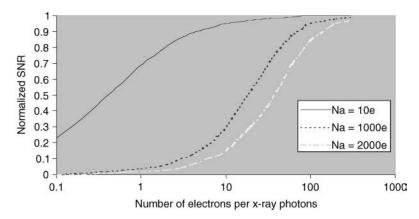

FIGURE 26.18 Normalized SNR curves plotted as functions of total quantum gain (electrons/x-ray) and additive noise (electrons).

detector candidates. For current CCD devices, a typical total quantum gain can be expressed as $g_1g_2g_3 = (500)(0.031)(0.6) = 9.3$ electrons/x-ray photon. Using Equation 26.21, the SNR is calculated to be:

$$SNR = \frac{C(\eta N_i)^{1/2}}{(1.1 + 0.002)^{1/2}} = 0.95C(\eta N_i)^{1/2}$$
 (26.25)

Therefore, the degradation in SNR caused by the cascaded stages and the additive noise is nearly negligible for a cooled CCD system. It illustrates that an optically coupled CCD imaging system can indeed be x-ray quantum noise limited.

Assuming a contrast (C) of 1 and a constant phosphor noise level for all three systems, the preceding analyses can be summarized as shown in Table 26.3. Note that, in this table, the value of $g_1g_2g_3$ for the lens TV was calculated assuming the quantum efficiency of the TV tube is 0.2. The value of $g_1g_2g_3$ for the lens CCD was calculated assuming the quantum efficiency of a back-illuminated CCD to be 0.6. Figure 26.18 plots the relationships of SNR to the total quantum gain (electrons/x-ray) and total additive noise (electrons) for three detector systems and illustrates that a total quantum gain of ten electrons per absorbed x-ray makes a CCD imaging system x-ray quantum noise limited at the low-frequency range. According to our calculations and experiments, it is feasible to design a lens-coupled or a fiber optically coupled CCD x-ray imaging system to meet these requirements under clinical conditions. In comparison, other electronic detectors have noise levels of a few hundreds or even a thousand electrons.²² To achieve x-ray quantum noise limitation under these conditions, a total quantum gain of 100 to 200 electrons/absorbed x-ray photon is needed.

NPS analysis of image noise and noise transfer provides a complete description of noise. When characterizing the noise properties of real or proposed digital mammographic systems experimentally, we calculate the NPS directly from the noise fluctuations using the fast Fourier transform (FFT):

$$NPS(f_x, f_y) = FFT_{2D}[N(x, y)]$$
 (26.26)

where FFT_{2D} represents the fast Fourier transform and N(x, y) is a two-dimensional data array of noise fluctuation or a so-called "noise-only" image. This image is acquired using the following procedure:

- 1. Acquire images A(x, y) and $B_1(x, y)...B_{50}(x, y)$ under identical conditions simulating clinical mammography procedures. A 4.5-cm-thick lucite slab is used and the entire imaging field is uniformly irradiated.
- 2. Determine the "noiseless" image as an average of 50 images:

$$\langle B(x,y)\rangle = \frac{\sum B_n(x,y)}{50}$$
 (26.27)

- 3. Calculate N(x, y) = A(x, y) B(x, y) as the difference between the single image A(x, y) and the noiseless image; N(x, y) is the noise-only image we are seeking.
- 4. $NPS(f_x, f_y)$ is a two-dimensional data array in the frequency domain. We assume the proposed CCD imaging system to be symmetric in the x and y directions; therefore, a slice of the data, $NPS(f_x)$, is taken to evaluate the noise properties of the whole image.

Repeating these procedures 20 times (n = 20), 20 $NPS(f_x)$ curves are generated. Furthermore, the $NPS(f_x)$ is normalized with respect to its value at zero frequency, making the value at zero frequency equal to 1; the normalized noise power spectrum is given by:

$$NPS'(f_x) = \frac{1}{20} \sum_{x} \frac{NPS(f_x)}{NPS(0)}$$
 (26.28)

The averaging process in Equation 26.27 is usually necessary to avoid statistical uncertainty.

The preceding discussion on noise power spectrum provides a foundation for understanding the concept of noise propagation in a cascaded imaging chain, and its relation to the SNR and DQE. The measured NPS curves of various optically coupled CCD x-ray imaging systems can be found in the literature.^{23,24}

The DQE expresses the SNR transfer characteristics of an imaging system as a function of the spatial frequency: 23,25

$$DQE(f) = \frac{SNR_{out}^{2}(f)}{SNR_{in}^{2}(f)}$$
(26.29)

where $SNR_{out}(f)$ is the output SNR and $SNR_{in}(f)$ is the input SNR. The DQE(f) provides a measure of how efficiently the imaging system transfers information in terms of spatial frequency. In order to determine DQE(f), we conducted the following derivation:

$$SNR_{out}^{2}(f) = \frac{S_{out}^{2}(f)}{NPS(f)} = \frac{S_{out}^{2}(0)MTF^{2}(f)}{NPS(0)nps(f)} = \frac{SNR_{out}^{2}(0)MTF^{2}(f)}{nps(f)}$$
(26.30)

where $S_{out}(f)$ is the output signal. It can be expressed as the product of its zero frequency value, $S_{out}(0)$, and MTF(f), the norm of the system transfer function. Similarly, the NPS(f) can be expressed by its normalized form, nps(f), and the normalization factor NPS(0). Assuming the input x-ray quanta obey Poisson statistics and have a flat noise spectrum within the range of the spatial frequency of practical interest, then

$$SNR_{in}^{2}(f) = SNR_{in}^{2}(f) = CN_{i}$$
 (26.31)

where N_i is the incident x-ray photon flux (number of x-ray photons per pixel at the entrance of the intensifying screen). Thus,

$$DQE(f) = \frac{DQE(0)MTF^{2}(f)}{nps(f)}$$
(26.32)

where the ratio $MTF^2(f)/nps(f)$ provides a spatial frequency modulation term for DQE.

DQE(0) can be determined using the following method. We have shown that, at zero frequency, repeating Equation 26.21 above:

$$SNR_{out}(f) = C(\eta N_i)^{1/2} \left[1 + \frac{1}{g_1 g_2} + \frac{1}{g_1 g_2 g_3} + \frac{N_a^2}{(g_1 g_2 g_3)^2 \eta N_i} \right]^{-1/2},$$

$$SNR_{in}(f) = CN_i^{1/2}$$
(26.33)

Therefore,

$$DQE(0) = \frac{SNR_{out}^{2}(0)}{SNR_{in}^{2}(0)} = \frac{\eta}{\left[1 + \frac{1}{g_{1}g_{2}} + \frac{1}{g_{1}g_{2}g_{3}} + \frac{N_{a}^{2}}{\left(g_{1}g_{2}g_{3}\right)^{2}\eta N_{i}}\right]}$$
(26.34)

Analyses of DQE(0) and of SNR at low frequency provide a useful tool for evaluating design tradeoffs for electronic x-ray imaging systems, such as choice of scintillator, optical coupling techniques, and electronic imagers.

Using Equation 26.34, the DQE(0) values for several electronic x-ray imaging systems were plotted as a function of total quantum gain $(g_1g_2g_3)$ and the additive noise (N_a) in Figure 26.19. For a low additive noise system such as the optically coupled CCD, a total quantum gain of ten electrons per x-ray brings the DQE close to its maximum value. Further increasing the total gain will not improve the DQE significantly. The preceding analysis applies to the low-frequency range. To preserve high-frequency DQE and to ensure that the system is x-ray quantum limited at high frequencies, a total quantum gain of ten electrons per x-ray is again required.²³ These guidelines have been used in developing both lens- and fiber optically coupled CCD systems.

For a lens-coupled prototype, a large aperture lens was custom designed and a back-illuminated CCD used that had a quantum efficiency nearly two times greater than a front-illuminated CCD and met the required ten electrons/x-ray. A fiber optically coupled CCD could be designed with a total quantum gain

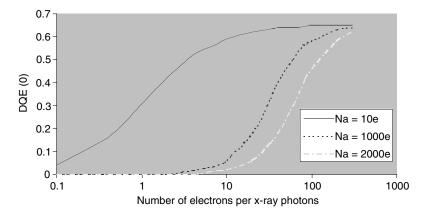

FIGURE 26.19 Detective quantum efficiency curves plotted as functions of total quantum gain (electrons/x-ray) and additive noise (electrons). The quantum efficiency of the scintillating screen was assumed to be $\eta = 0.65$. Note that the DQE values presented in this figure are the maximum achievable values.

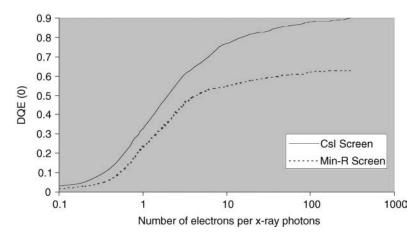

FIGURE 26.20 The effect of the quantum efficiency of the scintillating screen (η) on the x-ray quantum efficiency for the overall system. In this figure, DQE(0) curves of two optically coupled CCD systems using different scintillator are plotted as a function of the quantum efficiency of the scintillator screen, (η) , and total quantum gain (electronics/x-ray). Note that the DQE values presented in this figure represent the maximum achievable values.

much higher than ten electrons per x-ray due to the high efficiency of the optical fiber.²⁷ In a practical design tradeoff, however, we selected an optical fiber component with heavy extra-mural absorption material having only moderate efficiency in return for improved contrast and lower cost.²⁸ The curves presented in Figure 26.19 also show that 100 to 200 electrons per x-ray are needed to maximize the DQE for other electronic imaging systems with higher detector noise.

The quantum efficiency η of the scintillating screen plays an important role in DQE and radiation efficiency. According to Equation 26.34, the maximum achievable DQE of an x-ray quantum noise limited system is limited primarily by η . In practice, a variety of scintillating screens are used in radiological imaging. In some of our early optically coupled CCD spot mammography systems, ²⁸ Min-R screens with a quantum efficiency of 55 to 65% (η = 0.55 to 0.65) were used. Recently developed cesium iodide crystal offers a higher efficiency (η = 0.90 or higher), leading to a higher system DQE.²⁹ In Figure 26.20, the DQE(0) curves of two optically coupled CCD mammographic systems are plotted as a function of total quantum gain and the quantum efficiency of the scintillating screen. (Note that the DQE values presented in this figure represent the maximum achievable values.) This figure demonstrates that the scintillating screen used will significantly affect the DQE of the overall system. Based on the DQE analysis, we have developed a high-resolution digital imaging system; Figure 26.21 shows a bone image acquired by using this system.²⁹

We wish to emphasize that the SNR analyses performed in this chapter are based on single pixel values (x-ray photons/pixel, electrons/pixel). Single pixel analysis is useful and convenient for determining if an imaging system is x-ray quantum noise limited, but is not valid for lesion detectability evaluations. The Rose model³⁰ or quasi-ideal SNR^{31,32} is more appropriate for these types of analyses. The methods presented here can also be applied to other optoelectronic x-ray imaging systems.

26.4 Phase Contrast X-Ray Imaging

As we mentioned in Section 26.1, the in-line phase contrast imaging measures the Laplacian of phase $\nabla^2 \phi$ directly, while the x-ray interferometry and diffraction-enhanced imaging directly measure the phase ϕ and phase gradient $\nabla \phi$, respectively. Using an x-ray tube as x-ray source, one can perform the in-line phase contrast imaging, so this mode holds great potential for clinical applications. Although this imaging modality is still in its infancy, we would like to discuss it in detail, considering its great potential in biomedical diagnostic imaging.

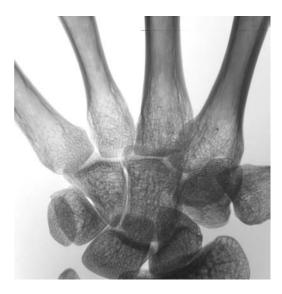

FIGURE 26.21 Image of bones acquired by a prototype high-resolution digital x-ray imaging system.

The setting of in-line phase contrast imaging is similar to conventional radiography, but the object-detector distance is larger than that in CR. Consider a plane wave x-ray source. If the x-ray projection is along the z-axis direction, we can then model the phase shift and attenuation effects of a body part as a two-dimensional transmission function q(x, y) in the x-y plane

$$q(x, y) = \exp\left(i\phi(x, y) - \frac{\mu(x, y)}{2}\right)$$
 (26.35)

where the phases $\phi(x, y)$ and $\mu(x, y)$ are the *z*-projection of the object phase and linear attenuation coefficient. More specifically, if the object has three-dimensional distributions of refraction index decrement $\delta(x, y, z)$ and linear attenuation coefficients $\mu(x, y, z)$), then the projected phase and attenuation are, respectively,

$$\phi(x,y) = \frac{2\pi}{\lambda} \int \delta(x,y,z) dz$$

and

$$\mu(x,y) = \int \mu(x,y,z)dz \tag{26.36}$$

Assume a plane x-ray wave $\exp(-ikz)$, where $k = 2\pi/\lambda$, the wave number, and λ is the x-ray wavelength, illuminates the object at z = 0. Of course, in this scenario the object is assumed to be thin for x-ray so that the projection approximation holds. It can be shown that, as long as the size of the finest feature is larger than $\sqrt{\lambda}\sqrt{T}$, the object can be deemed thin. Here T is the object thickness.

Table 26.4 lists the maximally allowed object thickness for valid projection approximation for different resolutions and x-ray photon energies. It is clear from this table that human body parts can be treated as thin objects for resolutions of 10 μm and photon energy of 10 to 150 keV. In general, the incident x-ray will be refracted and diffracted by the object. For diagnostic x-ray, the x-ray wavelength is much smaller to image than object features. The diffraction angles due to tissue structure are very small — in milliradians. Therefore, the diffracted x-ray wave field can be described by the small angle (i.e., paraxial) approximation of the Fresnel diffraction theory:³³

TABLE 26.4 Maximally Allowed Object Thickness for Valid Projection Approximation for Different Resolutions and X-Ray Photon Energies

X-Ray Energy (keV)	Object's Finest Feature (mm)	Maximum Allowed Object Thickness (m)
20	1.00E-02	8.06E-01
20	1.00E-03	8.06E-03
50	1.00E-02	2.02E+00
50	1.00E-03	2.02E-02
100	1.00E-02	4.03E+00
100	1.00E-03	4.03E-02

$$f(x,z) = \left(\frac{i}{\lambda z}\right)^{1/2} \exp(-ikz) \int q(X) \exp\left(-ik\frac{(x-X)^2}{2z}\right) dX$$
 (26.37)

where z is the distance in wave propagation from the object (body part) and X is the coordinates in transverse plane. For the sake of concise notation, we omit the y-dimension without loss of generality. If we knows the object transmission function, we can then calculate the integral in Equation 26.37 and find the transmitted x-ray wave field f(x, z) at z. The x-ray detector used in imaging is x-ray phase insensitive; therefore, what is detected is the intensity of transmitted x-ray at z:

$$I(x,z) = ff^* = |f(x,z)|^2$$
 (26.38)

Obviously, in conventional x-ray imaging the diffraction effects are negligible; then $f(x, z) = q(x)\exp(-ikz)$. Using Equation 26.35, we find

$$I(x,z) = |f(x,z)|^2 = |q(x)|^2 = \exp(-\mu(x))$$
 (26.39)

This I(x, z) is exactly the conventional radiographic image of the object q(x). Of course, the object does really diffract x-ray, and the diffracted wave f(x, z) is different from q(x) in general; thus, the detected I(x, z) at z can be considered an in-line hologram, and I(x, z) is, in general, a complicated function of q(x). This I(x, z) is the phase contrast image of the object.

In order to explore the general features of phase contrast imaging, we can treat the Fresnel diffraction process as a linear filtering of the object transmission function.³³ The concept of linear filtering is not new to x-ray imaging. In fact (as mentioned in Section 26.4), a conventional x-ray image is a tissue attenuation map filtered by the imaging system's optical transfer function (e.g., the MTF analysis, etc.). Here a phase contrast image is a map of object transmission function filtered by a linear filter corresponding to the Fresnel diffraction process. In fact, the Fresnel integral for diffracted x-ray wave field f(x, z) is of convolution type and the Fourier transform (FT) of f(x, z) (Equation 26.37) with respect to x is

$$F(u) = \exp(-ikz)Q(u)\exp(i\pi\lambda zu^2)$$
 (26.40)

where u is the spatial frequency in the object plane, and F(u, z) and Q(u) are the FTs of x-ray wave field f(x, z) and object transmission function q(x), respectively. From Equation 26.40 it is clear that the linear filter $\exp\{i\pi\lambda zu^2\}$ acting on the transmitted frequencies accounts for the Fresnel diffraction in the in-line phase contrast imaging. To see the effects of this filter, consider a pure phase object with

TABLE 26.5 Phase Transfer Parameter as a Function of X-Ray Photon Energy, Object Detector Distance, and Targeted Spatial Frequency with a Plane Wave X-Ray Source

X-Ray (keV)	X-Ray Wavelength λ (nm)	Object-Detector Distance Z (m)	Target freq · (1p/mm)	$\chi=\pi\lambda zu^2$	At Target Frequency $\sin(\chi)$
10	1.24E-01	0.5	20.0	7.79E-02	7.78E-02
20	6.20E-02	0.5	20.0	3.90E-02	3.89E-02
50	2.48E-02	0.5	20.0	1.56E-02	1.56E-02
150	8.27E-03	0.5	20.0	5.19E-03	5.19E-03

small phase $\phi(x)$. In this case, the object transmission function can be approximated by using Equation 26.35:

$$q(x) \approx 1 + i\phi(x) \tag{26.41}$$

and the FT of q(x) is

$$Q(u) \approx \delta(u) + i\Phi(u)$$
 (26.42)

where $\delta(u)$ is the δ -function and $\Phi(u)$ the FT of object phase $\phi(x)$. Substituting Equation 26.42 into Equation 26.40, one can find the FT of the diffracted x-ray wave field:

$$F(u) \approx \exp(-ikz) \{ \delta(u) + i\Phi(u) \} \exp(i\pi\lambda z u^2)$$
 (26.43)

and F(u) can be further written as

$$F(u) \approx \exp(-ikz) \left\{ \delta(u) - \Phi(u) \sin(\pi \lambda z u^2) + i\Phi(u) \cos(\pi \lambda z u^2) \right\}$$
 (26.44)

In x-ray diagnostic imaging the energy of x-ray photons ranges from 10 to 150 keV, and the corresponding wavelength of x-rays varies from 0.124 to 0.0083 nm (from Equation 26.1 of Section 26.1.) For clinical applications the object detector distance z cannot be larger than 1 m, and the maximum spatial resolution needed is about 20 lp/mm. We have calculated the phase transfer factor $\sin \chi$ as a function of x-ray photon energy, object detector distance and targeted spatial frequency with a plane wave x-ray source. The calculations are for cases relevant to clinical imaging and the results are shown in Table 26.5. This being so, $\sin(\pi \lambda z u^2) \approx \pi \lambda z u$, $\cos(\pi \lambda z u^2) \approx 1$, and the FT of the diffracted x-ray wave becomes

$$F(u) \approx \exp(-ikz) \left\{ \delta(u) - \pi \lambda z u^2 \Phi(u) + i \Phi(u) \right\}$$
 (26.45)

Using inverse FT, we find the diffracted x-ray wave field at z:

$$f(x,z) \approx \exp(-ikz) \left\{ 1 + \frac{\lambda z}{4\pi} \nabla^2 \phi(x) + i\phi(x) \right\}$$
 (26.46)

Using Equation 26.38, we find the phase image intensity for a pure phase object of small phase to first order in $\phi(x)$:

$$I(x,z) = |f(x,z)|^2 = 1 + \frac{\lambda z}{2\pi} \nabla^2 \phi(x)$$
 (26.47)

This result shows that the detected image contrast will be proportional to $\nabla^2 \phi$, the Laplacian (second derivatives) of the object's projected phase ϕ . Remember that ϕ is related to the tissue refractive index decrement δ by Equation 26.36, and is related to tissue composition by Equations 26.9 and 26.10 in Section 26.1. Away from the x-ray absorption edge of tissue, the object phase $\phi(x)$ is proportional to tissue electron density, and the phase contrast of image is proportional to the Laplacian of tissue electron density. Therefore, the boundary of areas with different tissue electron densities will be greatly enhanced, as if the images have been edge enhanced by using digital processing.

In addition, it is clear from the preceding equation that the phase contrast is proportional to the object detector distance. Apparently, if this distance z=0, no phase contrast will be seen. Moreover, it is easy to see (Equation 26.47) that this technique works even with polychromatic x-ray sources such as x-ray tubes. In Section 26.2 we mentioned that x-ray from a x-ray tube consists of the bremstrahlung and characteristic radiation. The bremstrahlung is broadband x-ray; however, because the phase contrast here is not interferometry in nature, but rather proportional to the Laplacian of tissue electron densities, the generated phase contrast by photons of different wavelengths simply adds up, as long as these x-ray photons propagate along almost the same path.

It should be noted that, although temporal coherence (monochromacity) is not required, spatial coherence is critical for phase imaging. In practice a plane wave source emits a bundle of plane waves with a divergent angle α . A plane wave x-ray beam's spatial coherence is characterized by the so-called lateral coherence width $2\lambda/\alpha$. The diffraction patterns generated by tissue from individual plane waves can blur each other. Obviously, the larger the lateral coherence width, the better phase image resolution. A quantitative analysis of the phase image resolution can found in Pogany et al.³³ Figure 26.22 is a phase contrast image of a mouse sample that clearly shows the edge enhancement of anatomic structures.

For clinical imaging applications, an x-ray tube is more likely to be used. For a point x-ray source the x-ray wave field from the source is spherical. Suppose the source object distance (SOD) is R_1 , and the source detector distance (SID) is $R_1 + R_2$. The Fresnel diffraction wave field formula in this case is the same as that for plane wave (Equation 26.37) except to replace z with R_2/M and x by x/M, where $M = (R_1+R_2)/R_1$ is the geometric magnification factor. For a point-like source such as an x-ray tube, the spatial coherence criteria for phase imaging require very small focal spot sizes of x-ray tubes in few tens of microns or smaller. As discussed in Section 26.2, conventional x-ray tubes have focal spot sizes ranging from 0.1 to 1.5 mm. An x-ray tube with a tiny focal spot is also limited in operating tube current and therefore limited in output exposure rates. These problems are the focus of current active research in phase contrast imaging.

On the theoretical analysis of phase contrast imaging, note that the phase image intensity formula of Equation 26.47 is derived under a weak phase assumption ($\phi(x) \ll 1$). One derives a similar formula to Equation 26.47 under the assumption that $\phi(x) \ll 1$ and $\mu(x) \ll 1$. We know that these assumptions will be grossly violated for body parts in possible clinical applications.

From the discussion of tissue attenuation in Section 26.1, even for a kVp as high as 120 kVp, average $\mu(x)$ for an anterior–posterior projection of an abdomen will be approximately 4 to 6. A phase change of 2π can result from a few tens of micron thickness of breast tissue for x-rays in mammography. Therefore, the phase image intensity formula of Equation 26.47 is invalid for these cases. With a goal for analyzing phase contrast in clinical imaging, we have recently derived a phase image intensity formula for a point-like x-ray source. This formula is valid for any strong or weak object phase $\phi(x)$ and attenuation $\mu(x)$.³⁴

Acknowledgments

The authors are grateful to Dr. Steve Wilkins for providing the phase contrast image of the mouse sample and to Dr. Yuhua Li for help with graphics.

Introduction 27.1

Nuclear spins and their interaction with the electromagnetic field form the basis of nuclear magnetic resonance (NMR). Based on NMR, magnetic resonance imaging (MRI) is one of the two most powerful clinical imaging modalities. To perform MRI, the targeted nuclear spins need to be placed in a strong magnetic field to become polarized. The polarization is proportional to the magnetic field strength in conventional MRI, as is the signal-to-noise-ratio (SNR). The ever-increasing demand on high SNR drives magnetic field strengths of MRI scanners ever higher. Presently, the standard high field strength is 1.5 T (1 tesla [T] = 10⁴ gauss [G]), and a new trend in this new century is redefining the standard to 3 T. Needless to say, the higher the field strength, the more expensive the MRI scanner. Currently, a 3-T MRI scanner costs at least \$1 million more than a 1.5-T scanner. Moreover, high field strengths make scanners bulky and aggravate problems such as magnetic susceptibility artifacts and lengthening of the spin-lattice relaxation time.

Ironically, the nuclear spin polarizations at these high magnetic fields are really tiny because thermal spin polarizations are determined by the Boltzmann factor $e^{-h\mu/k_BT}$, where T is the temperature and v the magnetic transition frequency. Here h (6.6266 × 10^{-34} J/s) is Planck's constant and k_B (1.38 × 10^{-23} J/K) is Boltzmann's constant. The magnetic transition frequencies are radio frequencies (RF) and range from 10^8 to 10^9 Hz in MRI. The resulting polarizations are approximately 10^{-6} to 10^{-5} only.

On the other hand, the optical photons are much more energetic than the RF quanta in MRI. The optical transition frequencies are much higher ($v \sim 10^{14}$ to 10^{15} Hz), and the thermal polarizations for optical transitions are of the order of unity. Optical pumping uses light photons to polarize the atomic electron spins first, and then the nuclear spins of noble gases are polarized through the spin exchange between atomic electron spins and nuclear spins. Using optical pumping, nuclear spins of noble gases such as 3 He and 129 Xe can be polarized to 50% or higher — 100,000 times higher than the proton polarization in conventional MRI. A powerful imaging technique developed in the mid-1990s, 1 MRI of hyperpolarized 3 He and 129 Xe shows great potential for clinical applications. Moreover, as we will show in this chapter, the SNR of MRI with hyperpolarized spins is almost independent of the magnetic field strength of the scanner. Therefore, relatively inexpensive low field scanners will benefit greatly from this SNR characteristic.

We discuss optical pumping from a biomedical photonics perspective in detail in Section 27.3. The special features of hyperpolarized spin MRI, such as the signal intensity estimates, the RF flip angle optimization, and diffusion-associated signal attenuation, are covered in Section 27.4. This relatively short chapter is not intended to present a comprehensive review of the field; rather, the emphasis is placed on working principles, analytical methods, and general techniques of optical pumping and MRI of hyperpolarized spins. A brief introduction to MRI is also presented in Section 27.2.

27.2 MRI Basics

27.2.1 Nuclear Magnetism

All atoms are composed of protons, neutrons, and electrons. The nucleus of an atom consists of protons and neutrons. Nuclei with an odd number of protons or neutrons possess a net nuclear spin-angular momentum. These nuclei have a magnetic moment μ that characterizes the magnetic field localized around the nucleus. This magnetic field is analogous to the magnetic field generated by a bar magnet.

In free space at room temperature, these magnetic moments (dipoles) are randomly oriented in space due to thermal fluctuations. However, in the presence of an external static magnetic field, these dipoles are inclined to align with the magnetic field. For hydrogen protons, the nuclear spin quantum number I = 1/2. The external magnetic field, denoted by B_0 , creates two different energy states for hydrogen protons. Each energy state is identified by the magnetic quantum number $m_s = \pm 1/2$. The energy state $m_s = +1/2$ has a component parallel to the external magnetic field and has a lower energy than the energy state $m_s = -1/2$, which has a component antiparallel to B_0 .

The phases of the magnetic moments are randomly distributed for both energy states with each ensemble of spins forming the surface of a cone. The net magnetization is the vector sum of all the individual magnetic moments. At room temperature, both energy states have approximately the same number of spins, which results in zero net longitudinal magnetization along the *z*-axis. Furthermore, because of the lack of phase coherence, no net transverse magnetization exists in the *x-y* plane.

On the other hand, in the presence of a strong external magnetic field (e.g., 1.5 T = 15,000 G, which is about 20,000 times the Earth's magnetic field), the populations in the two energy states are no longer equal. In fact, the lower energy state will have an excess population of about 3 spins per million at 1.0 T. A more general formula for the thermal equilibrium polarization will be given in Equation 27.37. Thus, in 1 cc of water at 1.0 T there are roughly 10^{15} excess spins in the lower energy level. The number of excess spins in the lower energy state is directly related to the external magnetic field strength. This imbalance of spins in the two energy states gives rise to a net magnetization along the external magnetic field. Of course, thermal noise will cause spins to go from one energy state to the other, but as time passes, an equilibrium longitudinal magnetization, M_0 (along the z-axis), will be produced. Because the human body

is composed primarily of water (H₂O), hydrogen (protons) is the preferred imaging isotope because of its relative abundance and sensitivity compared with other atomic nuclei found in the human body.

27.2.2 Magnetic Resonance

Resonance is a phenomenon through which energy can be transferred between objects or systems. In MRI, resonance refers to the induction of transitions between different energy states ($I = \pm 1/2$ for protons) by an RF wave with its magnetic field perpendicular to the static magnetic field B_0 . The frequency of the RF wave must be such that the energy of the resonant RF quanta is equal to the difference in energy between the levels, which is given by:

$$\Delta E = \gamma \hbar B_0 \tag{27.1}$$

where $h = h/2\pi$ is the reduced Planck's constant. The resonance frequency, the so-called Larmor frequency f_L , is

$$f_L = \frac{\gamma}{2\pi} B_0 \tag{27.2}$$

where γ is the gyromagnetic ratio specific to the nuclear isotope, for hydrogen, $(\gamma/2\pi) = 42.58$ MHz/T. This energy will cause the proton magnetic moments to "flip" from the lower energy state (m = +1/2, parallel) to their higher energy state (m = -1/2, antiparallel). By doing so, the net longitudinal magnetization can be diminished, reduced to zero, or even reversed entirely, depending on the amount of energy deposited to the protons.

The RF energy, in addition to causing spins to flip energy states, also forces the protons to precess in phase with each other at the resonant frequency. This phase coherence generates a transverse net magnetization, which is the only magnetization that we can physically measure, because the transverse magnetization precesses around the B_0 -field and generates the inductive voltage in the receiver coil (Figure 27.1). The precession angular frequency ω_L is:

$$\omega_L = 2\pi f_L = \gamma B_0 \tag{27.3}$$

Because f_L is the Larmor frequency, ω_L is called the angular Larmor frequency, or simply the Larmor frequency in the literature. Obviously, the Larmor frequency increases with the magnetic field B_0 .

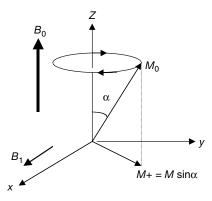

FIGURE 27.1 The magnetization vector M_0 is precessing about the static magnetic field B_0 . The magnetic field B_1 of the RF pulse flips magnetization vector M_0 by an angle α . The projection of magnetization vector M_0 onto x-y plane is the transverse magnetization M_+ .

The resonance process can also be viewed as exerting a torque generated by a resonance RF field (an RF wave with the resonant frequency) on the magnetization vector. This is like Earth's magnetic field exerting a torque on the magnetic needle of a compass. This is especially convenient to view the RF wave in the so-called rotating frame, a reference frame rotating about B_0 with Larmor frequency. In this frame the effect of a resonant RF wave is represented by a stationary magnetic field in the rotating frame. This field is also called the flip field, B_1 , because it flips magnetization. This torque exerted by the flip field B_1 is equal to the vector product of the flip field and magnetization. As we know from mechanics, the effect of a torque is to change the angular momentum, and the speed of change of angular momentum is equal to the torque. Nuclear magnetization is proportional to nuclear spin angular momentum; hence,

$$\frac{d\vec{M}}{dt} = \gamma \vec{M} \times \vec{B}_1 \tag{27.4}$$

From this torque equation it is clear that the flip angle, α , by which a magnetization vector is flipped away from B_0 field direction by the torque, is proportional to the resonant RF field strength B_1 and lasting time (the width) of the RF pulse:

$$\alpha = \gamma B_1 t_{D} \tag{27.5}$$

If magnetization M_0 is originally in the z-direction (B_0 field direction), then the longitudinal magnetization $M_z = M_0$. After the application of an RF pulse of B_1 , and the transverse magnetization M_+ in the x-y plane and longitudinal magnetization M_z are (see Figure 27.1)

$$M_{+} = M_{0} \sin \alpha, \qquad M_{z} = M_{0} \cos \alpha \tag{27.6}$$

From these equations it is obvious that a 90° RF pulse tips the equilibrium magnetization vector into the x-y plane, yielding zero net longitudinal magnetization and maximum net transverse magnetization M_+ .

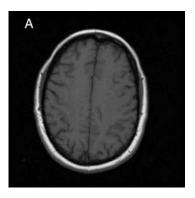

When RF energy is no longer applied to the protons, the net magnetization continues to precess around the external magnetic field at the Larmor frequency. This precessing magnetization can be detected as a time-varying electrical signal across the leads of a coil of wire that can be represented as a complex number with real and imaginary parts. The net magnetization also decays exponentially, having a time constant T_2 . Hence, because the induced voltage can be characterized by a decaying cosine function, it is often referred to as the free-induction decay, or FID.

27.2.3 Spin Relaxation, Tissue Characteristics, and Bloch Equation

The precessing protons interact with the surrounding tissue as well as with other protons that cause them to dephase. Each proton experiences a different local magnetic field depending on the orientation of other nearby protons. The fact that each proton feels a different local magnetic field leads to each proton having a different Larmor frequency. Consequently, because protons are now precessing at different frequencies, the phase coherence created by the RF pulse is slowly destroyed. Subsequently, the transverse magnetization decays because of the individual magnetic moments interacting with other magnetic moments causing them to dephase. This process is known as T_2 (or spin–spin) relaxation. The value of T_2 is different for various tissues and characterizes the rate at which the transverse magnetization decays to zero. The transverse magnetization decays according to the following relationship:

$$M_{+}(t) = M_{+}(0)e^{-t/T_{2}}$$
 (27.7)

Note that this equation represents the decay of the transverse magnetization in a perfectly homogeneous static external magnetic field. Of course, it is impossible to create a perfectly uniform magnetic field. Pockets of tiny, but nonetheless significant, magnetic field inhomogeneities that affect the decay of

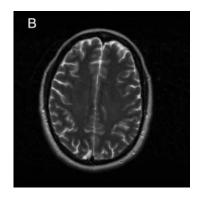

FIGURE 27.2 (A) The T_1 weighted brain image of a patient. (B) The T_2 weighted brain image of the same patient.

the transverse magnetization always exist. When magnetic field inhomogeneities exist, the T_2 relaxation of the tissue speeds up, yielding T_2^* relaxation.

When a short RF pulse is applied to the ensemble of protons with a flip angle of 90°, the longitudinal magnetization is tipped into the x-y plane, resulting in zero longitudinal magnetization. Once the RF pulse is removed from the system, the spins in the higher state will return to the lower state, in the process giving off energy to the surrounding tissue (lattice). As more spins return to the lower energy state, the longitudinal magnetization will grow back to its original value, M_0 . The rate at which the longitudinal magnetization recovers is given by the T_1 (or spin–lattice) relaxation rate of the tissue and obeys

$$M_z(t) = M_{eq} + \left[M_z(t=0) - M_{eq} \right] \exp\left(\frac{-t}{T_1}\right)$$
 (27.8)

where M_{eq} is the thermal equilibrium magnetization in magnetic field B_0 .

The value of T_1 depends on the dissipation of absorbed energy into the surrounding molecular lattice. Energy is most easily transferred if the proton precession frequency overlaps with the "vibrational frequencies" of the lattice. The more overlap, the easier it is to transfer energy, yielding shorter T_1 values. The less overlap, the harder it is to transfer energy, yielding longer T_1 values. It is important to note that the two processes, T_1 and T_2 relaxation, are independent of each other and often quite different from one another for the same tissue. Furthermore, T_1 is greatly dependent on external magnetic field strength, but T_2 is relatively independent of the field strength. Finally, in general, $T_1 > T_2 > T_2$ *.

Figure 27.2 shows two brain images of a patient at the same brain slice. The image shown in Figure 27.2A is T_1 weighted, that is, the image reflects the T_1 relaxation difference of different brain tissues. The longer the T_1 , the lower the signal for that tissue. The image shown in Figure 27.2B is T_2 weighted, that is, the T_2 relaxation difference of different brain tissues is weighted in the image. In contrast to Figure 27.2A, in Figure 27.2B the longer the T_2 , the higher the signal for that tissue.

Combining the torque equation with the spin relaxation effects as described previously, one can write the magnetization change rate due to the flip field and relaxation as the so-called Bloch equation

$$\frac{d\vec{M}}{dt} = \gamma \vec{M} \times \vec{B}_1 - \frac{1}{T_1} (M_z - M_{eq}) \vec{k} - \frac{1}{T_2} (M_x \vec{i} + M_y \vec{j})$$
 (27.9)

where the vectors \vec{i} , \vec{j} , and \vec{k} are the unit vectors of the *x*-, *y*-, and *z*-axes, respectively. The Bloch equation is the most fundamental equation of NMR and MRI.

27.2.4 Mapping Spatial Distribution of Spins

In MRI the spatial distribution of spins is mapped by applying magnetic field gradients and performing the Fourier transform. Consider a magnetic field gradient, G_{xy} in the x-direction superimposing on the

 B_0 field of an MRI scanner's magnet. The magnetic field gradient specifies magnetic field change per unit length. For example, if $B_0 = 1.5$ T, and $G_x = 10$ mT/m, then the resulting magnetic field is 1.5 T at x = 0 and 1.501 T at x = 10 cm. Therefore, spins at different position x will experience slightly different magnetic fields. From Equation 27.3 it is clear that the spins at x will have a precessing frequency $\omega(x)$ when the spin is flipped to the transverse plan by an RF pulse:

$$\omega(x) = \gamma \cdot B_0 + \gamma G_x x \tag{27.10}$$

Therefore the MRI signal intensity at time t generated by these spins at x will be

$$s(x,t) = CM_{+}(x)e^{(-i\omega(x)t)} = (Ce^{-i\omega_{L}t})M_{+}(x)e^{-i\gamma G_{x}xt}$$
(27.11)

where C is a calibration constant for converting precessing M_+ to the signal. The receiver coil detects the total signal from spins all over the scan volume; hence, the total signal at time t is

$$s(\gamma G_x t) = (Ce^{-i\omega_L t}) \int M_+(x) e^{-i\gamma G_x x t} dx$$
 (27.12)

Using Equation 27.6, the total signal can be related to the spin magnetizations as

$$s(\gamma G_x t) = (Ce^{-i\omega_L t}) \sin \alpha \int M_z(x) e^{-i\gamma G_x x t} dx$$
 (27.13)

Note that the integral

$$\int M_z(x)e^{-\dot{\gamma}G_xxt}dx \tag{27.14}$$

is a Fourier transform of the magnetization at x. Therefore, Equation 27.13 tells in words that the signal intensity received by the receiver coil essentially is a Fourier transform of spin's spatial distribution. This being so, collecting the coil signal as a function of time t and performing an inverse Fourier transformation of the signal, we reconstruct the spin spatial distribution: the image of the spin along the x-axis. The field gradient G_x is thus called the x-encoding field gradient. Using the magnetic field gradients G_y and G_z along the y- and z-axes and applying the same strategy to the other two dimensions (y and z), we can reconstruct a three-dimensional spatial distribution of spins, i.e., a three-dimensional MRI image. In MRI, G_x is also called the frequency encoding gradient, and G_y the phase-encoding gradient. The encoding gradients used in the new generation MRI scanner can go as high as 40 to 50 mT/m.

From the MRI point of view, the spin spatial distribution $M_z(x)$ and the MRI signal $s(\gamma G_x t)$ form a Fourier pair; they are really two incarnations of the same identity. $M_z(x)$ represents an image characterized in the real space, and the signal $s(\gamma G_x t)$ represents the same image characterized in the k space (Fourier space or the spatial frequency space) with $k_x = \gamma G_x t$. As we collect the signal data $s(\gamma G_x t)$ for different times such as t_1, t_2, \ldots , etc., one is really sampling the image at k space positions (also called encoding steps) $k_{x1} = \gamma G_x t_1, k_{x2} = \gamma G_x t_2, \ldots$, etc. Simply stated, MRI is a technique to reconstruct M_z by sampling it in the k space through detecting NMR signals s(k).

In order to sample an image in the k space, one applies a sequence of RF pulses and field gradients. Figure 27.3 shows a typical gradient echo pulse sequence. Note that the label FEG denotes the frequency encoding gradient $G_x(t)$, PEG denotes the phase encoding gradient $G_y(t)$, PEG denotes the phase encoding gradient $G_y(t)$, and SEG denotes the slice encoding gradient $G_z(t)$. In this sequence an RF pulse of flip angle α establishes a transverse magnetization M_+ first, and then spins start to precess in the x-y plane with the Larmor frequency. Meanwhile, a negative field $-G_{x1}$ gradient is applied for a short period δt , followed by a second positive field gradient G_{x2} , as shown in Figure 27.3. The data acquisition starts during the positive gradient period, which lasts for a sampling period of T_s (from a few to ten millisecsonds). From Equation 27.14, the coil detects a time-varying signal proportional to

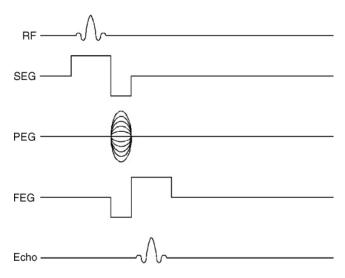

FIGURE 27.3 A typical gradient echo pulse sequence.

$$\int M_{z}(x)e^{-i\gamma(-G_{x1}\delta_{t}+G_{x2}t)x}dx, \qquad 0 \le t \le T_{s}$$
 (27.15)

Again, as discussed previously, the signal detected during $0 < t < T_s$ samples magnetization $M_z(x)$ in the k space from a negative value $-\gamma G_{x1} \delta t$ to a positive value $\gamma (G_{x2} T_s - G_{x1} \delta t)$. In this way a k space line is completed. Note that, at $t = G_{x1} \delta t / G_{x2}$, the phase $(-G_{x1} \delta t + G_{x2} t)$ in the above equation becomes zero. This means all spins are precessing in the same phase at this moment; hence, the signal reaches the maximum, i.e., an echo is formed at this moment. That is why this type of pulse sequence is called the gradient echo pulse sequence. The gradients G_y shown in Figure 27.3 encode the spin's y-position on the same principle. Each G_y step encodes spins such that each k_x -line corresponds to different k_y . When the next spin-flipping RF pulse is applied, the same k_x sampling repeats but with a different G_y step. In this way, by repeating RF excitations (pulses) and using different G_y steps after each pulse (RF excitation), one samples magnetization through the k space line by line (Figure 27.4).

In MRI one often views a three-dimensional image by slices. The slice-selecting gradient G_z in Figure 27.3 encodes the z-position of spins. For a detailed introduction to MRI, refer to Smith and Lange² and Chen and Hoult.³ The higher the G_z , the thinner the resulting slice. It should be noted that the popular spin-echo pulse sequences of conventional MRI are not suitable for MRI with hyperpolarized spins (see Section 27.4.2).

27.3 Nuclear Spin Hyperpolarization by Optical Pumping

In the optical pumping and spin exchange approach for nuclear spin hyperpolarization, one shines a glass pumping cell (several hundred cubic centimeters in volume) containing alkali–metal vapors such as rubidium (Rb) vapor and noble gas (³He or ¹²⁹Xe) with a circularly polarized infrared light. The cell is heated to 80 to 150°C to maintain the desired Rb vapor density. ³He or ¹²⁹Xe gas is kept at a pressure of several atmospheres in the cell, and approximately 100 torr of N₂ is also added to the cell for buffering. The circularly polarized infrared light polarizes the valence electrons of Rb atoms as explained later, and the polarized Rb atoms transfer their electronic spin polarization to nuclear spins of ³He or ¹²⁹Xe by the spin-exchange collisions (Figure 27.5). In this way nuclear spin polarization of ³He or ¹²⁹Xe can be as high as 50% or more.

It should be noted that 3 He may also be polarized by the optical pumping and metastability exchange. Using 1.083 μ m circularly polarized laser light, one can polarize the metastable 3 He * (the $2{}^{3}S_{1}$ state) atoms in a 3 He plasma at 1 mbar by optical pumping. Through the metastable exchange collisions between 3 He * and 3 He, the angular momentum is transferred from polarized 3 He * to 3 He nuclear spins of the ground

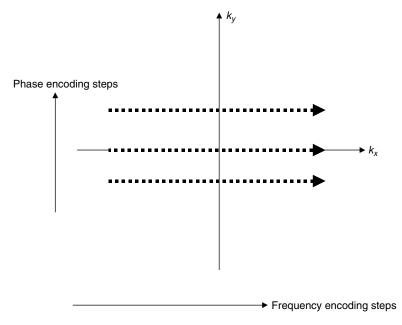

FIGURE 27.4 The k-space sampling process for a gradient echo pulse sequence. Each dot line represents the k_x sampling process during a signal read-out. Each dot represents a k_x point for which the signal is acquired. After the next RF excitation (RF pulse) the k_x sampling process repeats but with a new phase-encoding step (new k_y step).

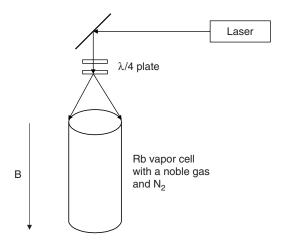

FIGURE 27.5 Schematic of the optical pumping setup. The $\lambda/4$ plates are used to generate a circular polarization of the light.

state (the 1^1S_0 state).⁴ However, the metastability exchange polarization of 129 Xe does not work so far. In this section we will discuss the optical pumping and spin exchange approach in detail.

27.3.1 Optical Depopulation Pumping of Alkali-Metal Atoms

In order to hyperpolarize nuclear spins, the first step is to use light to polarize the valence electronic spins of atoms of alkali–metal vapors such as rubidium (Rb), potassium (K), and cesium (Cs) vapors. This electron polarization process is based on the idea of depopulation pumping.⁵ As is well known, an electron carries spin s = 1/2, just as the proton (hydrogen nucleus) carries spin s = 1/2. A spin-1/2 particle has two spin states, one up and one down, as discussed previously. Therefore, in ground state the valence

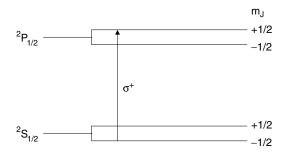

FIGURE 27.6 Energy level diagram for Rb ground state and the lowest excited state. The energy differences between the sublevels are tiny because of the weakness of the magnetic holding field.

electron of an alkali metal atom has two different spin states, one up, one down. In a weak magnetic field (the holding field) of about 10 to 150 G, these two states have slightly different energy levels. In other words, the ground state has two sublevels (Figure 27.6).

Ordinarily these two spin states are almost equally populated; thus, the valence electron is not polarized. The idea of depopulation pumping is as follows. Shine light on the atoms. If one ground sublevel absorbs light much more strongly than the other, then atoms are pumped out more rapidly from the strongly absorbing sublevel. The populations of the two sublevels will not be equal any more as a result of the processes of the selective light absorption, atom excitation, and transition from the excited state to ground state via the spontaneous emission. Obviously the weakly absorbing sublevel will gain excess population and electron polarization results. In order to understand the factors affecting the yield of electron polarization, let us consider the optical pumping of rubidium atoms in detail.

27.3.2 Atomic States of Rubidium

For optical pumping, one places the rubidium vapor glass chamber in a weak magnetic field (e.g., 10 to 150 G), as shown in Figure 27.5. In order to understand the optical pumping of Rb atoms, one should know the atomic states and energy levels. Rubidium has two isotopes: ⁸⁵Rb has a natural abundance of 72.17% and ⁸⁷Rb a natural abundance of 27.83%. First, we assume that the nuclear spins of Rb (I = 5/2 for ⁸⁵Rb and I = 3/2 for ⁸⁷Rb) are not involved in the optical pumping process. This assumption will be justified later. With this assumption, the atomic states are labeled by conventional spectroscopic notation. A letter symbol indicates the total orbital angular momentum L of the valence electrons. For example, symbols S, P, and D indicate L = 0, 1, and 2, respectively. A right subscript attached to the letter indicates the total angular momentum J (the sum of orbital and spin angular momenta) of the state. A left superscript attached to the letter indicates the spin multiplicity 2s + 1, where s is the total spin of valence electron. Rubidium has only one valence electron; its ground state has zero orbital angular momentum, hence L = 0, s = 1/2, and J = s = 1/2, indicated as ${}^2S_{1/2}$ (more exactly, $5^2S_{1/2}$).

Note that the ground state has two spin states; one is the spin-up state of $m_J = m_s = 1/2$, and the other is the spin-down state of $m_J = m_s = -1/2$. Here the number m_J denotes the projection of the total angular momentum along the applied holding magnetic field. Therefore the ground state has two subenergy levels. Although their energy levels are approximately the same due to the weakness of the holding field, they differ in electron spin orientations (Figure 27.6). The lowest excited state of Rb is $^2P_{1/2}$ (more exactly, $5^2P_{1/2}$). This state has two sublevels with $m_J = 1/2$ and $m_J = -1/2$ as well. (Note that, for the $^2P_{1/2}$ state, m_J is a good quantum number and m_s is not.) The energy difference between the ground state $^2S_{1/2}$ and the excited state $^2P_{1/2}$ is 1.56 eV, which corresponds to rubidium D1 absorption line at 794.8 nm.

27.3.3 Selective Absorption of Circularly Polarized Light

When a light with wavelength of approximately 794.8 nm shines on the glass cell of Rb vapor, the light propagates along the holding-field direction. The oscillating electric field of the light will induce the

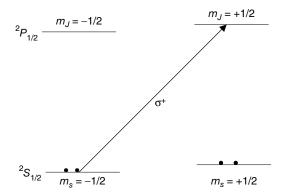

FIGURE 27.7 Schematic of the ground state excitation by optical pumping using a σ^+ -polarized light.

electric dipole and cause transitions between the ground state and the excited state. Remember that each has two sublevels with different m_J . At first glance it seems true that the valence electron from any ground state sublevel ($m_J = 1/2, -1/2$) could be promoted to any sublevels of the state ${}^2P_{1/2}$ just by photon absorption; however, this is not true. In fact, the angular momentum conservation imposes the selection rules on what transitions are allowed.

Suppose that the input light is a left-hand circularly polarized light (i.e., a σ^+ -polarized light). A circularly polarized light can be thought of as generated by two waves whose electric field components are orthogonal and 90° out of phase. This phase difference between these two waves causes an effective rotation of the total electric field vector about an axis in direction of propagation. For a left-hand circularly polarized light, the electric field vector is perpendicular to and rotating about the holding magnetic field direction in the left-hand sense.

As is well known, a photon carries a spin s = 1. A σ^+ -polarized photon carries a spin pointing along the magnetic field and thus the spin projection $m_s = 1$. The angular momentum conservation dictates that a σ^+ -polarized light can be absorbed by the $m_J = -1/2$ sublevel of ground state ${}^2S_{1/2}$ to induce a transition to the $m_J = 1/2$ sublevel of excited state ${}^2P_{1/2}$. This is because the total change of m_J with the transition is $\Delta m_J = 1$, and this change can be compensated by absorption of a σ^+ -polarized photon. By the same reason of angular momentum conservation, a σ^+ -polarized light cannot be absorbed by the electron in the $m_J = 1/2$ sublevel of the ground state. In this way the σ^+ -polarized light is absorbed only by the spin-down sublevel ($m_J = -1/2$) of ground state; the spin-up sublevel ($m_J = 1/2$) is "left in dark." Absorbing a light photon, the valence electron from the spin-down sublevel ($m_J = -1/2$) is promoted to the $m_J = 1/2$ sublevel of the excited state ${}^2P_{1/2}$ (Figure 27.7).

27.3.4 De-Excitation of Rb Atoms and Ground State Polarization

The atom cannot stay in the $m_J = 1/2$ sublevel of the excited state ${}^2P_{1/2}$ for long because of radiative decay via the spontaneous emission of light. When the excited state decays back to the ground state by spontaneous emission, it can decay to either of the two ground state sublevels. For an isolated atom, the probability of decay back to the $m_J = -1/2$ sublevel of ground state is twice that for returning to the $m_J = 1/2$ sublevel. From depopulation pumping point of view, this, of course, is not desirable, because it is against depopulation efforts. Fortunately, one can use the buffer gas to improve this problem.

In the Rb vapor cell there are usually noble gas atoms such as He and Xe gas for the spin exchange polarization (see below). If this gas has high enough density in the cell, the excited Rb atom will collide with these noble gas atoms many times during its lifetime. These collisions will redistribute the sublevel populations of the excited state. In other words, the sublevels of $m_J = 1/2$ and $m_J = -1/2$ are to be equally populated. In this way, when these excited state sublevels undergo radiative decay via spontaneous emission, the probabilities for returning to each of the ground state sublevels become the same (Figure 27.8).

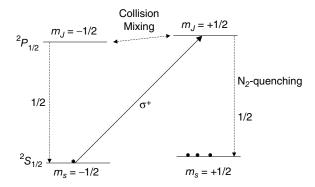

FIGURE 27.8 Schematic of the state transitions via optical pumping, collision mixing, and N₂ gas quenching.

This process of collisional mixing of excited state sublevel populations ensures that the spin-up or spin-down sublevels will be repopulated at the same rate during the atomic de-excitation. In this way, because the spin-down sublevel of ground state is continuously pumped into the excited state by light absorption, eventually the spin-down sublevel is completely depopulated, and the valence electron is polarized to the spin-up state eventually.

In optical pumping practice, N_2 gas is added as the quenching gas into the Rb vapor cell to eliminate the radiation trapping problem (Figure 27.8). The remitted light (spontaneous decay) from the excited state is unpolarized and propagates in any direction. Once reabsorbed by Rb atoms, these remitted unpolarized photons can depolarize the atoms. Thus, if the mean free path of these photons is much less than the cell dimension, these unpolarized photons are trapped inside the cell and reduce the yield of electron polarization from optical pumping. The added N_2 gas allows the excited Rb atoms to decay nonradiatively (without emission of photons) from the excited state $^2P_{1/2}$ back to the ground state by collisions with the N_2 .⁶ Therefore the N_2 gas eliminates radiation trapping as a source of depolarization. The required N_2 densities are of 0.1 amagat or more.⁵ Note that the density of an ideal gas is 1 amagat = 2.69×10^{19} cm⁻³. With adding N_2 gas to the Rb cell, the N_2 quenching becomes the main source of de-excitation.

27.3.5 Optical Pumping Dynamics and the Generalized Bloch Equation

The yield of rubidium ground state polarization depends obviously on the input light intensity, light spectral profile, and the lifetime of excited state. In order to understand the effects of these factors on polarization yield, one should find the equation of motion of ground state polarization. Similar to the longitudinal (along the magnetic field B_0) magnetization in NMR discussed earlier, the ground state polarization $S_z = [P(1/2) - P(-1/2)]/2$ specifies ground state polarization, where P(1/2) and P(-1/2) are the occupation probability of the $m_I = 1/2$ sublevel and the $m_I = -1/2$ sublevel, respectively.

There may exist transverse (perpendicular to B) magnetizations S_x and S_y as well, since these transverse magnetizations may result from the coherence between ground state sublevel. Different from that in NMR, the pressing frequency of S_x and S_y about the magnetic field direction is faster than the Larmor frequency defined previously. The amount of difference, the so-called light shift, is proportional to the optical pumping rate and the light detuning (the amount of off-resonance of the light from the rubidium D1 line).⁷ Fortunately, for typical cases where rubidium is in thermal equilibrium when the laser light is turned on, no transverse magnetization (S_x , S_y) will be generated by optical pumping. Therefore, for these cases optical pumping generates polarization S_z only.

Similar to M_z in NMR, the dynamics of S_z can be described by a generalized Bloch equation. This is no surprise because the laser–atom interactions can be described very well by the optical Bloch equation. Merging the optical Bloch equations and the magnetic resonance Bloch equation for spins (electron spins), we have a generalized Bloch equation of optical pumping:

$$\frac{dS_z}{dt} = -\frac{1}{T_{eff}} (S_z - S_{op-eq})$$
 (27.16)

where S_{op-eq} is the equilibrium achieved using optical pumping and is given by

$$S_{op-eq} = \frac{1}{2} \frac{P_{+}(\Delta)}{\Gamma_{SD} + P_{+}(\Delta)}$$
 (27.17)

where Γ_{SD} is the S_z -destroying (spin-destruction) relaxation rate. The most important contribution to Γ_{SD} is from collision between Rb atoms themselves. $P_+(\Delta)$ is called the optical pumping rate:

$$P_{+}(\Delta) = \frac{\Omega_{1}^{2} \Gamma_{2}^{2}}{4 \Gamma_{2} (\Gamma_{2}^{2} + \Delta^{2})}$$
 (27.18)

Here Δ is the offset of the laser frequency from the resonance frequency (D1 line) ω_{DI} , $\Delta = (\omega - \omega_{DI})$. Γ_2 is the optical coherence decay rate and equal to one half of the Rb D1 absorption linewidth broadened by collisions. Obviously, the optical pumping rate $P_+(\Delta)$ is a function of the frequency offset. Ω_1 is the so-called optical Rabi frequency,

$$\hbar\Omega_{1} = -\vec{E} \cdot \vec{D}_{ge} \tag{27.19}$$

The Rabi frequency is the scalar product of electric field E and the induced atomic dipole D_{ge} of the transition from the ground state to the excited state. Optical Rabi frequency characterizes the strength of the coupling between the incident light and Rb atoms. Because light is an electromagnetic wave, the light intensity is proportional to the square of the electric field. Therefore, squared Rabi frequency is proportional to the light intensity, and the optical pumping rate P_+ is proportional to light intensity as well.

Equations 27.16 through 27.18 determine the optical pumping dynamics. The spin polarization grows as

$$S_z(t) = S_{op-eq} \left(1 - e^{-\frac{t}{T_{eff}}} \right)$$
 (27.20)

With optical pumping, the spin polarization increases with time exponentially according to this equation. Eventually spin polarization S_z reaches the maximal value S_{op-eq} . The speed with which the maximal value is reached is determined by the effective relaxation rate $1/T_{eff}$:

$$\frac{1}{T_{eff}} = \Gamma_{SD} + P_{+} \tag{27.21}$$

It is important to note that the maximal spin polarization S_{op-eq} is not proportional to light intensity, as is shown by Equation 27.17. If we want to achieve 100% polarization ($S_{op-eq}=1/2$), we should have $P_+ \gg \Gamma_{SD}$. For Rb vapor, $\Gamma_{SD}=k$ [Rb], where $k=7.8\times 10^{-13}$ cm³/sec, and [Rb] is the Rb density. Obviously Γ_{SD} is proportional to the Rb density. As shown later, in order to get more hyperpolarized He or Xe nuclear spins, the Rb densities used must be high enough. This requires even higher P_+ , since $P_+ \gg \Gamma_{SD}$ must be kept for high Rb spin polarization. In order to see the effect of the frequency offset on the optical pumping rate of a narrow band laser light, we can rewrite Equation 27.18 as

$$P_{+}(\Delta) = \frac{\Gamma_{2}^{2}}{(\Gamma_{2}^{2} + \Delta^{2})} P_{+}(0) = \frac{\Gamma_{2}^{2}}{(\Gamma_{2}^{2} + \Delta^{2})} \sigma_{0} I_{0}$$
 (27.22)

Here we use the fact that $P_+(0)$ is proportional to photon number intensity (photons per unit area per unit time), and σ_0 is the on-resonance photon scattering cross section that depends on the induced dipole of Rb atom and its D1 linewidth. Using the above equations, we can rewrite σ_0 in terms of the spontaneous emission rate and the D1 line wavelength:

$$\sigma_0 = \frac{\lambda_0^2 \Gamma_{nat}}{4\pi \Gamma_2} \tag{27.23}$$

where λ_0 is the D1 line wavelength, and Γ_{nat} is the natural linewidth of Rb D1 line. Note that Rb has a small natural width Γ_{nat} of 5.66 MHz for the D1 line because, for the excited state $5^2P_{1/2}$, n=5 and the natural linewidth is $n^{-4.5}$ for alkali metals. Thus, σ_0 depends on total pressure in the pumping cell due to the D1 line pressure broadening (see below).

This equation shows that $P_+(\Delta)$ decreases with increasing offset Δ (or detuning) showing a Lorentz line shape. It is interesting to note that the NMR spectral line shapes for nuclear spins in liquid and many biological tissues are Lorentzian as well. This is no surprise; the similarity can be traced back to the underlying dynamics described by similar Bloch equations, i.e., by the optical Bloch equation for optical pumping and by the magnetization Bloch equation for NMR spectroscopy. Again, as in NMR, the full width of half-maximum (FWHM) of $P_+(\Delta)$ is given by the optical coherence decay rate; hence, FWHM of $P_+(\Delta)$ is equal to $2\Gamma_2$. Remember that Γ_2 is the optical coherence decay rate and equal to one half of the Rb D1 absorption linewidth. Note that Rb D1 absorption linewidth increases with pressure. The Rb D1 line is broadened by about 18 GHz per amagat of 3 He.

27.3.6 Spin Exchange and Hyperpolarized Nuclear Spins

Once Rb atomic electrons are polarized, the Rb electronic polarization is transferred to nuclear spins of He and Xe by atomic collisions. The key process is the collision transfer. During collisions, the electronic spin S of a polarized Rb atom interacts with nuclear spin I_{ng} of a noble gas atom through the hyperfine interaction

$$A(R)\vec{I}_{ng}\cdot\vec{S} \tag{27.24}$$

The hyperfine interaction arises from the magnetic field inside the nucleus of noble gas atom, and the magnetic field interacts with Rb electron spins. The factor A(R) represents the coupling strength and strongly depends on the interatomic distance separation R. Because the hyperfine coupling is a scalar coupling, it is well known in NMR that a scalar coupling between spins causes mutual spin flipping. That is, during the collision the Rb electron spin and the nuclear spin of noble gas atoms are likely to flip in opposite directions. For example, an Rb electron spin flips from up to down during the collision, while the nuclear spin of the noble gas atom flips from down to up. Rb atoms have already been polarized via optical pumping; hence, certain polarization is transferred from Rb atoms to nuclear spins of noble gas during collision. That is, the polarization loss for Rb atoms is the polarization gain for nuclear spins of noble gas. Fortunately, the polarization of Rb can be constantly replenished by optical pumping. In this sense it is the angular momenta of circular polarized light that have been transferred to nuclear spins of noble gas.

The spin exchange rate equation is

$$\frac{dP_K}{dt} = \gamma_{SE}(2S_z - P_K) - \Gamma_K P_K \tag{27.25}$$

In the steady state, the noble gas nuclear spin polarization is

$$P_K = 2S_z \frac{\gamma_{SE}}{\gamma_{SF} + \Gamma_K} \tag{27.26}$$

where P_K is the noble gas nuclear spin polarization, and Γ_K is its relaxation rate.

The relaxation is often dominated by wall collision, although dipole–dipole coupling and impurities contribute as well. Obviously, the portion of Rb electron polarization transferred to noble gas nuclear spin is determined by $\gamma_{SE}/(\gamma_{SE} + \Gamma_K)$. If the light intensity is high enough and light reaches all parts of the pumping cell, this can reach the maximal value $S_{op-eq} \sim 1/2$, so $2S_z = 2S_{op-eq} \sim 1$. In order to achieve high polarization for noble gas nuclei, one must achieve a high Rb electron polarization and suppress Γ_K such that $\gamma_{SE} \sim \Gamma_K$. Since γ_{SE} is proportional to [Rb] (the Rb number density of the Rb vapor), one needs to increase the temperature of the cell (the oven temperature) to vaporize more rubidium. Then a higher light intensity is needed to maintain high Rb polarization such that $2S_{op-eq} \sim 1$. Therefore, the practical limitation is the light intensity achievable, i.e., the cost and complexity of the laser power employed.

27.3.7 Laser Source Considerations

From the previous discussion it is clear that a laser source with high output near the Rb D1 line is needed for optical pumping. However, we should also decide the bandwidth requirement for lasers. For example, we can use a narrow band laser source such as the Ti:Sapphire laser, or a broadband laser source such as the laser diode arrays (LDA) with power of a few tens of watts. A titanium-doped sapphire laser (Ti:Sapphire laser) is a narrow band laser; in fact, the lasing medium Ti³⁺:Al₂O₃ has a very broad (about 300 nm) emission band with the peak emission at 790 nm.

However, laser source bandwidth will have important effects on the yield nuclear spin polarization of the noble gas. At first glance, it seems that a narrow band laser with output close to the Rb D1 line is better than a broadband laser, because the optical pumping rate $P_+(\Delta)$ decreases with increasing light detuning (offset). However, we must consider the light attenuation along propagation, since optical pumping needs to absorb those left circularly polarized photons. Let us denote the optical pumping rate at z as $P_+(\Delta, z)$; then, similar to Equation 27.22, we have

$$P_{+}(\Delta, z) = \frac{\Gamma_{2}^{2}}{(\Gamma_{2}^{2} + \Delta^{2})} \sigma_{0} I(z)$$
 (27.27)

I(z) is the laser photon flux as z. Hence, the optical pumping rate $P_+(\Delta,z)$ is, in fact, decreasing with I(z) due to light absorption. Traveling a very small distance dz, the laser photon flux decreases by

$$\frac{dI(z)}{dz} = -[Rb]P_{+}(\Delta, z) \frac{\Gamma_{SD}}{P_{+}(\Delta, z) + \Gamma_{SD}}$$
(27.28)

Note that the fraction at the right in this equation is the equilibrium occupation probability of the sublevel $m_s = -1/2$ of Rb ground state, since only that sublevel absorbs left-circularly polarized photons. It is clear from this equation that photon flux attenuation along propagation decreases with increasing light detuning. Therefore, we need to balance two things for optimal results of pumping. On the one hand, for increasing the polarization yield, we want to use high Rb density and have high optical pumping rate $P_+(\Delta, z)$. On the other hand, we want to have penetrating laser light to pump more volume fraction of Rb vapor in the cell. To find out if a narrow or broadband laser source is better, we must use the above equations to calculate optical pumping yield averaged for the whole cell. Of course, in the calculations the optical pumping rate should be summed over the line shape of a broadband laser source. That is, if the photon flux at a frequency v and position z is $\Phi(v, z)$, then the spectrum-summed optical pumping rate $P_+(z)$ at z is

$$P_{+}(z) = \int \Phi(v, z) P_{+}(\Delta, z) dz \qquad (27.29)$$

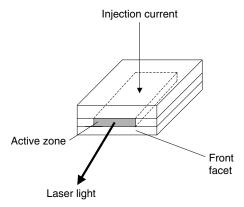

FIGURE 27.9 Schematic of the laser diode.

With an 8-W Ti:Sapphire laser (with a linewidth of approximately 0.1 nm) the light penetration is approximately 6 cm for He gas of 5 amagat and the average Rb polarization is approximately 95%. For a 15-W laser diode array of 1.9 nm FWHM linewidth, the Rb polarization decreases from approximately 100% at z=0 to approximately 25% at z=15 cm. These results show that, because the Rb D1 linewidth is very much broadened by the high-density He gas (45 to 75 GHz), the achieved Rb electron spin polarization averaged over the whole volume is about the same for the two laser sources. However, compared to the Ti:Sapphire laser, the laser diode array costs much less. A Ti:Sapphire laser pumped by an argon ion laser costs approximately \$20K per watt; a laser diode array laser costs approximately \$200 per watt.

The laser diode is a semiconductor device with the p–n junctions. The band structures of the semiconductor substrates largely determine the wavelength that a laser diode emits. Semiconductors have energy band structures consisting of the valence band and conducting band. GaAs, a III-V compound semiconductor, has a direct energy band structure such that the top of the valence band is directly below the bottom of the conducting band in the reciprocal space. Therefore, when an electron from the conducting band is recombined with a hole in the valence band, the energy released can be almost completely converted into that of the photon without energy loss to the crystal lattice. Doped with aluminum, gallium–aluminum arsenide [(GaAl) As] has an energy band structure such that a recombination of an electron–hole pair inside the p–n junction of (GaAl)As diode emits from 750 to 880 nm.

To cause an amplification of the light by the stimulated emission, the (GaAl)As is "pumped" up to the population inversion state by injecting sufficient minority carriers (electrons) into the p–n junction. The laser outputs are at wavelengths that satisfy two conditions. First, the wavelength must be within the bandwidth of the laser gain medium ([GaAl]As). Second, the wavelength must be in the passband of the laser resonator. The emitted light in laser diode is guided in the active zone (Figure 27.9). The common guiding provides a horizontal resonator structure. The guiding is realized by the built-in refractive index profiles (the index guiding) or by the concentration of the stimulating electric field.

A common type of resonator structure is the Fabry–Perot resonator. Using this resonator the emitted light will be selected and amplified by reflecting back and forth from the end-facet mirrors. For wavelengths for which the resonator length is an integral multiple of half the wavelength, all these light waves are transmitted in phase. As a result of in-phase addition, these waves are amplified greatly. Once the combination of amplification gain and end-facet reflectivity is larger than the loss, the device lases out light at these wavelengths. All these matched lasing wavelengths are called the longitudinal modes of the laser diode. The wavelengths satisfy

$$\lambda = 2l/k \tag{27.30}$$

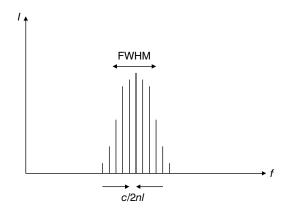

FIGURE 27.10 Schematic of the multiple longitudinal modes of a laser diode array. The laser cavity length is l, and its refractive index is n. The mode spacing is c/2nl.

where l is the laser resonator length, and k an integer, so the spacing between these mode frequencies (Figure 27.10) is

$$\delta f = \frac{c}{2nl} \tag{27.31}$$

where n is the refractive index of the resonator.

Obviously, the shorter the resonator, the larger the spacing of laser modes. For example, if a laser diode's cavity length is 1 mm, then the mode spacing is approximately 150 GHz. Combined with the 1 to 2 THz gain bandwidth, a laser diode's output spectrum consists of 150-GHz-spaced peaks modulated by the gain frequency curve (Figure 27.10). It should be noted that laser diodes are formed in arrays. A typical 40-W array of 795 nm consists of 19 diodes with emitting area $200 \times 1 \, \mu m$ equally spaced along a 1-cm long stripe. ¹⁰ The arrays can also be coupled via the optical fiber for higher output power. External cavity effects from fiber coupling may perturb the output spectrum as well.

One important feature of LDAs is that the emitted wavelengths strongly depend on the operating temperature and injection current. Therefore, setting up the operating point in terms of the temperature and injection current is important. The temperature tuning is approximately 0.2 to 0.4 nm/K, and the current tuning coefficients obviously depend on the total number of diodes in LADs. For example, it was found that the current tuning is 0.18 to 0.42 nm/A for LDAs of 15-W power.¹¹ The total output power is approximately linear with the current; however, the wavelength tuning and the power saturate at large current.

As Equation 27.27 shows, the large spectral width of LADs (2 to 4 nm) limits the laser power absorbed by Rb vapor. Although one may increase the absorption by adding high-pressure buffer gas to increase the Rb D1 line broadening, mechanical constraints from cell strength and collision-induced polarization destruction limit the maximal buffer gas pressure to approximately 10 atm. At this pressure, the D1 line may be broadened to 0.4 nm only. Currently, some research efforts are directed to narrowing the LDA linewidth for increasing light absorption by Rb vapor. An approach that reduced the LDA linewidth by a factor of 2 with only 6% power loss by using the etalon reflection has been reported recently.¹⁰

27.4 MRI of Hyperpolarized ³He and ¹²⁹Xe

In the last section we discussed how to hyperpolarize 3 He and 129 Xe nuclear spins. Because these nuclei have nuclear spin I = 1/2 — the same as a proton — the basic approaches of proton MRI can still be applied to these nuclear spins. However, there are many differences in imaging techniques as well. In this section we discuss special features of MRI with these hyperpolarized spins.

27.4.1 Signal Intensities

As mentioned in Section 27.2, in MRI the signal S from the precessing transverse magnetization M_+ is proportional to

$$S = \gamma B_0 M_+ f(T_2, TE) \tag{27.32}$$

where γ is the gyromagnetic ratio of the nuclei, B_0 is the field strength of the scanner magnet, and M_+ is the transverse magnetization. $f(T_2, TE)$ is a factor depending on scan parameters such as TE and tissue relaxation times T_2 .

Compared to the proton, 3 He and 129 Xe have smaller gyromagnetic ratios. While the proton's Larmor frequency is 63.9 MHz at 1.5 T, 3 He's Larmor frequency is 48.6 MHz (76% of the proton's) at the same field strength, 129 Xe's Larmor frequency is only 17.8 MHz (28% of the proton's). The signal is proportional to Larmor frequency γB_0 because it is the Larmor frequency with which the transverse magnetization precesses about the B_0 direction (see Section 27.2). The different Larmor frequencies of 3 He and 129 Xe require broadband RF systems for excitation and signal reception. Many installed MRI systems are already equipped with broadband capabilities for P-31 Na-23, and C-13 MRI, and they can be used for 3 He and 129 Xe as well. The RF coils should be tunable to the appropriate Larmor frequencies. Usually these are manually tuned surface coils 12 0 or Helmholtz coils. 13

To compare signal intensities, we rewrite the longitudinal magnetization M_z before spin flipping by an RF pulse:

$$M_z = N\gamma\hbar\langle I_z\rangle$$
 (27.33)

where *N* is the nuclear spin density and $\langle I_z \rangle$ is the average nuclear spin along the B_0 -axis before flipping. Because M_+ is determined by the flip angle α (defined in Section 27.2) and M_z :

$$M_{+} = M_{z} \sin \alpha = N \gamma \hbar \langle I_{z} \rangle \sin \alpha \tag{27.34}$$

Using these equations, we find that the signal intensity S is

$$S = \gamma^2 B_0 N \hbar \langle I_z \rangle \sin \alpha f(T_2, TE)$$
 (27.35)

We can then compare the signal intensities from MRI of protons and hyperpolarized spins to determine their signal intensity ratio, assuming the same magnetic field, the same flip angle, and the same f-factor:

$$\frac{S_{\text{He}}}{S_{\text{H}}} = \frac{\gamma_{\text{He}}^2 N_{\text{He}} \langle I_z \rangle_{\text{He}}}{\gamma_{\text{H}}^2 N_{\text{H}} \langle I_z \rangle_{\text{H}}}$$
(27.36)

For thermally polarized spins such as protons, the value of average nuclear spin $\langle I_z \rangle$ depends on the particular pulse sequence used in the scan, but it never exceeds the thermal equilibrium value $\langle I_z \rangle_{eq}$:

$$\left\langle I_{z}\right\rangle _{eq}=\frac{1}{4}\frac{\hbar \omega _{L}}{k_{R}T}\tag{27.37}$$

Using Equation 27.33, we obtain the equilibrium magnetization M_0

$$M_0 = \frac{N\gamma^2 \hbar^2 B_0}{4k_B T} \tag{27.38}$$

Here $k_B=1.38\times 10^{-23}$, J/K is Boltzmann's constant, T is the absolute temperature, and ω_L is the Larmor frequency of the nuclear spin. At $T=310\,\mathrm{K}$ and 1.5 T field strength, the proton's maximal $<I_z>_{\mathrm{H}}=<I_z>_{eq}=2.47\times 10^{-6}$. Although the proton's spin polarization $<I_z>_{eq}$ is tiny, proton spin density N_{H} is high in tissue water, $N_{\mathrm{H}}=6.69\times 10^{22}/\mathrm{cm}^3$. On the other hand, for hyperpolarized ³He, the polarization from the optical pumping and spin exchange can be as high as 50% or more. At 50% polarization, $<I_z>_{\mathrm{He}}=1/4$. Hence the optically pumped helium's spin polarization $<I_z>_{\mathrm{He}}$ is 1.01×10^5 times higher than the proton spin polarization $<I_z>_{\mathrm{He}}$. However, the spin density of ³He in the human body is much lower than the spin density of proton in human tissue water.

Suppose 3 He is administered by inhalation in MRI, and at one bar pressure with dilution of 1/8 and body temperature ($T = 310 \,\mathrm{K}$), the 3 He spin density is $2.92 \times 10^{18}/\mathrm{cm}^3$, assuming an ideal gas state equation. Using the signal ratio formula of Equation 27.36, we find the signal intensity ratio $S_{\mathrm{He}}/S_{\mathrm{H}} = 2.56$. It should also be noted that this calculation of $S_{\mathrm{He}}/S_{\mathrm{H}}$ assumes use of the same flip angle for both 3 He and proton. We will see that the flip angle for 3 He is usually smaller than that used for proton MRI. Use of a smaller flip angle tends to reduce the 3 He signal. In any case, the small spin density of 3 He is more than compensated for by its hyperpolarization to generate higher MRI signal intensity than that in proton MRI.

It should be noted that, in some organs such as the lung, proton MRI lung imaging encounters many difficulties. First of all, proton density is low in the lungs. Second, the differences of proton bulk magnetic susceptibilities between pulmonary tissue and air generate changes of local Larmor frequencies. This causes shot T_2^* relaxation times and gross reduction of proton MRI signals by a factor $\exp(-TE/T_2^*)$, as pointed out in Section 27.2. Therefore, for lung imaging, the signal intensity turns more favorably to ³He MRI. It should also be noted that, in the above comparison, we have assumed proton spin polarization is the thermal equilibrium value. This is the maximum the spin polarization can reach for protons. However, in many cases, especially with short pulse sequence repeating time TR, the spin polarization is much lower than $\langle I_z \rangle_{eq} = 2.47 \times 10^{-6}$ because, if TR is short compared to the longitudinal relaxation time T_1 , the spin polarization does not have enough time to be restored to the equilibrium value $\langle I_z \rangle_{eq}$. As for ¹²⁹Xe, the signal intensity ratio S_{Xe}/S_H is reduced to 13.4% of S_{Xe}/S_H if all other conditions are the same because of the small gyromagnetic ratio of ¹²⁹Xe.

27.4.2 General Considerations for ³He and ¹²⁹Xe as MRI Contrast Media

The above calculations are based on the inhalation administration of the noble gases. Note that helium is an inert and nontoxic gas. It is widely used in other cases such as in deep-sea diving, where helium is inhaled in quite a high amount and concentration (80% helium and 20% oxygen) without severe adverse effects. As shown in Table 27.1, He has a tiny natural abundance (0.014%) produced from tritium radioactive decays and generated mainly in production of nuclear weapon material. Unpolarized He costs approximately \$100/l and recovery after exhalation is necessary. Currently He can be polarized as high as 50% or more.

 ^{129}Xe has a natural abundance (26.4%). It is an inert and nontoxic gas used as an inhalation anesthetic (70% xenon and 30% oxygen). Xenon has a long history of use in medical imaging. As an inhalative contrast media, radioactive xenon isotope (^{133}Xe and ^{135}Xe) imaging has been used for the γ -ray scintigraphy in nuclear medicine, and nonradioactive xenon (^{131}Xe) for CT brain perfusion studies using its high attenuation to x-ray.

One advantage of using xenon is its relatively high solubility in water and lipid; compared to helium, it is more than 10 times more soluble in water and 100 times more soluble in fatty tissue. This also makes

TABLE 27.1 Physical Parameters for ¹H, ³He, and ¹²⁹Xe

Isotope	¹ H	³He	¹²⁹ Xe
Natural abundance	99.9 %	0.014 %	26.4 %
Nuclear spin	1/2	1/2	1/2
Larmor freq. @ 1.5 T (MHz)	63.9	48.6	17.8

xenon more suitable for preparation of ¹²⁹Xe carriers for injection. Moreover, among all NMR-sensitive nuclei, ¹²⁹Xe presents the largest chemical shift range; its chemical shift in tissue can be as high as a few hundred parts per million, making ¹²⁹Xe very sensitive to its chemical environment. Additionally, the chemical shift disperses from gas to blood and tissue, allowing selective imaging of xenon in blood, brain, and gas. ¹⁵ Xenon with natural abundance costs approximately a few dollars per liter. Compared to ³He, ¹²⁹Xe can only be polarized to approximately 20% because the rate of Rb electron spin depolarization in the spin–rotation collisions with ¹²⁹Xe is higher. (The spin–rotation interaction is the coupling between electron spin and the rotational angular momentum of an Rb¹²⁹Xe pair. ¹⁶) However, spin polarization up to 60% has been theoretically predicted, and the spin–exchange efficiency can be improved to increase polarization. ¹⁷ Compounded with its low gyromagnetic ratio, the signal intensity from ¹²⁹Xe will be much lower than that from hyperpolarized ³He.

27.4.3 Signal-to-Noise Ratio and Magnetic Field Strength

SNR is a key imaging performance measure. In MRI it is very important to find out the SNR's dependence on magnetic field strength. Looking at just the B_0 -dependence of signal intensity, Equation 27.35 states that

$$S \propto B_0 \langle I_z \rangle$$
 (27.39)

For thermally polarized spins like protons, its nuclear spin along the B_0 -axis is, at most, $\langle I_z \rangle_{eq}$. Using Equation 27.37, we find that

$$S_{\rm H} \propto B_0^2 \tag{27.40}$$

since the equilibrium polarization is proportional to the field strength B_0 as well. But for hyperpolarized helium and xenon, their nuclear spin $\langle I_z \rangle$ is achieved by optical pumping and spin exchange and is independent of field strength B_0 ; hence, the signal from hyperpolarized ³He or ¹²⁹Xe is

$$S_{\text{He/Ye}} \propto B_0 \tag{27.41}$$

It differs from the quadratic dependence of the proton signal intensity on B_0 . On the other hand, the Johnson noise voltage V_{noise} in the RF receiver coil is equal to³

$$V_{noise} = \sqrt{4k_B T \Delta f(R_c + R_b)}$$
 (27.42)

where Δf is the signal frequency bandwidth, R_c is the coil resistance, R_b is the effective resistance caused by RF dissipation by the body parts, and Δf is the frequency bandwidth of the MRI signals. Roughly speaking, all spins would generate signals in Larmor frequency. However, during the data acquisition period, spins at different locations actually experience slightly different Larmor frequencies due to the applied magnetic field gradient for position encoding. Therefore, the frequency bandwidth Δf is given by

$$\Delta f = \frac{\gamma}{2\pi} G_x d_{FOV} \tag{27.43}$$

where G_x is the magnetic field gradient in the x direction, and d_{FOV} is the dimension of image field of view. Hence, Δf is independent of the field strength B_0 .

However, the resistances R_c and R_b are field strength B_0 dependent. R_c increases with Larmor frequency, due to the skin-depth effect, because the high-frequency current tends to stay in the skin layer of the coil's wire. This skin-depth effect effectively makes the coil's resistance increase. It turns out that R_c is proportional to $B_0^{1/2}$. The RF dissipation-caused resistance R_b increases with B_0 as B_0^2 . For $B_0 > 0.2$ T, R_b dominates over R_c . Therefore, for $B_0 > 0.2$ T, the noise varies with B_0 according to

$$V_{\text{noise}} \propto \sqrt{R_h} \propto B_0 \tag{27.44}$$

Using Equations 27.40 through 27.43, we find that the SNRs for proton and hyperpolarized He/Xe are

$$SNR_{\rm H} \propto \frac{B_0^2}{\sqrt{B_0^2}} \propto B_0, \qquad SNR_{\rm He/Xe} \propto \frac{B_0}{\sqrt{B_0^2}} \propto 1$$
 (27.45)

This result shows that, although the SNR of conventional MRI is proportional to B_0 , the SNR of MRI with hyperpolarized spins is independent of B_0 . As we mentioned at the beginning of this chapter, the ever-increasing demand on high SNR drives the magnetic field strengths employed in conventional MRI higher. The higher the field strength, however, the more expensive and bulky the MRI scanner. The high field strength aggravates problems such as magnetic susceptibility artifacts and spin–lattice relaxation time lengthening. Fortunately, the SNR for hyperpolarized spins is independent of B_0 . A study of MRI using hyperpolarized 3 He at 0.1 T has been reported in the literature. Moreover, MRI images were obtained using MRI using hyperpolarized 3 He at 21 G. 19 These efforts open doors for many potential applications such as portable MRI scanners for lung imaging.

Another advantage of low field imaging is the reduction of magnetic susceptibility artifacts. Consequently, the apparent spin–spin relaxation time T_2^* can be greatly extended from a few to hundreds of milliseconds.

27.4.4 Pulse Sequence Considerations

Hyperpolarization is a spin state that is far away from the thermal equilibrium state, which has an important consequence for flip angle selection. Suppose one flips spin by 90° for maximal signal, since $\sin 90^\circ = 1$. We also suppose the transverse magnetization becomes dephased after forming echo. After the flip, the longitudinal magnetization $M_z = 0$ and spins experience spin–lattice relaxation, regardless of whether the spins are thermally polarized, such as water protons, or hyperpolarized spins generated by optical pumping. As shown in Equation 27.8, the longitudinal magnetization M_z evolves as a function of time t

$$M_z(t) = M_{eq} + (M_z(t=0) - M_{eq}) \exp\left(\frac{-t}{T_1}\right)$$
 (27.46)

where T_1 is the so-called spin-lattice relaxation time, as mentioned in Section 27.2, and M_{eq} is the thermal equilibrium magnetization. More specifically, after a 90° flip, $M_z(t=0) = 0$, $M_z(t)$ recovers according to

$$M_z(t) = M_{eq} \left(1 - e^{-\frac{t}{T_1}} \right)$$
 (27.47)

Therefore, for proton, M_z can be restored to its equilibrium M_{eq} after a long enough time (approximately 95% of M_{eq} at $3T_1$). This is true for hyperpolarized 3 He and 129 Xe as well. The difference is clear here: for proton, M_{eq} is the maximum of M_z ; hence the spin–lattice relaxation restores M_z . However, for hyperpolarized 3 He and 129 Xe, the equilibrium magnetization M_{eq} for 3 He and 129 Xe are approximately 10^5 times smaller than their initial M_z before the flipping. Therefore, the RF pulses really destroy hyperpolarization irreversibly, and spin–lattice relaxation cannot restore it. With thermal equilibrium magnetizations, we cannot get strong enough signals because of the low concentration of noble gas spins. Due to this difference, we should avoid applying the conventional "pre-scan" calibration procedures to hyperpolarized 3 He and 129 Xe for preventing destroying hyperpolarization before the scan.

If we apply RF excitations of flip angle α to hyperpolarized ³He or ¹²⁹Xe by *n* times, and if all transverse magnetization after each RF excitation gets completely dephased, then the remaining longitudinal magnetization is

$$M_z(n) = M_z(0)\cos^n\alpha \tag{27.48}$$

Here we also assume that T_1 relaxation times for 3 He and 129 Xe are long compared to the scan duration. The signal-generating transverse magnetization M_+ is

$$M_{\perp}(n) = M_{z}(0)\cos^{n-1}\alpha\sin\alpha$$
 (27.49)

Hence, the signal intensity gets weaker by a factor of $\cos\alpha$ for each RF pulse. Because RF excitations are applied one by one for acquiring scan data in phase-encoding direction or, equivalently, for sampling the data in the k space line by line, then the later sampled lines get reduced signal due to the "consumption" of the initial hyperpolarization. Consequently, this results in nonuniform weighting of k-space scan data.

Depending on the k-space sampling order, this nonuniform weighting can cause some loss of image resolutions. As for selection of α , Equation 27.49 suggests that we must balance two needs: we want a larger flip angle for a larger signal and we must ensure that enough M_z is left for phase-encoding steps with large n. Image quality is determined largely by the data from the center of the k space; therefore, we may want to ensure optimal signal intensity there. If sequential phase encoding is adopted, and n_c is the phase-encoding step corresponding to the k-space center, then transverse magnetization M_+ at this phase-encoding step is

$$M_{+}(n_{c}) = M_{z}(0)\cos^{n_{c}-1}\alpha\sin\alpha$$
 (27.50)

From the stationary point of $M_+(n_c)$ with respect to flip angle α , we find the optimal α_0 that maximizes the signal:

$$\alpha_0 = a \tan \left(\frac{1}{\sqrt{n_c - 1}} \right) \tag{27.51}$$

For example, if $n_c = 64$, the optical flip angle $\alpha_0 = 7.2^{\circ}$. It is interesting to note that, with this flip angle, after the 127th RF pulse the remaining longitudinal magnetization is approximately 37% of the starting M_+ .

To try to get constant signal as the RF excitation progresses, we must increase the flip angle to compensate the loss of hyperpolarization from previous excitation.²⁰ Note that if the flip angle varies as the RF-excitation progresses, then after n pulses M_z becomes

$$M_z(n) = M_z(0)\cos\alpha_1\cos\alpha_2...\cos\alpha_{n-1}\cos\alpha_n \qquad (27.52)$$

and the signal $M_{+}(n)$ after the nth RF pulse is

$$M_{+}(n) = M_{z}(0)\cos\alpha_{1}\cos\alpha_{2}...\cos\alpha_{n-1}\sin\alpha_{n}$$

The signal $M_{+}(n + 1)$ after the (n + 1)th RF pulse is

$$M_{+}(n+1) = M_{z}(0)\cos\alpha_{1}\cos\alpha_{2}...\cos\alpha_{n-1}\cos\alpha_{n}\sin\alpha_{n+1}$$
 (27.53)

Comparing these two equations, we get the condition for a constant signal; on the other hand, in order to get a constant signal for all phase-encoding steps, we should require that

$$\tan \alpha_n = \sin \alpha_{n+1} \tag{27.54}$$

Let us suppose that we apply a 90° flip angle at the last phase-encoding step N. In this way we maximize the signal from what is left in M_z and we need not save M_z for later steps any more. From the above equation the flip angle for the (N-1)th pulse should be

$$\tan \alpha_{N-1} = \sin \alpha_N = 1 \tag{27.55}$$

so the flip angle for the (N-1)th pulse should be 45°. Using Equation 27.54 we find the flip angle for the nth pulse is

$$\alpha_n = a \tan\left(\frac{1}{\sqrt{N-n}}\right) \tag{27.56}$$

So if N = 128, we start the sequence with a flip angle of 5.1° for the 1st pulse, and end the sequence with the 128th pulse of 90°. The variable flip angle approach can provide uniform k-space sampling and more efficient use of hyperpolarization.

Most studies performed with hyperpolarized spins, however, use a constant flip angle approach because it is difficult to implement the variable flip angles accurately, and the approach's performance is sensitive to variable flip angle errors from RF-B₁ field inhomogeneity and RF transmitter calibration errors. The variable flip angle technique can also be used in NMR spectroscopy. For example, to measure hyperpolarized xenon's T_1 relaxation times in blood, one usually applies multiple excitations to measure the relaxation-induced signal decay. With variable flip angle technique, the signal decay is truly contributed by the T_1 relaxation with the RF-induced loss of magnetization being compensated. So if a variable flip angle sequence with eight pulses is used, then, according to Equation 27.56, we should start with a flip angle of 21° and end with a flip angle of 90°.

The self-diffusion coefficient of He gas is high: $D_{\rm He} = 1.8~{\rm cm^2/sec}$ at 1 atm and 20°C; self-diffusion coefficients of Xe gas are much lower: $D_{\rm Xe} = 0.06~{\rm cm^2/sec}$ at 1 atm and 20°C. ²² In the data acquisition period, the frequency-encoding gradient is applied. In a magnetic field gradient diffusion creates additional random and position-dependent phases to the transverse magnetizations of spins, since diffusion is a random translation. The coherence between transverse magnetizations of spins at different locations has been partially destroyed by the random phases. When these transverse magnetizations are summed over all the spins at different locations, the total dephasing effect of these random phases is to attenuate the total transverse magnetization by a factor:

$$\exp\left(-\frac{\gamma^2 G^2 D T_g^3}{12}\right) \tag{27.57}$$

where G is the field gradient strength of a bipolar rectangular gradient waveform, and T_g is the time period of the transverse magnetization under field gradient. For a gradient echo sequence, G is the frequency-encoding gradient and $T_g = T_s$, the data sampling time. Because higher resolution corresponds to higher G, Equation 27.57 means that the diffusion-associated signal attenuation mainly affects the imaging of fine details. In fact, this equation can be equivalently written as

$$\exp\left(-\frac{\pi^2 DT_s}{3d^2}\right) \tag{27.58}$$

where *d* is the size of detail (one line pair) resolved. Consequently, the signal reduction is resolution-dependent.

The signal decreases rapidly with decreasing d. For example, for He gas and with $T_s = 6$ ms, 97% of the signal will be attenuated for d = 1 mm, but only 80% of the signal will be attenuated for d = 1.5 mm, and 33% of the signal will be attenuated for d = 3 mm. Reducing sampling time improves resolution rapidly as well. In the previous example, if T_s is reduced to 4 ms, 90.7% of the signal will be attenuated for d = 1 mm, but only 65% of the signal will be attenuated for d = 1.5 mm, and 23% of the signal attenuated will be for d = 3 mm. Xe's self-diffusion coefficient is much smaller; hence the diffusion-associated signal intensity reductions are mild. For Xe gas and with $T_s = 6$ ms, 11% of the signal will be attenuated for d = 1 mm, but

only 5% of the signal will be attenuated for d = 1.5 mm, and 1.2% of the signal will be attenuated for d = 3 mm. These results show the diffusion-associated signal attenuation as function of feature size. As for the minimal resolvable size, it depends on the feature's contrast as well. It should also be noted that the slower Xe diffusion allows one to use larger sampling time T_s . This means a smaller frequency bandwidth Δf of the signals, and hence less noise (Equation 27.42). This helps improve the SNR for Xe imaging.

This analysis is based on pure He or Xe. Diluting He with heavier gases such as N_2 reduces helium's diffusion coefficient, thus reducing diffusion-associated signal attenuation. Furthermore, helium's apparent diffusion coefficient in lung parenchyma is further reduced due to the restricted diffusion imposed by the bronchial and alveolar walls. Some studies have reported that the apparent diffusion coefficient (ADC) of helium diluted with N_2 in lung parenchyma is reduced by an order of magnitude compared to self-diffusion coefficient.

On the flip side of the diffusion problem, one may very well use diffusion to help examine the lungs by performing diffusion-weighted MRI.²³ Using ³He-MRI it was determined that He gas diffusion in the lungs is anisotropic, because the diffusion restrictions are much less along the airway axis than perpenticular to it.²⁴ This technique is useful for emphysema studies. In emphysema the restrictions to diffusion are reduced because of expansion of the alveoli and airway and tissue destruction. It was found that the ADCs of lungs of patients with severe emphysema are increased by a factor of 2.7 compared to the normal lung, and all the transverse and longitudinal ADCs are elevated.²⁴

27.4.5 Hyperpolarized Spin Relaxation

As noted earlier, the spin–lattice relaxation (T_1 relaxation) and spin–spin relaxation (T_2 relaxation) are the basis of tissue contrast in conventional MRI. This is true for hyperpolarized spins as well; however, spin–lattice relaxation becomes more important for hyperpolarized spins. This is because in proton MRI spin–lattice relaxation restores magnetization, but in ³He or¹²⁹Xe MRI spin–lattice relaxation destroys the magnetization of hyperpolarized spins. If the hyperpolarization is generated at t=0, using Equation 27.8) for spin–lattice relaxation and the condition $M_z >> M_{eq}$, the magnetization of hyperpolarized spins relaxes as

$$M_z(t) \approx M_z(t=0) \exp\left(\frac{-t}{T_1}\right)$$
 (27.59)

After $5T_1$ hyperpolarization is reduced to 0.6% of the initial hyperpolarization, and MRI signals from that much relaxed polarization will be diminished. Obviously, an MRI scan should be completed before the polarization consumed by relaxation. Relaxation time T_1 varies with the state and environment of hyperpolarized spins. Tables 27.2 and 27.3 show relaxation time T_1 for 3 He and 129 Xe in different conditions, respectively. Pure 3 He and 129 Xe would have long T_1 if there were no interaction with other impurities because the electrons of noble gases are in the filled orbitals. These electrons produce neither an electric field gradient nor a magnetic field at their nucleus. Also, noble gases are monoatomic, thus there is no intramolecular dipole–dipole coupling. That is why 3 He has a T_1 of several days in a clean glass container as listed in Table 27.2. The listed T_1 in glass container is obtained with a holding magnetic field of 10 to 20 G to fend off the stray magnetic field gradients. The holding field can be provided by a permanent magnet or battery-powered coils. For 129 Xe the distribution task is far more labored because 129 Xe should

TABLE 27.2 Spin-Lattice Relaxation Times for ³He

Perfluorocarbon emulsion: $\lambda_{solv} = 0.6$ at 37°C	100 s	28

be stored at low temperatures, as shown in Table 27.3. In fact, 129 Xe's relaxation time T_1 increases with higher B/T for a holding field up to 1 kG.

The dominated relaxation mechanism for 3 He and 129 Xe in the human body is the relaxation by paramagnetic molecules and ions. Of clinical significance is the relaxation induced by paramagnetic molecular oxygen and by paramagnetic deoxyhemoglobin. Molecular oxygen has an atomic electronic spin S = 1. The intermolecular dipole–dipole coupling between the oxygen electronic spin and noble gas nuclear spins dominates the relaxation. T_{1} of 3 He in the presence of oxygen has been measured: 25

$$\frac{1}{T_1} = 0.45[O_2] \left(\frac{299}{T}\right)^{0.42} s^{-1} / \text{amagat}$$
 (27.60)

where T is the temperature in degrees Kelvin and $[O_2]$ is the oxygen concentration. This equation provides the quantitative basis for measuring $[O_2]$ using ³He MRI. For human subject imaging, at the airway T is approximately 37.5°C, so

$$\frac{1}{T_1} = \frac{1}{2.27} [O_2] s^{-1} / \text{amagat}$$
 (27.61)

Another important aspect of noble gases MRI is the relaxation of noble gas hyperpolarization during vascular transport. The vascular transport is necessary for noble gases reaching other tissue such as brain tissues. Xe has much higher solubility in blood than He, so 129 Xe is more suitable than 3 He for brain imaging. Table 27.3 shows the spin–lattice relaxation times of 129 Xe in blood reported in Wolber et al. 21 At a temperature of 37°C and a field strength of 1.5 T, $T_1 = 6.4$ sec for arterial blood and $T_1 = 4$ for venous blood. This is because deoxyhemoglobin in blood is paramagnetic, while oxyhemoglobin is diamagnetic. The increased relaxation of 129 Xe for deoxygenated blood may originate from Xe interaction with paramagnetic Fe ions in the heme group of deoxygenated hemoglobin. 21 In fact, there are four iron atoms in each hemoglobin molecule, which can bind four oxygen atoms. However, this difference of relaxation times in oxygenated and deoxygenated blood could be used for functional MRI as well. The deoxygenated hemoglobin exposes their paramagnetic iron ions to Xe causing Xe spin relaxation. Therefore Xe's spin–lattice relaxation time T_1 increases with the blood oxygenation saturation sO₂ as measured by Wolber et al. 26 Note that the physiological oxygenation range from sO₂ = 0.6 for the venous blood to sO₂ = 0.98 for the arterial blood. These measurements of T_1 as a function of sO₂ also provide a quantitative basis for measuring blood and tissue oxygenation by using 129 Xe MRI.

To see the great potential of this capability of ¹²⁹Xe MRI, consider the functional proton MRI of the human brain, which has undergone explosive development in recent years. This functional proton MRI technique is based on the blood oxygenation level dependent (BOLD) effect. This BOLD effect is sensitive to changes in oxygenation and blood flow in response to neural stimulation. However, BOLD effect does not provide a direct measurement of blood oxygenation because blood flow changes are blended in as well. So ¹²⁹Xe MRI might be able to elucidate the relative contributions of perfusion and oxygenation to

the BOLD effect. Finally, it should be noted that relative shift of intra- and extracellular ²⁹Xe spectral peak is also sensitive to the blood oxygenation level.²⁷

From this discussion it is also clear that delivery of hyperpolarized 129 Xe from inhalation to other organs such as the brain is critically limited by loss of polarization during vascular transport. This calls for development of intravenous injection of hyperpolarized spins in biocompatible media. These media should allow much longer T_1 for 129 Xe and high solubility. As listed in Table 27.3, T_1 for 129 Xe has been increased to 66 s in saline and 100 s in perfluorocarbon emulsion. However, perfluorocarbon emulsion has much higher Ostwald solubility λ_{solv} than saline does, as shown in Table 27.3. (The Ostwald solubility is defined as the volume of gas dissolved per unit volume of solvent at equilibrium.) The search of biocompatible media for 129 Xe and 3 He is just beginning. 29

For 129 Xe dissolved in liquid, dipole–dipole coupling between xenon nuclear spins and dipole–dipole coupling between xenon nuclear spins and solution nuclear spins (e.g., protons) play an important role in determining xenon's T_1 . Among these spins the spin polarization transfer from hyperpolarized xenon to solution nuclear spin is observed and called SPINOE, the spin–polarization-induced nuclear Overhauser effect. 30 The mechanism underlining the polarization transfer is the nuclear Overhauser effect generated by the cross-relaxation between Xe and solution nuclear spins. Therefore, through SPINOE, hyperpolarized Xe can "light up" solution nuclear spins by enhancing their polarization. In addition, differential SPINOE enhancements in solution should provide information of selective binding of xenon to biomolecules in solution. 31

So far, all the spin–lattice relaxation is based on the assumption that hyperpolarized Xe relaxes in the same way as the thermally polarized Xe. In fact, some data of Xe T_1 in blood are measured by using thermally polarized Xe. We note that this assumption is not completely true.³² First, the conventional relaxation laws are derived from the assumption of weak polarization near the thermal equilibrium. Second, we find that hyperpolarization and spin dipole–dipole coupling result in multipole spin orders for hyperpolarized spins. In another words, a hyperpolarized spin state may include not only the magnetization (the dipole spin order $\langle I_z \rangle$), but also other multipole order, such as the quadrupole spin order. These multipole spin orders cross-relax each other. The longitudinal magnetization relaxation of hyperpolarized spins is, in general, bi-exponential decay, although the ordinary T_1 component dominates in many but not all cases. These findings have potential applications in quantifying the paramagnetic source in lung and other tissue and in modeling hyperpolarized xenon spin auto-relaxation and cross relaxation in biocompatible media.³³

27.4.6 MRI of Hyperpolarized ³He and ¹²⁹Xe for Human Subjects

Hyperpolarized spin MRI has already been applied to human subjects in recent years. Here we discuss several examples in accordance with the scope of this chapter. Hyperpolarized 3 He has been used to image human pulmonary morphology. This is done usually in a period of one breath after inhalation of 3 He gas. The pulse sequences are usually the low-flip angle-spoiled gradient echo sequences. The spatial resolution of 3 He MRI depends on the sampling time, T_{s} , used because, as shown by Equation 27.58, T_{s} controls the adverse effect of the He diffusive movement in air space on the resolution. In any case, the image resolution is definitely better than that of ventilation scintigraphy. 34,35 Figure 27.11 shows 3 He-MRI images of the lungs from a healthy volunteer and a smoker. The lung image of the smoker presented patchy and wedge-shaped signal defects due to reduced or absent entry of 3 He.

In addition to morphological study, 3 He gas can be used to measure the regional alveolar partial pressure of oxygen (pO₂). It is well known that, in the air space of the lungs, the partial pressure of oxygen varies regionally and temporally. These variations reflect the differences in ventilation-dependent oxygen delivery and perfusion-dependent oxygen uptake. Currently, there is no noninvasive means to measure pO₂ within occluded pulmonary segments, and the intrapulmonary pO₂ beyond the bronchi could not be measured even by invasive methods. However, as we pointed out earlier, the T_1 relaxation rate of He gas is proportional to the oxygen concentration [O₂], as shown in Equation 27.61, because molecular oxygen is paramagnetic (S = 1).

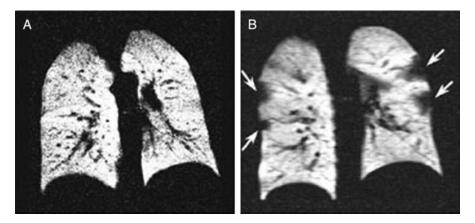

FIGURE 27.11 (A) A ³He MRI image of the lungs of a healthy volunteer. (B) A ³He MRI image of the lungs of a smoker. (Images courtesy of Drs. W. Schreiber and R. Surkau, University of Mainz, Germany.)

Therefore, using 3 He MRI one can derive the local alveolar pO $_{2}$ from the 3 He signal decay curve generated from a series of images acquired at a series of times. 3 6 Briefly speaking, this can be done as follows. Suppose one acquires N images, each is separated by a period Δt , and one uses a constant flip angle α . Equation 27.49 gives the signal intensity with the RF depolarization effect, but without T_{1} relaxation during the acquisitions. On the other hand, Equation 27.59 gives the relaxation law of the hyperpolarized magnetization of 3 He. Compared to signal intensity of the nth image, the signal intensity of the (n+1)th image should be reduced by the relaxation and the RF depolarization effects. Therefore, combining these two effects by using Equations 27.49 and 27.59, we can find the signal ratio of the two images:

$$q = \frac{S_{n+1}}{S_n} = \cos^{N_p - 1} \alpha \exp\left(-\frac{\Delta t}{T_1}\right) = \cos^{N_p - 1} \alpha \exp\left(-\frac{pO_2 \Delta t}{2.27}\right)$$
(27.62)

where N_p is the total number of the phase-encoding steps per image, and the partial pressure of oxygen pO_2 is expressed in amagats. Once the ratio q of a local region is found, then pO_2 can be calculated from the above equation. For further details of the technique, see Reference 36. This approach provides a quick and noninvasive way to assess ventilation–perfusion matching, since the local alveolar pO_2 manifests the local ventilation–perfusion ratio.

Acknowledgments

We are grateful to Drs. W. Schreiber, R. Surkau, and J. Schmiedeskamp for providing ³He MRI images.

28.1 Introduction

In the past several decades, fluorescence spectroscopy has had a dramatic effect on many different fields of research. One field that has seen significant advancements is biomedical diagnostics. Within this field, fluorescence spectroscopy has been applied to the analysis of many different types of samples, ranging from individual biochemical species (e.g., NADH, tryptophan) to organs of living people. These studies have given rise to new methods for the early or noninvasive diagnosis of various medical conditions, including tooth decay, atherosclerosis, heart arrhythmia, cancer, and many others.

The medical condition that has seen the largest effort toward fluorescence-based analyses and truly demonstrates the potential of fluorescence-based diagnoses is cancer. Fluorescence spectroscopy and imaging have been investigated for the diagnosis of almost every type of cancer and early neoplastic difference found in humans. The detection of early neoplastic changes is important from an outcome viewpoint because, once invasive carcinoma and metastases have occurred, treatment is difficult. At present, excisional biopsy followed by histology is considered the "gold standard" for diagnosis of early neoplastic changes and carcinoma. In some cases, cytology rather than excisional biopsy is performed. These techniques are powerful diagnostic tools because they provide high-resolution spatial and morphological information of the cellular and subcellular structures of tissues. The use of staining and processing can enhance contrast and specificity of histopathology. However, both of these diagnostic procedures require physical removal of specimens, followed by tissue processing in a laboratory. These

^{*}Current affiliation: University of Maryland Baltimore County, Baltimore, Maryland

procedures incur a relatively high cost because specimen handling is required; more importantly, diagnostic information is not available in real time. Moreover, in the context of detecting early neoplastic changes, excisional biopsy and cytology can have unacceptable false negative rates often arising from sampling errors.

Fluorescence techniques have the potential for performing *in vivo* diagnosis on tissue without the need for sample excision and processing. Another advantage of fluorescence-based diagnoses is that the resulting information can be available in real time. In addition, because removal of tissue is not required for optical diagnoses, a more complete examination of the organ of interest can be achieved than with excisional biopsy or cytology.

This chapter provides an overview of fluorescence spectroscopy and its basic principles as well as its biomedical applications. Because biomedical fluorescence spectroscopy represents an extremely large and growing field of research, we have attempted to classify the ongoing research and clinical studies into three different categories: (1) biochemical analyses of individual compounds, (2) *in vitro* analyses (cellular and tissue systems), and (3) *in vivo* analyses (animal and human studies). In addition to the overview of fluorescence spectroscopy in this chapter, special methods and instrumental aspects for fluorescence analyses are further described in other chapters in this handbook: Chapter 33 on near-infrared fluorescence imaging and spectroscopy in random media and tissues, Chapter 9 on lifetime-based imaging, microscopy, Chapter 10 on confocal miscroscopy, and Chapter 11 on two-photon excitation fluorescence microscopy.

28.2 Principles of Fluorescence Spectroscopy

28.2.1 Fluorescence Techniques

Luminescence is a branch of spectroscopy that deals primarily with the electronic states of an atom or molecule, as opposed to the vibrational, rotational, or nuclear energy states. Fluorescence and phosphorescence are the two sister techniques covered by the umbrella known as "luminescence spectroscopy." These techniques involve the optical detection and spectral analysis of light emitted by a substance undergoing a transition from an excited electronic state to a lower electronic state. Most luminescence-based medical diagnoses involve fluorescence spectroscopy because organic compounds fluoresce and do not phosphoresce at room temperature. In most phosphorescence studies, the measurements need to be performed using low-temperature frozen solvents to minimize collisional quenching. A unique technique called room temperature phosphorescence (RTP) uses various solid substrates to adsorb analytes into rigid matrices (e.g., cellulose, silica gel, and alumina) in order to allow phosphorescence measurements.¹ Because the vast majority of medical applications involve fluorescence analysis, this chapter focuses mainly on the theory of fluorescence. However, because phosphorescence is also involved in the field of photodynamic therapy (PDT), we will also describe the relationship between fluorescence and phosphorescence.

Fluorescence diagnostic methods can be grouped into two main categories:

- 1. Methods that detect endogenous fluorophores in tissues
- 2. Methods that detect or use exogenous fluorophores or fluorophore precursors [such as 5-amino-levulinic acid (ALA)]

Fluorescence that originates from native fluorescent chromophores already present in the tissue is often referred to as "autofluorescence." Fluorescence may also originate from administered exogenous chromophores that have been synthesized to target specific tissues (e.g., dysplastic vs. normal), or it may be activated by functional changes in the tissue. In a fluorescence analysis, excitation light at some specific wavelength (typically near-ultraviolet or visible) excites the tissue or exogenous fluorophore molecules and induces fluorescence emission. Then some measure of the fluorescent emission is obtained, typically an emission spectrum (fluorescence emission intensity vs. wavelength).

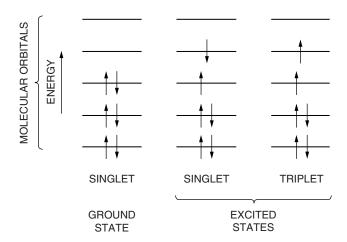

FIGURE 28.1 Schematic diagram of typical spin arrangements in molecular orbitals for the ground, excited singlet, and triplet states.

28.2.2 Photophysical Basis of Luminescence

Most organic molecules contain an even number of electrons. In the ground state, the electrons fill the various atomic orbitals with the lowest energies in pairs. By the Pauli exclusion principle, two electrons in one given orbital must have spins in opposite directions, and the total spin *S* must equal 0. For this reason, the ground state has no net electron spin; this state is called a "singlet" state.

Excitation of a molecule usually results in the promotion of one electron from the highest occupied orbital to a previously unoccupied orbital (also referred to as a "virtual" orbital). Whereas the ground state is generally a singlet, the excited state can be a singlet or a triplet, depending on the final spin state of the electron promoted to the higher orbital. For illustration, Figure 28.1 shows one ground state and two excited-state configurations. The spins of the two electrons in the unoccupied orbitals are no longer restricted by the Pauli exclusion principle. The singlet state has two antiparallel spins, whereas the triplet state has two parallel spins and a net spin, *S*, of 1. In the general case, the configuration is not so easily visualized by schematic diagrams.²

The nature of the orbitals involved in an electronic transition is an important factor in determining the luminescence characteristics of the molecule. Organic compounds that are known to be strongly luminescent are molecules with extensive π electron systems. These compounds include aromatic molecules and a few unsaturated aliphatics. For molecules with no hetero-atom, electronic transitions generally involve promotion of an electron from a bonding π orbital to an antibonding π^* orbital. Such a transition is known as a $\pi - \pi^*$ transition, and the resulting electronic state is called the $\pi\pi^*$ excited state. For conjugated systems with hetero-atoms (N, O, or S) in the conjugated system, or with substituents containing the N, O, or S atoms, an electronic state may result from the promotion of an electron from a bonding n orbital to an antibonding n orbital; this electronic state is called an $n\pi^*$ excited state.

28.2.2.1 Molecular Electronic Energies

In the study of luminescence, we are first concerned with determination of the electronic states between which luminescence and other related processes such as intersystem crossing, vibrational relaxation, and internal conversion occur. The basic approach for studying luminescence behavior of molecules is to calculate the stationary-state electronic energies by solving the time-independent Schrödinger equation. A suitable wave function, Ψ , chosen to describe the properties of various molecular orbitals (MO) involved in the photophysical processes, is given by the Schrödinger equation

$$H(q,Q)\Psi(q,Q) = E\Psi(q,Q), \tag{28.1}$$

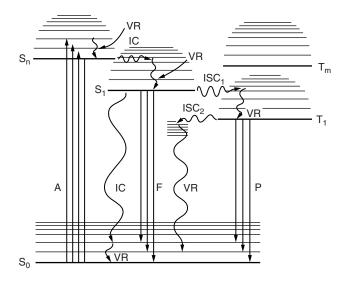

FIGURE 28.2 Jablonskii diagram showing the different radiative and nonradiative transitions in a molecule upon excitation into a singlet state, S_n : S_0 = singlet ground state; S_1 = first excited singlet state; T_1 = first excited triplet state; T_m = excited triplet state; ISC, ISC₁, and ISC₂ = intersystem crossings; A = absorption; F = fluorescence; IC = internal conversion; P = phosphorescence; and VR = vibrational relaxation.

where H is the Hamiltonian operator of the molecule, q is the electronic spatial coordinates, Q is the nuclear spatial coordinates, and E is the energy eigenvalue.

The exact solutions for the Schrödinger equation are impossible to calculate for any molecular system except H⁺. Therefore, calculations of electronic energies for excited singlet and triplet states of larger systems usually involve some method of approximation. The most commonly used method is the MO method, which utilizes one-electron orbitals to form molecular orbitals. One of the simplest of these MO-based methods for calculating, or rather estimating, molecular electronic energies is the Hückel molecular orbital (HMO) method, which treats certain integrals as parameters and selects these parameters such that calculated values are in agreement with physical observables. This approach has been quite successful in describing bonding in aromatic and highly conjugated molecules.

Figure 28.2, known as the Jablonskii diagram, shows energy levels for an organic molecule. In this figure, $S_0 ext{...}, S_n$ and $T_1 ext{...}, T_m$ represent the discrete electronic energy levels of a molecule. The electronic state having the lowest energy, S_0 , is known as the ground state. $S_0 ext{...}, S_n$ and $T_1 ext{...}, T_m$ are the excited singlet and triplet states, respectively. Each electronic state has its own set of vibrational levels. Superimposed on each vibrational level is a series of closely spaced rotational levels not shown in Figure 28.2.

28.2.2.2 Population of the Excited Electronic States

The main photophysical processes involved in the population and deactivation of excited electronic states, both singlet and triplet, are shown in Figure 28.2. These processes — absorption (A), vibrational relaxation (VR), internal conversion (IC), fluorescence (F), intersystem crossing (ISC), and phosphorescence (P) — and related photophysical processes are discussed next.

Absorption (A)

At equilibrium, a group of molecules has a thermal distribution at the lowest vibrational and rotational levels of the ground state, S_0 . When a molecule absorbs excitation energy, it is elevated from S_0 to some vibrational level of one of the excited singlet states, S_n , in the manifold $S_1, ..., S_n$. As postulated by the Franck–Condon principle, the time for an electronic transition (on the order of 10^{-15} s) is shorter than the time for nuclear rearrangement (on the order of 10^{-13} to 10^{-14} s). As a consequence, the molecular configuration following absorption is often a nonequilibrium nuclear configuration because the electronic

absorption process is so rapid that the atomic nuclei do not have time to change positions or moments. Thus, the adiabatic (Born-Oppenheimer) approximation is often applied to solve the Schrödinger equation (Equation 28.1) and partially separates the eigenstates of the electronic ("fast") and nuclear ("slow") subsystems. The intensity of the absorption (i.e., fraction of ground-state molecules promoted to the electronic excited state) depends on the intensity of the excitation radiation (i.e., number of photons) and the probability of the transition with photons of the particular energy used. A term often used to characterize the intensity of an absorption (or induced emission) band is the oscillator strength, f, which may be defined from the integrated absorption spectrum by the relationship

$$f = 4.315 \times 10^{-9} \int \varepsilon_{\nu} d\nu$$
, (28.2)

where ε_{v} is the molar extinction coefficient at the frequency v.

Oscillator strengths of unity or near unity correspond to strongly allowed transitions, whereas smaller values of f indicate smaller transition dipole matrix elements of forbidden transitions.

Vibrational Relaxation (VR)

In condensed media, the molecules in the S_n state deactivate rapidly, within 10^{-13} to 10^{-11} s via VR processes, ensuring that they are in the lowest vibrational levels of S_n possible as described by the thermal Boltzmann distribution. Because the VR process is faster than electronic transitions, any excess vibrational energy is rapidly lost as the molecules are deactivated to lower vibronic levels of the corresponding excited electronic state. This excess VR energy is released as thermal energy to the surrounding medium.

Only under special circumstances — for example, in the gas phase at very low pressures (<10⁻⁶ torr) — may emission be observed from higher vibrational levels of the excited state. These emission mechanisms, known as single-vibronic-level (SVL) luminescence processes, do not generally occur in condensed media such as tissues.

Internal Conversion (IC)

From the S_n state, the molecule deactivates rapidly to the isoenergetic vibrational level of a lower electronic state such as S_{n-1} via an IC process. IC processes are transitions between states of the same multiplicity. The molecule subsequently deactivates to the lowest vibronic levels of S_{n-1} via a VR process. By a succession of IC processes immediately followed by VR processes, the molecule deactivates rapidly to S_1 . As a result, a molecule may be excited to S_1 or higher excited states, S_n , depending on the excitation energy used, but the emission takes place only from the lowest excited electronic state, S_1 . This is known as Kasha's rule. Fluorescence emission from upper electronic states (above S_1 or S_1) of polyatomic molecules, however, is a rare phenomenon in the condensed phase.

After vibrational relaxation or internal conversion, the thermal population at a given electronic state is determined by the Boltzmann distribution, which gives the relative population of species in a given electronic or vibronic state as compared with those in all other states. The Boltzmann distribution is expressed by

$$\frac{n_i}{\sum_{j} n_j} = \frac{g_i \exp(-E_i/kT)}{\sum_{j} g_j \exp(-E_i/kT)}$$
(28.3)

where n_i is the number of molecules in electronic or vibronic state I, g_i is the statistical weight of state of that state, E_i is the energy of state I, k is the Boltzmann constant, and T is the temperature.

Fluorescence (F)

Relaxation of the molecule from the S_1 state may occur by one of a several different of processes, including:

- (1) further deactivation to S_0 in a radiationless fashion via internal conversion (IC) and VR processes or
- (2) emission of a photon without a change in spin multiplicity. The latter $S_1 \rightarrow S_0$ transition is known

as fluorescence. The energy of the resulting photon corresponds to the difference in energy between the lowest vibrational level of the excited state and the vibrational level of the ground state. Thus, the fluorescence spectrum primarily provides information about the vibrational structure of the ground state.

These radiative transitions are electric-dipole in nature. The probability of a radiative transition $(S_i \rightarrow S_j)$ is proportional to the square of the matrix element, $|(\mathbf{M})_{ij}|^2$, where \mathbf{M} is the electric dipole moment defined by

$$M(S_i \to S_j) = \left\langle \psi(S_i) \middle| \sum_{q} e \mathbf{r}_q \middle| \psi(S_j) \right\rangle$$
 (28.4)

where *e* is the electronic charge, \mathbf{r}_q is the position vector of electron *q*, and ψ (S_i) is the wave function of electronic state S_i . For fluorescence (i = 0, j = 1) the electronic transition corresponds to $M_{1,0}^2$.

Intersystem Crossing (ISC)

Another process through which molecules in the S_i state may relax is through a transition to some vibrational level of the triplet manifold via a mechanism known as an intersystem crossing (ISC) process (ISC₁ transition shown in Figure 28.2). The ISC process involves a change in spin multiplicity. The molecule then relaxes to the lowest vibrational level of T_i via successive IC and VR processes.

From this T_1 state, the molecule may return to the ground state S_0 either by a radiationless deactivation path (ISC₂ process shown in Figure 28.2) or by the emission of a photon. This latter radiative transition is known as phosphorescence.

The radiationless deactivation that quite often competes with phosphorescence is the reverse ISC process (ISC₂). This process, which is often dominant, determines the observed phosphorescence lifetime. The nonradiative rate constant corresponding to the ISC process $T_1 \to S_0$ is strongly dependent on the magnitude of the energy gap $\Delta E(T_1 \to S_0)$. The rate constant decreases exponentially with increasing ΔE ; this feature is known as the energy gap law. The energy gap law not only is specific to ISC but also applies to other nonradiative transitions such as IC.

Phosphorescence and the Triplet State

The triplet state manifold consists of states T_1 , T_2 ,... T_n , which have energy levels lower than the corresponding singlet states S_1 , S_2 ,... S_n . This is a consequence of Hund's rule, which states that the energy associated with a state having parallel spins is always lower than that of the corresponding one with antiparallel spins. Qualitatively, Hund's rule may be explained by the tendency for electrons with parallel spins to be further separated in space (i.e., to lie in different molecular orbitals) and consequently experience less coulombic interaction. As a result of Hund's rule, phosphorescence occurs at longer wavelengths than does fluorescence.\(^{1/2}

Properties of singlet and triplet states are significantly different. The singlet state is diamagnetic, whereas the triplet state is paramagnetic. The nomenclature "singlet" and "triplet" is derived from multiplicity considerations of the energy level splitting that occurs when the molecule is exposed to a magnetic field. Under the application of an external magnetic field, the triplet state with a spin magnetic momentum splits into three Zeeman levels. The singlet state, which has no magnetic momentum, is unchanged.

Spin-Orbit Coupling

Production of the triplet state in some compounds is important to photosensitization in certain biomedical applications, such as photodynamic therapy (PDT). A process that leads to the production of the triplet state is spin-orbit coupling. Transitions between different excited singlet states of the same multiplicity $(S_n \to S_m \text{ or } T_n \to T_m)$ may occur easily, but transitions between pure spin states of different multiplicities $(S_n \to T_n)$ are forbidden by quantum mechanics under the spin-selection rule $(\Delta S = 0)$. Spin-forbidden transitions, however, do occur under certain conditions. If the spin and orbital motions of the electrons are independent of one another, triplet–singlet transitions do not give rise to electric

dipole radiation because of the spin selection rule. However, the spin and orbital motions are actually not independent. Basically, the occurrence of spin-forbidden transitions — for example, singlet—triplet transitions — is made possible by coupling of the electron spin with the orbital angular momentum, a nonclassical phenomenon that produces a quantum mechanical mixing of states of different multiplicities. Qualitatively, this mechanism may be explained by the fact that the orbital motion of the electron induces a magnetic field that interacts with its spin magnetic moment. This interaction results in a change of the direction of the spin angular momentum of the electron.² This phenomenon is known as spin—orbit (S—O) coupling.

The S–O coupling mechanism actually mixes some singlet character into triplet states and vice versa. This process therefore removes the spin-forbidden nature of the transitions between pure-spin states. Because of the importance of S–O coupling in understanding the phosphorescence process, it is essential to consider briefly the theoretical treatment of S–O coupling.

General Considerations for Nonradiative Properties

The VR, IC, and ISC processes are known as "radiationless transitions." In the framework of the Born-Oppenheimer approximation, in which the nuclear and electronic motions are assumed to be independent of each other, the probability of W_{mn} of a radiationless transition between two electronic states n and m can be treated by perturbation theory and is given by the following expression:^{1,2}

$$W_{mn} = \frac{8\pi^2 \tau}{h^2} \prod_{ij} \left\langle \Theta_{mi} | \Theta_{nj} \right\rangle^2 \left\langle \Phi_m | H' | \Phi_n \right\rangle^2$$
 (28.5)

where h is Planck's constant, θ_{mn} is the vibrational wave function i of the electronic state m, θ_{m} is the electronic wave function of the electronic state m, τ is the relaxation time of the vibronic levels, H' is the perturbing Hamiltonian and Π_{ij} is the product over all vibronic states i and j.

For radiationless transitions between states of similar multiplicity — for example, VR and IC processes — H' may be the electron–electron repulsion term or the vibronic interaction term. For radiationless transitions between states of different multiplicity — for example, ISC processes — H' is the spin–orbit coupling term.

A common expression that describes the probability W_{mn} is the so-called Fermi Golden Rule for the statistical limit of a dense manifold for the final states. In this case W_{mn} is given by

$$W_{mn} = \frac{2\pi}{h} V_{mn} \cdot \rho$$

where V_{mn} is the matrix element of the perturbation between the initial state m and final state n, ρ is the density of the final state, and h is Planck's constant.

Delayed Fluorescence (DF)

Fluorescence and phosphorescence are the two most common luminescence processes. A less common emission process is delayed fluorescence (DF). With some chemical systems, the molecule in the triplet state T_1 reverts back to the excited singlet state manifold. Because T_1 is always of lower energy than S_1 , this transition requires some additional activation energy. Delayed fluorescence may occur from the S_1 state, exhibiting a spectrum identical to conventional fluorescence (often called "prompt fluorescence") but having a longer lifetime due to the additional stay in the triplet state. Two types of DF processes can be differentiated: (1) an eosin-type (E-type) DF produced by repopulation of S_1 from the triplet state by thermal activation, and (2) a pyrene-type (P-type) DF produced when pairs of triplet state molecules interact, providing an activation energy greater than or equal to the S_1 energy. At room temperature, E-type DF can be an important mechanism and has been observed for many organic compounds adsorbed on solid substrates.

28.3 Characterization of Luminescence

Several physical observables may be used to characterize fluorescence and phosphorescence. These include the following:

- 1. Emission, excitation, and synchronous spectra
- 2. Quantum yields
- 3. Lifetimes
- 4. Polarization

28.3.1 Emission, Excitation, and Synchronous Spectra

It is first important to determine the positions and nature of the energy levels of the electronic states involved in the luminescence excitation and emission processes because these energy levels are characteristic properties of the compounds of interest. In general, the simplest method of studying the energy levels of the excited state is absorption spectroscopy. An alternative method for investigating the absorption process for luminescent compounds is excitation spectroscopy.

The general relationship between the absorption and emission spectra and the vibrational levels of the electronic states is illustrated in Figure 28.3. Because a fluorescence emission spectrum is due to radiative decay from S_i to different levels of S_0 , the emission spectrum exhibits the vibrational frequencies that correspond to the vibrations of the molecule in its ground state, whereas the absorption spectrum exhibits frequencies of the excited state. The intensities of the vibrational bands are determined in quantum theory by the magnitude of the wave-function overlap (Franck–Condon coefficients) for the various vibrational levels in the ground and excited states (Figures 28.3B and 28.3C). The overlap coefficients are the Franck–Condon factors.

Figure 28.3A shows the potential energy curves of the excited and ground states and the transitions corresponding to an excitation (or absorption) and emission process. Figures 28.3B and 28.3C show two typical cases of electronic states with their potential minima at different relative positions on the internuclear distance coordinate R. In Figure 28.3B, the strongest transition is the 0–0 transition, at which the overlap is the largest. In Figure 28.3C, the most probable transition is the 0–4 transition involving the vibrational level $\mathbf{v}' = 4$ of the ground state and the vibrational level $\mathbf{v}' = 0$ of the excited state. The envelopes of the vibrational progressions illustrated in Figures 28.3B and 28.3C depend on the relative displacement δR between the potential minima of the excited and ground states; for the simple case in which the ground vibrational level is thermally populated, the shape of the envelopes is determined by the Pekarian formula. For $\delta R = 0$, there is no vibrational progression; for large δR , the Pekarian distribution becomes a Gaussian distribution. Examination of the vibronic structure of the fluorescence, or phosphorescence, spectrum can therefore yield important information about the potential curves of the singlet and ground states or triplet and ground states, respectively.

With conventional emission (excitation) spectra, the excitation (emission) wavelength is fixed while the emission wavelength is scanned over the spectral region of interest. With synchronous spectra, excitation and emission wavelengths are scanned synchronously while maintaining a constant wavelength interval between them.^{3,4}

28.3.2 Quantum Yields

Emission quantum efficiencies, also known as quantum yields, determine the sensitivity of the luminescence measurements. Quantum efficiencies are intrinsic molecular parameters of a compound under given conditions of temperature, solvent, and other environmental factors.

The fluorescence quantum efficiency Φ_F is defined as:

$$\Phi_F = \frac{\text{Number of luminescence photons}}{\text{Number of photons absorbed}}$$
 (28.6)

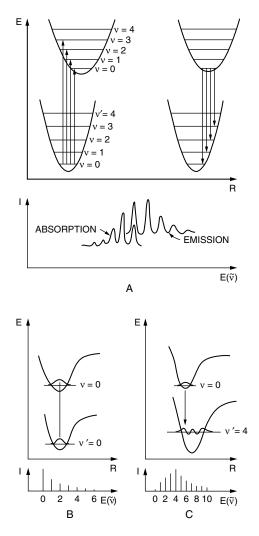

FIGURE 28.3 (A) Diagrams of the potential energy curves of two electronic states showing the absorption and emission transitions between these two states and the typical intensity distribution of the corresponding spectra. (B) Potential energy curves with unchanged potential minima. The most intense transition is 0–0 (maximum overlap of the vibronic wave functions). (C) Potential energy curves with potential minima shifted with respect to each other. In this example, the most intense transition is 0–4.

The phosphorescence quantum efficiency Φ_p is defined in a similar manner. Quantum efficiencies can also be defined for processes other than emission and are used to define the fraction of molecules that undergoes a specific process.

28.3.3 Lifetimes

Another means for characterizing a luminescence emission process is the determination of its lifetime. The luminescence lifetime, τ , is defined as the time required for the emission to decrease to 1/e of its original intensity following a δ -pulse excitation.

If I(t) is the luminescence intensity at time t and I_0 is the intensity at t = 0, then τ is given by:

$$I_{I}(t) = I_{0} \exp(-t/\tau) \tag{28.7}$$

TABLE 28.1 Radiative Lifetimes and Oscillator Strengths in the Electronic Transitions for Polynuclear Aromatic Compounds

Origin of Transitions	Radiative Lifetime (s)	Oscillator Strength
$S_1 \rightarrow$	S ₀ Transitions	
$\pi\pi^*$	$10^{-7} - 10^{-9}$	$10^{-3} - 1$
πσ or $σπ*$	> 10 ⁻⁶	< 10 ⁻²
$n\pi^{\star}$	~ 10 ⁻⁶	$\sim 10^{-6}$
$T_I \rightarrow$	T _o Transitions	
$n\pi^*$ (or $\sigma\pi^*$ or $\pi\sigma^*$)	$10^{-2} - 10^{-4}$	$10^{-7} - 10^{-5}$
$\pi\pi^*$ in halo-aromatic	$1-10^{-3}$	$10^{-9} - 10^{-6}$
$\pi\pi^*$ in unsaturated hydrocarbons	~ 10-2	10-11

It is important to differentiate the intrinsic natural lifetime, τ^* , from the observed lifetime, τ , for a given radiative process. The intrinsic natural lifetime, τ^* , is measured only when there is no radiationless deactivation process competing with the emission — that is, when $\Phi_L = 1$ for the resulting luminescence.

Experimentally, fluorescence can be differentiated from phosphorescence by its shorter lifetime. Fluorescence lifetimes of organic molecules are on the order of 10^{-9} to 10^{-7} s, while phosphorescence lifetimes range from 10^{-3} s to several seconds. Table 28.1 compares the oscillator strengths and radiative lifetimes of fluorescence $(S_1 \rightarrow S_0)$ and phosphorescence $(T_1 \rightarrow S_0)$ emission and absorption of different origins.

28.3.4 Polarization

Polarization is another physically observable characteristic of luminescence. Polarization is caused by unique symmetries and orientations of electric moment vectors and wavefunctions involved in electronic transistions. The electric dipole moment determines the direction along which charge is displaced in a molecule undergoing an electronic transition. It is possible to study the polarization of the transition using polarized light to excite and detect luminescence.

A common method for determining the degree of polarization, *P*, is photoselection. In this method, one excites the sample with polarized light and measures the luminescence intensity along two perpendicular directions. The degree of polarization is defined as

$$P = \frac{I_{EE} - I_{EB}}{I_{EE} + I_{EB}} \tag{28.8}$$

where I_{EE} and I_{EB} are the luminescence intensities measured along the direction parallel and perpendicular to the excitation electric vector, E, respectively. P is related to the angle, θ , between the absorption vector and the emission vector by the relationship

$$P = \frac{3\cos^2\theta}{\cos^2\theta + 3} \tag{28.9}$$

If the absorption and emission vectors are parallel ($\theta = 0^{\circ}$), P = 0.5. If these vectors are perpendicular ($\theta = 90^{\circ}$), P = -0.33. In practice, P has a value between these two limiting cases.

28.4 Biomedical Applications

Biomedical fluorescence spectroscopy is an extremely large and growing field of research. In an attempt to classify the various types of research and clinical studies that are being performed, we have grouped this field into three categories:

- 1. Biochemical analyses of individual compounds
- 2. In vitro analyses
- 3. In vivo analyses

Biochemical analyses are the basis for the fundamental or general studies of individual biochemical compounds that form the basic constituents of biological samples (i.e., tryptophan, NAD, NADH, hemoglobin, etc.). From these studies the basic fluorescence properties of common fluorophores are generally determined and characterized. The second category, *in vitro* analyses, is further divided into two subcategories: cellular measurement and tissue measurement. These analyses typically provide additional information associated with complex systems such as cells and tissues. The third classification category, *in vivo* analyses, can also be subdivided into two more subcategories: animal studies and human clinical studies. These experiments are generally performed only for fluorescence analysis techniques meant to be used for optical diagnostic procedures. In addition to classification based upon the type of analysis performed, it is also possible to subcategorize based upon the type of analyte measured and whether it is an endogenous species or an exogenous fluorophore (e.g., used as a label or marker for the tissue area of interest).

28.4.1 Biochemical Analysis of Individual Species

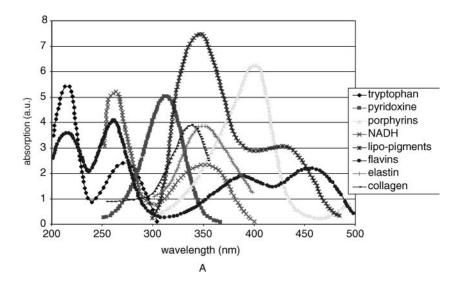

Fluorescence analyses of a wide variety of biochemical species that have been applied to and extracted from biological samples have been performed for quite a long time. These analyses are generally classified based upon whether or not the fluorescent species is an endogenous (naturally occurring) or exogenous (externally administered) fluorophore.

28.4.1.1 Endogenous Fluorophores

A large number of endogenous fluorophores, autofluorescent species, exist within biological samples.⁵⁻⁷ The majority of these species are typically associated with the structural matrix of tissues (e.g., collagen⁸ and elastin⁹) or with various cellular metabolic pathways (e.g., NAD and NADH).¹⁰ In the case of structural matrices, the most common fluorophores are collagen and elastin. The resulting fluorescence from these compounds is due primarily to the cross linking of various amino acids in their structure, which typically provides the conjugated systems that are generally found in most fluorescent molecules. In addition, because of the various degrees of cross linking that can occur in these species, the resulting fluorescence emission spectrum is typically very broad and featureless, ranging anywhere from approximately 325 to 600 nm.

Some of the most intense endogenous fluorophores that exist in humans and animals are involved in cellular metabolism. The predominant species in this category include the reduced form of nicotinamide adenine dinucleotide (NADH),¹¹ the various flavins (FAD, etc.),¹² and the strongly fluorescent lipopigments (e.g., lipofuscin, and ceroids).^{13,14} In addition to these species, many other endogenous fluorophores exist, exhibiting emission of various strengths and covering various spectral ranges in the ultraviolet (UV) and visible regions of the electromagnetic spectrum. These fluorophores include aromatics, amino acids such as tryptophan, tyrosine, and phenylalanine,⁶ various porphyrins (hemoglobin, myoglobin, etc.),⁶ and in certain cases and locations, red porphyrin fluorescence due to bacteria.¹⁰ Figure 28.4 shows the absorption and fluorescence spectra of various tissue fluorophores.

These biochemical species are generally structural or metabolic, so they can provide a significant amount of information about differences in tissues. One of the most common reasons for investigating these fluorescent species is the possibility for diagnosis of various diseases (e.g., cancer) without requiring exogenous fluorescent markers or tags. Because cells in various disease states often undergo different rates of metabolism, or have different structures, there are often distinct differences in their fluorescent emission spectra. These differences in fluorescence emission generally depend on at least one of the following parameters: fluorophore concentration or spatial distribution throughout the tissue, local microenvironment surrounding the fluorophores, the particular tissue architecture being interrogated, and a wavelength-dependent light attenuation due to differences in the amount of nonfluorescing chromophores.

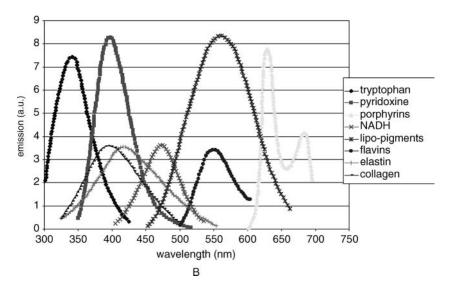

FIGURE 28.4 Absorption (A) and fluorescence emission (B) spectrum of many of the dominant fluorophores present in tissue. (Adapted from Wagnières, G.A., Star, W.M., and Wilson, B.C., *Photochem. Photobiol.*, 68, 603, 1998.)

The first of these reasons, change in fluorophore concentration, can be attributed to many different events. In certain cases, various chemicals may not be produced in a diseased tissue. In other cases, the distribution or form of the fluorophore may vary throughout the tissue. For instance, NADH is an extremely fluorescent molecule in its reduced form but is nonfluorescent in the oxidized form. Therefore, depending on the specific phase of a particular metabolic reaction that may be occurring, the relative faction of NADH in the reduced and oxidized forms may vary greatly. Another reason for differences in the fluorescence emission from various tissue types is the difference in the local environment surrounding the fluorophore.

Change in the microstructure (local environment) surrounding a particular fluorophore can have significant effects on its fluorescence properties. Fluorescence properties that are often affected by such changes include the fluorescence quantum yield, the spectral position of its fluorescence emission maximum, its spectral line width, and its fluorescence lifetime. All these factors can have a significant impact

on the overall fluorescence emission of the entire tissue sample. In addition to the local environment surrounding the fluorophore, the larger macrotissue structure or architecture also plays a significant role in the resulting fluorescence because of its specific optical properties (e.g., refractive index, scattering cross sections). This feature is described in more detail in Section I (Photons and Tissue Optics) chapters of this handbook.

An important factor that often plays a significant role in the differences associated with various disease states of tissue is the presence of nonfluorescing chromophores (hemoglobin, etc.). These chromophores, which can vary in concentration depending upon the state of the tissue, can absorb various wavelengths of fluorescent light emitted from the tissue or even absorb specific wavelengths of the excitation light used for the analysis. One example of this case is in the fluorescence diagnosis of tumor tissue, which typically has an increase in vascularization over normal tissues due to angiogenesis. Because of this increase in vascularization, the increased presence of hemoglobin often causes increased absorption of light in the visible region of the electromagnetic spectrum.

Due to this complex nature of biological tissues, extensive studies have been performed on individual species at the fundamental biochemical level. These fundamental studies of the absorption and fluorescence properties of various biochemical fluorophores give us a better understanding of the complex interactions that may be occurring in tissue samples.

In addition to conventional spectrally resolved fluorescence analyses, which are capable of providing a significant amount of information about the various fluorophores present, as well as some information about their local environment, some work in the field of time-resolved fluorescence analyses has also taken place. An in-depth analysis of this subject can be found in Chapter 9 of this handbook. Time-resolved spectroscopic analyses can provide information about molecular interactions and motions that occur in the picosecond–nanosecond time-scale range. Understanding these interactions can be especially useful in the analysis of biomolecular structure and dynamics. Recent advances in time-resolved fluorescence spectroscopy in the field of biological analyses have led to a better understanding of the origin of nonexponential fluorescence decay in proteins, the use of tryptophan analogs as unique spectroscopic probes of protein–protein interactions, the detailed characterization of protein-folding processes and intermediates, the development of new approaches to the study of DNA-protein interactions, ¹⁵ and the analysis of subdomains in proteins. ^{16,17}

28.4.1.2 Exogenous Fluorophores and Molecular Markers

In addition to the large number of endogenous fluorophores that have been used for biological diagnostics, many different exogenous fluorophores have been created and studied as well. These fluorophores have been created for many different purposes and applications in the field of biological monitoring, ranging from monitoring cellular function using fluorescent reporter dyes or molecules for various biochemical species (Ca⁺², Mg⁺², pH, nucleic acid sequences, etc.) to the demarcation of tumors with a relatively recent class of exogenous fluorophores. In the case of the monitoring of cellular function and chemical distribution, a large number of dyes with varying fluorescence properties for most of the more common cellular species can be obtained commercially from companies such as Molecular Probes, Inc. (Eugene, OR). These fluorescent reporter dyes are typically used to monitor the distribution of important chemical species throughout a cell by obtaining fluorescence microscopy images after injecting it with the dye. In addition to simply monitoring the distribution of certain chemicals, several dyes can be used to determine the viability of the cells or the permeability of their membranes. A more detailed description of these dyes and the types of analyses of which they are capable is presented in Section 28.4.2.

A second type of fluorescent reporter dye developed recently is known as a molecular beacon. 18–21 These molecular beacons are constructed by attaching a fluorescent dye (e.g., fluorescein) to one end of an oligonucleotide sequence, and a quencher molecule (e.g., DABSYL) to the other end. The particular oligonucleotide sequence chosen for the molecular beacon comprises the complementary sequence to the RNA or DNA sequence to be measured. For the molecular beacon to function properly, the last several nucleic acids on either end of the oligonucleotide strand must be complementary to each other. This forces the molecule to assume a hairpin form in its native state that brings the quencher molecule

in close proximity to the fluorophore of the other end. The proximity of the quencher molecule to the fluorophore prevents the fluorophore from emitting any fluorescent light. However, when the molecular beacon is in the presence of its complementary sequence to the remainder of the oligonucleotide, the beacon is opened up, thus separating the quencher and fluorophore molecules and allowing the fluorescent dye to emit. This feature is described in more detail in Chapter 57 of this handbook.

In addition to fluorescent reporter dyes and molecular beacons, a third major area of research in biologically useful exogenous fluorophores has been in the area of tumor demarcation or sensitization. The most common of these tumor markers also act as sensitizers, or tumor-killing agents, for a unique scheme of cancer treatment known as photodynamic therapy (PDT). (A much more detailed description of PDT is offered in Chapter 36 of this handbook.) Some of the most commonly used and best characterized of these photosenstizers are hematoporphyrin derivatives (HpD),^{22,23} phenophorbide-a,²⁴ mTHPC,²⁵ benzoporphyrin derivatives (BPD),^{26,27} tin etiopurpurin (SnET₂),²⁸ hypericin,^{29,30} and 5-aminolevulinic acid (ALA).^{31–35} HpDs (i.e., Photofrin) are the best studied of these compounds.

HpDs were derived from the functionalization of hematophorphyrins (Hp) with hydrophobic substitutents that would allow these compounds to be taken up more readily in the tumor tissues than the unsubstituted Hps.³⁶ After these compounds had been developed, it was found that they could also serve as photosensitizers because they are capable of being excited and activated by the absorption of visible light. Although HpDs are still used quite extensively today for PDT treatments, many other compounds or classes of compounds with more appropriate characteristics for clinical drugs (such as those listed previously) have been developed.

The most desirable optical properties of PDT sensitizers are strong absorbtivity in the red or near-infrared (NIR) region of the electromagnetic spectrum and a high triplet-state quantum yield. The first of these two properties is important for several reasons. One reason is that the use of red or NIR wavelengths of light for excitation of the sensitizer causes much less damage to nearby healthy tissue. At red and NIR wavelengths, naturally occurring chromophores in the tissue absorb little light. In addition, because the absorption of these wavelengths by natural chromophores is minimal, the resulting background fluorescence from nearby healthy tissue is minimized, providing a much more accurate tumor marker as well as sensitizer. A third potential benefit gained by having photosensitizers with strong absorption spectra in the red and NIR is the ability to destroy tumors under thin layers of normal tissue.

When photosensitizers activated with visible or ultraviolet light are used, the absorption cross section of the healthy overlaying tissue is too great to allow a significant fraction of the light to penetrate deeper than approximately 100 μ m. However, lower-energy photons, such as those in the red or NIR, penetrate significantly and could allow for the activation of sensitizers in tumors below healthy overlaying tissue. In addition to the desire to develop new sensitizers and markers with red-shifted absorption profiles, it is also important to obtain a high triplet-state conversion rate in these molecules. Triplet-state conversion is very important to formation of the reactive oxygen species responsible for the drug's activity. 10

28.4.2 In Vitro Analyses and Diagnostics

In vitro analyses can typically be classified in two different categories: cellular analyses and tissue analyses. *In vitro* analyses are important for gaining a greater understanding of basic fundamental biological processes that are occurring and understanding any potential interferences or problems that may be present when investigating more complex biological systems (i.e., living animals).

In addition to gaining better fundamental biochemical understanding, *in vitro* fluorescence analyses are often performed to better understand the interactions or interferences that often take place in complex systems as opposed to individual chemicals. By investigating these effects on *in vitro* samples such as cells or tissues, investigators can determine potential diagnostic procedures that could be performed *in vivo* or identify problems with potential diagnostic procedures prior to involving live subjects. When performing analyses on neat biochemical systems, it is not possible to investigate the interactions of various biochemicals with others that are present in functional systems (i.e., cells, tissues, etc.). In addition, the

effect of the local environment on the optical properties of the various fluorophores can be investigated much more accurately by using *in vitro* systems as compared to biochemical analyses alone.

28.4.2.1 Cellular Analyses

Cells represent one of the most basic of biological systems capable of performing chemical reactions. Monitoring endogenous as well as exogenous fluorophores on the cellular level has provided a great deal of information about many different processes. Several different fluorescence techniques have been developed for the performance of such analyses. These techniques include probing with chemical or biochemical sensors as well as obtaining fluorescence images using any of several different forms of fluorescence microscopy. In this section, we provide a brief review of the various types of cellular processes that have been investigated using fluorescence spectroscopy.

Several other chapters in this handbook provide a more detailed description of the techniques and their applications. Chapter 54 discusses living cell analysis using optical techniques and provides a general review of various optical methods used for analyzing living cells. Chapter 20 on biosensors in medical applications, Chapter 59 on PEEBLE nanosensors for *in vitro* bioanalysis, and Chapter 60 on nanosensors for single-cell analysis provide detailed descriptions of chemical and biochemical sensors used for cellular analyses. Chapter 10 on confocal microscopy, Chapter 11 on two-photon excitation fluorescence microscopy, and Chapter 9 on lifetime-based imaging provide detailed reviews of the theory and application of fluorescence microscopy.

28.4.2.1.1 Autofluorescence of Cells

The vast majority of fluorescence microscopy is performed with the use of exogenous reporter dyes; however, a growing field of fluorescence microscopy relies on autofluorescent species inside the cells for diagnostic information. Such autofluorescence measurements provide an important tool for biomedical diagnostics. Much of the research in autofluorescence microscopy is performed as preliminary research prior to testing *in vivo* diagnostic procedures or as a medical diagnostic procedure itself. Some recent examples are described next.

Cell Proliferation and Cell Analysis — One of the most sought-after applications of fluorescence spectroscopy in biomedical optics is the ability to distinguish normal tissue from cancerous or even precancerous tissue in a real-time clinical setting, without administering any drugs. In order to determine the potential of this technique, several researchers have sought to answer the questions of whether or not unique fluorescence spectral patterns were associated with cell proliferation and whether differences between rapidly growing and slowly growing cells could be identified. Native cellular fluorescence was used to identify terminal squamous differentiation of normal oral epithelial cells in culture (Figure 28.5).³⁷

In one such analysis, fluorescence excitation spectra were capable of distinguishing between slow- and rapidly growing cells in three different types of cells. To perform the analyses, excitation spectra were obtained by scanning the spectral range of 240 to 430 nm while monitoring the fluorescence emission at 450 nm. By taking the ratio of the intensity of the major broad-band peak at 320 to 350 nm to a point on the down slope of the curve at 370 nm, investigators found a statistical difference between slow- and rapidly growing cells. In addition, it was also possible to distinguish the slow-growing cells from the rapidly growing cells by obtaining fluorescence emission spectra of the various cells with an excitation wavelength at 340 nm and an emission wavelength range of 360 to 660 nm. These results demonstrate a great potential for discrimination of proliferating and nonproliferating cell populations *in vivo*.³⁸

In a similar study, laser-induced fluorescence, with excitation by the 488-nm laser emission line of an argon ion laser, was used to differentiate between normal and tumor human urothelial cells. Experiments were performed using a confocal microspectrofluorimeter, allowing individual cells to be probed; the broadband autofluorescence emission between 550 and 560 nm, corresponding to oxidized flavoproteins, was monitored. An analysis of the data showed that the maximum autofluorescence intensity of normal urothelial cells was approximately ten times higher than that of any of the tumor cell types tested, thereby suggesting that the concentration of an oxidized flavoprotein in tumor urothelial cells is significantly less

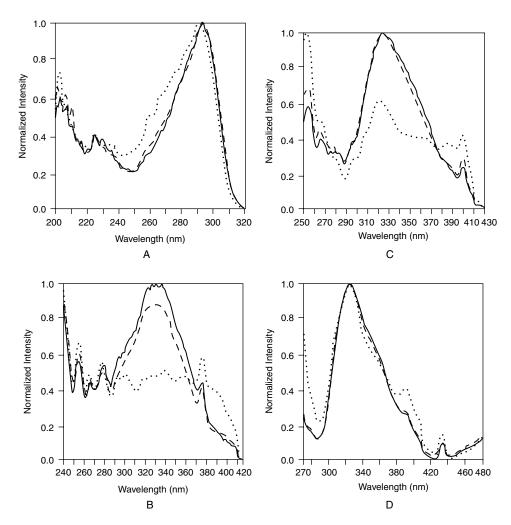

FIGURE 28.5 Native cellular fluorescence of normal oral epithelial cells in culture. This figure shows several normalized fluorescence excitation spectra of normal oral epithelial cells that have been grown in several different media: KGM (dashed line), DMEM/F12/FCS (solid line), and DMEM/F12/NaCl (dotted line). The various culturing media were used to induce different stages of squamous differentiation in the cells, with KGM providing a medium for normal growth without differentiation, DMEM/F12/FCS providing a medium known to cause cell stratification within keratinocytes, and DMEM/F12/NaCl providing a medium capable of inducing the terminal stage of squamous cell differentiation in keratinocytes. The fluorescence excitation scans were taken under the following conditions: (A) λ_{ex} 200 to 360 nm; λ_{em} 380 nm; (B) λ_{ex} 240 to 415 nm; λ_{em} 450 nm; (C) λ_{ex} 250 to 420 nm; λ_{em} 480 nm; (D) λ_{ex} 270 to 480 nm; λ_{em} 520 nm. From such spectra, it is possible to differentiate between the various states of the cells *in vitro*. (Adapted from Sacks, P.G. et al., *Cancer Lett.*, 104, 171, 1996.)

than in a normal urothelial cell. Not only could this observation lead to the development of a clinical diagnostic procedure for the real-time differentiation between normal, cancerous, and potentially precancerous urothelial tissues, but it also provides a better understanding of the biochemical differences between normal and cancerous tissues.³⁹

Synchronous luminescence (SL) is a unique approach that could improve the selectivity of fluorescence techniques for cancer diagnostics. As discussed previously, autofluorescence of neoplastic and normal tissues has been observed using fixed-wavelength laser excitation. However, the use of fixed excitation might not be sufficiently selective in some diagnostic applications due to strong overlap of the emission spectra from different fluorophores. An alternative approach is the SL method, which involves scanning

excitation and emission wavelengths simultaneously while keeping a constant wavelength interval between them. 40,41 This method, also referred to as synchronous fluorescence (SF), has been developed for multicomponent analysis and used to obtain fingerprints of real-life samples, as well as for enhancing selectivity in the assay of complex systems. This SF procedure has been shown to simplify the emission spectrum and provides for greater selectivity when measuring fluorescence or phosphorescence from mixtures of compounds. 3,4,42,43

Spectral differences in SF emission profiles are related to the specific macromolecules that differed between neoplastic and normal cells. The SF technique has been shown to improve spectral selectivity in detecting normal and cancer cells for potential use in biomedical diagnostics.⁴³ Whereas conventional fixed-excitation fluorescence could not show any differentiation between normal and cancerous cell lines, spectral difference between the fluorescence spectra of the normal rat liver epithelial (RLE) and neoplastic rat hepatoma McA cell lines were detected using SF. The results demonstrated the great potential of SF as an improved screening tool for cancer diagnosis in specific cases where conventional fixed-excitation methods are not sufficiently effective.

Biological Fluids, Semen, Seminal Plasma, and Spermatozoa — In addition to being used for the study of cancer, autofluorescence microscopy is also being investigated for its potential in many other forms of biomedical diagnostics. One potential application involves the determination of sperm viability and motility for real-time fertility diagnoses. In one study, fluorescence emission spectra of human semen, seminal plasma, and spermatozoa, excited at 488 nm, were obtained over the range of 500 to 700 nm.

Under these conditions, emission peaks from each component were observed at 622 nm. The intensity of the emission peaks from spermatozoa at 622 nm was strongly correlated with the concentration of spermatozoa (r = 0.837; p = 0.0001). In addition, sperm motility could also be correlated significantly, although to a poorer extent, with the intensity of the fluorescence emission peaks from spermatozoa (r = 0.369; p = 0.019) and semen plasma (r = 0.356; p = 0.024). The SF method has been investigated as a rapid screening tool for monitoring DNA damage (DNA adduct metabolites) and in monitoring biological fluids in animal studies, thus providing a technique for early cancer prescreening at the DNA level.

28.4.1.1.2 Cellular Fluorescence Using Exogenous Dyes

Fluorescence analyses of living cells by means of exogenous reporter molecules represent the vast majority of spectroscopic analyses performed on cells. Such analyses can generally be classified into one of two categories: optical sensor-based analyses or fluorescence imaging-based analyses. Both techniques have advantages and disadvantages for measurement of individual chemical species inside a single living cell. Optical sensors allow for accurate determination of chemical concentrations at individual points in the cell, while imaging-based analyses provide a means of monitoring the spatial distribution of the analyte throughout the cell.

Several types of optical sensors have been developed for minimally invasive fluorescence monitoring of individual chemical species inside a single cell.^{45–52} These sensors are based on the same principles and concepts as those discussed in the chapter on biosensors in medical applications, but their dimensions are much smaller. Usually, an exogenous fluorescent dye whose properties (i.e., quantum yield, emission maximum, etc.) change in the presence of the analyte of interest is attached to the probing end of the sensor. Such sensors have been used to measure many analytes within living cells, thus providing information about many different biological processes. These analytes include calcium ions, magnesium ions, nitric oxide, glutamate, lactate, glucose, benzo[a]pyrene tetrol, and even oligonucleotides (i.e., DNA, RNA).^{43–50} Because this relatively new field of sensors is described in greater detail in this handbook in Chapter 59 on PEEBLE nanosensors for *in vitro* analysis and Chapter 60 on nanosensors for single-cell analysis, this chapter will not go into any further detail on the subject.

Fluorescence microscopy is the most common technique for monitoring the spatial distribution of a particular analyte at many different locations simultaneously throughout a cell. In such analyses, one or several different exogenous fluorescent dyes are introduced into the cell and allowed to disperse. After dispersing throughout the cell, they begin to interact with the analyte of interest; this interaction, in turn,

causes change in the fluorescence properties (intensity, spectral shift, etc.) of the dye. Therefore, by obtaining a fluorescence image of the cell at a specific wavelength corresponding to the maximum emission wavelength of the dye, one can determine the relative concentrations of the analyte at specific locations.

The great amount of information derived from such analyses has allowed researchers and companies (e.g., Molecular Probes) to develop many different fluorescent dyes for a wide variety of compounds. These dyes are available with many different excitation and emission maxima for most analytes, allowing the experimenter to choose the best dye for the particular application. The dyes most commonly used today for fluorescence microscopy have red or NIR excitation profiles, thus allowing the dye to be excited without providing the energy necessary to excite any of the autofluorescent species present inside the cell. In addition, the lower-energy light also causes less damage to the living cells than would visible or UV wavelengths, which are capable of cross linking DNA or proteins.

Cell Proliferation — Cell proliferation analyses are one of many types often performed using exogenous dyes. Learning about the part of the cell cycle that a particular cell or group of cells is in, or about the way in which it died (necrosis vs. apoptosis, for example) can provide a great deal of biomedically useful information. For instance, the determination of apoptotic cell death is of particular importance in the study of chemical carcinogenesis as well as in the development of novel PDT drugs. For this reason, many different types of fluorescence analyses have been developed to determine the extent of apoptosis in cells or tissues.

One such method employed a commercially available ApopTag kit (Serologicals Corporation, Norcross, GA) and automated fluorescence image analysis to quantify the distribution of apoptosis in formalin-fixed, paraffin-embedded liver tumor sections from rats whose tumors were induced by 2-acetylaminofluorene. In this work, specific treatments of tissue sections were developed for quenching the autofluorescence background from the cells of the tissue sample. Once the autofluorescence had been quenched, propidium iodide was used as a counterstain for the nuclei. Automated statistical evaluation of the percentage of nuclei stained positively for apoptosis was determined by using dual fluorescence detection and optical microscopy. The quantitative results indicated that the staining index for apoptosis in normal rat liver cells was $0.14 \pm 0.04\%$, whereas well- and poorly differentiated tumor cells showed increases of $3.48 \pm 0.59\%$ and $7.41 \pm 0.81\%$, respectively.⁵³

Cellular Response — Another important application of fluorescence microscopy using exogenous fluorophores is in elucidating the role of particular chemicals in cellular biology and determining the associated kinetic constants for those processes. One chemical and cellular process that has been investigated using fluorescence microscopy and exogenous fluorophores is protein kinase C (PKC) and its role in signal transduction of many bioactive substances. In this study, phorbol-13-acetate-12-N-methyl-N-4-(N,N'-di(2-hydroxyethyl)amino)-7-nitrobenz-2-oxa-1,3diazole-aminododecanoate[N-C12-Ac(13)], the fluorescent derivative of 12-o-tetradecanoylphorbol-13-acetate (TPA), was synthesized to monitor the location of phorbol ester binding sites and evaluate its potential use as a probe for PKC in viable cells. The maximum excitation wavelength of N-C12-Ac(13) is close to 488 nm, making possible the use of an argon-ion laser for excitation of the dye molecule. When incubated with 100 nM N-C12-Ac(13), P3HR-1 Burkitt lymphoma cells accumulated the dye rapidly, reaching a maximum fluorescence (20-fold above the autofluorescence background) within 25 min. The subsequent addition of unlabeled TPA significantly decreased the fluorescence of N-C12-Ac(13) in the cells, in a dose-dependent manner, indicating specific displacement of the bound fluoroprobe.

Using this same competitive displacement technique, researchers displaced [3H]-phorbol-12,13dibutyrate ([3H]-PBu2) from rat brain cytosol with *N*-C12-Ac(13), which was found to exhibit an apparent dissociation constant and biological activity similar to that of TPA. In addition, like TPA, *N*-C12-Ac(13) also induced the expression of Epstein-Barr viral glycoprotein in P3HR-1 cells and differentiation of promyelocytic HL60 cells and caused predicted changes in the mitotic cycle of histiocytic DD cells. Microscopic fluorometric images of single cells for such analyses verified that the bound dye *N*-C12-Ac(13) showed bright fluorescence in the cytoplasm and dim fluorescence in the nuclear region, a phenomenon consistent with dye binding mainly to cytoplasmic structures or organelles.⁵⁴

Immunocytofluorometric Analyses — In addition to using exogenous fluorescent dyes to monitor the concentration or distribution of various chemicals or ions within a cell, investigators have found useful applications for fluorescence spectroscopy in the identification of specific types of cells in immunocytof-luorometric analyses. In such analyses, fluorescent molecules are attached to a monoclonal or polyclonal antibody that is specific to a surface protein or a class of surface proteins on a particular type of cell. The cells to be analyzed are then exposed to these fluorescently labeled antibodies. Once the antibodies have attached to the cells with the appropriate surface proteins, a fluorescence analysis system (e.g., a flow cytometer) can distinguish the cells of interest from the other cells present on the basis of a fluorescent property (e.g., spectral band) of the dye molecule attached to the antibody.

In a recent example, a time-resolved laser-induced fluorescence measurement system was used in conjunction with pyrene-derivatized molecules to perform immunocytofluorometric analyses. By using these pyrene-derivatized molecules [N-(1-pyrene)] maleimide, 1-pyrenesulfonyl chloride and 1-pyreneisothiocyanate], fluorescent lifetimes for the labeled antimouse-IgG were in the range of 20 to 55 ns. Due to this long lifetime, it was possible to distinguish these cells easily from other nonlabeled cells whose fluorescence lifetimes were much shorter. 55

28.4.2.2 Tissue Analyses and Diagnostics

Many studies have been performed on tissue samples^{7,40,41,56-62} to help us understand the interaction between cells and to bring us closer to the much more complex area of *in vivo* analyses. Tissue studies provide a platform much closer to true *in vivo* analyses in terms of structural architecture on microscopic and macroscopic scales than do cellular analyses. *Ex vivo* tissues provide an excellent starting point for the development of many *in vivo* diagnostic procedures (e.g., optical biopsy). In addition, when compared with *in vivo* systems, *ex vivo* tissue samples are much easier to handle and manipulate.

Over the last two decades, many different types of fluorescent tissue analyses have been performed on a wide variety of samples. The types of tissues range from mouse and rat tumors⁴¹ to human teeth.⁶⁰ Instrumentation has ranged from commercially available fluorescence microscopes to laboratory-built research instruments for specialized measurements. The development of fiber-optic instrumentation has made it possible to perform analyses in any area accessible to an endoscope.

28.4.2.2.1 Autofluorescence of Tissues

Many fluorescent species are present in biological tissues, and we want to develop diagnostic techniques that do not require chemical pretreatment of tissues. Therefore analyses based on autofluorescence represent a large portion of the fluorescence diagnostic procedures being developed. Some of the more promising autofluorescent diagnostic results as well as their state of development are described in the following sections.

Cancer Diagnostics — Recently, there has been a great deal of interest and research in the development of rapid, fluorescence-based clinical oncology. ^{6,10} Many different techniques have been developed for such analyses in different types of tissues and have shown a great deal of promise. These techniques and the instrumentation used for these measurements are described in greater detail in the following sections of this chapter. The effectiveness of the techniques is often determined by comparing their results with histological data, which are considered the "gold standard." Based upon the results of these comparisons, we can calculate three quantitative values to provide an objective comparison of various techniques.

Calculation of these three quantities (sensitivity, specificity, and accuracy) depends upon classifying a particular analysis as either a true positive (TP), which represents classification by both techniques as malignant; a false positive (FP), which corresponds to a classification as malignant by fluorescence spectroscopy and normal by histology; a false negative (FN), which corresponds to a normal classification by fluorescence and a malignant classification by histology; or a true negative (TN), which corresponds to classification by both techniques as normal. Once the appropriate classifications have been performed, sensitivity, specificity, and accuracy are calculated as follows:

```
Sensitivity = TP/(TP + FN)

Specificity = TN/(TN + FP)

Accuracy = (TP + TN)/(TP + TN + FP + FN)
```

An example of a laboratory-constructed instrument for tissue analyses is given by Alfano and coworkers, who developed a system for the differentiation of cancerous and normal human breast tissues and lung tissues. In this work they developed a system that uses a pulsed or a continuous-wave (CW) excitation source for the differentiation of normal and cancerous tissues., The fluorescence emission spectrum for normal tissue caused by excitation with 488-nm light from an argon ion laser was found to be quite different from that for tumor tissue. The resulting spectra from tumor tissues had smooth emission curves with a maximum at approximately 530 nm. The resulting emission spectra from normal tissues appeared to have three peaks, at 530, 550, and 590 nm. In another study, Feld and co-workers attempted to determine the optimal excitation wavelength for distinguishing between normal and tumor tissues based upon their biochemical and histomorphological (architectural) components. They found that the most marked differences occurred when an excitation wavelength of 410 nm was used. Using this wavelength, they correctly diagnosed 20 of 22 samples studied. This optimal wavelength, determined with *in vitro* studies, is consistent with results obtained by Vo-Dinh and co-workers from *in vivo* clinical studies of gastrointestinal cancer diagnostics using laser-induced fluorescence.

Cervical Cancer — In the field of *in vitro* fluorescence diagnostics for the detection of cervical cancer, there is a relatively small amount of information. However, results that have been published forecast a promising future for this technique. In one such study, Richards-Kortum and co-workers investigated fluorescence excitation–emission matrices (EEMs) to analyze 18 cervical biopsies from 10 patients. A all excitation–emission maxima, most prominently at 330-nm excitation and 385-nm emission, the average normalized fluorescence intensity of histologically normal tissue was significantly greater than that of histologically abnormal tissue. A diagnostic algorithm based upon this relative intensity difference was developed to differentiate between histologically normal and abnormal biopsies with a higher sensitivity but a lower positive predictive value and specificity than colposcopy. However, when comparisons of histologically normal and abnormal biopsies from the same patient were performed, sensitivity results of 75%, positive predictive value results of 86%, and specificity results of 88% were achieved for the spectroscopic identification of histological abnormality. These results compare favorably with colposcopy results. Based on these results, *in vivo* studies of cervical tissue fluorescence have also been conducted.

In addition to research demonstrating the ability to distinguish between normal cervical tissues and invasive carcinomas in cervical tissue, research has also attempted to distinguish between dysplasia and invasive carcinomas. To this end, a technique developed recently for the *in situ* detection of melanomas has been applied for determining *in vitro* dysplasia and invasive carcinomas in the cervix uteri. Cervix uteri exhibit a fluorescence band with a peak at about 475 nm upon excitation with 365 nm light. At a fluorescence intensity of 475 nm, the fluorescence intensity increases concomitantly with the degree of dysplasia, ranging from 30 counts/100 ms (healthy) to approximately 200 counts/100 ms (carcinoma *in situ* 3). At the rim of a malignancy, the intensity is 250 counts/100 ms and higher. The excitation and emission spectra of the tissue suggest that the endogenous chromophore responsible for the observed fluorescence is NADH.⁶⁷

Colon Cancer — Another major form of cancer that has seen a significant amount of research and advancement in terms of *in vitro* fluorescence diagnosis is colon cancer. In one study, unstained frozen sections of colon were studied by fluorescence microscopy to determine which structures fluoresce and to what extent in normal colon tissue and colonic adenomas. Tissues were excited by a 351- to 364-nm emission from an argon ion laser. The resulting fluorescence signals from various locations in the tissue samples were correlated to the tissue morphology at those locations via histological analyses with conventional stains (hematoxylin and eosin [H&E]), Movat pentachrome, mucicarmine, and oil red O dye).

In normal colon tissues, the measured fluorescence signals correlated morphologically with connective tissue fibers (mainly collagen) in all layers of the bowel wall and with cytoplasmic granules within

eosinophils present between the crypts in the lamina propria of the mucosa. In addition, fluorescent signals from the crypts of normal cells were very faint. However, a significant fluorescence emission was observed in the cytoplasms of dysplastic epithelial cells in the crypts of colonic adenomas. In the lamina propria of colonic adenomas, a decrease in fluorescence intensity compared to that of normal colon tissue was found to exist. The decrease could be correlated to fewer fluorescent connective tissue fibers in the case of the adenomas. Finally, it was found that a larger number of fluorescent eosinophils exist in adenomatous colonic tissue than in normal colon tissue.⁶⁸ Similar results were also found in another study, in which a confocal fluorescence microscope was used.⁶⁹

In an additional study, also aimed at determining the biochemical differences between fluorescence signals from normal and adenomatous colonic tissues, it was found that the fluorescent signals from plasma-soluble melanins derived from various sources were related to the overall autofluorescence signal of adenomatous tissue samples. It was also determined in this study that the fluorescence component of melanins derived from 3-hydroxyanthranilic acid, excited by 324-nm light and measured at 413 nm, was less than the fluorescence caused by melanins derived from other sources (i.e., dopa, catecholamines, catechol, and 3-hydroxykynurenine), with fluorescence excitation and emission maxima at 345 and 445 nm, respectively. ⁷⁰

In a quantitative determination of the efficacy of fluorescence spectroscopy to classify colonic tissues as adenoma, adenocarcinoma, or non-neoplastic, a series of analyses were performed on 83 biopsy specimens from several patients. In these tests, fluorescence emission spectra covering a spectral range of 450 to 800 nm were measured. From these measurements, it was found that the spectral properties were significantly different for the three different tissue classifications. In fact, the results of these analyses had a sensitivity of 80.6 and 88.2%, and a specificity of 90.5 and 95.2% in discriminating neoplastic from non-neoplastic mucosa and adenoma from non-neoplastic mucosa, respectively.⁷¹

With preliminary fluorescence analyses of colon tissues providing promise for a minimally invasive real-time classification procedure for colon cancer, a great deal of effort is being devoted toward the optimization of this procedure, both experimentally and through data analysis methods. In one such study, fluorescence EEMs were obtained to determine the optimal excitation regions for obtaining fluorescence emission spectra that can be used to differentiate normal and pathologic tissues. In the case of normal and adenomatous colon tissue, the optimal excitation wavelengths were found to be 330, 370, and 430 nm \pm 10 nm. These excitation wavelengths were used with simple difference techniques as well as ratiometric analyses to determine the optimal emission wavelengths.

Based upon these results, the optimal excitation wavelength for discrimination between normal and adenomatous colon tissues *in vitro* was found to be 370 nm and the optimal emission wavelengths for analysis based upon this excitation were found to be 404, 480, and 680 nm.⁷² In a second study, in which the optimization was based upon data analysis algorithms, 35 resected colonic tissue samples were excited by the 325-nm line of a helium cadmium laser and the resulting fluorescence spectra were measured over the spectral range of 350 to 600 nm. Scores were derived from these analyses by a multivariate linear regression analysis that accounted for six wavelengths in the emission spectra. Normal tissue samples, adenomatous tissue samples, and hyperplastic tissue samples were classified by using the resulting scores with accuracies of 100, 100, and 94, respectively. ⁷³

Gastric Cancer — Application of fluorescence spectroscopy to *in vitro* detection of gastric cancers has also been performed. In this work, fluorescence was measured following tissue excitation with the 325-nm light from a helium cadmium laser.⁶³ Fluorescence images of 72 surface areas of 21 resected tissue samples were recorded in six regions of the visible spectrum by a cooled charge-coupled device (CCD) camera. The fluorescence emission intensities measured at 440 and 395 nm, normalized to the intensity measured at 590 nm, differed significantly for malignant tissues, premaligant tissues, and normal gastric tissues. When these differences were used as a diagnostic parameter, classification of malignant tumor tissues with a sensitivity of 96% and a predictive value of 42% was possible. Additionally, the same approach applied to diagnosis of abnormal (but nontumor) stomach tissues gave values of 80 and 98%, respectively.⁷⁴

Oral Cancer — Biopsy specimens from clinically suspicious lesions and normal-appearing oral mucosa were obtained from patients and fluorescence EEMs were measured.⁵⁶ From these EEMs, it was determined that the optimal excitation wavelength for differentiation between normal and dysplastic tissues was 410 nm. Based upon the fluorescence emission spectra produced by this wavelength for excitation, the 22 different resected samples, 12 histologically normal and 10 abnormal (dysplastic or malignant), were analyzed. From this analysis, 20 of the 22 samples were correctly classified as normal or abnormal tissues.⁶³

Atherosclerosis — Laser-induced fluorescence has been used for the differentiation of calcified and non-calcified plaques in arterial tissues.⁶⁴ In this work, 248-nm laser light from a krypton-fluorine excimer laser was used to irradiate normal and severely atherosclerotic segments of human postmortem femoral arteries. In order to analyze deeper layers of the tissue while measuring the resulting fluorescence from each layer, 16-ns laser pulses were used, each having a fluence of 5 J/cm². Pulse powers of this magnitude were sufficient to ablate as well as excite the tissue. By synchronizing the detector with each of the laser pulses, it was possible to determine the characteristic composition of the ablated tissue layer. Normal tissue layers provided fluorescence spectra exhibiting a broad-continuum emission between 300 and 700 nm with peak fluorescence of equal intensity at wavelengths of 370 to 460 nm. Fluorescence maxima of atheromas without calcification occurred at the same wavelengths but with significantly reduced intensity at 460 nm.

In contrast to these broad-continuum fluorescence signals from normal and noncalcified atheromas, calcified plaques displayed multiple-line atomic fluorescence (atomic emission) with the most prominent peaks at wavelengths of 397, 442, 450, 461, 528, and 558 nm. These fluorescence/emission criteria identified the histologically classified target tissue precisely. Comparison of this technique to histological examination of the corresponding arterial layers indicated an extremely accurate characterization. These results demonstrated the potential for simultaneous real-time tissue identification and the feasibility of ablation by laser irradiation under strict laboratory conditions.⁷⁵

To diagnose arterial tissue before ablation, many researchers have attempted to use less powerful and less energetic lasers for fluorescence excitation alone, and have experienced a great deal of success. In one such study, ultraviolet excited laser-induced fluorescence (LIF) using excitation wavelengths ranging from 306 to 310 nm was used to distinguish between normal and atherosclerotic arteries.⁶⁵ In this study, two distinct fluorescence emission bands were observed in the LIF spectra of normal and pathologic aorta: a short-wavelength band peaking at 340 nm (attributed to tryptophan) and a long-wavelength band peaking at 380 nm (attributed to a combination of collagen and elastin). In addition, the intensity of the short-wavelength band was found to be very sensitive to the choice of excitation wavelength while the long-wavelength band remained unchanged; this feature allowed for the relative contributions of each band to be controlled precisely by choice of excitation wavelength.

It was found that, by using 308-nm excitation to observe emissions from the short- and long-wavelength bands simultaneously, two ratios could be determined; from them it was possible to distinguish between normal and atherosclerotic aortic tissue. These two ratios characterized the relative tryptophan fluorescence content and the ratio of elastin to collagen. In addition, normal and atherosclerotic aorta were correctly distinguished in 56 of 60 total cases by a binary classification scheme in which these parameters were combined. Furthermore, atherosclerotic plaques, atheromatous plaques, and exposed calcifications could be classified individually with sensitivities and predictive values of 90 and 90%, 100 and 75%, and 82 and 82%, respectively.⁷⁶

In another study, even less energetic light was used to excite autofluorescent species in blood vessels for the differentiation of normal tissue and atherosclerotic lesions. The use of longer wavelengths of light for excitation not only caused less photodamage to the irradiated tissue, but also allowed better transmission through optical fibers, which were necessary for *in vivo* light delivery. In this work, 325-nm light was used for excitation of the sample, and a ratio of the fluorescence intensity at 480 nm to the fluorescence intensity at 420 nm was determined for each of the different types of tissues. Based upon these ratios, a clear differentiation between normal and mild, as well as between normal and severe, atherosclerotic lesions was observed. In the case of normal tissue, there was an increased intensity in the range from

420 to 540 nm, whereas atherosclerotic lesions had no or only a small peak at 480 nm. In addition, the spectroscopic results showed no differences between samples taken from different types of vessels.⁷⁷

Further studies have extended the wavelengths used for excitation of atherosclerotic tissue samples to 458 nm⁷⁸ and even 476 nm.⁷⁹ In both cases, even though the autofluorescent tissue components responsible for the fluorescence emission were different from those excited by ultraviolet light, good differentiation between normal arterial tissue, noncalcified arterial plaques, and calcified arterial plaques was demonstrated. When these longer wavelengths are used for excitation, differentiation is based upon the ratio of the fluorescence signals from structural proteins (elastin and collagen) and ceroid, which can be correlated to the concentration of these various components.

Several other studies have been performed to correlate LIF signals to the histochemical composition of human arteries and veins. ^{80,81} In one such study, unstained frozen sections of normal and atherosclerotic human aorta and coronary artery were examined by histochemical and fluorescence microscopy techniques to identify the species responsible for autofluorescence following excitation with light ranging from 351 to 364 nm. The species investigated included the structural proteins elastin and collagen in normal and atherosclerotic specimens, calcium deposits in calcified plaques, and granular or ring-shaped deposits histochemically identified as ceroid found in calcified and noncalcified plaques. The emission wavelength and intensity of ceroid autofluorescence differed greatly from those of elastin or collagen, with the ceroid emission red-shifted and showing a much greater resistance to photobleaching than the structural proteins, thus making it a prime candidate for investigation in the classification of arterial plaques. ⁸⁰

In another study aimed at determining the relationship between the histochemical and morphological characteristics of atherosclerotic tissue and their LIF spectra, unstained frozen sections of 47 normal and atherosclerotic human aortas and coronary arteries were excited by 476-nm laser light. The resulting fluorescence images were measured with a bright-field epifluorescence microscope. The samples were then stained with various dyes (including H&E, Movat pentachrome, and oil red O) for histological analysis. In the case of normal artery autofluorescence, the signals correlated with the structural proteins elastin and collagen in the intima, media, and adventitia. In atherosclerotic plaque, autofluorescence correlated morphologically with lipid or calcific deposits in the atheroma core. The autofluorescence of these deposits was different from that of elastin and collagen in distribution, intensity, and wavelength, and increased with the severity of the plaque.

Such excellent correlation qualitatively and quantitatively suggests that 476-nm excitation-based LIF analyses of arterial tissues would be useful.⁸¹ However, it has recently been found that 476-nm-induced autofluorescence in arterial tissues suffers from changes in two prominent spectral characteristics of the emission spectrum. The changes related to alterations in the individual tissue chromophores being excited are a permanent decrease in the peak fluorescence intensity and a reversible change in the fluorescence emission profile (line shape). The permanent changes in absolute fluorescence intensity are due to irreversible photodamage to the tissue fluorophores; the reversible changes in fluorescence line shape are due to some type of alteration in tissue absorbers. An attempt has been made to minimize these effects; excitation intensity levels and exposure times have been investigated to establish the thresholds at which these alterations are minimized.^{82,83}

To develop a fluorescence guidance system for the laser ablation of arterial plaques in femoral arteries, Gaffney and co-workers developed a technique that employs dual excitation wavelengths. Information about the fatty plaque content could be obtained from 325-nm excited fluorescence; information about structural proteins and calcific content could be obtained from fluorescence following 476-nm excitation. The fluorescence emission spectra obtained from each of the excitation wavelengths were used to perform ratiometric analyses. For 325-nm excited fluorescence spectra, 78 ratios were determined based upon 13 different wavelengths, and for 476-nm excited spectra, 55 ratios were determined based upon 11 different wavelengths. From these analyses, atherosclerotic lesions in human coronary arteries were characterized by an increase in normalized fluorescence intensity at longer wavelengths when excited with either ultraviolet or visible light. Calcific plaque content greater than 10% in lesions more than 1-mm thick were identified by increased normalized fluorescence intensity at 443 nm produced by excitation at 325 nm. Fatty plaque content was found to correlate with fluorescence intensity ratios produced

by 325-nm excitation, whereas fibrous and calcific content correlated well with fluorescence ratios during 458-nm excitation.⁷⁸

In addition to using multiple-excitation wavelengths to increase the accuracy and sensitivity of prediction of atherosclerotic tissue, there has also been a recent investigation into the use of time-resolved fluorescence detection rather than spectral-based detection for the differentiation of atherosclerotic tissue from normal tissue. Based upon the temporal differences in the fluorescence emission from atherosclerotic plaques and normal blood vessels, an enhanced differentiation between the two tissue types was reported.

84

Heart Arrhythmia — Autofluorescence spectral properties of tissue have also been used in the diagnosis of heart-related illnesses. Heart arrythmias are often caused by formation of nodal conductive tissues; in severe cases that cannot be treated through conventional medical therapies, transcatheter ablation of the nodal conductive tissue can be performed. Therefore, prior to any tissue ablation, it is important to be able to classify the tissue of interest as nodal conductive tissue, atrial endocardium, or ventricular endocardium. To perform this diagnosis, Lucas and co-workers studied the fluorescence emission of *in vitro* heart tissue samples excited by the 308-nm laser line of an XeCl excimer laser (1.5 mJ/pulse, 10 Hz). Following excitation at 308 nm, the nodal tissue could clearly be distinguished from atrial endomy-ocardial tissue by a visible decrease in fluorescence emission intensity between 440 and 500 nm, peak area between 440 and 500 nm, and peak width. Nodal conduction tissue could also be distinguished from ventricular endocardium by its relative increase in fluorescence emission between 430 and 550 nm. Specificities of 73 and 88% and sensitivities of 73 and 60% were possible for sinus nodal and atrioventricular nodal conduction tissue identification, respectively.⁸⁵

Tooth Decay — The field of dentistry has also seen a recent growth of research in the use of fluorescence spectroscopy. In work involving the use of a confocal scanning laser microscope (CLSM), autofluorescence spectra were taken of teeth with demineralized dentin on the root surfaces. The resulting spectra were then compared with spectra taken at other locations on the tooth with minimal to no demineralization in the dentin. When observed in CLSM images, demineralized dentin (excited at 488 nm) exhibited an increased fluorescence emission at 529 nm when compared with the spectra of healthy dentin. This difference in fluorescence intensity decreased deeper into the root, as the healthy dentin underneath the lesion was beginning to be excited.

In contrast, when fluorescence spectrophotometry was used with excitation around 460 and 488 nm, it yielded fluorescence emission intensity (about 520 nm) for demineralized dentin that was lower than for healthy dentin, but in a more pronounced peak. From excitation spectra obtained by a fixed emission wavelength of 520 nm, it could be seen that the contribution of excitation between 480 and 520 nm was more important in demineralized dentin than in healthy dentin. Because of the small sampling volume used in CLSM image acquisition, the recorded fluorescence was not affected by demineralization-induced changes in scattering and absorption properties. Thus the increased fluorescence for demineralized dentin implies an increased quantum yield. However, in fluorescence spectrophotometry, where the measurement volume is large relative to the lesions, changes in scattering and absorption properties do have an influence on the fluorescence signal. Therefore, increased absorption by nonfluorescing chromophores and increased reabsorption around the emission wavelength may compensate for the increase in quantum yield and absorption around the excitation wavelength by the fluorophores.⁸⁶

Eosinophils — Eosinophils are rare granulocytes typically associated with allergic diseases or responses to various parasitic infections. Many types of human cancers, however, are also associated with extensive eosinophilia, either within the tumor, in the peripheral blood, or in both locations. Special techniques such as autofluorescence or immunohistochemistry are sometimes needed to detect the presence of intact and degranulating eosinophilis within the tumors. With the help of these techniques, extensive amounts of eosinophilia have been found in hematologic tumors such as Hodgkin's disease and certain lymphomas. However, many other types of cancer, such as cancers of the colon, cervix, lung, breast, and ovary, also contain eosinophilia, and it can be identified if diligently sought. Although the presence or absence of eosinophilia within these tumors does not appear to have a major influence on the prognosis of the

disease, eosinophils may play an important role in the host interaction with the tumor, perhaps by promoting angiogenesis and connective tissue formation adjacent to the cancer.

In addition, tumor-related eosinophilia provides some interesting clues into tumor biology, particularly with regard to production of cytokines by the tumor cells. ⁸⁷ Characterization of the fluorescence properties of human eosinophils isolated from peripheral blood of normal donors has been performed by measuring EEMs over a wide range of wavelengths. Circulating eosinophils possess three fluorescence emission maxima: one at 330 nm following excitation at 280 nm, which can be attributed to tryptophan, a second peak at 440 nm following excitation at 360 nm, and the last at 415 nm following excitation with 380-nm light. Fluorescence microscopy studies also showed that the fluorescence of eosinophils appears to be site dependent. For instance, when observed following excitation by 365-nm light, circulating eosinophils fluoresce blue–violet, while tissue-dwelling eosinophils fluoresce amber–gold. Therefore, when fluorescence spectroscopy is used to develop optical biopsy techniques based upon eosinophils in human tissue, the differences in their local environments may have a significant impact on fluorescence spectra. ⁸⁸

28.4.2.2.2 Tissue Analysis Using Exogenous Dyes

Due to the significant differences in tissue uptake and storage of various exogenous fluorophores between *in vitro* and *in vivo* specimens, relatively few studies have been performed in this area in terms of developing diagnostic procedures. In most cases where exogenous fluorophores are used, the actual location and kinetics of tissue uptake are important; therefore, because *in vitro* tissues differ in these properties, such studies generally do not provide any useful information. However, properties such as tissue reactivity to a specific chemical can be studied by using *in vitro* systems to provide a better understanding of the mechanism by which specific reactions take place.

Lipid Peroxidation — One system studied by using fluorescence CLSM is the well-established experimental model of lipid peroxidation induced by haloalkane intoxication in liver tissues. In this study, the fluorescent reagent 3-hydroxy-2-naphtholic acid hydrazide was used to derivatize the carbonyl functional groups originating from the lipoperoxidative process in liver cyrostat sections from *in vivo* intoxicated rats, as well as isolated hepatocytes that were exposed *in vitro* to the haloalkanes. The resulting CLSM images were able to visualize the tissue areas and the subcellular sites first involved in oxidative stress and lipid peroxidation. The images also showed that haloalkane-induced lipid peroxidation in hepatocytes primarily involves the perinuclear endoplasmic reticulum, whereas the plasma membrane and the nuclear compartment are unaffected, and that lipid peroxidation also induces an increase of liver autofluorescence.⁸⁹

28.4.3 In Vivo Analyses and Diagnostics

While *in vitro* studies can reduce the complexity of the biological system analyzed and provide useful information about basic biological functions or reactions, the need to develop *in vivo* analysis techniques for medical diagnosis of diseases is critical. The range of fluorescence-based *in vivo* diagnostic techniques spans from monitoring of atherosclerosis⁹⁰ to the detection of tooth decay.^{60,91} One of the most common biomedical diagnostic procedures performed using fluorescence spectroscopy is known as "optical biopsy."^{10,24,92–102} In this procedure, some form of optical spectroscopy, typically fluorescence spectroscopy, is used to identify differences between healthy, malignant, and premalignant tissues of various organs. Over the past two decades, a great deal of research has been performed in this field for the diagnosis of many different forms of cancer.^{6,59,61,65,99,103–120} In order to ensure that the various diagnostic procedures will work in complex living systems, two types of analyses are generally performed: animal studies and clinical human trials.

28.4.3.1 Animal Studies

Animals typically provide an excellent test system for many different types of disease diagnoses prior to clinical studies. The key in choosing an animal for these studies is to ensure that the biochemical structure of the particular organ or location of the animal used is comparable to that of a human. In addition, the

animal should be relatively easy to care for and should match any other criterion for the particular type of analysis to be performed. Mice and rats are often used as a suitable alternative for humans in many preliminary studies because of their 98% genetic compatibility with humans and because they are relatively easy to handle; however, many other animal models have also been investigated (e.g., hamster and pigs).

In the case of "optical biopsy" work or photodynamic therapy (PDT), transgenic mice with transplantable tumors are the most common model system. These mice have been genetically altered to prevent their providing an immune response to the tumors that are induced in them. By using these mice with transplantable tumors, valuable information useful to later clinical trials can be obtained. However, use of animal models could have artifacts as well. For instance, when using mice with transplantable tumors for tumor detection diagnostics, the implanted tumor tissue generally comes from a different type of tissue and therefore may not have the same biochemistry, architecture, and vasculature as the tissue into which it is being placed.

In addition, unlike spontaneous tumors in humans, transplanted tumors often remain mostly separated from the normal tissue. When exogenous fluorophores are used as contrast agents in fluorescence diagnostics, there is also an issue of species-dependent chemical distribution or pharmacokinetics. These problems also begin to become convoluted by the fact that drug pharmacokinetics are often very different between early stages and more advanced stages of cancer or transplanted tumors because vascularization differs. ^{121,122} One way to minimize these problems in tumor studies is to induce the tumor chemically or radiologically. This will allow the tumor to be integrated into the tissue as well as ensure that the tumor being investigated comes from the same type of tissue in which it is growing.

One well-established tumor model procedure is to use dimethyl benzanthracene (DMBA) to induce lesions in the cheek pouches of hamsters. This particular model is useful because it progresses through many different stages of cancer development: normal tissue to hyperplastic tissue to dysplastic tissue to carcinoma *in situ* (CIS), and finally to invasive carcinoma.¹²³ Endogenous and exogenous fluorophores have been used for *in vivo* diagnostics based on this model. In the case of autofluorescence diagnostics, it has been reported that 76% sensitivity and 86% specificity have been obtained in the detection of early neoplastic tissue. In addition, by intravenously administering the photosensitizer Photofrin™ 24 h prior to analysis, the sensitivity and the specificity could be increased to 100%.

28.4.3.1.1 Animal Studies Using Autofluorescence

With analyses on living animals, it is possible to gain a much more accurate picture in most cases than can be achieved *in vitro*. For instance, one of the strongest chromophores present in tissues is hemoglobin (oxy- and deoxy-); in *in vitro* studies, no blood flow is present, and the ratio of oxygenated hemoglobin to deoxygenated hemoglobin is very different from that in live animal studies. This factor alone could have a significant effect on the autofluorescence spectrum of the tissue by absorbing the fluorescent light or by changing the oxidative state of some of the autofluorescent chemicals present.

Cancer Diagnostics — Esophageal Cancer — The capacity to identify subclinical neoplastic diseases of the upper aerodigestive tract using tissue autofluorescence spectroscopy has significantly contributed to the field of fluorescence cancer screening. In 1993, the applicability of tissue autofluorescence for the early diagnosis of precancerous states in esophageal mucosa was studied through various model systems. ¹²⁴ In an N-nitroso-N-methylbenzylamine (NMBA)-induced rat esophageal cancer model, alteration of the fluorescence emission pattern at 380 nm was found to correspond to disease progression from normal mucosa through dysplasia to invasive cancer. Although gross assessment of the tissue was indistinguishable from the saline-treated controls, histopathologic evaluation revealed NMBA-induced preneoplastic changes in the epithelium. ¹²⁵ In addition, a multicellular tumor spheroid model, induced by transretinoic acid (RA), was also found to alter autofluorescence intensities at multiple wavelengths including 340, 450, and 520 nm. Such RA-induced alterations corresponded to changes in the state of spheroid differentiation. ¹²⁴

Brain Cancer — Brain tumors are one of the more difficult types of cancer to treat. Unlike many other forms, where tumor margining can be less important and healthy tissue surrounding the tumor can be removed to ensure that no malignant cells are left behind, the removal of excess brain tissue during tumor removal can have dramatic adverse effects. Because of this important requirement, a technique capable of providing an accurate demarcation between malignant cells and normal brain cells is extremely important. One method that is being developed is autofluorescence-based optical biopsy.

In initial animal studies, EEMs of rat gliomas revealed three distinct regions of decreased autofluorescence emission with respect to the normal rat brain tissue. These differences in the fluorescence emission spectra of the two different types of tissue samples occurred at 470, 520, and 630 nm, with corresponding excitation wavelengths of 360, 440, and 490 nm. The fluorescence emission at 470 nm corresponds to NAD(P)H, while the emissions of 520 nm and 630 nm correspond to various flavins and porphyrins, respectively. Due to the nature of the chemical differences between the normal tissue and the glioma tissue, this finding suggests a relationship between brain tissue autofluorescence and metabolic activity. This is in contrast to *in vitro* brain tissue studies, which also found that NAD(P)H fluorescence was lower in all measured human brain tumors, but, depending on their nature, flavin and porphyrin autofluorescence in neoplastic tissues was not always lower than in normal tissue.¹²⁶

Atherosclerosis — Due to the high occurrence rate of atheriosclerosis in adults and the preliminary success of LIF in diagnosing the disease in its various stages *in vitro*, animal studies have been performed to ensure that the same fluorescence phenomena occur in living systems. In one such study, an XeCl excimer laser operating at 308 nm was used to excite proteins of human aortas containing early lipid-rich noncollagenous lesions. The emitted fluorescence exhibited significant red shifts and spectral broadening compared with spectra from nonatherosclerotic human aortas. Similar red-shifted and spectrally broadened autofluorescence profiles were observed from oxidatively modified low-density lipoproteins excited by 308-nm illumination. However, in the case of native low-density lipoproteins, neither the red shift nor the spectral broadening was found to exist. In order to compare these tissue results to the autofluorescence emission from live animals, LIF studies were performed on hypercholesterolemic rabbits with early foam cell lesions. The resulting autofluorescence spectra were similar to those of oxidized beta low-density lipoprotein, the major lipoprotein accumulating in arteries of rabbits fed cholesterol and an early indicator of atherosclerosis.¹²⁷

28.4.3.1.2 Animal Studies Using Exogenous Dyes

The study of exogenous fluorophores in living animals can provide a great deal of information. In addition to being a model system that more closely resembles human when testing fluorescence-based diagnostic systems prior to clinical trials, they also play a large part in the field of pharmacokinetics. Using living animals with functioning circulatory systems, it is possible to watch the real-time distribution of various drugs throughout the body as well as study their uptake into various tissues and, finally, their excretion from the body. This is an extremely important field of research because it ensures timely deliverey of drugs to the target tissue areas of interest.

Cancer Diagnostics — Some of the more commonly studied exogenous fluorophores in biomedical analyses are used for cancer diagnosis or treatment, or both. These fluorophores, known as photolabels in the case of the former and photosensitizers in the case of the latter, represent an extensive class of compounds whose pharmacokinetics properties as well as their tumor demarcation abilities need to be studied prior to use in human trials. These studies are generally performed on animal subjects; several of the more common ones are described in the following sections.

Pharmacokinetics of Photosensitizers — Photosensitizers represent a unique class of compounds that, upon being activated by the absorption of a specific wavelength of light, are capable of killing the surrounding tissues. A detailed description of the mechanism of action of these photosensitizers can be found in Chapter 36 of this handbook. Therefore, only salient features are briefly described here. The

concept behind these photosensitizers is to develop drugs that are preferentially taken up or localized in malignant tissues and can then be photoactivated. After the drug is administered and a specific amount of time has passed for optimal uptake, light is shown on the tissue area of interest and absorbed by the sensitizer. The sensitizer then kills the surrounding tumor tissue, leaving the healthy tissue undamaged.

Although the number of available photosensitizers approved for clinical use is relatively small, a large number of new potential candidates are continually being developed. These new agents are then compared with the better characterized sensitizers based upon many parameters, including tissue localization ability, effectiveness in promoting cell death, and toxicity, as well as several other parameters. In a study to determine the most effective photosensitizer of five commonly used drugs, their tissue localization properties were studied *in vivo* using "sandwich" observation chambers and tumors that were growing in thigh muscle. Several common dyes were studied, including hematoporphyrin derivative, PhotoFrin II, aluminum phthalocyanine tetrasulphonate, uroporphyrin I, and acridine red. Of the photodynamically active dyes (the first three), aluminum phthalocyanine tetrasulphonate was found to exhibit the best *in vivo* tumor localization properties as determined by fluorescence spectroscopy.¹²⁸

LIF studies have also been used to investigate the pharmacokinetic properties of 5-aminolevulinic acid (ALA)-induced protoporphyrin IX (PpIX). These analyses were performed in normal and tumor tissues of rats following intravenous (i.v.) injection of ALA. The aim of the study was to investigate ALA-induced (PpIX) formation and its accumulation in different types of rat tissues after the systemic administration of ALA. Tissue types investigated included a malignant rat tumor and normal tissue from 13 different organs in 8 rats. The various rats were injected with two different doses of ALA (30 and 90 mg/kg body weight), and fluorescence analyses were performed 10, 30, and 240 min after injection.

Fluorescence analyses were performed by exciting the sample with 405-nm light and monitoring the resulting fluorescence with a fiber-optic probe over the spectral region of 400 to 750 nm. The fluorescence signal consisted of a broadband autofluorescence background with a maximum at approximately 500 nm and a characteristic dual-peak emission from the PpIX at 635 and 705 nm. From this work, it was found that the maximum tumor buildup of PpIX was achieved in less than 1 h after ALA injection, that the fluorescence demarcation between tumor and surrounding tissue was between 7:1 and 8:1 after 30 min, and that it decreased with longer retention times. Of the 13 different organs investigated in this study, PpIX buildup was found to be particularly high in the stomach and the intestine. 129

Another class of exogenous dyes that have been used for tumor demarcation are hematoporphyrins and hemotoporphyrin derivatives. In a pharmacokinetic study of hematoporphyrin, rats were administered i.v. injections of the dye, followed by immediate and continuous analysis by LIF. Excitation of the hematoporphyrins was provided by the 337-nm output of a nitrogen laser; the signal was collected by an optical multichannel analyzer (OMA), which allowed for acquisition of entire fluorescence spectrum for each laser shot. Upon analysis of data from several of the rat's organs, it was found that the fluorescence emission from the hematoporphyrin at 630 nm exhibited an initial peak intensity as well as a delayed peak intensity. The delayed fluorescence peak was described as due to the chemical components of intracellularly transformed hematoporphyrin derivatives. In addition, it was also discovered that, by dividing the background-free 630-nm signal by the autofluorescence intensity at shorter (blue) wavelengths, a ratio exhibiting a larger contrast between tumor and surrounding tissue could be obtained that would greatly aid in tumor demarcation. 130

A third and relatively recent photosensitizer used for the demarcation of tumor tissues is benzoporphyrin derivatized-monoacid (BPD-MA). In LIF studies designed to provide pharmacokinetic information about this compound, 337-nm light from a nitrogen laser was used to excite the BPD-MA in rats that had been administered the drug via i.v. The fluorescence emission, over the spectral range of 380 to 750 nm, was then monitored with a spectrometer equipped with a diode array detector. Three hours after the injection period, the fluorescence signals were measured from many different types of rat tissue, including malignant tumors that had been experimentally induced. These results were then compared with results from several other common sensitizers, such as hematoporphyrin (HP), polyhematoporphyrin ester (PHE), tetrasulfonated phthalocyanine (TSPc), and the commercially available Photofrin™. After three hours, the demarcation potential between tumor and surrounding tissue in terms of fluorescence

signal for the tumor model used was 2:1 for BPD-MA. When compared with other drugs such as HP, it shows about the same demarcation potential, whereas Photofrin and PHE exhibit about 3 times better and TSPc about 1.5 times better demarcation. Employing the endogenous tissue fluorescence signature enhanced the contrast by a factor of about two for each of the five drugs.¹³¹

In work by Nilsson et al., the biodistribution of two recently developed tumor markers, trimethylated (CP[Me]3) and trimethoxylated (CP[OMe]3) carotenoporphyrin, was investigated by means of LIF. In this study, 38 tumor-bearing (MS-2 fibrosarcoma) female BALB/c mice were administered the drugs through i.v. injection. At 3, 24, 48, or 96 h after administration, the carotenoporphyrin fluorescence was measured in tumoral and peritumoral tissue, as well as in the abdominal, thoracic, and cranial cavities. Excitation of the exogenous dye was performed by using the 425-nm emission of a nitrogen-pumped dye laser and was measured by a spectrometer equipped with an intensified charge-coupled device (ICCD) at 490, 655, and 720 nm. The emission bands at 655 and 720 nm corresponded to carotenoporphyrin (CP), whereas the band at 490 nm represented a location near the maximum of the autofluorescence emission of the tissue. The tissues that showed the greatest extent of CP-related fluorescence were the tumors and the liver tissues, whereas the cerebral cortex and muscle tissues consistently exhibited weak CP-related fluorescence. Additionally, although the fluorescence intensity of most tissue types decreased over time, it was found that the fluorescence intensity in the liver remained constant the full 96 h over which it was investigated.¹³²

Oral Cancer — Apart from pharmacokinetic analyses of various sensitizers, animal studies with these compounds have also been performed to verify and quantify the ability of these drugs for tumor demarcation in different types of tissues. One such study investigated the effectiveness of porfimer sodium-derived drugs for the detection of early neoplastic changes in the oral cavity of hamsters. Neoplasia was induced in the hampsters' cheek pouches by the application of 9,10-dimethyl-1,2-benzanthracene. Following formation of neoplastic tissue in the hamster cheek pouch, autofluorescence analyses as well as fluorescence analyses using porfimer sodium as an exogenous tumor demarcation drug were performed and compared with histologic results of the same tissue sites. When the two fluorescence diagnostic techniques were compared with the histological results, it was found that the autofluorescence analysis was capable of 76% sensitivity and 83% specificity, whereas the porfimer sodium-based fluorescence technique provided 100% sensitivity and specificity for the samples investigated. 133

Pancreatic Cancer — Pheophorbide-a (Ph-a) represents another of the many different types of tumor demarcation drugs that have been used for optical differentiation of normal tissues and tumor tissues. To test its viability for the detection pancreatic tumors, LIF analyses of Ph-a were used to image six intrapancreatic tumors and six healthy pancreases in vivo in rats. Ph-a was intravenously administered to the rats at a concentration of 9 mg/kg body weight, and fluorescence images were acquired up to 48 h after injection of the drug. Excitation of the blue tissue autofluorescence was performed by using 355nm light from a frequency-tripled Nd:YAG laser and excitation of the dye was performed by the 610-nm output from an Nd:YAG pumped dye laser. Fluorescence images were obtained at three different wavelengths; bandpass filters were used for wavelength selection. Images at 470 nm and 640 nm were used to monitor the autofluorescence of the tissue, while images at 680 nm were taken to obtain composite images of the dye and autofluorescence emissions together. In order to achieve a good contrast between the normal pancreatic tissue and the tumor tissue, the autofluorescence intensity of the 640-nm image was normalized to the background fluorescence intensity in the 680-nm image prior to being subtracted from the 680-nm image. Following this subtraction, the differential image was divided by the autofluorescence image at 470 nm. The resulting ratiometric images allowed for safe diagnoses to be made by providing well-contrasted tumor images.24

Brain Tumors — Animal models have also been used in studies in which hematoporphyrin derivative (HPD) was used for the diagnosis of brain tumors. In this study, adult Wistar rats had C6 glioma cells implanted into their brains to act as a cerebral glioma model. After the tumors had developed to a size of 7 to 12 mm in diameter, they were injected intravenously with 5 mg/kg body weight of HPD, and

continuous fluorescence analyses were performed for 24 h using a fiber optic-based fluorimeter. The fluorescence intensity of the normal brain tissue reached a plateau 60 min after injection, while the glioma region reached a plateau 80 min after injection. Fluorescence analyses of glioma, brain tissue adjacent to the tumor (BTAT), and normal brain tissue 24 h after injection revealed that the fluorescence intensity of the glioma was 6.1 times greater than that of normal brain tissue; the BTAT also was 3.9 times greater than the normal tissue.¹³⁴

Liver Cancer — Testing efficacy of PDT using ALA-induced PpIX sensitization for the treatment of heptic tumors was performed with rat models. Liver tumors were induced in the rats by local innoculation of tumors cells or by administration of the tumor cells through the portal vein. Following tumor formation, 60 mg/kg body weight of ALA was administered intravenously. After 60 min, the PpIX in the heptic tumor tissue was excited, initiating the PDT treatment as well as allowing the PpIX to be excited. The resulting fluorescence emission was monitored at 635 nm. Fluorescence analyses revealed that large accumulations of the PpIX occurred in the heptic tumor, as well as in normal liver tissue, but not in the abdominal wall muscles.

In addition to fluorescence analyses, laser Doppler imaging was used to determine changes in the superficial blood flow in connection with PDT. Histopathological examinations were also performed to evaluate the photodynamic therapy effects on the tumor and the surrounding liver tissue, including pathological features in the microvascular system. Laser Doppler imaging results indicated an effect on the vascular system in the tumor as well as on the surrounding tissue following PDT treatment, as determined by decreased blood flow in the treated area. In addition, the tumor growth rate decreased significantly when evaluated 3 and 6 days after the treatment, showing that ALA-induced PDT holds promise for treatment of heptic tumors.¹³⁵

28.4.3.2 Human Studies and Clinical Diagnostics

By far the most common type of fluorescence-based biomedical diagnostic procedure used in clinical studies is the optical detection of malignant or premalignant tissues in various organs. Among the more common types of tumors that have been investigated with this technique are skin, urinary bladder, bronchus, gastrointestinal, head and neck, gynocological, breast, and brain cancers. Currently, two very different approaches to these fluorescence-based optical biopsy techniques are employed. The first of these techniques relies on subtle differences in the tissue composition and morphology between normal, dysplastic, and malignant tissues and their effect on the autofluorescence properties for differentiation. Examples of this type of diagnoses are discussed in the next section of this chapter. The second type of fluorescence-based diagnostic technique relies on the presence of exogenous fluorophores, such as PDT photosensitizers, for the tissue differentiation.

28.4.3.2.1 Clinical Studies and Diagnostics Using Autofluorescence

Autofluorescence-based optical biopsy techniques represent the ideal form of fluorescence-based diagnostic procedure. In these analyses, laser light is used to excite the naturally occurring fluorophores in the tissue; differences in chemical composition between the various types of tissue will allow for real-time diagnoses without removal of a tissue sample or treatment with a contrast-enhancing drug. Because of this and the great deal of promise that initial studies have shown, research in this field is currently experiencing tremendous growth.

Cancer Diagnostics (Optical Biopsy) — Cervical Cancer — Cervical cancer is the second most common malignancy in women worldwide and remains a significant health problem. Despite the widely used Papanicolaou smear (Pap smear) screening procedure and costly treatments, the overall survival rate remains 40%. For these reasons, efforts to strengthen screening and prevention are needed. Autofluorescence optical biopsy techniques offer just such a screening technique with automated diagnosis in real time and comparable sensitivity and specificity to colposcopy. Feld and co-workers have demonstrated the ability to distinguish between various types of tissues, *in vivo*, based upon multicomponent analysis (Figure 28.6).

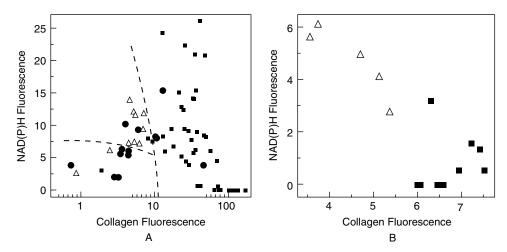

FIGURE 28.6 Study of *in vivo* quantitative fluorescent biomarkers of epithelial precancerous changes. This figure demonstrates the ability to distinguish between various types of tissues, *in vivo*, based upon a multicomponent fluorescence analysis. (A) Demonstrates the ability to differentiate between normal ectocervical tissue (\blacksquare), squamous metaplasia sites (\blacksquare), and high-grade squamous intraepithelial lesions (\triangle), based upon this two-dimensional analysis procedure. The dashed lines represent the boundary between the different tissues, based upon logistic regression analysis. (B) Demonstrates the ability to differentiate between nondysplatic tissues (\blacksquare) and high-grade dysplastic tissues sites (\triangle). (Adapted from Georgakoudi, I. et al., *Cancer Res.*, 62, 682, 2002.)

Richards-Kortum and co-workers have used laser-induced fluorescence, employing 337-nm excitation to differentiate in vivo cervical intraepithelial neoplasia (CIN), non-neoplastic abnormal, and normal cervical tissues from one another.¹³⁸ In this work, a colposcope was used to identify normal and abnormal sites on the cervix. These sites were then interrogated via fluorescence spectroscopy with an optical fiber probe. Based upon results from the fluorescence analyses, two algorithms were developed for the diagnosis of CIN. The first of these algorithms allowed for differentiation of histologically abnormal tissues from colposcopically normal tissues with a sensitivity, specificity, and positive predictive value of 92, 90, and 88%, respectively. The second algorithm then allowed for the differentiation of preneoplastic and neoplastic tissues from non-neoplastic abnormal tissues with a sensitivity, specificity, and positive predictive value of 87, 73, and 74%, respectively. These results found that as the tissue progresses from a normal state to an abnormal state in the same patient, it is accompanied by a decrease in the absolute fluorescence contribution of collagen, an increase in the absolute attenuation by oxyhemoglobin, and an increase in the relative contribution from reduced nicotinamide dinucleotide phosphate [NAD(P)H]. Differentiation of the various tissues is then determined by the extent of each of these factors. Such results provide a great deal of hope to the future of in vivo fluorescence spectroscopy for the diagnosis of CIN at colposcopy. 138,139

Esophageal Cancer — Esophageal cancers, like most other cancers, generally progress through a series of stages. Barrett's esophagus, named after the physician who first identified the condition, ¹⁴⁰ is an abnormality resulting from long-term acid reflux, and is associated with an increased occurrence of mucosal dysplasia and adenocarcinoma in the specialized glandular mucosa. ^{141–143} In addition, individuals with Barrett's esophagus have a tendency to develop cancer of the esophagus, with a 30- to 52-fold increase over individuals without this condition. ^{144,145} In esophageal cancer, the mucosa progresses from "normal" through low-grade dysplasia (LGD) to high-grade dysplasia (HGD), and, finally, cancer. If detected early, endoscopic treatment of dysplasia with photodynamic therapy or thermal ablation can be effective, thereby eliminating the need for surgical esophagectomy.

Vo-Dinh and co-workers have developed a laser-induced fluorescence diagnostic procedure for *in vivo* detection of GI cancer that uses 410-nm laser light from a nitrogen-pumped dye laser passed through a fiber-optic probe to excite the tissue.^{104,105,119,120,146} After the tissue is excited, the resulting fluorescence

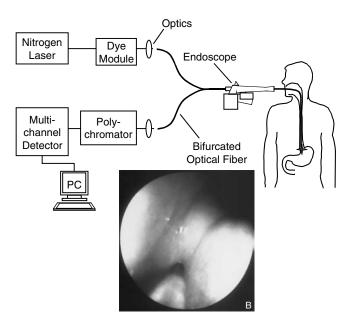

FIGURE 28.7 Laser-induced fluorescence instrument for *in vivo* gastrointestinal cancer diagnostics. This figure shows a typical fluorescence-based optical biopsy system in which a fiber optic probe is transmitted down a biopsy channel of an endoscope for point-by-point types of analyses. Insert: photograph of the optical fiber inside the GI tract. (Modified from Vo-Dinh, T. et al., *Appl. Spectrosc.*, 51, 58, 1997.)

emission is collected by the same fiber-optic probe and is recorded on an OMA in 600 ms. Based upon the resulting fluorescence spectra, a diagnostic technique known as differential normalized fluorescence was employed to enhance the slight spectral differences between normal and malignant tissues. ^{64,65} This technique greatly improves the accuracy of diagnosis, compared to direct intensity measurements, because each spectrum is normalized with respect to its total integrated intensity and therefore becomes independent of the intensity factor. This in turn enhances small spectral features in weak fluorescence signals, making classification much easier. The sensitivity of the DNF method in classifying normal tissue and malignant tumors is 98%. ^{65,119,120,146}

The LIF methodology was also employed in clinical studies of over 100 patients, in which Barrett's mucosa without dysplasia was diagnosed with a specificity of 96% (208 of 216 data points) and high-grade dysplasia was diagnosed with a sensitivity of 90% (9 of 10 data points). Figure 28.7 shows the instrument setup for GI cancer diagnostics. A photograph of the optical fiber inside the GI tract is shown in the insert of this figure. Figure 28.8 shows clinical data demonstrating the capability of LIF to differentiate normal from malignant tissues.

Bladder Cancer — Bladder cancer has also shown a significant amount of promise for clinical diagnosis by autofluorescence analyses. In one such study, a quartz fiber-optic probe, placed in the working channel of a cytoscope, was used to deliver 337-nm laser light from a nitrogen laser to the tissue area of interest. Following excitation, the resulting fluorescent light was collected by a second fiber and then spectrally dispersed before being detected by an OMA. Resulting fluorescence emission spectra were then analyzed by taking a ratio of the intensity of the fluorescent light at 385 nm to the fluorescence intensity at 455 nm. This ratiometric analysis was used to analyze 114 lesions, and it was possible to differentiate clearly between malignant and nonmalignant bladder tissues with a sensitivity of 98%.¹⁴⁷

In another study, the ability of laser-induced autofluorescence spectroscopy to distinguish between neoplastic urothelial bladder lesions and normal or nonspecific inflammatory mucosa was investigated. In this study, three different pulsed-laser wavelengths were used successively for excitation: 308 nm (XeCl laser), 337 nm (N₂ laser), and 480 nm (coumarin dye laser). The excitation beam was delivered through

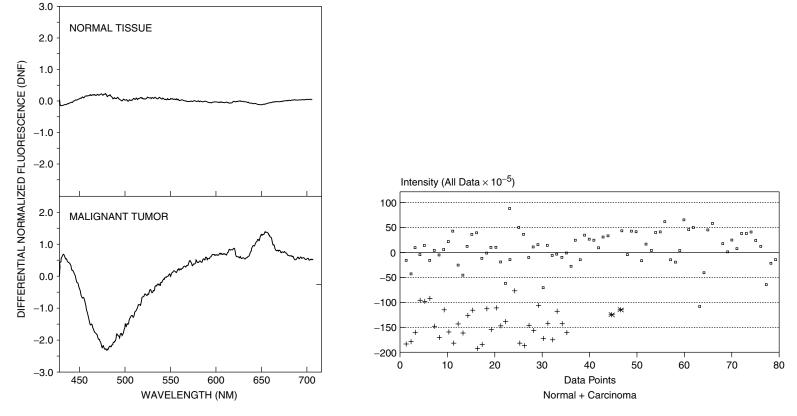

FIGURE 28.8 Clinical data demonstrating the capability of LIF to differentiate normal from malignant tissues. Left: Differential normalized fluorescence (DNF) emission spectra of normal tissue (top) and malignant tissue (bottom). These spectra were obtained by normalizing the fluorescence intensity at every point in the spectrum to the overall area under the curve, thus emphasizing small differences between the two types of tissues. By subtracting the DNF spectrum of a particular sample from an average DNF normal tissue spectrum, a single index value at each wavelength can be determined. (From Vo-Dinh, T. et al., Appl. Spectrosc., 51, 58, 1997.) Right: Plot of DNF indices at 480 nm for different tissue samples using in vivo LIF measurements (taken prior to biopsy). These tissue samples were then characterized via histology as normal (•) or as carcinoma (+). As expected, the normal tissue results are scattered about the index value of zero while the carcinoma values are significantly lower due to a decrease in fluorescence intensity at this wavelength. The samples denoted by (*) represent points initially classified by histology as normal but later reclassified as malignant. The sensitivity of the DNF method in classifying normal tissue and malignant tumors for GI cancer is 98%. (From Vo-Dinh, T., Panjehpour, M., and Overholt, B.F., in Advances in Optical Biopsy and Optical Mammography, New York Academy of Sciences, New York, 1998, p. 116; Vo-Dinh, T., et al., Lasers Surg. Med., 16, 41, 1995.)

optical fibers placed in the working channel of a standard cystoscope, and the resulting fluorescence was detected using an OMA. When 337- and 480-nm excitation wavelengths were used, the overall fluorescence intensity of bladder tumors was clearly decreased compared with normal urothelial mucosa regardless of tumor stage and grade. However, when 308-nm excitation was employed, the shape of the tumor spectra, including CIS, was markedly different from that of normal or nonspecific inflammatory mucosa. 148

Colon Cancer — Autofluorescence diagnostic procedures are used extensively to investigate colon cancers. In one such study, 337-nm light from a nitrogen laser was launched into a fiber-optic probe placed in the working channel of a colonoscope and was used for excitation of *in vivo* and *in vitro* colon tissues. The fluorescence spectra were then measured and analyzed. In all cases, the spectra exhibited peaks at 390 and 460 nm, which are believed to arise from collagen and NADH, as well as a minimum at 425 nm, consistent with absorption attributable to hemoglobin. Despite the presence of these bands in the *in vivo* and *in vitro* samples, the relative intensity of each was quite different, especially for the NADH component, whose intensity was found to decay exponentially with time after resection. Differentiation of normal colonic tissue from hyperplastic or adenomatous tissues of the same type (i.e., *in vivo* vs. *in vitro*) could be accomplished based upon a decrease in the collagen component of the autofluorescence and an increase in hemoglobin reabsorption.

When multivariate linear regression (MVLR) analysis based upon these differences was used, neoplastic tissues could be distinguished from non-neoplastic tissues with a sensitivity, specificity, positive predictive value, and negative predictive value toward neoplastic tissue of 80, 92, 82, and 91%, respectively. However, when this same MVLR technique was used to distinguish neoplastic polyps from non-neoplastic polyps, values of 86, 77, 86, and 77%, respectively, were obtained. This suggested that the LIF measurements sense changes in polyp morphology rather than changes in fluorophores specific to polyps, and that this change in morphology leads indirectly to polyp discrimination.¹⁴⁹

Laser-induced autofluorescence spectroscopy has been investigated to detect colonic dysplasia *in vivo* using an excitation wavelength of 370 nm.¹⁴¹ In this work, fluorescence emission data were used to devise an algorithm to classify colonic tissue as normal, hyperplastic, or adenomatous, based on probability distributions of the fluorescence intensity at 460 nm and the ratio of the intensity at 680 nm to that at 600 nm. Fluorescence spectra were then collected from normal mucosa and colonic polyps during routine colonoscopy exams; the predictive abilities of the diagnostic algorithm were tested in a blinded fashion, with histology results the standard against which they were measured. Results revealed that the algorithm correctly determined the tissue type in 88% of cases, equal to the agreement of independent pathologists. In addition, the sensitivity, specificity, and positive predictive value for the detection of dysplasia were 90, 95, and 90%, respectively.¹⁵⁰

In additional work by Feld and co-workers, LIF studies were performed on 20 different patients, providing analyses on 31 colonic adenomas, 4 hyperplastic polyps, and 32 samples of normal mucosa. From these studies, it was found that classification of the tissue as adenomatous or normal colonic mucosa/hyperplastic polyp was correct, based upon an automated probabilistic algorithm, 97% of the time. The sensitivity, specificity, and positive predictive value of the technique were 100, 97, and 94%, respectively — once again showing a great deal of promise for this technique in the future. ¹⁵¹

Lung Cancer — Lung cancer accounts for 25% of all cancer deaths and is currently the most common cause of cancer death among both men and women in the United States. Currently, patients are diagnosed only when the cancer is already in a severe state because no rapid, practical, and effective screening test is available for lung cancer. In lung cancer, premalignant epithelium usually progresses to a malignant tumor through the development of dysplasia, starting from LGD and progressing to HGD, which is then typically followed by carcinoma. 152,153 Although this well-known stepwise progression could provide the basis to survey premalignant epithelium by random biopsies, histology analyses from expert to expert typically have poor agreement, particularly for the most severe and highest-risk samples such as HGD or CIS. 154 Based on such results, it appears that optical biopsies could eventually be well suited for early diagnosis of lung cancer and could greatly increase the survival rate of this disease.

In one study determining the potential of fluorescence spectroscopy for the diagnosis of dysplastic tissues and CIS, fluorescence bronchoscopy was performed on 82 volunteers, 25 nonsmokers, 40 exsmokers, and 17 current smokers with mean ages of 52, 55, and 49 years, respectively. Excitation of the tissue was performed using the 325-nm emission of an HeCd laser and the ratiometric analyses of the resulting fluorescence emission wavelengths were determined. Upon analysis of the results, it was found that the sensitivity of the autofluorescence bronchoscopy was 86%, which is 50% better than conventional white-light bronchoscopy for the detection of dysplasia and CIS. 93,114,

Upper Aerodigestive Tract Cancers — In order to determine the potential of laser-induced autofluorescence for the diagnosis of dysplastic tissues in the upper aerodigestive tract, many different research groups have developed many types of analyses. In one study, various fluorescence excitation and emission scans were employed for differentiation of normal mucosa from neoplastic tissues. One spectral difference was the disappearance of an excitation peak at 330 nm in tumor tissue that existed in normal tissue, when an emission wavelength of 380 nm was used for fluorescence monitoring. Therefore, by ratioing the excitation scan intensity at 290 nm to that of 330 nm, the resulting value could be directly correlated to increases epithelial thickness resulting from carcinogenesis.

In addition to changes in the excitation spectrum between tumor and normal tissue, it was also found that the fluorescence emission intensity at 390 nm, upon excitation with 340-nm light, was also decreased in tumor tissue relative to normal tissue. A ratio of the fluorescence emission intensity at 390 and 450 nm correlated negatively with the mean epithelial thickness, again providing an indication of the stage of dysplasia. ¹⁵⁵ In a similar study, the same autofluorescence ratios were used to differentiate between normal and neoplastic tissues in the oral cavity and pharynx of patients with previously untreated mucosal neoplasias. Using the same ratios, researchers found that significant differences existed between the neoplastic tissue and the contralateral normal sites, leading to the thought that this technique could represent a noninvasive screening method for head and neck squamous cell cancers. ¹⁵⁶

In another study, autofluorescence spectral characteristics of untreated oral and oropharyngeal lesions in patients were studied with excitation wavelengths of 370 and 410 nm generated by a nitrogen-pumped dye laser. Upon examining the resulting fluorescence emission of normal and neoplastic tissues, differences in the spectral profile were noted in two regions of the spectrum for both excitation sources. However, it was found that these differences were more significant when 410-nm light is used for excitation. By ratioing the fluorescence maximum intensity of dysplastic tissue to that of normal mucosa, a quantitative means of differentiation has been developed for the differentiation of the two types of tissue. ¹⁵⁷

In addition to being able to determine the presence of a cancerous or precancerous lesion in a patient, it is also important to be able to determine the point or margin where the tumor ends and the healthy tissue begins. Bohle and co-workers have used autofluorescence spectroscopy of tumor connective tissue to determine accurately where the tumor ends and the healthy skin begins. In this work, 365-nm light was used for the excitation of the tissue, and the resulting fluorescence, either from the elastic fibers of a tumor or the keratinization of precancerous lesions, was used for delineation of the tissue. Contrary to previous results in the literature, no homogeneous fluorescence gradient could be proved between darker marginal epithelium and the brighter tumor connective fibers. The greatest differentiation between tumor and nontumor tissues was exhibited in tissues from the same patient; however, comparisons between different patients also showed promise for the margining of lesions using autofluorescence.¹⁵⁸

Laryngeal and Oral Cancer — Like other cancers involving mucosal membranes, oral and laryngeal carcinomas have also been studied by autofluorescence. Fluorescence spectroscopy has been used to differentiate normal tissue from dysplastic or cancerous tissue with a sensitivity of 90% and a specificity of 88% in a training set and a sensitivity of 100% and a specificity of 98% in a validation set (Figure 28.9).¹⁵⁹ A study of laryngeal cancer employed an HeCd laser operating at 325 nm for excitation of the sample and an ICCD for fluorescence image collection. Images were obtained at various wavelengths with optical filters for wavelength discrimination and were analyzed to provide diagnostic fluorescence images of the area of interest. This technique was used to evaluate 30 patients, of whom 18 had suspect malignancies that were confirmed via histopathological findings.¹⁶⁰

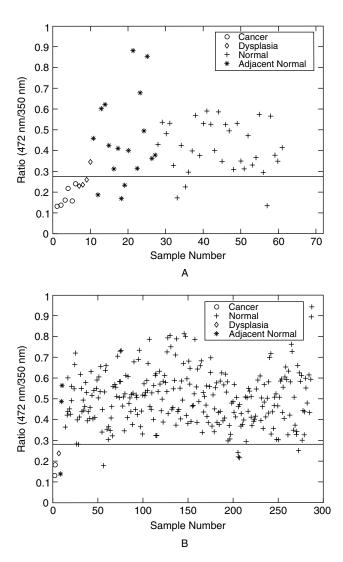

FIGURE 28.9 In vivo detection of oral neoplasia using fluorescence spectroscopy The results demonstrate the ability of automated data analysis algorithms to classify tissues as normal (+), dysplastic (\diamondsuit) , cancerous (\diamondsuit) , or normal tissue adjacent to cancerous (*), based upon ratios of fluorescence emission data at multiple wavelengths following excitation of the oral tissue at 350 nm. Data in (A) represent the training set for automated analyses, while (B) represents the validation set. The solid line at 0.28 represents the threshold for separation of normal and dysplastic or cancerous tissue. Based upon these results, differentiation of normal tissue from dysplastic or cancerous tissue can be achieved with a sensitivity of 90% and a specificity of 88% in the training set, and a sensitivity of 100% and a specificity of 98% in the validation data set. (Adapted from Heintzelman, D.L. et al., *Photochem. Photobiol.*, 72, 103, 2000.)

Skin Diagnostics — To better understand the role of various tissue components in the autofluorescence of skin, Gratton and co-workers ¹⁶¹ have employed multiphoton fluorescence microscopy for the analysis of skin tissue *in vivo*. In this work, multiphoton fluorescence microscopy using excitation wavelengths of 730 and 960 nm was used to image *in vivo* human skin cells from the surface to a depth of approximately 200 μ m. (Details on multiphoton fluorescence techniques are described in Chapter 11 of this handbook.) Fluorescence emission spectra and fluorescence lifetime images were obtained at selected locations near the surface (0 to 50 μ m) and at deeper depths (100 to 150 μ m) for both excitation wavelengths.

The resulting spectroscopic data suggest that reduced pyridine nucleotides and NADH are the primary source of skin autofluorescence when using 730-nm excitation. With 960-nm excitation, a two-photon

fluorescence emission at 520 nm indicates the presence of a variable, position-dependent intensity component caused by flavoproteins. In addition, a second fluorescence emission component that starts at 425 nm is observed when using 960-nm excitation. Such fluorescence emission at wavelengths less than half the excitation wavelength suggests an excitation process involving three or more photons. This is further confirmed by observation of a super-quadratic dependence of the fluorescence intensity on the excitation power. Further work is still required to identify these emitting species spectroscopically; however, this study demonstrates the use of multiphoton fluorescence microscopy for functional imaging of the metabolic states of *in vivo* human skin cells.¹⁶¹

In addition to microscopic analyses, macroscopic autofluorescence-based analyses have also provided useful information about the tissue state of skin. One property about which autofluorescence analyses of skin can provide information is the extent of photoaging that an individual's skin has undergone. Two of the more common fluorescent components in the dermis of skin are the structural proteins elastin and collagen, which are altered by age and photoexposure. Based upon *in vivo* fluorescence analyses of skin from 28 volunteers, it was found that fluorimetry could provide a marker for the extent of photoaging that has occurred in a person. In this study, by monitoring the fluorescence emission from ultraviolet irradiated skin, it was possible to determine the extent of photoaging in a way that was independent of the age, pigmentation, and skin thickness of the individual. Such a marker could lead to development of a technique capable of determining an individual's risk of cancer due to ultraviolet exposure from the sun.¹⁶²

28.4.3.2.2 Clinical Studies and Diagnostics Using Exogenous Dyes

Exogenous fluorophores are used for many reasons in clinical applications. The most common reason is to provide a contrasting agent that will make medical diagnoses easier, much like radionucleotides are sometimes used as contrast agents in circulation studies. However, due to the limited penetration of optical wavelengths into biological tissues, the most common type of fluorescence analyses performed *in vivo* are cancer diagnoses of optically accessible tissues. For this reason the majority of clinical fluorescence diagnoses using exogenous fluorophores is in the area of cancer visualization. The most common exogenous fluorophores used for these studies are photosensitizers that have been developed for PDT treatments.

These drugs generally exhibit strong fluorescence properties, and preferentially locate in malignant tissues. Figure 28.10 illustrates the use of a fluorescence method for monitoring the production of PDT products produced *in vivo* during treatment. The development and applications of PDT drugs are described in this handbook in Chapter 36 on mechanistic principles of photodynamic therapy, Chapter 37 on synthetic strategies in designing prophyrin-based photosensitizers, and Chapter 38 on photodynamic therapy (PDT) and clinical applications.

Photosensitizers — Determining the optimal photosensitizer to use for various types of tumors is a continuous field of investigation. In one such study, fluorescence analyses of the HPD-type photosensitizer PhotogemTM were tested in 22 patients with tumors of the lungs, larynx, and skin; gastric and esophageal carcinoma; and cancer of the gynecological organs. Retention of the drug in the various types of tumors and tissues was monitored by fluorescence spectroscopy after excitation of the drug with 510-nm light. The results demonstrated that tumor detection by fluorescence spectroscopy when using Photogem as a contrast agent was possible even in low selectivity of drug accumulation, which appeared to be dependent on the stage and type of the disease and the organ involved.¹⁶⁴

Cancer Diagnostics — Liver Cancer — Monitoring and comparison of the results of ALA-induced PpIX tumor demarcation in chemically induced adenocarcinoma in the liver of rats and in an aggressive basal cell carcinoma in a patient were studied using LIF. In this study, *in vivo* point monitoring and fluorescence microscopy incorporating a CCD camera were used to study the fluorescence distribution of ALA-induced PpIX in tumors. Fluorescence analyses were performed after i.v. injection of 30 mg/kg body weight of ALA. These analyses revealed a slightly larger concentration of PpIX in the tumor than in surrounding healthy liver tissue or abdominal muscles in the rat. In the aggressive basal cell carcinoma of the human, a much greater concentration of PpIX was found in the visible regions of the basal cell carcinoma than

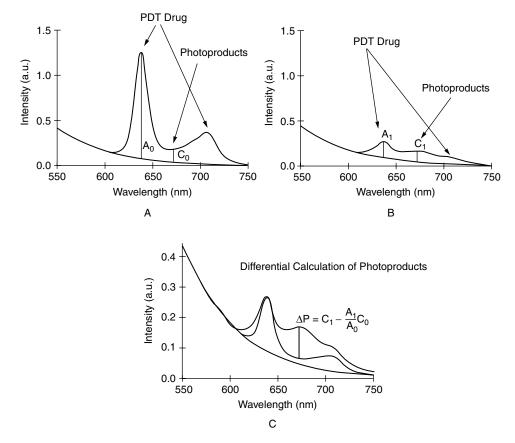

FIGURE 28.10 Fluorescence method for monitoring the production of PDT photoproducts produced *in vivo* during treatment. Immediately prior to activation of the PDT drug, a fluorescence emission spectrum is measured (A). Then immediately following treatment a second fluorescence spectrum is obtained (B). The fluorescent signal due to the PDT drug is designated A_0 for measurements prior to irradiation, and A_1 for measurements following irradiation, while C_0 represents the fluorescence intensity of the photoproducts prior to irradiation and C_1 the fluorescence intensity of the photoproducts after irradiation. In order to determine the change in fluorescence intensity due to the formation of photoproducts during PDT treatment, at the appropriate wavelength, the fluorescence intensity of the irradiated tissue is subtracted from the fluorescence intensity of the nonirradiated tissue, as shown in (C). (Adapted from Klinteberg, C. et al., *J. Photochem. Photobiol. B*, 49, 120, 1999.)

in the necrotic regions and the surrounding normal skin, thereby demonstrating selective uptake and retention of PpIX in the carcinoma. 165

Oral Cancer — Diagnosis of neoplastic lesions in the oral mucosa of 11 patients was investigated using ALA-induced PpIX as a contrast agent. In this work, semiquantitative fluorescence measurements were performed at regular intervals of 3 h, following 15 min of continuous topical application of 0.4% ALA solution to the lesions. Excitation of the PpIX was performed using violet light from a xenon lamp (375 to 440 nm). Fluorescence images in the red region of the visible spectrum were recorded with a CCD while quantitative spectral analyses were performed with an OMA. From these analyses, it was found that PpIX accumulated earlier in the necrotic tissue than in surrounding normal tissue and that a contrast ratio of 10:1 was found for tumor tissue relative to normal tissue 1 to 2 h after application of ALA. 166

Esophageal Cancer — Investigation of PhotofrinTM-enhanced LIF differentiation of Barrett's metaplastic epithelium and esophageal adenocarcinoma in five patients was performed following low-dose intravenous injections (0.35 mg/kg body weight). In this work, LIF measurements were performed on tissue specimens

of normal mucosa, Barrett's epithelium, and tumor tissue treated with Photofrin. Based upon fluorescence measurement ratios of the Photofrin intensity divided by the autofluorescence intensity, quantitative values demonstrating the differentiation ability for the various degrees of dysplasia were determined. The mean ratio \pm standard deviation for each type of tissue was found to be 0.10 ± 0.058 for normal esophageal mucosa, 0.16 ± 0.073 for normal gastric mucosa, 0.205 ± 0.17 for Barrett's epithelium with moderate dysplasia, 0.79 ± 0.54 for severe dysplasia, and 0.78 ± 0.56 for adenocarcinoma.

Bladder Cancer — Diagnosis of bladder cancer based upon the LIF of exogenous fluorophores has also been performed. In this study, a point-monitoring fluorescence diagnostic system based on a low-energy pulsed laser, fiber transmission optics, and an OMA was used for the diagnosis of 24 patients with bladder malignancies. Malignancies ranged from bladder carcinoma, CIS, and dysplasia. In order to provide a better contrast than can be achieved using autofluorescence, the hematoporphyrin derivative, Photofrin, was injected into the tissue at a concentration of 0.35 or of 0.5 mg/kg body weight. Fluorescence measurements were taken 48 h after injection and a ratio of the red photosensitizer fluorescence to the blue autofluorescence of the tissue was calculated. Based upon this ratio, excellent demarcation between papillary tumors and normal bladder wall tissue was achieved. In addition, these ratios allowed for objective differentiation of certain cases of dysplasia from normal mucosa and benign exophytic lesions such as malakoplakia from malignant tumors. ¹⁶⁸

Skin Cancer — Due to the great success in using fluorescence spectroscopy for diagnosis of many other types of malignancies, LIF has also been suggested for the noninvasive diagnosis of malignant melanomas. In one study, LIF was used for real-time monitoring of the PpIX distribution in tumor tissues and in the normal surrounding skin, before and after treatment in all patients. Based upon comparison of fluorescence intensities from normal and tumor tissue of the same pigmentation from the same individual, PpIX distribution demonstrated excellent demarcation between tumor and normal skin of approximately 15:1 for basal cell carcinoma BCC and Bowen's disease, and 5:1 for T-cell lymphomas. However, the reliability of such measurements can be seriously compromised by spatial variations in the optical properties of the tissue that are not related to malignancy (e.g., pigmentation).

One approach to fluorescence-based analyses that minimizes this problem employs a double ratiometric analysis procedure and the use of the photosensitizer ALA. In this technique, two types of fluorescence ratios were calculated. The first of these ratios was the ratio of the skin's fluorescence emission between 660 and 750 nm to the emission between 550 and 600 nm following 405-nm excitation. The second ratio was calculated by dividing the fluorescence emission between 660 and 750 nm by the emission between 550 and 600 nm following excitation with 435 nm. These two excitation wavelengths were chosen to be close to the fluorescence emission wavelength of ALA-induced PpIX, but some distance from the Soret excitation band of the porphyrins. Analysis of either of the two single ratios showed a significant correlation to the presence of a lesion and also to the color of the skin tissue. However, when the 405-nm excited ratio is divided by the 435-nm excited ratio, a value independent of skin coloration can be determined and can be based primarily on the presence of the ALA-induced photosensitizer. Such a technique will enable *in vivo* studies of the pharmacokinetics of tumor-localizing agents in pigmented lesions and may significantly contribute to development of a noninvasive diagnostic tool for malignant melanoma.¹⁷⁰

Colon Cancer — Another class of compounds beginning to be tested for *in vivo* tumor demarcation is fluorescently labeled antibodies. Based on previous experiments performed using nude mice, a feasibility study was performed to determine whether or not LIF of fluoresceinated monoclonal antibodies against carcinoembryonic antigens localized specifically in human carcinoma xenografts could be used for clinical colon cancer diagnoses. In this study, six patients with known primary colorectal carcinoma were given an i.v. injection of 4.5 or 9 mg of mouse—human chimeric anticarcinoembryonic antigen monoclonal antibody labeled with 0.10 to 0.28 mg of fluorescein. In addition, the monoclonal antibody was labeled with 0.2 to 0.4 mCi of ¹²⁵I. Photodetection of the tumor was performed *ex vivo* on surgically resected tissues from all six patients and *in vivo* by fluorescence rectosigmoidoscopy for one of the six patients.

Fluorescence analyses revealed that the dye-labeled antibody localized preferentially in the tumor tissue at concentrations up to 0.059% of the injected dose per gram of tumor. This was ten times greater than in the normal tissue, which exhibited a concentration of 0.006% of the injected dose per gram of normal mucosa. Such immunophotodiagnoses may prove very useful in the clinical setting for rapid tumor diagnoses in the colon and, potentially, other organs.¹⁷¹

28.5 Conclusion

This chapter illustrates the usefulness of fluorescence spectroscopy in a wide variety of medical applications spanning cellular screening to tissue analysis and *in vivo* diagnostics. The major advantage of fluorescence (as well as of other techniques such as Raman scattering, diffuse scattering, elastic scattering, and NIR absorption) is that biochemical and morphological information about the native tissue state can be obtained without physically removing tissues. In addition, because tissue removal is not needed for diagnostics, a more comprehensive examination of the organ can be achieved than is possible with excised tissue. Fluorescence techniques can also be combined with imaging so that images of diseased tissue sites vs. normal sites can be constructed. Thus, these diagnostic techniques inherently provide superior coverage and do not suffer from the sampling errors that often occur with biopsy or cytology. Real-time diagnostic information is a significant added benefit.

At the early stage of development, fluorescence diagnostic techniques need to be verified by comparison with pathology, the current "gold standard," which also varies in reliability. Thus, the sensitivity and specificity of spectroscopic diagnostics depends upon the reliability of pathology in each specific desired application. If "optical biopsy" is to have a role in clinical diagnosis, the problem becomes which gold standard to use for calibrating optical measurements. Using pathology as the gold standard for intraepithelial neoplasia (preinvasive cancer) has its own difficulties because pathologists often disagree on their interpretations of these lesions, with the level of consistency varying for different organs. Therefore, building decision-making boundaries using optical measurements based on conventional pathology is problematic. Because under- and over-diagnosis are undesirable, it is imperative to establish objective and standardized pathological classification systems for grading preinvasive lesions for each separate organ area where these new optical technologies may be applied.

Another important application for optical diagnostic technologies such as fluorescence is the possible use of these techniques for guidance of surgical intervention and treatment. In such surgical-assist applications, the ability of fluorescence diagnostic technologies to provide real-time information would be critically useful. Fluorescence techniques may also be used to provide real-time assessment of tissue response to therapy — as in the assessment of tissue viability and necrosis in thermal, laser interstitial therapy, or PDT.

Fluorescence technologies could also be used for noninvasive measurement of concentrations of various drugs and biological species in tissues. This capability would provide a variety of benefits in medical research. One example of such a benefit is the use of chemotherapy drugs for treatment of various cancers. The therapeutic benefit is determined by the concentration of the drug in the tissues of the targeted organ or site; currently, the only minimally invasive check available to the oncologist is to track the blood serum concentration and to assume a relationship between the amount of drugs at the target organs and the tissue concentration. More generally, the ability to track concentrations of compounds in tissue noninvasively would be a tremendous advantage. Optical methods such as fluorescence could bypass many tedious and time-consuming trials that attempt to relate dosage to metabolic rates and target organ concentrations. Because of all of these desirable features, it is evident that fluorescence spectroscopy can be a powerful tool for the medical researcher to obtain a better understanding of the disease process and for the physician to perform real-time *in vivo* diagnoses and, ultimately, provide treatment at the point of care.

29.1 Basic Concepts

Wavelength-dependent spectral measurements of elastically scattered light from tissue, performed in a manner that is sensitive to scattering and absorption properties, may be used to detect and diagnose tissue pathologies. Many tissue pathologies, including a majority of cancers, exhibit significant architectural changes at the cellular and subcellular level. In making a diagnosis, pathologists determine some of these architectural changes by examining surgically removed samples called biopsies. Microscopic assessment, often referred to as histopathology, is performed on the biopsy samples to determine cell and tissue architecture, including the sizes and shapes of cells, the ratio of nuclear to cellular volume, the form of the bilipid membrane, cell clustering patterns, etc. The properties of light elastically scattered in tissue also depend on architectural features. For example, the size of the structures in tissue responsible for the scattering of light determines how much more strongly a short wavelength, e.g., blue light, is scattered than a long wavelength, e.g., red light.

This concept is illustrated in Figure 29.1, where the likelihood of scattering is plotted as a function of wavelength for suspensions of two different sizes of spheres. If the scattering structures are much smaller than the measurement light wavelengths, the scattering probability decreases as $1/\lambda^4$, where λ is wavelength. If the particles are of a size near that of the measurement light wavelengths or larger, scattering will not decrease nearly as rapidly with wavelength. Light is scattered by structures with a variety of shapes and sizes in tissue. Properties of light that has scattered inside tissue, such as the wavelength-dependent intensity, can provide information on cell and tissue structure.

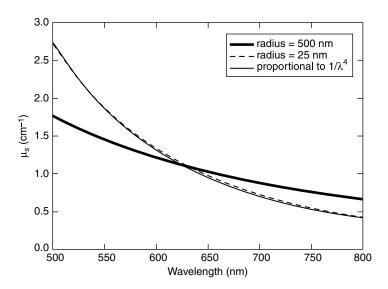

FIGURE 29.1 The wavelength dependence of the scattering coefficient, μ_s , for two sizes of spheres. The scattering coefficient, typically denoted by μ_s , is the inverse of the mean free path between scattering events. The spheres had an index of refraction of 1.39 and were immersed in a medium of index 1.35. The concentration of spheres with a radius of 25 nm was 300 times greater than the concentration of spheres with a radius of 500 nm. All calculations were performed using a solution to Maxwell's equations for a plane wave incident on an object, in this case a sphere called Mie theory. (For a discussion of Mie theory, see Bohren, C.F. and Huffman, D.R., *Absorption and Scattering of Light by Small Particles*, Wiley-Interscience, New York, 1983.)

The full range of information available and its relationship to traditional histopathology are still under investigation. Most likely, noninvasive light scattering methods will provide a subset of traditional histopathologic characterization as well as some information not traditionally available. The propagation of light through tissue depends on absorption as well as scattering properties. The three primary light absorbing compounds in healthy, nonskin tissue are oxygenated hemoglobin, deoxygenated hemoglobin, and water. Absorption spectra of these chromophores are shown in Figure 29.2. Concentrations of these compounds can serve as important diagnostic criteria. The importance of hemoglobin oxygenation and the ability of optical systems to provide quantitative information have already been demonstrated by the pulsed oximeter, which is in widespread use.¹

The basic geometry of the measurements described in this chapter is shown in Figure 29.3. Broad bandwidth light is incident on the tissue, typically through a flexible optical fiber with a diameter of 0.2 to 0.4 mm. This light travels into the tissue and can be absorbed and scattered. The absorption depends strongly on wavelength; it is greatest at visible wavelengths for which hemoglobin absorbs and much lower at near-infrared wavelengths between the hemoglobin and water absorption bands. Tissue is highly scattering, and the average distance between scattering events is on the order of $100~\mu m$ (0.1 mm). A small fraction of the light that is not absorbed will be scattered such that it can be collected by a probe on the surface near the original delivery location. Thus, the light collected and transmitted to the analyzing spectrometer has typically undergone several scattering events through a small volume of the tissue. No light is collected from surface reflection. The measurements typically take a fraction of a second and cause no damage to the tissue.

Systems that use light levels meeting FDA guidelines have been designed. The components of the optical system in Figure 29.3 have an intrinsic wavelength dependence; for example, silicon CCD detectors are more efficient at some wavelengths than at others. Consequently, the spectral dependence of the measurement system must be determined. Commonly, this is accomplished using a control sample that reflects equally at all wavelengths. An example of the elastic-scatter spectrum of tissue (from the esophagus), corrected for the wavelength dependence of the measurement system, is shown in Figure 29.4. The

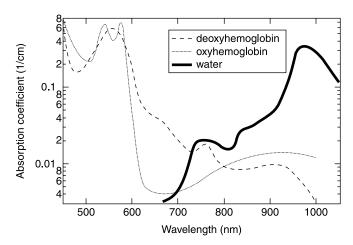

FIGURE 29.2 Absorption spectra of oxyhemoglobin, deoxyhemoglobin, and water. The concentration of heme groups is taken to be 20 mM. The hemoglobin spectra are a combination of data taken by the authors and from van Assendelft, O.W., *Spectrophotometry of Haemoglobin Derivatives*, Royal Vangorcum Ltd., Assen, the Netherlands, 1970 and Wray, S., Cope, M., Delpy, D.T., Wyatt, J.S., and Reynolds, E.O.R., *Biochim. Biophys. Acta*, 933, 184, 1988. The absorption of water has been scaled by a factor of 0.7 to be consistent with the idea that tissue is about 70% water. The water spectra data are from Kou, L., Labrie, D., and Chylek, P., *Appl. Opt.*, 32, 3531, 1993.

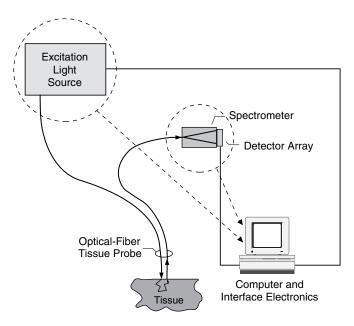

FIGURE 29.3 A schematic of a system for measuring elastic scattering and diffuse reflectance. The excitation light source is typically a tungsten bulb or a mercury arc-lamp. The optical fibers are multimode, often with diameters of 200 μ m, although larger diameter fibers are sometimes used. The spectrometer is commonly a CCD (charge-coupled device), although diode arrays have also been used.

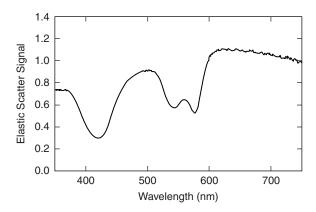

FIGURE 29.4 In vivo elastic scatter spectra of Barrett's esophagus. Light was delivered to the tissue with a 400-μm diameter optical fiber and collected with an adjacent 200-μm diameter optical fiber.

dips at 419, 543, and 577 nm are due to absorption by hemoglobin. Past 650 nm and before water absorption becomes significant, the decreasing intensity is due to the decreased scattering probability with increasing wavelength. The distance the collected photons travel in the tissue is several times greater than the separation of the light delivery and detection points. Consequently, in addition to the scattering spectral sensitivity to microscopic tissue morphology, this type of system can have good sensitivity to the optical absorption bands of the tissue components.

Sensitivity to absorption increases as the source and detector are separated. Quantitative measurements of the compounds in Figure 29.2 as well as possibly other absorbing compounds, such as fat and melanin, may be made at the same time tissue structural properties are determined. The intensity and wavelength dependence of the elastic-scatter spectrum depend on several light transport properties. The likelihood of scattering is generally quantified as the scattering coefficient, μ_s , which has units of inverse length. The scattering coefficient is the inverse of the average distance light travels between scattering events.

In addition to the scattering coefficient, μ_s , a complete description of the scattering properties of a tissue requires knowledge of the angular scattering probability distribution, often written as $P(\theta)$, where the deflection angle, θ , ranges from 0 to π . Physically, $P(\theta)$ is the probability that when a photon is scattered it is deflected by an angle θ . Using $P(\theta)$ as the angular scattering probability distribution is a simplification of the physics of light scattering in tissue that assumes the scattering centers are spherical in shape. In tissue, the scattering structures are not spherically symmetric and the angular scattering probability is, in principle $P(\theta, \phi)$, where ϕ is the azimuthal angle, ranging from 0 to 2π . To complete the description of the light transport properties of a medium, the absorption coefficient, μ_a , must be known. The absorption coefficient quantifies the decrease in light intensity when light is absorbed. If light with an initial intensity I_0 travels a distance I through an absorbing medium, the resultant intensity, I, is given by

$$I = I_0 \exp(-\mu_a L) \tag{29.1}$$

When the scattering coefficient, μ_a , absorption coefficient, μ_a , and angular scattering probability, $P(\theta, \phi)$ are all known, the transport of light through tissue can be calculated using the "transport equation."^{2–4} (This equation can be derived from conservation of photons traveling into and out of a small volume.²) However, it can only be solved analytically for special geometries and consequently approximations are often used.

The most common approximation is the diffusion equation, which holds when the light collection is well separated from light delivery — typically a few centimeters.^{5,6} (This approximation assumes that $P(\theta,\phi)$ and the light source term can be expanded in Legendre polynomials and only terms with $\ell \le 1$ kept.) In this approximation, the light transport properties can be described by μ_a and the reduced scattering coefficient, $\mu_s' = \mu_s(1-g)$, where $g = \langle \cos \theta \rangle$. The anisotropy parameter, g, is 0 when scattering

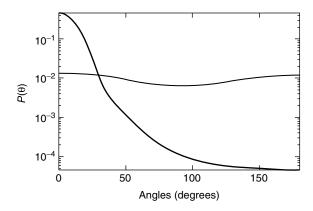

FIGURE 29.5 The probability of scattering s to s', where s is the incoming direction of propagation, s' is the direction of propagation after scattering, and $\cos\theta = s \cdot s'$. The thin line was calculated for spheres of 25-nm diameter with an index of 1.39 immersed in a medium of index 1.35 at 600 nm, g = 0.025. The thick line was calculated for spheres of 500-nm diameters with all other parameters the same, g = 0.948.

from an object is equally likely in the forward and backward directions and is near 1 when scattering is primarily forward directed. The reduced scattering coefficient, μ_s , is quite intuitive; it is greater for a substance that appears more scattering, such as whole milk compared to skim milk. In contrast, two scattering suspensions with the same scattering coefficients may appear quite different. A suspension in which scattering is forward directed will not appear to scatter light as strongly as a scattering medium in which scattering is equally likely in the forward and backward directions. In tissue, most light scattering is forward directed; in other words the deflection angle, θ , is on average quite small.

The identity of the morphological features that scatter light is not known with certainty and is an active area of research. Several structures have been proposed, including the cell membrane, the nucleus, mitochondria, and features within these and other organelles. The size, shape, and refractive index of tissue and cellular structural features determine how light is scattered. Figure 29.1 demonstrated how size affects the wavelength dependence of the scattering coefficient, μ_s . The size shape and refractive index also strongly influence the angular dependence of scattering at each wavelength. For example, as shown in Figure 29.5, particles much smaller than the measurement wavelength scatter light equally in the forward and backward directions, while light scattering from particles with dimensions on the order of the measurement wavelength is primarily in the forward direction.

The intensity of the collected light depends strongly on $P(\theta)$ and consequently on details of tissue structure. When the light source and collection areas are adjacent⁷ and especially if they overlap,⁸ the intensity of collected light correlates with the probability of high angle scattering events. For these measurement geometries, the details of $P(\theta)$ are quite important. As the separation between the small area of light delivery and the small area of light collection is increased, the dependencies of the collected light on the probability of large angle scattering events and on the details of $P(\theta)$ decreases. In fact, at larger separations (centimeters), only μ_s' and μ_a are needed to predict light collection and the diffusion approximation becomes valid. In this chapter, we are only interested in measurements with small source–detector separations because that geometry provides the greatest sensitivity to details of light-scattering properties. A further advantage of small distances between light delivery and detection is that the measurements can be made using fiber optics through the working channel of an endoscope. This feature enables access to many of the epithelial layers of tissue where most adult cancers arise.

29.2 Clinical Studies

Several small-scale, in vivo clinical trials have demonstrated the potential of elastically scattered light to diagnose tissue pathologies. Results of these trials are commonly presented in terms of the sensitivity

and specificity for detecting a specified abnormality. Sensitivity is defined as the percentage of abnormal samples that the test found to be abnormal, whereas specificity is the percentage of normal samples that the test found to be normal. These two metrics can sometimes provide a quantitative method for comparing studies; however, the numbers should be interpreted with care. In many of the early studies, separate training and testing data sets were not used. Consequently, the reported sensitivity and specificity may be higher than they would be if determined with an independent data set. Furthermore, the gold standard used for these studies, histopathology, is not perfect; therefore, a sensitivity of 100% means that the test agrees with the pathologists, not that 100% of the abnormal samples were detected.

The measurement methods used in the following studies varied significantly. Methods for optimizing sensitivity to tissue pathology based on a detailed understanding of the physics and biology of light scattering in tissue are discussed in subsequent sections. The clinical studies described here will hopefully motivate that discussion by demonstrating the potential of light transport to provide clinically relevant information.

Skin is the most accessible organ for testing light-scattering methods for cancer diagnosis. Consequently, the earliest work examined lesions of the skin. Research in this area is still motivated by a need for noninvasive methods to distinguish melanoma from benign pigmented lesions (nevi). The earliest work involved only a small number of *in vivo* measurements⁹ and concentrated on the absorption properties of skin due to melanin and hemoglobin. Attempts to understand these spectra have led to a detailed understanding of the optical properties of skin. 12–14 In studies with a greater number of patients, statistical methods were applied to determine the significance of the results. Measurements of 31 primary melanomas and 31 benign nevi were made using a modified integrating sphere with a standard ultraviolet–visible spectrophotometer over the spectral range of 420 to 780 nm. The data were used to develop discriminant functions. A sensitivity of 90.3% and a specificity of 77.4% were obtained for distinguishing the melanomas from nevi with leave-one-out cross validation. 15

More recently, wavelength-dependent reflectance images of skin have been obtained. Light that entered the tissue and was scattered back to the surface as well as reflection off of the tissue surface was measured, making interpretation of the multispectral images difficult. It was noted that images of benign lesions fade faster with increasing wavelength than do images of cutaneous melanoma. The analysis of the data, however, did not make use of the wavelength dependence of any features, but rather used properties of individual images, such as lesion size and border irregularity. A sensitivity of 80% and a specificity of only 51% were obtained on the training data set.

A recent study by V.P. Wallace et al. measured the diffuse-reflectance spectra of skin over the spectral range of 300 to 1100 nm without any artifacts due to surface reflectance.¹⁷ These data were analyzed using multivariate discriminant analysis and artificial neural networks.¹⁸ The best results were obtained with the artificial neural network and yielded a sensitivity of 83.6% and specificity of 85.3% for diagnosing melanoma compared to compound nevi for the training set. When the artificial neural network was applied to new cases, the sensitivity and specificity changed to 90.9 and 58.8%, respectively.

As with most cancers, the survival rate for bladder cancer increases with early detection. While most frank tumors can be detected by a clinician, some flat (early) cancerous lesions are indistinguishable from inflammation. One of the earliest endoscopic clinical studies of elastic-scattering spectroscopy involved ten patients undergoing examination for bladder cancer. Light was delivered using fiber optics with a center-to-center separation of about 350 µm at the distal end of the probe, which was placed in contact with the tissue. With knowledge of the pathology for each measured spectra, the slope from 330 to 370 nm found to be a diagnostic criteria with a sensitivity of 100% and a specificity of 97%. Koenig et al.²⁰ have also tested scattering spectroscopy for sensing bladder cancer, but with distributed illumination of the tissue. They sensed the changes in hemoglobin absorption due to increased perfusion in neoplastic areas, but did not sense the spectral differences associated with structural changes. Consequently, the sensitivity was good (91%) but the specificity was poor (60%), because simple inflammation also causes increased perfusion. As with the previous study, the method has not been tested on a separate data set.

Several diseases of the gastrointestinal tract have been correlated with increased risk for the development of adenocarcinoma, including Barrett's esophagus, Crohn's disease (in the colon), and chronic ulcerative colitis of the colon. Consequently, clinical tests for diagnosis of cancer in the gastrointestinal tract have been performed. In an early study of 60 sites in the colon and rectum of 16 patients, a spectral metric was developed based on the regions of the hemoglobin absorption bands (400 to 440 nm and 540 to 580 nm). Eight sites diagnosed under histopathology as being dysplasia (a potentially premalignant condition), adenoma (premalignant growth), or adenocarcinoma were differentiated from sites of normal mucosa or more benign conditions such as hyperplastic polyps or quiescent colitis. The sensitivity of this metric on the set of data used to generate the metric was 100% with a specificity of 98%.²¹

A very clinically relevant study of the colon with both training and testing data sets has been published by Ge et al. ²² in which adenomatous polyps, which must be removed, and hyperplastic polyps, which do not need to be surgically resected, were distinguished. Three methods for spectral classification were tried: multiple linear regression, linear discriminant analysis, and neural network pattern recognition. The best predictive sensitivity and specificity were 89 and 75%, respectively, obtained using multiple linear regression. In a third study of the colon, diffuse reflectance spectra of 13 patients were measured and analyzed to obtain information on specific morphological and biochemical features. ²³ These data were analyzed by applying the diffusion approximation to the transport equation in order to separate the effects of scattering and absorption. While the use of the diffusion approximation is possibly inappropriate because of the close proximity of the light detection and delivery fibers and may lead to systematic errors, this approach does have the advantage of yielding quantitative results. Hemoglobin concentration was significantly increased in the adenomatous polyps as compared to the normal mucosa, while hemoglobin oxygenation was essentially unchanged. Effective scatter density was decreased and effective scatterer size increased in the adenomatous polyps.

A few studies of light scattering for the diagnosis of dysplasia in patients with Barrett's esophagus have also been performed. M.B. Wallace et al. measured spectra at 76 sites in 13 patients.²⁴ These data were analyzed by a model assuming two components to the scattered light. One component is light that has been diffusely reflected and has an intensity that decreases monotonically with wavelength; the other is assumed to be an oscillatory component due to scattering from epithelial nuclei. After using eight samples to define the criteria for classifying the samples, the spectra were prospectively analyzed resulting in a sensitivity of 90% and a specificity of 90% for detecting dysplasia.

Bigio et al. measured spectra at 67 sites in 39 patients with Barrett's esophagus.²⁵ These data were analyzed using artificial neural networks and hierarchical cluster analysis. Sensitivity and specificity were calculated using 80% of the data for training, 20% for testing, and repeating this method five times until the sensitivity and specificity were determined for all of the data. The best results were obtained with hierarchical cluster analysis and resulted in an average sensitivity of 82% and an average specificity of 80%.

Light-scattering methods have also been combined with fluorescence to increase the accuracy of diagnosis of dysplasia in patients with Barrett's esophagus. In a study of 15 patients, the combined methods were able to separate dysplasia from nondysplastic Barrett's with a sensitivity and a specificity of 100% using leave-one-out cross validation.²⁶

The advantages of early detection for cervical cancer have been demonstrated by the Papanicolaou (Pap) smear. However, the Pap smear has limitations such as sampling errors and a low sensitivity.²⁷ Nordstrom et al. have studied the ability of reflectance spectra to identify the stages of cervical intraepithelial neoplasia (CIN) in 41 patients.²⁸ Their measurements used flood illumination in a geometry that did not block the surface reflectance and consequently caused reduced sensitivity to the spectral differences associated with structural changes. They obtained a predictive sensitivity and specificity of 77 and 76%, respectively, for distinguishing CIN II/III from metaplasia.

Georgakoudi et al. demonstrated that when light-scattering methods are combined with fluorescence, the sensitivity and specificity for detecting squamous intraepithelial lesions increases substantially. Using pathology as the gold standard, and leave-one-out cross validation, their method had a sensitivity of 92% and a specificity of 71% for detecting squamous intraepithelial lesions vs. mature squamous epithelium or squamous metaplasia.²⁹ Richards-Kortum's group has investigated the application of reflectance spectroscopy to

additional gynecological cancers. In an exploratory study of ovarian cancer with 18 patients, Utzinger et al. were able to separate ovarian cancers retrospectively from normal ovary and benign neoplasms with a sensitivity of 86% and specificity of 80%.³⁰

Clinical studies have also addressed applications to assist in the diagnosis and management of breast cancer. If a reliable method of diagnosing lesions through a needle could be developed, thousands of lumpectomies could be avoided each year in the United States alone. In the surgical arena, elastic-scattering spectroscopy could potentially assist the surgeon in determining tumor margins. An *in vivo* study of 72 biopsy sites in 24 patients has been performed; 80% of the data was used for training and 20% for testing of an artificial neural network. This procedure was repeated five times with disjoint testing sets and the average sensitivity and specificity for separating cancerous breast tissue from noncancerous breast were calculated to be 69 and 85%, respectively.³¹ Another important diagnostic criterion in the evaluation of breast cancer is the involvement of the sentinel node, which is the first lymph node that drains the part of the breast containing the tumor. In the same breast cancer study cited above, hierarchical cluster analysis was used to separate involved from noninvolved sentinel nodes with a sensitivity of 91% and a specificity of 77%.

Another potential clinical benefit of optical light-scattering measurements using small probes is identification of tissues during brain surgery. Johns et al.³² investigated the use of scattering spectroscopy to distinguish gray matter from white matter *in vivo*. This identification is important for surgeries such as pallidotomy, a treatment for Parkinson's patients. For this treatment the boundary of the globus pallidus, a structure composed of gray matter surrounded by white matter, must be accurately determined. The ability of reflectance spectroscopy in combination with fluorescence spectroscopy to identify brain tumors and infiltrating margins *in vivo* has been investigated by Mahadevan-Jansen and co-workers.³³ Using a two-step empirical discrimination algorithm, they obtained a retrospective sensitivity of 100% and a specificity of 76%.

29.3 Increasing Sensitivity to Structures of Interest

The details of the measurement geometries employed in the studies described above varied. This variation is likely to have influenced the reported sensitivities and specificities. An active area of research has been, and continues to be, the development of measurement methods to enhance the ability of elastic light scattering to detect cancerous and precancerous changes. Most cancers originate in the epithelium, which is typically 100 to 300 μ m thick. Consequently, methods that only probe this top layer of tissue are desired. The separation of the source and detector is one controlling factor for sampling the top layer. As the source and detector are moved closer together a more superficial region is probed. If the illumination and detection areas overlap, the sensitivity will be further restricted to the epithelium.

Some of the probes designed by the biomedical spectroscopy group at MIT have this quality. By placing a quartz wedge on the probe surface, they were able to have overlapping light delivery and collection without interference from surface reflectance.²³ The use of a single fiber with a beveled tip for light delivery and detection can also increase sensitivity to the top surface. Measurements with linearly polarized light can be used to reject some of the multiply scattered light from deeper than the tissue layer of interest. An example of linearly polarized light is light propagating perpendicular to and toward the tissue surface while the electric field is oscillating in a direction parallel to the tissue surface (such as parallel to a line connecting the source and detector fibers). If polarized light incident on tissue returns to the surface after only a few scattering events, the polarization is likely to be very similar to the incident light polarization. If light penetrates more deeply into the tissue, the polarization will be randomized.

Measurement systems can be set up for which the light incident on the tissue is linearly polarized and the intensities of light returning to the surface with the same polarization or a perpendicular polarization are separately collected. Subtraction of these two light intensities is a measure of scattering near the tissue surface. Jacques et al. have demonstrated that when imaging with polarized light, they could obtain images that only pertained to approximately the top 265 µm of skin.³⁴ Backman et al. used broadwavelength, polarized light scattering to isolate light scattered from near the tissue surface. Measurements

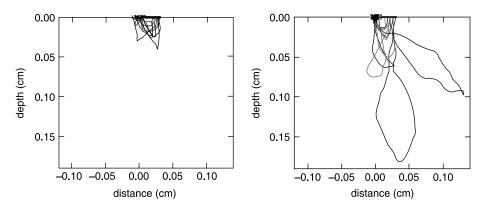

FIGURE 29.6 Trajectories for light transport through tissue calculated using Monte Carlo simulations. For both simulations, the scatterers were 500-nm radii spheres at a concentration such that the scattering coefficient was 245 cm⁻¹ leading to a reduced scattering coefficient of 12.4 cm⁻¹ at 600 nm. For the graph on the left, there was no absorption; for the graph on the right absorption was 1 cm⁻¹. The entry points for all trajectories are marked with crosses that lie between –0.01 and 0.01 cm; a black bar marks the position of the collection fiber, 0.01 to 0.03 cm. The trajectories have been projected onto the plane containing the delivery and detection fibers. Many more photons were run in the Monte Carlo simulation. The average trajectory length for the case of no absorption was found to be 0.30 cm; when absorption was present, the average trajectory length was 0.17 cm.

were made individually of the light intensities scattered with polarizations parallel to or perpendicular to the incident light polarization, and the two intensities were subtracted.³⁵ Sokolov et al. have also made measurements of the diffuse reflectance of polarized light that are particularly sensitive to scattering near the surface.³⁶ In addition to localizing the measurement volume to the epithelium, these techniques are reported to provide quantitative characteristics of nuclei and are discussed in more detail in Section 29.6.

A third way to focus measurements primarily on the epithelium and not the underlying tissue is to make measurements of tissue morphology using wavelengths of light that do not penetrate deeply into tissue. When diffuse reflectance measurements are made at wavelengths that strongly absorb light, a shallower region of tissue is probed and the distance traveled in tissue is reduced. These results are illustrated in Figure 29.6, which shows typical trajectories for collected photons, as calculated by a Monte Carlo simulation. (This technique is described later in the chapter.) Representative trajectories for light transport with absorption are plotted on the left, while trajectories with no absorption are plotted on the right. For the case of absorption, the trajectories are quite short. In the case of no absorption, there are very few short trajectories; most are medium to long in length. By keeping the statistics on a large number of collected photons, the average pathlength for the case of no absorption was found to be 0.30 cm, and when absorption was present the pathlength was 0.17 cm. Similarly the median depth of scattering interactions changed from 0.062 to 0.037 cm. Light cannot penetrate deeply into tissue at wavelengths for which hemoglobin absorbs strongly. Therefore, if methods can be developed for measuring tissue morphology and architecture with only a single wavelength, then measurements that probe different tissue depths can be potentially achieved by using different wavelengths.

Techniques that use linearly polarized light, in a geometry different from that described above, are being developed to quantify the effective size and concentration of scattering centers in cells. This work will be described in more detail in Section 29.6. The basic physics of polarized light propagation in scattering media is still under active investigation. Yao and Wang have presented time-resolved movies of polarized light propagation in turbid media.³⁷ The preservation of polarization in lipid, myocardium, and polystyrene spheres has been studied in detail,^{38,39} and methods for examining light scattered from tissues in the exact backscattering direction have also been developed.⁴⁰

29.4 Understanding the Origins of Light Scattering in Tissue

The development of measurement systems to sense small changes in tissue and cellular architecture can be facilitated by an understanding of what structures in tissue are responsible for the scattering of light. In particular, the development of measurement systems may be improved with knowledge of the properties of light scattered from specific structures. Furthermore, the analysis of diffuse reflectance measurements, in terms of particular tissue or cellular structures, requires an understanding of scattering properties for specific architectural features.

Light scattering occurs at refractive index boundaries. As examples, light will scatter off an interface between two media of different indices, or from a sphere with an index of refraction different from its surrounding medium. Tissue is composed of materials with different refractive indices. For example, membranes have a higher index than water and will scatter light. Similarly high concentrations of DNA or protein can also scatter light. A wide variety of physical structures contain high concentrations of lipid, protein, or DNA within mammalian cells. Nuclei are on the order of 5 to 10 μm in diameter;⁴¹ mitochondria, lysosomes, and peroxisomes have dimensions on the order of 0.2 to 2 μm.⁴² Ribosomes are on the order of 20 nm in diameter⁴³ and structures within various organelles can have dimensions up to a few hundred nanometers. Refractive indices for some of these organelles have been compiled.⁴⁴ In liver tissue, mitochondria have been demonstrated to be a significant source of scattering.^{45,46} Also for liver tissue, Schmitt and Kumar demonstrated that the spectrum of index variations exhibits a power-law behavior for a wide range of spatial frequencies.⁴⁷

Models of tissue having a broad range of discrete particle sizes have been proposed; calculated scattering properties compared well with those available in the literature. Further evidence for a broad size range of architectural features contributing to tissue light scattering comes from experimental measurements of light scattering from epithelial cells. Because the epithelium is primarily a cellular structure without much intracellular material, studying scattering from only the cells is quite relevant. The size distribution of refractive-index structure variations in epithelial cells was found to include particles with effective radii from smaller than a few hundred nanometers to \sim 2 μ m. There are orders of magnitude more structures the size of macromolecules than there are particles the size of organelles scattering light. Onsistent with results that most scatterers are small, cell shape and cell—cell contact were found to have only very minor effects on light scattering. Furthermore, the result that much of the light scattering occurs from structures a few hundred nanometers or less in radius implies that light scattering is likely to be sensitive to some structures smaller than those commonly investigated by standard pathology methods.

As discussed earlier, the importance of high angle scattering events for determining the intensity of collected light is increased when the separation between the illumination and light collection locations is reduced. Therefore, changing the source–detector separation may change the contribution of different structures to the elastic-scatter signal, if the contribution of various structure sizes to light scattering varies with scattering angle. There is evidence that different physical structures within cells are responsible for scattering at different angles. Cell size can be determined by measurements of scattering in the angle range of $\theta = 0.5$ to $1.5^{\circ}.^{51}$ Scattering at angles between about 2 and 25° has been attributed to scattering from the nuclei. Measurements of Chinese hamster ovary (CHO) cells showed a fine structure between $\theta = 2.5$ and 25° that could be modeled as a coated sphere, i.e., a nucleus surrounded by cytoplasm, although for HeLa cells no fine structure was observed.⁵²

Both experimental and modeling work indicate that small internal structures have a strong influence on the scattering pattern at angles greater than 40°.44,53 Consequently, a decreased source–detector separation may increase the relative contribution of small structures to the measured diffuse reflectance. The contribution of the nucleus to light scattering from biological cells has been a topic of investigation by several groups because of the known changes in the nucleus accompanying carcinogenesis, including an increased nuclear-to-cytoplasmic ratio and changes in nuclear structure, one of which is apparent in histopathology as hyperchromaticity (dark irregular staining of DNA).

For fibroblast cells, less than 40% of the scattered light at any angle was determined to have been scattered from the nucleus.⁵³ Finite difference time-domain methods, which can calculate scattering from objects with very inhomogeneous index of refraction structures, have been used to study potential contributions of nuclei to light scattering.^{44,54} Consistent with the idea that the nuclei contribute significantly to scattering at angles less than 25°, increasing the size of the nucleus increased the forward scattering.

If the nucleus is heterogeneous, high angle scattering also increases with nuclear size. 44 There is experimental evidence for nuclear heterogeneity. A determination of the size distribution of scattering centers within nuclei isolated from epithelial cells found that the size of scattering structures ranged from less than a few hundred nanometers to 2 μ m. 49 Not only is the physical composition of biological cells very heterogeneous, but so also is the composition of the nuclei within them. A correlation between DNA content and light-scattering properties has been observed. When cells are growing exponentially, their DNA content is increased compared to cells in the plateau phase of growth. Light scattering measurements of cells harvested in the exponential phase of growth showed stronger backscattering and a steeper decrease in scattering as a function of wavelength than did cells harvested in the plateau phase of growth. Both these scattering changes are indicative of an increased concentration of small scattering centers.

Nearly all of the research described here focused on understanding scattering from cells. Scattering from tissue layers underlying the epithelium has not been as well studied. Mechanical support for most epithelial layers is provided by the lamina propria, a thin layer of connective tissue with a large collagen content. Muscle tissue commonly underlies the lamina propria. Studies of skin provide a small amount of information relevant to the lamina propria because skin also contains a large amount of collagen, although the organization of collagen fibers in the lamina propria varies with the organ studied and, therefore, may be different from the organization of collagen fibers in skin. The large collagen fibers from the dermis of the skin can be one of the primary sources of scattering from skin; microscopic changes in collagen fibers have been correlated with macroscopically observed light-scattering changes.⁵⁵ Collagen fibers can also cause an anisotropy in the macroscopically measured light scattering. The measured reduced scattering coefficient of the skin can vary by a factor of two depending on the measurement orientation.⁵⁶ Muscle also demonstrates large scale anisotropy, particularly with polarized light.⁵⁷

Several microscopic methods for examining the spatial variations of the angular scattering probability, $P(\theta)$, are under development. A microscope-based, light-scattering instrument that can measure the angular dependent scattering of an 80- μ m spot from 0 to 60° has been developed.⁵⁸ The ratio of wide angle to narrow angle scatter can be examined at microscopic resolution;⁵⁹ an interferometric method for measuring of scattering at angles near 180° has been demonstrated⁶⁰ and could potentially be integrated into a microscopic imaging system.

29.5 Monte Carlo Methods

An important tool for developing and understanding elastic-scattering spectroscopy has been Monte Carlo simulation of light transport.^{61,62} In a Monte Carlo simulation, a photon is injected into a scattering medium and then propagated through the medium based on knowledge of μ_s , μ_a , and $P(\theta, \phi)$ for the scattering medium. Photon propagation is then simulated, typically, for millions of photons. A common assumption is that the scattering centers are spherical. In this case, all ϕ are equally likely and $P(\theta)$ can be calculated using a solution to Maxwell's equations for a plane wave incident on a sphere, called Mie theory.⁶³ Henyey–Greenstein phase functions, which resemble phase functions computed by Mie theory, are sometimes used.⁶⁴ The advantage of Henyey–Greenstein phase functions is their simple analytical form; however, they cannot be used in simulations of polarized light scattering or to simulate scattering from nonspherical particles. In principle, the scattering centers could be ellipsoids of revolution or other particles because computational codes for calculating scattering parameters from these shapes are now available.⁶⁵ In fact, the evidence is that, when polarized light propagation in tissue is simulated, a model

using spherical particles will not be adequate. Ellipsoids of revolution or other nonspherical particles must be used because the physical structures in epithelial cells do not scatter light like spherical scatterers.⁴⁹

Monte Carlo simulations are particularly useful for determining features of light transport that are not easily measured, such as the depth to which light penetrates into tissue before being collected, the length of the path the light travels in tissue, and the polarization of light within the tissue. The degree of polarization in a scattering medium as a function of depth and lateral distance from the delivery point can be seen in simulations by Yao and Wang.³⁷ The depth probed as a function of the incident and detected light polarization for fixed source-detector separations has also been examined using Monte Carlo simulations.⁶⁶ The depth probed depends on the collected polarization relative to the incident polarization. As expected from the discussion in Section 29.3, a deeper depth can be probed when the collected light is polarized perpendicular to the incident light polarization. A less intuitive result is that the depth probed when the incident and collected polarizations are the same depends on the measurement geometry.

Consider two collection fibers, each 550 μ m from the light delivery fiber, such that a line connecting the first collection fiber to the delivery fiber and a line connecting the second collection fiber to the delivery fiber form a right angle. If the polarization for delivery and collection is oriented along one of the lines, then the depth probed by the fiber connected by that line will be greater. For example, for $\mu_s' = 15$ cm⁻¹, $\mu_a = 2$ cm⁻¹, and g = 0.61, the median depth probed is 230 μ m for one of the collection fibers and ~ 300 μ m for the other. Regardless of polarization, the depth probed decreases with fiber separation. The depth probed when using a single fiber-optic for delivery and for detection of unpolarized light is 170 μ m for a similar highly scattering medium with $\mu_s' = 15$ cm⁻¹, $\mu_a = 2$ cm⁻¹, and g = 0.83.8 (There is an error in Table 2 of Reference 8: cm⁻¹ should be mm⁻¹.)

Monte Carlo simulations indicate that, with a fiber optic probe separation of 250 μ m, primarily the epidermal layer and papillary dermis of skin are probed. Monte Carlo simulations also make clear that the distance photons travel in tissue is much greater than the depth they probe. When the mean path length within myocardium for diffusely reflected light is 1.3 mm, the depth examined is only ~365 μ m. Measurements of the average distance traveled by light in tissue between the delivery and collection fiber have been calculated for a few different sets of light transport parameters. For example, when the source and detector are separated by 1.75 mm and the absorption is 0.01 mm⁻¹, the distance traveled by light in the tissue is about 10 mm. As discussed in Section 29.7, at this fiber separation, the distance light travels between the source and detector does not depend strongly on the scattering properties. Finally, the distribution of scattering angles of the scattering events undergone by light that reaches the collection fiber can be calculated using Monte Carlo simulations. When the source and detector are in close proximity, e.g., 200 or 250 μ m apart, the collected photons undergo significantly more high angle scattering events than do photons that entered the tissue, but were not collected. Monte Carlo methods are also used for the determination of quantitative optical properties from experimental measurements as described in Section 29.6.

29.6 Quantification of Morphological and Biochemical Properties

An ultimate goal of several research groups is to provide quantitative biochemical and morphological information from noninvasive optical measurements of tissue. Georgakoudi et al. provide a review of much of the work in this area using a wide variety of techniques (see Chapter 31 of this handbook). Here, we discuss methods aimed at obtaining quantitative information from wavelength-dependent, light-scattering measurements.

In order to develop methods for quantifying optical properties or specific morphological parameters, it is necessary to have well-characterized media for which the optical and morphological properties are known. Tissue is much too complicated to use and requires special handling procedures. Consequently, tissue phantoms are frequently used. Two common phantoms are intralipid and suspensions of polystyrene

spheres. Intralipid is a fat emulsion consisting of soybean oil, glycerin, lecithin, and water. 71,72 Small vesicles formed primarily of soybean oil scatter light; polystyrene spheres can be used to make tissue phantoms with precisely known properties. Measurements of these phantoms can be compared directly to theory. The disadvantages of phantoms made with polystyrene spheres are that the relative index of polystyrene in water is very different from that of biological materials in water and the broad distribution of structure sizes found in tissue is hard to reproduce with polystyrene spheres. Absorbing materials, such as oxy- or deoxyhemoglobin can be added to intralipid of polystyrene sphere suspensions and both types of phantoms have proven very useful in the development of quantitative methods.

When the source and detector are sufficiently separated, the diffusion approximation to the transport equation can be applied and the absorption coefficient, μ_a , and reduced scattering coefficient, μ_s' , calculated. Initially, this method was demonstrated to measure the absorption of methemoglobin⁷³ using a frequency-domain system — a more intricate measurement system that oscillates the incident light.^{74,75} The addition of broad-wavelength, steady-state techniques to frequency-domain measurements performed only at a few wavelengths can improve the accuracy of absorption measurements.⁷⁶ Steady-state illumination alone can be used^{77–81} and the concentration of cytochrome and hemoglobin quantified in scattering suspensions containing mitochondria and red blood cells.⁸¹ A probe with an oblique angle of light incidence has also been developed for separately measuring absorption and the reduced scattering coefficient using a steady-state source.^{82,83}

When the source–detector separation, ρ , and the reduced scattering coefficient, μ_s' , have values such that their product, $\rho\mu_s'$ is less than about 2, the diffusion approximation is no longer valid. This limit of applicability of the diffusion solution depends on several additional factors such as absorption, numerical aperture of the fiber, and details of $P(\theta)$. A Consequently, different researchers have found different limits for the validity of the diffusion approximation. The value of 2 stated above for the source-detector separation is smaller than values obtained and discussed by Bevilacqua and Depeursinge.

Modifications to diffusion equation solutions have been made in order to increase their accuracy. Venugoplan et al. have presented an extension of the standard diffusion approximation that shows improved agreement with experimental results at small fiber separations and high absorption. For A different improvement on the diffusion approximation is the P_3 approximation. For the diffusion approximation, the radiance and source term of the Boltzmann transport equation are expanded in spherical harmonics and terms up to $\ell=1$ are kept. The P_3 solution keeps terms up to $\ell=3$. This solution demonstrates significantly improved results for the determination of optical properties, particularly for the determination of large absorption coefficients (>0.25 mm⁻¹) when light transport is measured with relatively small (<1 cm) source–detector separations. See

Multiple polynomial regression methods⁸⁹ and an iterative Monte Carlo method⁹⁰ have been proposed as methods to more accurately determine tissue optical properties using source–detector separations less than 1 cm. An iterative Monte Carlo method has been applied to hyperspectral data. When reflectance data measured over the range of 0.5 to 2.5 mm from the source location were used, the accuracy of calculated μ_a and μ_s' were ± 12 and $\pm 4\%$, respectively.⁹¹ A fast perturbative Monte Carlo method can accurately quantify changes in μ_a or μ_s' . In test cases using layered media with a top layer thickness of only 0.5 mm and detectors up to 3 mm from the source, excellent results were obtained for μ_a and μ_s' perturbations in each layer.⁹²

Many of the papers cited in the previous paragraph used Henyey–Greenstein phase functions. When $\rho\mu_s'$ is small enough that the diffusion approximation does not hold, the intensity of collected light will depend on details of the phase function. For example, with $\rho\mu_s'=2.4$, Monte Carlo simulations of photon transport demonstrate that the intensity of light collected can be 60% greater when a Mie phase function is used rather than a Henyey–Greenstein phase function, assuming the other scattering parameters, g, μ_s , and μ_a , are held constant. Bevilacqua and Depeursinge have determined the effect of the moments of $P(\theta)$ on light transport. The first moment is g; the second moment is given by

$$g_2 = \int_0^{\pi} \frac{1}{2} (3\cos^2 \theta - 1) P(\theta) \sin \theta d\theta \tag{29.2}$$

An important result from their work is that, from $\rho\mu_s'>0.5$ up to values for which the diffusion equation holds, light transport can be described by three parameters: μ_s' , μ_a , and $\gamma=(1-g_2)/(1-g_1)$. A procedure to determine μ_s' , μ_a , and γ from diffuse reflectance data, taken at several fiber separations from 0.3 to 1.4 mm, resulted in values of μ_s' with errors <10% and values of μ_a accurate to approximately 0.01 mm⁻¹. 93

So far the quantification of morphological and biochemical properties has been stated as the quantification of light transport properties. As an alternative to quantifying μ_s or μ_a and the properties of the angular dependent scattering function, it may be useful to determine the effective size of scattering structures and their concentrations directly. Methods using polarized light are being developed to quantify morphological properties directly. At least two separate approaches are being taken. One method is based on the observation of interesting optical patterns generated by the propagation of polarized light many years ago. A crosslike pattern was observed over the macular area of the eye when the macula was photographed using crossed polarizers as early as 1978.94 The physical origin of pattern features is well understood^{95–99} and methods for obtaining effective scatterer size and concentration from polarized backscattering images of polystyrene sphere suspensions have been described. 100 Recently a fiber-optic method for measuring polarized light scattering that can determine average scatterer size and density of polystyrene spheres was demonstrated.66 Polarized fiber-optic and imaging measurements of cell suspensions also provide information about scattering structures. 66,101,102 For example, the apparent size of scattering centers in tumorigenic MR1 rat fibroblast cells is greater than the apparent size of scattering centers in nontumorigenic M1 rat fibroblast cells as determined by polarization images obtained with circularly polarized light. 102

The other method, mentioned in Section 29.3, subtracts measurements of light returning to the same location on the surface with polarizations parallel and perpendicular to the incident light polarization. When the subtraction is performed as a function of wavelength, the resulting spectrum can be fit to a theoretical expression for scattering from spheres. Backman et al. have assumed that this spectrum is due to backscattering from nuclei, and they report that the distribution of cell-nucleus sizes obtained agrees with microscopic measurements of nuclear size. This technique has also been implemented in an imaging geometry, for which the analyses to determine nuclear size and refractive index are performed for each $25 \,\mu\text{m} \times 25 \,\mu\text{m}$ pixel. The section is a performed for each $25 \,\mu\text{m} \times 25 \,\mu\text{m}$ pixel.

Sokolov et al.³⁶ have also made measurements of the diffuse reflectance of polarized light. Specifically, they measured the depolarization ratio,

$$[I_{||}(\lambda) - I \perp (\lambda)]/(I_{||}[\lambda) + I \perp (\lambda)],$$

for epithelial cells in phosphate buffered saline above a highly scattering medium. They assumed a cell in phosphate buffer consisted of two independent scatterers: a spherical nucleus in an environment with the refractive index of cytoplasm and a spherical cytoplasm in an environment with the refractive index of water. Additionally, their model assumes that the wavelength-dependent scattering is a linear sum of forward and backward scattering from these spheres. With this model they were able to obtain wavelength-dependent fits to the data using sphere sizes similar to those obtained for the cells and nuclei by phase-contrast microscopy.

29.7 Other Applications

In addition to the diagnosis and detection of cancer, elastic-scattering spectroscopy may be used for diagnosing other tissue pathologies, for tissue identification, and for monitoring changes to tissue. Freezing of tissue is used in cancer treatment (cryosurgery) and in tissue preservation and transplantation. For these

applications, it is important to know the location of the ice-front boundaries. Benaron and co-workers found that there is a large overall intensity change in the transmitted light upon freezing. ¹⁰⁴ The opposite of cryosurgery, thermotherapy, also affects the optical properties of tissue. There is an increase in absorption, probably due to accumulation of erythrocytes and a decrease in the size of scattering centers. ¹⁰⁵

Applications of reflectance spectrometry have also been developed for measurement of bilirubin concentration on the market. One of the difficulties with measuring absorption in tissue is that the distance traveled by light between the source and detector is not known and depends on the scattering properties, which are generally also not known. In order to mitigate this problem, an illumination—detection separation can be chosen for which the effect of scattering variations on the pathlength is weak. Mourant et al. have demonstrated that, for a source—detection separation of ~1.7 mm, the variation in pathlength for a large range of scattering properties found in tissue (5 to 20 cm⁻¹) is less than about 20%. This result is being further developed to measure the pharmacokinetics of investigational drugs. The basis of the technique is a simple manipulation of Equation 29.1, given by

$$\log[I(t)/I_0] = \mu_a L \tag{29.3}$$

where I(t) is the intensity of light measured at time t after a drug was administered, I_0 is the intensity of light measured before the drug was administered, μ_a is the absorption coefficient, and L is the distance light travels through the tissue. By measuring with a geometry (shown in Figure 29.3) using a distance of ~1.7 mm between the illuminating and collecting fibers, the dependence of pathlength on variations in scattering coefficient can be substantially ignored. However, as mentioned in Section 29.3, the pathlength will still depend on absorption. The dependence of L on μ_a can be parameterized as $L = x_0 + x_1 \exp(-x_2\mu_a)$, where x_0 , x_1 , and x_2 are parameters that depend on details of the measurement probe, such as the exact fiber separation and the numerical aperture of the fibers.

The measurement of drug concentrations in tissue as a function of time using the principles described previously has been named "optical pharmacokinetics" and a proof of principle demonstration of optical pharmacokinetics has been published. The concentration of mitoxantrone (a chemotherapy drug) was followed as a function of time in subcutaneous human cancer tumors grown in nude (immune-suppressed) mice. The conventional method used for pharmacokinetics studies during drug development is animal sacrifice followed by tissue assay. This method is time- and labor-intensive as well as quite costly in terms of laboratory animals required — statistically significant studies require hundreds of animals (multiple animals for each time-point for each dose tested). An alternative method of measuring pharmacokinetics sometimes used in hospitals, microdialysis, is also invasive and utilizes a needle with a semipermeable membrane that may irritate surrounding tissue. Another drawback of microdialysis is that intracellular concentrations cannot be determined. Intracellular concentrations are more significant for understanding the therapeutic dose of a drug than the intercellular concentration.

Single photon emission computed tomography and positron emission tomography have been used to quantify *in vivo* imaging of radiolabeled drugs. 109-111 These techniques do not depend on the optical properties of tissue; however, they do require handling radioactive compounds and using expensive equipment. Also, the spatial resolution of the imaging is limited and subsecond imaging of fast drug dynamics is likely to be difficult. In contrast to animal sacrifice/tissue assay or microdialysis, optical pharmacokinetics is noninvasive and can provide real-time, site-specific measurements of absolute drug concentrations *in vivo*. Measurements over time can determine the entire pharmacokinetic time history (for a given dosage) of a drug at specific tissue sites with just one laboratory animal.

Optical measurements can also be used to assess properties of tumor neovasculature. A fast sequence of measurements made immediately following intravenous administration of a short bolus of optical contrast agent can be used to determine important parameters of angiogenesis. Because tumor capillaries (particularly those that are still immature) in the angiogenesis process are leaky, 112 macromolecules that do not leak from normal capillaries will often pass through the permeable walls of angiogenic microvessels

and can be used to quantify the leakiness of these capillaries and, therefore, the angiogenesis process. 113 Very rapid sequences of optical pharmacokinetics measurements (>2 measurements/second) would permit tracking the fast dynamics of the first-pass kinetics of compounds in neovascularized tissue, and the leakage into the extracellular fluid space, following administration of a short bolus of an optical contrast agent with a known leakage rate.

Thus, possible clinical applications of optical pharmacokinetics include monitoring photodynamic therapy drug concentrations so that the drug can be activated by light at the optimum time, measuring blood pooling, and using first-pass kinetics to monitor neovasculature and assess the response to treatment by antiangiogenic drugs.

29.8 Summary

Elastic-scattering spectroscopy and diffuse reflectance are two terms for noninvasive methods of measuring the propagation of light through tissue to obtain biochemical and morphological information that can be used in diagnosing tissue pathologies. Light is incident on a small area, typically a spot 200 to 400 µm diameter, and enters the tissue where it is scattered or absorbed. Some of the light will return to the surface where properties such as intensity vs. wavelength and polarization can be measured. The properties of the light returning to the surface will depend on some of the structural and biochemical properties of the tissue. Clinical trials using elastic scattering and diffuse reflectance have demonstrated the potential of light scattering to diagnose cancerous and precancerous lesions. For many of these trials, the same set of data was used to calculate the sensitivity and specificity as was used to develop the distinguishing metrics. More prospective clinical studies that have independent testing data sets are now needed to prove the diagnostic accuracy.

The full power of elastic scattering and diffuse reflectance, however, has not yet been realized, partly because the relationship between the biology of the tissue and the physics of light propagation is not completely understood. Such an understanding will facilitate optimization of measurement methods and analysis to provide the most accurate and clinically relevant information possible. Significant progress has been made towards understanding which structural features in tissue are responsible for light scattering and the contribution of light scattering from these structural features to the properties of the detected light intensity.

New methods for quantifying physical scattering properties and biomedically important properties, such as nuclear characteristics or drug metabolism, are being developed. At present few of the methods have been implemented by more than one or two research groups and there are some apparent contradictions in results. For example, the idea that nuclear size can be determined from backscattering measurements may appear to be at odds with evidence that backscattering occurs primarily from structures much smaller than the nucleus and that the nucleus contributes primarily to forward scattering. It is important that published work include the details of measurements and analysis so that other research groups can validate, reconcile, and expand on results. The development of new analysis and measurement methods, along with new technical developments and ideas, will enable diffuse reflectance and elastic-scattering spectroscopy to reach their potentials as tools for the noninvasive characterization of tissue. Information about tissue presently only available by biopsy and histopathology, as well as new information not available via traditional methods, may be provided by light-scattering methods. We hope that in the coming years elastic scattering and diffuse reflectance will be developed into accurate, real-time, noninvasive, and, possibly, hand-held tools for measuring diagnostically relevant characteristics of tissue.

30.1 Introduction

Light can react with tissue in different ways and its response can yield information about the physiology and pathology of tissue. The light used to probe tissue does so in a nonintrusive manner; in contrast to therapeutic applications, very low levels of light are typically used. The use of fiber optics allows light to probe tissue in a minimally invasive manner. Because tissue response is virtually instantaneous, the results are obtained in real time, and data processing techniques and computers allow for automated detection of disease. These factors have resulted in a variety of applications that employ light and optical modalities for tissue diagnosis.

When a photon is incident on a molecule, it may be transmitted, absorbed, or scattered. The various techniques that are based on these different light–tissue interactions include:

- Absorption spectroscopy
- · Reflectance spectroscopy
- Fluorescence spectroscopy
- · Raman spectroscopy

Each of these four techniques has been studied for the purpose of tissue diagnosis with varying degrees of success. Of these techniques, fluorescence spectroscopy is perhaps the most researched one for tissue diagnosis.

Considerable evidence indicates that fluorescence spectroscopy of exogenous (see, for example, Reference 1) and endogenous chromophores can be used to identify neoplastic transformations in the breast,² lung,³ bronchus,⁴ oral cavity,⁵ cervix⁶ and gastrointestinal (GI) tract.^{7,8} Despite the success of this technique, results indicate that fluorescence spectra of precancerous tissues of the cervix and colon and benign abnormalities such as inflammation and metaplasia are similar in many patients.^{6–8} This suggests that the use of fluorescence diagnosis in a screening setting, where the incidence of precancer is expected to be low, may result in an unacceptably high false-positive rate. Many groups consider vibrational spectroscopy to be the solution to these problems because its molecular specificity enhances the specificity of spectroscopic diagnostics. The focus of this chapter is the application of Raman spectroscopy in biomedicine, especially as it pertains to disease detection.

Raman spectroscopy has been used for many years to probe the biochemistry of various biological molecules. 9,10 In recent years, there has been interest in using this technique in diagnostics. 11-14 Most of the diagnostic applications are still in the early stages of development. They range from the detection of (pre)malignant lesions in various organ sites to quantitative detection of blood analytes such as glucose, from measurement of skin hydration to the study of aging. The focus of all of these applications is on quantitative, *in vivo*, nonintrusive, automated detection in a real-time manner.

This chapter describes the concept, instrumentation, and application of Raman spectroscopy as it applies to biomedicine. We begin with a description of the basic concepts underlying Raman spectroscopy and Raman signatures of materials. We then review the past, present, and future directions of instrumentation that facilitates the use of this technique for detection of disease. Finally, we examine sample applications of Raman spectroscopy for disease diagnosis, with reference to work at the molecular and microscopic levels. Although many of the reported articles are based on *in vitro* work, this chapter focuses on the potential of the application of Raman spectroscopy to clinical diagnosis.

30.2 Principles of Raman Spectroscopy

Raman spectroscopy is based on the Raman effect that results from energy exchange between incident photons and the scattering molecules. When the energy of the incident photon is unaltered after collision with a molecule, the scattered photon has the same frequency as the incident photon. This is Rayleigh or elastic scattering. ^{15,16} During the collision, when energy is transferred from the molecule to the photon or vice versa, the scattered photon has less or more energy than that of the incident photon. This is inelastic or Raman scattering (Figure 30.1).

Quantum mechanically, Raman scattering is a result of an energy transition of the scattering molecule to a virtual excited state and its return to a higher (or lower) vibrational state with the emission of an altered incident photon (Figure 30.1). Because energy can be transferred from the photon to the molecule or from the molecule to the photon, the scattered photon can have less or more energy compared to the incident photon. When the scattered photon has less energy than the incident photons, the process is referred to as Raman Stokes scattering. When the scattered photon has more energy than the incident photons, the process is referred to as Raman anti-Stokes scattering.

A Raman spectrum is a plot of scattered intensity as a function of the frequency shift (which is proportional to the energy difference) between the incident and scattered photons (Figure 30.2). The frequency shift is characteristic of the molecule with which the photon collided, and the resulting spectrum is characterized by a series of Raman bands that correspond to the various vibrational modes of that molecule. The locations of the Raman bands are typically presented in terms of relative wavenumbers (or Raman shift) defined as shifts in wavenumbers (inverse of wavelength in cm⁻¹) from the incident frequency, which is set to zero. This is because the location of Raman bands for a given molecule in relative wavenumbers remains constant, regardless of the incident frequency (within the physical constraints of the light—tissue interaction).

Raman signals are usually weak and require powerful sources and sensitive detectors. Typically, Raman peaks are spectrally narrow (a few wavenumbers) and, in many cases, can be associated with the vibration of a particular chemical bond (or normal mode dominated by the vibration of a single functional group)

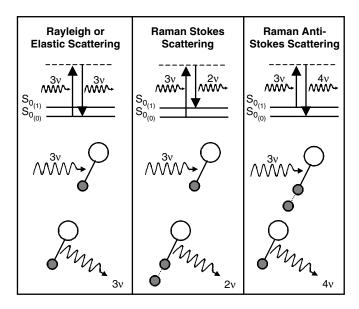

FIGURE 30.1 Schematic illustration of classical and quantum mechanical explanation of scattering.

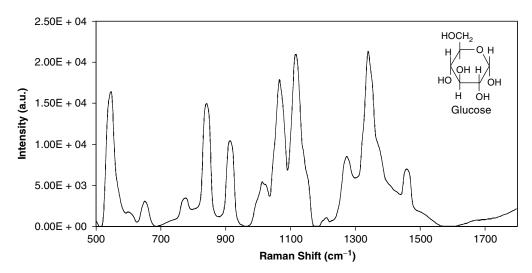

FIGURE 30.2 Raman spectrum of glucose in powdered form obtained with dispersive Raman spectroscopy at 785-nm excitation.

in a molecule. Consider a complex molecule such as glucose (Figure 30.2). Each of the stretching and bending modes of vibration of this molecule has a characteristic frequency. When a photon is incident on this molecule, each mode of vibration results in a characteristic shift in frequency that is indicated in the Raman spectrum. Because each type of bond has characteristic modes of vibration, each type of molecule has its own spectral "fingerprint." Thus, in a complex mixture of molecules such as in tissue, the presence of the unique bands of glucose can be traced; this results in the quantitative evaluation of the sample's chemical composition, which can then be related to the tissue pathology for diagnosis.

Raman spectroscopy probes characteristics of materials other than fluorescence. ¹⁵ The energy transitions of molecules are solely between the vibrational levels. When a photon is incident on a molecule, it may be transmitted, absorbed, or scattered. Fluorescence results from the emission of absorbed energy; Raman scattering results from perturbations of the molecule that induce vibrational or rotational

transitions. Only a limited number of biological molecules such as flavins, porphyrins, and structural proteins (collagen and elastin) contribute to tissue fluorescence, most with overlapping, broadband emission. In contrast, most biological molecules are Raman active with fingerprint spectral characteristics. Indications are that vibrational spectroscopy may overcome some of the limitations of fluorescence diagnosis of precancers and cancers.

Several different modalities of Raman scattering have been used to analyze the structure of various biological molecules. ^{17,18} These techniques include near-infrared (NIR) dispersive Raman, Fourier transform Raman (FT-Raman), surface-enhanced Raman (SERS), and ultraviolet resonance Raman (UVRR) spectroscopy. ^{15,16} In NIR dispersive Raman spectroscopy, NIR radiation typically in the range of 780 to 1100 nm is used for excitation. The advantage of this technique is that minimal fluorescence is produced, thus making detection of the weak Raman signal easier. In FT-Raman spectroscopy, the Fourier transform of the signal is detected and then inversely transformed to give the actual Raman signature. This technique yields improved signal-to-noise ratio (SNR) of hard-to-detect events, but requires high collection times. ¹³ Recent developments in spectroscopic instrumentation have resulted in reduced application of FT-Raman techniques in tissue diagnosis. Thus, while some early results from FT-Raman studies are referenced, the focus of this chapter is on dispersive Raman spectroscopy.

SERS is used to investigate the vibrational properties of single adsorbed molecules. ^{15,16} It was discovered that the rather weak Raman effect can be greatly strengthened (by a factor of up to 14 orders of magnitude) if single molecules are attached to nanometer-sized metal structures. Metal surfaces must be of high reflectivity and of a suitable roughness. In this way, many groups have detected single molecules attached to colloidal silver particles adhered to a glass slide or even in an aqueous solution. The advantages of this method are that it is fast, it can supply some structural information about the molecules, and it does not bleach the molecules. Single-molecule detection is of great practical interest in chemistry, biology, medicine, and pollution monitoring; examples include DNA sequencing and the tracing of interesting molecules such as those used in bioterrorism. Again, because the focus of this chapter is on clinical *in vivo* diagnosis, SERS will not be discussed here.

When the excitation frequency approaches or enters the region of electronic absorption of a molecule, the resonance Raman spectrum of that molecule is obtained. By choosing appropriate excitation frequencies, a sample is selectively excited at the maximum absorption frequency of a characteristic molecule to detect that feature above all else. Resonance excitation increases the scattering intensity by several orders of magnitude. Typical absorption frequencies of biological molecules such as proteins and nucleic acids are in the ultraviolet portion of the spectrum, where the Raman and fluorescence signatures may be spectrally resolved. However, the high intensities may cause photolysis of the sample and destroy it over time. Besides, this signal may be attenuated by simultaneous intensified absorption and fluorescence emission. In addition to these factors, the mutagenicity of UV radiation makes this technique inviable for clinical *in vivo* use. Therefore, UVRR studies are excluded from this chapter.

Many groups have recognized the potential of Raman spectroscopy in the study and diagnosis of disease because of its successful application in biology. Early attempts to measure Raman spectra of cells and tissues were hindered by two factors: (1) the highly fluorescent nature of these samples and (2) instrument limitations, which necessitated long integration times and high-power densities to achieve spectra with good S/N ratios. Improvements in instrumentation in the last decade, particularly in the near-infrared region of the spectrum where fluorescence is reduced, have resulted in a dramatic increase in biomedical applications of Raman spectroscopy. Recent reviews of this field^{11,20–22} illustrate the diversity of potential applications, ranging from monitoring of cataract formation *in vivo*²³ to the precise molecular diagnosis of atherosclerotic lesions in coronary arteries.^{24,25} Reports have begun to appear validating the potential of Raman spectroscopy to diagnose disease in human tissues *in vivo*.^{36,27}

30.3 Instrumentation Considerations

Despite the wealth of information provided by Raman spectroscopy about the structure of biological molecules, early attempts to measure Raman spectra of tissues were limited by two factors: (1) the highly

fluorescent nature of these samples and (2) instrument limitations, which necessitated long integration times and high-power densities to achieve spectra with good S/N ratios. The initial Raman spectra of tissue were measured with visible laser excitation, using primarily the argon laser lines (see, for example, Yu and East²⁸ and Clarke et al.²⁹). With the development of interferometers, FT-Raman spectroscopy was used to measure tissue Raman spectra, typically using 1064 nm (Nd:YAG) for excitation with germanium detectors.¹⁰

The development of diode lasers and cooled silicon CCD cameras sensitive in the near-IR has resulted in a wide range of applications beyond the laboratory. Diode lasers can provide excitation in the region of 750 to 850 nm, which allows the use of silicon detectors (sensitive only to 1100 nm). There are two advantages of this technique: (1) fluorescence emission is reduced and (2) spectra with acceptable SNRs ratios can be achieved with relatively short integration times on the order of a few seconds. Thus, Raman spectroscopy is now commonly used in environmental monitoring and manufacturing. Advances in the Raman instrument by the commercial sector that supplies this industry have positively impacted the application of Raman spectroscopy in biomedicine, making clinical use viable.

30.3.1 Basic Instrumentation

The basic instrument capable of measuring Raman spectra is similar to any spectroscopic system. It consists of a light source, which is typically a laser, light delivery and collection, and a detection system. Figure 30.3 shows a typical clinical Raman system used today.

The weak nature of the Raman phenomenon makes the details of this basic system challenging. These three basic components interact in terms of overall system performance, but as a first approximation they can be viewed as individual components contributing to the system. Significant technological advances in each of these areas have resulted in Raman instruments superior to similar systems from the previous decade. We consider each of the three components of this basic system individually; however each is dependent on the intended use of the system. For example, a system capable of confocality requires a single-mode laser and appropriate optics. A clinical fiber-based Raman system requires a multimode diode laser with stable frequency output and rugged design that facilitates portability.

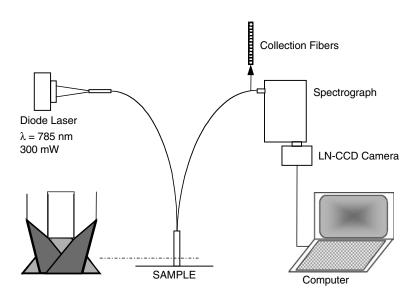

FIGURE 30.3 Schematic of a typical near-infrared dispersive Raman spectrometer used for tissue diagnosis today. This system is shown with an Enviva Raman probe.

30.3.1.1 Light Sources

Traditional Raman systems used the argon ion (Ar⁺) laser for visible excitation, the ND:YAG laser for FT-Raman applications and the Titanium:Sapphire (Ti:Sapph) laser for NIR excitation due to their high output powers, single spatial and longitudinal mode operation, and Gaussian beam profile that allows for near-diffraction-limited optical performance.^{30–33} However, the size and electronic and cooling requirements of these lasers make them impractical in a portable clinical system. Some current Raman instruments, especially those with confocal capabilities, still use the Ti:Sapph laser. However, advances in diode laser technology have completely changed the fingerprint of a typical Raman system.

Diode lasers utilize electro-optical components (diodes), which emit light as a function of applied current and operating temperature. The laser diodes are small (<1 mm³) and require highly accurate controlling electronics to obtain stable output. Laser diodes require highly stabilized temperature controllers to minimize thermoelastic effects on the laser cavity length (and thus output frequency), and highly stabilized current sources to minimize output power fluctuations. However, even with highly accurate controlling electronics, laser diodes are still susceptible to output variations, so users of these lasers must be aware of their limitations. In addition to the frequency and power considerations described, laser diodes are also characterized by their elliptical beam output (due to the rectangular shape of the output facet) and astigmatism (due to unequal beam divergence from each dimension of the rectangular facet). These issues also need to be accounted for when using a diode laser. Most commercial diode lasers, however, are available with a pig-tail option where a fiber is coupled directly to the laser diode, thus minimizing losses due to astigmatism and elliptical nature of the beam.

A diode laser with tunability in its wavelength is available; such a system tends to be more susceptible to changes in the laser cavity length, resulting in so-called "mode-hops" in which the primary resonant mode of the laser jumps from one frequency to another. Because Raman scattering is very sensitive to the frequency of the incident photon, a source stable in frequency with high line widths is essential to obtain reliable spectra. Diode lasers that are optimized for highly stable frequency output and powers of the order of 300 mW specifically designed for Raman spectroscopy are now commercially available (such as that offered by Process Instruments Inc., Salt Lake City, UT).

Most published reports of confocal Raman microspectroscopy utilize bulky Ar⁺ and Ti:Sapph lasers for excitation sources.³⁴ However, the size of these lasers, and their electronic and cooling requirement, make use in a portable clinical system impractical. Thus, in order to develop a truly portable confocal Raman microscope, an alternative excitation source is needed. By extending the length of the resonant cavity of a laser diode, the distance between the diode's longitudinal modes can be extended, thereby minimizing the effect of small thermoelastic changes on the output frequency. Such a source is called external cavity diode laser (ECDL). Compared to a bare laser diode, the ECDL nearly eliminates modehops, minimizes spectral bandwidth of the output light, allows substantial wave length tunability, and markedly decreases frequency dependence on temperature stabilization. A commercial ECDL singlemode system, previously available at a high price, is no longer on the market. An ECDL excitation source can be built in-house using off-the-shelf optics, hardware, and electronics at a price (~\$6,000) far less than the cost of commercially available Ar⁺ and Ti:Sapph laser systems (= \$20,000) typically used in confocal Raman systems.

30.3.1.2 Detectors and Spectrometers

A typical dispersive Raman detection system consists of a short focal length imaging spectrograph attached to a cooled CCD camera. Clinical implementation of the Raman system requires spectral acquisition on the order of a few seconds. This fast acquisition in turn needs a fast spectrograph and a highly sensitive detector, especially given the weak nature of the Raman signal. A typical CCD camera used in spectroscopy consists of a rectangular chip wherein the horizontal axis corresponds to the wavelength axis. The vertical axis is used to stack multiple fibers for increased throughput and is subsequently binned for improved SNR. Technological advances have led to CCD chips with quantum efficiencies on the order of 90% in the near-infrared. While various types of chips are commercially available for different applications, a back-illuminated, deep depletion CCD is highly recommended for NIR

Raman spectroscopy. These chips are known to be susceptible to the so-called "etaloning effect" wherein the thin silicon chip acts as an etalon, resulting in the introduction of sharp peaks in the sample signal that are hard to resolve from the narrow Raman signal. However, commercial cameras are now available (such as that offered by Roper Scientific Inc., Princeton, NJ) that incorporate technology that effectively eliminates this etaloning effect.

Most laboratory-grade systems currently utilize a liquid nitrogen–cooled CCD that allows the detector to be cooled to at least -80° C, resulting in extremely low dark noise as well as read-out noise. While this level of noise is important in a laboratory grade system where integration times and other system parameters are still being evaluated, a clinical system with a liquid nitrogen–cooled detector is cumbersome and impractical. Most recently, thermoelectrically cooled detectors are now available with multistage Peltier cooling systems that allow the camera to be cooled down to -80° C, thus solving this dilemma. It should be noted that shot noise due to tissue fluorescence continues to be a limiting factor.

Silicon-based detectors are relatively inexpensive and have high quantum efficiencies in the NIR, making them ideal detectors down to about 1100 nm. For longer wavelengths, other types of detectors such as indium gallium arsenide (InGaAs) and germanium (Ge) detectors need to be used. While the longer wavelengths do result in lower fluorescence interference, the quantum efficiency and noise exhibited by these detectors are less than silicon detectors. Research needs to be conducted in this area to verify that Raman spectra with adequate S/N can be acquired from tissue using 1064 nm excitation. New technological advances have yielded low-cost InGaAs and Ge detectors with compact Nd:YAG lasers resulting in extremely compact 1064 nm Raman systems (TRI, Inc., Laramie, WY).

A Raman-sensitive detection system requires an appropriate imaging spectrograph that couples to the light delivery device (such as a fiber probe) on one end and the CCD of choice at the other end. In order to resolve details of the Raman bands, the Raman system should have a spectral resolution of at least 8 cm⁻¹. Commercial spectrographs optimized for Raman use are now available that provide *f*-number matching with standard fiber optics and high throughput for rapid acquisition using holographic gratings. These spectrographs (such as that offered by Kaiser Optical Systems, Inc., Ann Arbor, MI) are compact by design and rugged for portable use. Additional components of the detection system include laser line rejection filters that remove any laser light as well as the elastically scattered light from the detected signal. Holographic notch filters can block the laser wavelength with an optical density of six with steep edges and provide 90% transmission elsewhere with a relatively flat curve.

Most Raman systems used in medical applications today are state-of-the-art, high-cost, high-performance Raman systems.^{27,35} This system at its best consists of a Kaiser imaging spectrograph, a Roper Scientific liquid nitrogen—cooled CCD detector, a 300 mW Process Instruments diode laser, and a custom fiber probe. Typical integration times are on the order of 5 to 10 sec for this type of system.

30.3.1.3 Light Delivery and Collection (Fiber Optics)

Raman scattering is a weak phenomenon, but most materials are Raman active, which allows for molecular-specific study of samples. On the other hand, because most molecules are Raman active, the materials used in the Raman system themselves interfere with the detection of sample signal. The development and availability of diode lasers, imaging spectrographs, and cooled CCD cameras has made it possible to build compact NIR Raman systems that acquire spectra with short integration times. However, the limiting factor remains the signal generated in the delivery systems (luminescence and Raman) used for remote sensing. Light is typically delivered using optical fibers made of silica in a remote sensing spectroscopic system. However, silica has a strong Raman signal, which overrides sample signal. The signal generated is proportional to the fiber length and limits the detection capability of the technique. The signal generated is proportional to the fiber length and limits the detection capability of the technique.

Figure 30.4 shows the Raman spectrum of fused silica fibers used to design a probe. Raman signal was observed to be generated from the core as well as the cladding and buffer of the fiber.^{20,37} This signal can have magnitudes equal to and sometimes greater than those of the sample under study and thus demands careful consideration. Fiber signal is generated in the delivery fiber by the excitation light. In addition, background signal is generated in the collection fibers by the elastically scattered excitation light returning to the collection fibers. Mathematical techniques cannot be used to remove this unwanted fiber signal.

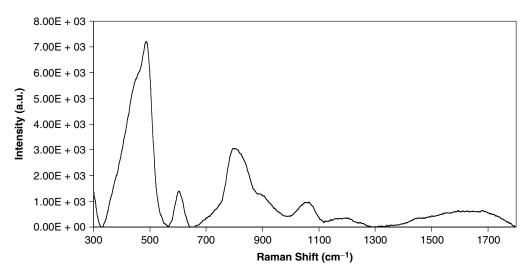

FIGURE 30.4 Raman spectrum at 785-nm excitation of fused silica fiber. (Modified from Berger, A.J. et al., *Appl. Opt.*, 38, 2916, 1999.)

A feasible probe design must prevent unwanted signal generated in the delivery fiber from illuminating the sample as well as prevent elastically scattered excitation light from entering the collection fibers and generating unwanted signal.

Several different designs have been proposed for potential clinical acquisition of Raman spectra using fiber optic probes. Early on, Myrick and Angel developed different dual fiber probes that could be used under different conditions with maximum collection efficiency but minimum fiber interference.³⁶ Most fiber designs since have been based on similar concepts with modifications. In general, Raman probe designs utilize a bandpass filter placed after the excitation fiber lens, thus allowing only the transmission of the excitation light from the delivery fiber, and a longpass or notch filter placed in front of the collection fibers that blocks the transmission of the Fresnel reflected excitation light and also prevents the elastically scattered light from entering the collection fibers. These filters are placed at the tip of the probe for maximum effectiveness and they must be sized on the order of a few millimeters or smaller. There is a demand in biomedicine for high-quality optical coatings and micro-optical components to simplify the design of much-needed compact fiber optic probes for Raman spectroscopy.

Multiple fiber bundles have been utilized for fluorescence measurements of tissue by several groups. 6-8 Such a bundle typically consists of a central excitation fiber surrounded by many collection fibers linearly aligned in front of the spectrometer. McCreery et al. used this design and tested it on different samples. 38 Although spectra with good SNR ratio could be obtained from transparent samples, fiber background was still a serious problem in samples with high elastic scattering such as tissue. Feld et al. have adapted an old design (used in solar energy collection) for improved signal collection to allow spectral acquisition in a few seconds. 39 A hollow compound parabolic concentrator (CPC) was used at the distal tip of the probe to yield signals with seven times greater collection than a fiber probe without the CPC. Fiber background was reduced by using a dichroic mirror and separate excitation and collection fiber geometries. Excitation light was reflected by the mirror (placed at 45° with respect to the sample normal) through the CPC onto the sample. Raman spectra were collected by the CPC, transmitted through the mirror into a collection fiber bundle (with about 100 fibers) to a detector. This probe design was used to acquire Raman spectra for transcutaneous blood glucose measurements.

In vivo applications thus far have been mostly confined to exposed tissue areas where fiber background could be circumvented using a macroscopic arrangement — e.g., noncontact probe (DLT, Laramie, WY) used for breast tissues by McCreery et al.³² and CPC probe for transcutaneous measurements of blood analytes by Feld et al.⁴² However, other applications such as in the colon, cervix, and oral cavity, require

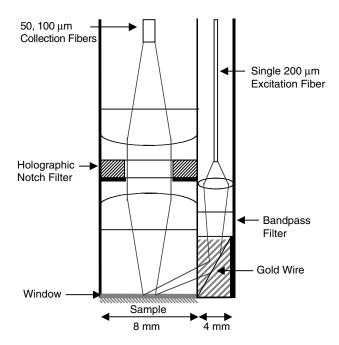

FIGURE 30.5 Transverse section of the clinical Raman probe implemented in the cervix.

a more compact configuration and probe design. Thus, while many reports have been published assessing the feasibility of Raman spectroscopy for disease detection, few reports have applied this technique *in vivo*. The main obstacle continues to be fiber probe design.

One of the first designs of a compact fiber probe used clinically in the cervix was reported by the author. 40 As stated previously, a feasible probe design must prevent unwanted signal generated in the delivery fiber from illuminating the sample, as well as prevent elastically scattered excitation light from entering the collection fibers and generating unwanted signal. Experimental results show that significant proportions of silica signal are generated in the excitation *and* collection fibers, indicating the need for filters in the excitation and collection legs of the probe. Figure 30.5 shows a transverse section of the design that was implemented as a Raman probe for the cervix. 40 Rather than placing the excitation leg at an angle, a mirror surface is placed in the excitation path to deflect the beam onto the sample.

This probe was designed using the smallest available physical dimensions of the bandpass and the holographic notch filters at that time. An angularly polished gold wire was glued in place such that the deflected excitation and normal collection spots overlap. One of the collection fibers was used to provide an aiming beam during placement of the probe on the sample. A quartz shield was used at the tip of the common end of the probe, forming a barrier between the probe optics and the sample. Quartz was selected as the material of choice because its fluorescence and Raman signal were known and any additional background signal from the probe could be identified. The inner surfaces of the metal tubings used to house the probe optics were anodized to reduce the incidence of multiple reflections of light.

The probe was tested in a pilot clinical study approved by the Institutional Review Board (IRB). NIR Raman spectra of the cervix were successfully measured *in vivo*, as shown in Figure 30.6, using integration times in the order of 90 sec.⁴³ Since this initial report was produced, several designs for a Raman probe have been reported. One design in widespread use is the beam-steered Enviva Raman probe designed by Visionex Inc. (now Cirrex Corp., Atlanta, GA), which incorporates in-line filtering of the laser light and the scattered light at the tip of the probe.⁴¹ The beam steering allows improved overlap of the excitation and collection volumes and thus improves signal collection efficiency (see Figure 30.3).

Another unique feature of this probe was its dimension in the order of 1 to 3 mm, which was not seen in other probes available commercially. However, the company no longer manufactures these probes and

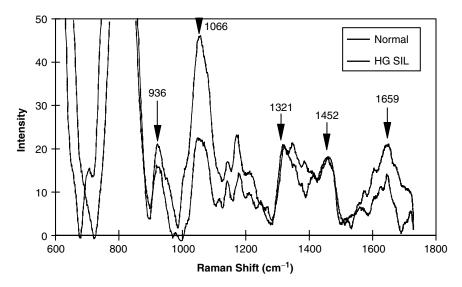

FIGURE 30.6 In vivo NIR Raman spectra of cervical tissue measured using the probe shown in Figure 30.5.

thus a need for such slickly designed Raman probes still exists. Attempts have been made by other companies such as InPhotonics Inc. to fill the gap. In a survey of currently available probes for biomedical Raman use, it was found that all commercially available probes were bulky (up to several millimeters in diameter) and expensive (~\$3500 or more). Proponents of Raman spectroscopy for tissue diagnosis must rely on custom-designed fiber probes built using commercial vendors.

Other new designs have been recently reported. Most recently, the Feld group has proposed a newer design for breast cancer detection, based on micro-optics and optical coatings.⁴² Results of spectra acquired with this probe have not yet been reported *in vivo*. The recent developments in the field of microfabrication (MEMs) open a new avenue for compact probe designs using reflective optics. Others (including the author) continue to develop new ideas for feasible probe designs that should be tested and reported in the near future.

30.4 Effect of Sample Conditions

The design and construction of a Raman system is clearly a critical part of the process. An often forgotten aspect in the use of a new technique deals with the application itself. In developing and applying a new technique, the technology must first be tested in a model system before it can be applied *in vivo*. Subsequently, when it is ready for *in vivo* use, several factors unique to clinical use must also be considered. These issues are addressed below.

30.4.1 Tissue Model Selection

In the field of spectroscopy, there are two philosophies on the approach to use in testing the feasibility of a given technique. Some researchers prefer to use an animal model that resembles human tissues in function and structure to simulate the behavior of human tissues, while others prefer *in vitro* human tissue studies before tackling *in vivo* studies. Each of these approaches needs to be carefully considered in the context of the human *in vivo* model.

Although an animal model allows *in vivo* testing, Raman spectra of animal tissues can in some cases differ from those of human tissues, resulting in conclusions not valid for humans. One example of this is the use of mouse eye lenses for the study of lens aging.⁴³ In early studies, Yu suggested that the intensity of Raman bands at 2580 cm⁻¹ due to sulfhydryl groups (–SH) and 508 cm⁻¹ due to disulfide groups (–S–S) can be used to calculate their relative concentrations. These can then be related to aging and

cataract formation. In an extensive study of mouse lenses, a fall in –SH concentration and a corresponding increase in –S–S concentration was observed along the visual axis of mouse lens nucleus from age 1 to 6 months. A tandem increase in protein development with a decrease in sulfhydryl was concluded to accompany the normal aging process. However, on repeating these studies on guinea pig and human lenses, a different phenomenon was observed. Although guinea pig lenses also showed a decrease in sulfhydryl intensity, no corresponding increase in disulfide band was observed. Human eye lenses behaved similarly to guinea pig lenses. This study clearly indicates the pitfalls in improper selection of an animal model and that independent verification of the model is needed to ensure that results will be applicable to human conditions.

A primary concern in devising a clinical diagnostic system based on Raman spectroscopy is whether the spectra of excised tissue resemble those of tissue spectra acquired *in vivo* and whether the information obtained from these *in vitro* studies can be applied to a clinical setting. It is well known that the spectra acquired from *in vitro* tissues (especially those that have undergone the freeze–thaw process) differ from those acquired *in vivo*.⁴⁴ Spectra from intact human stratum corneum were compared to those from excised human stratum corneum;⁴⁵ significant differences in the Raman spectral features were observed. Increased intensity of the C–C stretching vibrational bands at 1030 and 1130 cm⁻¹ was observed *in vivo*. An additional spectral band at 3230 cm⁻¹ of unknown origin is observed only *in vivo*. Thus, it is important to be aware of the potential differences that may occur when moving from *in vitro* studies to *in vivo* conditions. Most researchers who follow this approach use the *in vitro* studies as proof of concept before moving directly into *in vivo* studies.

30.4.2 In Vivo Considerations

In vivo clinical application of the technology is the goal of all researchers in this field. However, various issues specific to working *in vivo* must be considered in the planning of these clinical studies. Logistic issues such as IRB approval and consent forms have become challenging processes. When building a clinical system, some issues need to be considered. Because the probe must be sterilized or disinfected, depending on the application, it must be designed to withstand the physical and chemical conditions of these processes. The power consumption of the Raman system must not overload hospital and clinic systems. Such requirements can be verified by the biomedical engineering department of the hospital. Acquisition times must be on the order of a few seconds for the sake of both the patient and clinician participation. The system needs to be self-contained and nonobtrusive. Some of these issues may appear trivial, but they all contribute to smooth conduct of clinical studies.

Any technique that uses lasers must comply with certain safety standards to avoid potential hazards. Safety standards for laser exposure of skin and eye are established by the American National Standards Institute (ANSI). The power densities used for successful Raman spectral acquisitions can be quite high and thus warrant consideration as safety hazards. The maximum permissible exposures as set by ANSI are wavelength dependent and can be calculated for a given exposure time following the directions specified in the ANSI laser safety manual.⁴⁶

Sources of variability that need to be evaluated experimentally include ambient effects, physician variation, pressure effects, and procedural interference. Regardless of the short duration of the integration times used for Raman acquisition, ambient effects can be significant for spectral integrity. Although room lights may be turned off and windows may be light-tight in a laboratory setting, these are more critical issues in a clinical setting and require careful planning. Variability from physician to physician in terms of single-site placement, as well as site-to-site placement for a given pathology, must be evaluated. The effect of varying pressures applied to the probe during acquisition should also be considered. Another critical parameter is the measurement-site to biopsy-site variability. Because histology continues to be the gold standard against which we must compare this technology, it is critical that the biopsy be obtained from the precise site of spectral measurement using such techniques as marking inks, etc. placed appropriately. It is essential to account for sources of variability when acquiring Raman spectra from human patients *in vivo*.

30.5 Processing

Once a Raman spectrum is acquired using a feasible Raman system, it must be processed for different reasons, including calibration, noise smoothing, and fluorescence elimination and binning. Other processing methods may be applied depending on the requirements of the analysis tools and the variability in the data.

30.5.1 Calibration

Because different researchers have different approaches in the development of a given application for Raman spectroscopy, a standard must be set to allow transferability of data across systems and methods. Instrument and data calibration are key components of data processing immediately following data acquisition. Some calibration must occur at the time of acquisition and other calibration may be implemented later. Most biomedical Raman systems currently in use are based on dispersive CCD systems where the spectra are recorded as a function of pixel numbers along the horizontal axis. Thus, the spectrum of a known calibrated source such as a neon lamp is typically taken to calibrate the horizontal axis. Raman spectrum of a strong Raman scatterer such as naphthalene, a strong Raman scatterer and fluorophore such as rhodamine 6G, and a weak Raman scatterer such as methylene blue are used as intensity standards to account for day-to-day variations in the spectral intensity. A spectrum of the laser source is taken to verify the location (and thus the wavelength) of the laser line. This spectrum is also used with the neon spectrum to convert the horizontal axis in terms of relative wavenumbers.

Finally, there exists a wavelength-dependent efficiency of all the various components of the detection system such as the grating, the filters, optics, quantum efficiency of the CCD chip, etc.; therefore, the wavelength dependency of the system response must be calibrated. This is typically done using an NIST-calibrated source such as a tungsten lamp to generate correction factors for the instrument variation.⁶⁷ As various researchers acquire calibrated Raman spectra, a library of tissue Raman spectra is created that can be used to study cross links in the chemical compositions and correlation in tissue pathologies as well as to strengthen and standardize the use of Raman spectroscopy for tissue diagnosis.

30.5.2 Fluorescence Elimination

In recent years we have witnessed an explosion in the use of Raman spectroscopy for biological purposes such as tissue diagnosis, blood analyte detection, and cellular examination. The greatest benefits of this technique are its high sensitivity to subtle molecular (biochemical) change and its capacity for nonintrusive application. Because biological applications of Raman spectroscopy involve turbid, chemically complex, and widely varying target sites, much of the challenge in using Raman spectroscopy for biological purposes is not only the acquisition of viable Raman signatures but also the suppression of inherent noise sources present in the target media. Perhaps the greatest contributor of "noise" to biological Raman spectra is the intrinsic fluorescence of many organic molecules in biological materials. This fluorescence is often several orders of magnitude more intense than the weak chemical transitions probed by Raman spectroscopy and, if left untreated, can dominate the Raman spectra and make analysis of tissue biochemistry as probed by the technique impractical. Therefore, in order to extract Raman signal from the raw spectra acquired, it is necessary to process the spectrum to remove this fluorescence.

A number of techniques, implemented in both hardware and software, have been proposed for fluorescence subtraction from raw Raman signals. Hardware methods such as wavelength shifting and timegating have been shown to effectively minimize fluorescence interference in Raman spectra, but require modification of the spectroscopic system to achieve their results. 48,49 Mathematical methods implemented in software require no such system modifications, and have thus become the norm for fluorescence reduction. These methods include first- and second-order differentiation, 50,51 frequency-domain filtering, 42 wavelet transformation 52,53 and manual polynomial fitting. 20,54 Although each of these methods has been shown to be useful in certain situations, these methods are not without limitations.

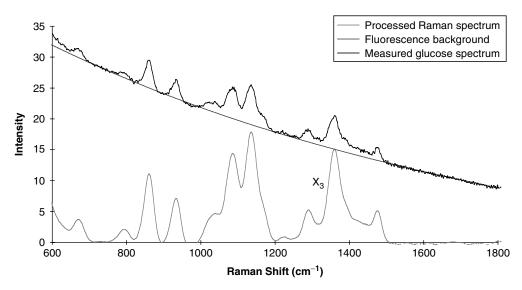

FIGURE 30.7 Processing Raman spectra of rhodamine 6G for fluorescence removal using a manual fifth order polynomial fit.

Differentiation can be implemented in various ways. One way is to measure the spectra at two slightly shifted excitation wavelengths and take their difference.⁵⁵ The fluorescence remains unchanged at both excitation wavelengths whereas the Raman peaks are shifted. The difference of the two spectra is comparable to the first derivative of the Raman spectrum; integrating the difference spectrum yields the original Raman signal. A similar result can be obtained by measuring the spectrum at a single excitation wavelength and taking the first derivative of the spectrum. The Raman spectrum can be obtained by integrating the noise-smoothed derivative spectrum following baseline correction.^{49,50} The derivative method is entirely unbiased and very efficient in fluorescence subtraction, yet it severely distorts Raman line shapes and relies on complex mathematical fitting algorithms to reproduce a traditional spectral form.⁴⁹

Frequency filtering can be achieved by using the fast Fourier transform (FFT). In this technique, the measured spectrum is Fourier transformed to the frequency domain by taking the FFT of the signal. The FFT signal can then be multiplied with a linear digital filter to eliminate the fluorescence. The inverse FFT then yields the Raman spectrum free of fluorescence. This method can cause artifacts to be generated in the processed spectra if the frequency elements of the Raman and noise features are not well separated. Wavelet transformation, a more recently utilized method, is highly dependent on the decomposition method used and the shape of the fluorescence background.

A simple, accurate, and more elegant method to subtract fluorescence is to fit the measured spectrum containing both Raman and fluorescence information to a polynomial of high enough order to describe the fluorescence line shape but not the higher-frequency Raman line shape (Figure 30.7). A fourth- or fifth-degree polynomial has been found to be optimal.²⁰ Polynomial curve-fitting has a distinct advantage over other fluorescence reduction techniques because of its ability to retain the spectral contours and intensities of the input Raman spectra. However, simply fitting a polynomial curve to the raw Raman spectrum in a least-squares manner will not efficiently reproduce the fluorescence background because the fit is based on minimizing differences between the fit and the measured, which includes the fluorescence background and the Raman peaks. Subsequent subtraction of this fit polynomial results in a spectrum that varies about the zero baseline.

This technique traditionally relies on user-selected spectral locations on which to base the fit from regions that do not include the more intense Raman bands. Unfortunately, this intervention has several drawbacks. It is time consuming because the user must process each spectrum individually to identify

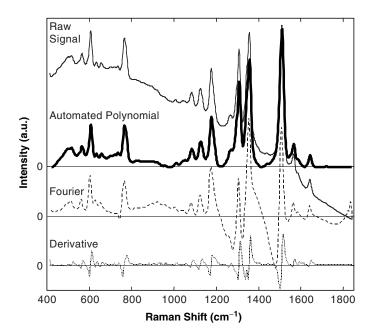

FIGURE 30.8 Raman spectra of rhodamine 6G processed using the derivative, manual curve-fitting, and modified-mean methods.

non-Raman-active spectral regions to be used in the fit. In addition, identification of non-Raman-active frequencies is not always trivial because biological Raman spectra sometimes contain several adjacent peaks or peaks that are not immediately obvious. The end effect is a method that is highly subjective and prone to variability. In order to address the limitations of existing methods of fluorescence subtraction, various methods to automate polynomial curve-fitting have been developed that retain the benefits of manual curve fitting, without the need for user intervention. ⁵⁶ One implementation of this automation is the modified-mean method. ⁵⁶

In one implementation of this automation, the basis is a simple sliding-window mean filter, in which the center pixel intensity in the window is set equal to the mean of all the intensities within the window. The modification involved in this method is that any filtered pixels with an intensity value higher than the original are automatically reassigned to the original intensity; therefore, the smoothing only eliminates high-frequency Raman peaks while retaining the underlying shape of the baseline fluorescence. This smoothing is repeated over the entire spectrum until a specified coefficient of determination (R^2) of the processed spectrum with an nth order polynomial (typically fifth order) is obtained. The smoothed spectrum is then subtracted from the raw spectrum to yield the Raman bands on a near-null baseline. This algorithm can be implemented easily in MATLAB, thus automating the entire procedure.

Figure 30.8 shows the Raman spectra of rhodamine 6G, as well as the processed Raman spectrum using derivative, FFT, and automated polynomial fluorescence subtraction techniques for direct comparison of the methods. The figure shows the effectiveness of the automated polynomial method for removing the slow varying fluorescence baseline while retaining the Raman features of rhodamine, especially in comparison to the other methods.

Each of the different techniques has advantages and disadvantages and the method should be selected based on the specific application and measurement technique used. Mosier-Boss et al. tested the use of the shifted excitation, first derivative, and FFT techniques for fluorescence subtraction; a preference for using the FFT technique was indicated due to its ability to filter out random noise from the spectrum.⁴⁹ In an analysis of the different techniques, the use of a polynomial fit was found to be the simplest technique from both experimental and computational points of view.

30.5.3 Other Preprocessing Methods

Because Raman scattering is such a weak phenomenon, the SNRs of most measured Raman spectra are such that noise-smoothing filters must be included in the processing procedure. Various types of filters that have been effectively used include the Gaussian filter, whose full-width-half-maximum is typically set equal to the spectral resolution of the system, and the Savitsky-Golay filter of various orders.²⁷ When using any method of noise smoothing, care should be taken to retain the integrity of the spectral line shape, especially in the case of multiple peaks.

Other preprocessing methods include binning of the spectral dataset for computational ease because of a large number of variables. Depending on the variability in the acquired data and the needs of the analysis methods used, other methods include normalization to intensity standards, normalization to its own maximum intensity, mean-scaling the spectra acquired from a given patient, etc.

30.6 Analysis

One advantage of spectroscopic diagnosis is automation, which allows objective and real-time diagnosis of pathologies. Differences in spectral features can be incorporated into diagnostic algorithms; several techniques have been identified and applied to enhance the differentiation and classification of tissues for potential automated clinical diagnosis. Because Raman spectroscopy is a molecular-specific technique, the contribution of the various participating chromophores can also be extracted from the measured spectra. These can, in turn, be used in diagnostic algorithms and in the understanding of the spectral signature as it pertains to the disease process. In addition, concentration of specific components such as glucose can be obtained for diagnostic use.

30.6.1 Automated Diagnosis

Early studies analyzed biological Raman spectra for differences in intensity, shape, and location of the various Raman bands between normal and non-normal materials such as tissues. Based on consistent differences observed among the various tissue categories, diagnostic algorithms are developed using empirical methods. These algorithms may be based on changes in intensity or ratios of intensities or number and location of peaks. For example, it has been observed that the intensity ratio of the CH₂ bending vibrational mode at 1450 cm⁻¹ to the amide I vibrational mode at 1655 cm⁻¹ varies with disease in several applications, including breast, gynecologic, and precancers.⁵⁷ These empirical algorithms indicate the specific changes that occur in the spectra acquired and provide information about the biochemical processes that result in these spectral differences.

This empirical analysis, however, has two important limitations. First, clinically useful diagnostic information is typically contained in more than just the few wavenumbers surrounding peaks or valleys observed in tissue; a method of analysis and classification that includes all the available spectral information can potentially improve the accuracy of detection. Second, empirical algorithms are optimized for the spectra within the study. Hence, the estimates of algorithm performances will be biased toward that tissue population. An unbiased estimate of the performance of the algorithms is required for an accurate evaluation of the performance of Raman spectroscopy for tissue diagnosis. To address these limitations, multivariate statistical techniques have become the practice to develop and evaluate algorithms that differentiate between normal and non-normal tissues.

In recent years, the potential for using multivariate techniques for spectroscopic data analysis in disease detection has been exploited with great success.²⁰ Discrimination techniques such as linear regression, as well as classification techniques such as neural networks, have been used.^{20,22} Data compression tools such as principal component analysis (PCA) are used to account for variability in the data.⁵⁸ Subsequently, methods such as hierarchical cluster analysis (HCA),¹¹ linear discriminant analysis (LDA)²² and others have been used to yield classification algorithms for disease differentiation. Partial least squares, a regression-based technique, and hybrid linear analysis have been used to extract

accurate concentrations of analytes such as glucose using NIR Raman spectra for transcutaneous blood analysis.⁵⁹

The consensus of the scientific community is that, while any of these methods may form the basis of performance estimates, the true measure of success of Raman spectroscopy for tissue diagnosis can be assessed by extensive unbiased (and independent) validation alone. This may best be accomplished by random distribution of the subject population into two equal datasets: one for calibration or testing and the other for validation. When this is not feasible, one can then rely (in a limited manner) on the leave-one-out or leave-five-out methods of cross validation.

30.6.2 Component Extraction

Analyzing Raman spectra for the purpose of disease classification may be sufficient when the goal of the study is to achieve tissue diagnosis alone; however, most researchers want to know if and why they can diagnose disease. In the case of Raman spectroscopy, the wealth of information provided in these spectra, especially with respect to biochemical composition, allows us to study the question of "why" in detail that can subsequently be used for the purpose of detection as well.

While most researchers study the biochemical basis of the measured Raman spectra from biological tissues, some groups have been particularly active in this area. For example, Puppels et al. have utilized skin Raman spectra to obtain quantitative information about skin hydration;¹³ Feld et al. have developed comprehensive models for biochemical component extraction that have subsequently been used for disease classification.⁶⁰ Each of these methods is based on the acquisition of Raman spectra from individually identified chromophores as morphological tissue components or as extracted biochemical constituents.

Pixelated Raman microspectroscopy is typically used (with or without confocality) to measure Raman spectra from individual morphologic tissue components using tissue sections. A Raman spectrometer is coupled to a microscope and is scanned across the tissue section to obtain Raman images that can then be correlated with serial hematoxylin- and eosin-stained sections to identify relevant morphologic components and their Raman signature. Alternatively, tissue chromophores can be extracted from biochemical assays and Raman spectra can be acquired from each of these extracted chromophores.⁶⁰ By using mathematical models such as those developed by the Feld group, contributions of the various extracted or morphologic components to intact tissue spectra can then be extracted.⁶⁰

30.7 Clinical Application of Raman Spectroscopy

In vivo studies are necessary to fully evaluate the potential of Raman spectroscopy for clinical diagnosis. Several groups have initiated this process with varying degrees of success.^{26,27,62} This progression has been made possible by the development of sensitive instrumentation, use of fiber optics, and development of automated algorithms. However, despite these significant developments, the majority of reported studies on the application of Raman spectroscopy for tissue diagnosis continue to be from *in vitro* studies. Only a limited number of reports exist on the application of Raman spectroscopy *in vivo* in humans in a clinical setting; most of them are pilot clinical studies. Nevertheless, these critical studies create the road map for the future of Raman spectroscopy in biomedicine.

Several biological molecules such as nucleic acids, proteins, and lipids have distinctive Raman features that yield structural and environmental information. These molecules have been studied in solutions and in their natural microscopic environments.²⁰ The molecular and cellular changes that occur with disease result in distinct Raman spectra that can be used for diagnosis. The transitional changes in precancerous tissues as well as in benign abnormalities such as inflammation can also yield characteristic Raman features that allow their differentiation.

Several groups have indicated the potential of vibrational spectroscopy for disease diagnosis in various organ sites. These groups have shown that features of the vibrational spectrum can be related to molecular and structural changes associated with disease. Raman spectroscopy has been studied extensively for tissue diagnosis in four main organ sites: breast,⁶⁰ esophagus (and the GI tract),⁶³ cervix (and other

gynecological tissues),²⁷ and skin.⁶⁴ Other organ sites include the brain, the eye, and biological fluids.^{11,20,21} Some examples of the application of Raman spectroscopy for disease diagnosis are detailed in the following sections.

30.7.1 Breast

Until recently, perhaps the most widespread application of Raman spectroscopy in cancer research has been for breast cancer detection. Breast cancer is the most common cancer in women, accounting for 18% of all cancer deaths in women.⁶⁵ The breast consists of mammary glands arranged in lobes separated by fibrous connective tissue and a considerable amount of fatty tissue.⁶⁶ Fibrocystic changes are benign proliferative processes that vary from the innocuous to those associated with increased risk of carcinomas. These benign changes take three forms: (1) cyst formation and fibrosis, (2) hyperplasia, and (3) adenosis. In most afflicted breasts, all forms occur simultaneously in fibroadipose stroma.

Breast tumors may arise from the ductal and lobular epithelium or connective tissue. These tumors vary from benign adenomas and malignant adenocarcinomas to benign fibromas and malignant fibrosarcomas. Infiltrating ductal carcinoma (IDC), the most frequent invasive form of breast cancer, has been studied using Raman spectroscopy. IDCs typically show an increase in dense fibrous stromal tissue and malignant proliferation of ductal epithelium. ⁶⁷ Although routine screening using mammography can aid in early detection of malignancy, lesions identified with this method must be biopsied and evaluated histopathologically to determine the presence of malignancy. In recent years, spectroscopic techniques have been used for breast cancer diagnosis. ^{31,68} Although fluorescence spectroscopy has shown some promise as a diagnostic tool, Raman spectroscopy may provide more definitive characteristics that allow differentiation of benign and malignant tumors.

Several groups have studied the potential of Raman spectroscopy for pathologies of the breast, from detection of breast cancers to study of capsules from breast implants.⁶⁹ Using an FT-Raman system, Alfano et al. obtained the first Raman spectra from excised normal human breast tissues and benign and malignant breast tumors and discussed the feasibility of using FT-Raman spectroscopy for differentiating normal and malignant breast tissues.³² The vibrational spectra of benign breast tissues (which include normal tissues) showed four characteristic bands at 1078, 1300, 1445, and 1651 cm⁻¹. The spectra of benign tumors showed bands at 1240, 1445, and 1659 cm⁻¹, and malignant tumors displayed only two Raman bands at 1445 and 1651 cm⁻¹. The intensity ratio of 1445 to 1651 cm⁻¹ was found to be larger in benign tissues compared to benign tumors and the same ratio was found to be even lower in malignant tumors.

Redd et al.^{30, 31} employed Raman spectroscopy using visible excitation to study excised human breast tissues. Spectra were also obtained from pure compounds, and the features observed in tissue spectra were determined to be primarily due to carotenoids, myoglobin, and lipids. The Raman spectra of normal breast tissues showed peaks assigned to carotenoids at 1005, 1157, and 1523 cm⁻¹ (not observed with IR excitation); peaks assigned to lipids, primarily oleic acid derivatives at 1302, 1442, and 1653 cm⁻¹; a peak at 1370 cm⁻¹ due to myoglobin; and several other smaller unassigned peaks.

A subsequent study by McCreery et al. assessed the feasibility of using NIR Raman spectroscopy for breast cancer detection. Chromophore contributions differed as excitation was shifted from the visible (yielding carotenoid and lipid bands) to the NIR (yielding only lipid bands) in normal tissues. NIR Raman spectroscopy yielded signals with lower fluorescence interference and higher SNR.

NIR Raman spectra were measured from excised normal human breast tissues, tissues with fibrocystic change, and infiltrating ductal carcinoma (IDC) at 784 nm excitation (Figure 30.9).³¹ The ratio of the areas under the peaks at 1654 cm⁻¹ and 1439 cm⁻¹ were found to increase in malignant breast tissues as compared to normal breast tissues. This increase is consistent with the changes reported by Alfano et al.³² The intensity of the 1654 cm⁻¹ C = C stretching band varies with the degree of fatty acid unsaturation; the CH₂ scissoring band at 1439 cm⁻¹ depends on the lipid-to-protein ratio. The spectra from IDC tissues showed an overall decrease in intensity with respect to normal tissue.

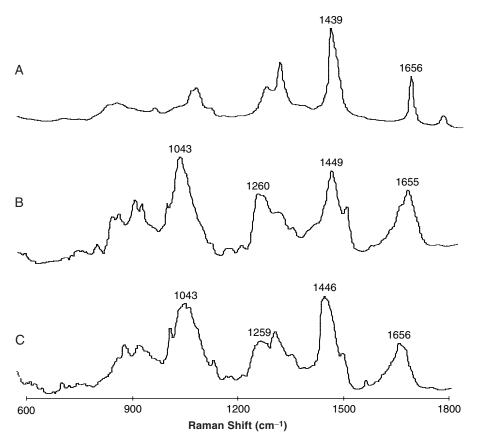

FIGURE 30.9 Raman spectra of (A) normal, (B) malignant and (C) benign human breast tissue at 784-nm excitation. (Modified from Frank, C.J., McCreery, R.L., and Redd, D.C., Anal. Chem., 67, 777, 1995.)

Several differences were also observed when IDC tissues were compared with benign abnormal tissue. In benign tissue, the intensities of the bands at 1656 cm⁻¹ and 1259 cm⁻¹ were smaller than the band at 1449 cm⁻¹ and this band is further shifted to 1446 cm⁻¹. The region of 850 to 950 cm⁻¹ showed only two bands in benign tissue as compared to four in IDC samples. The peaks observed in normal tissues were primarily attributed to oleic acid methyl ester, a lipid, and the peaks observed in IDC and benign tissues were primarily attributed to collagen I. This is consistent with histopathology where IDC and benign tissues show an increase in interstitial tissues microscopically. These spectral differences were found to be significant; subsequently, this group reported the development of a clinical probe and system for *in vivo* testing. Preliminary testing of the probe was reported on *in vitro* samples but no other reports have since been published.

Similar results were also obtained by Manoharan et al. using a comparable system. ⁶⁸ The Raman spectra acquired from this study were analyzed using multivariate statistical techniques and results yielded no false negatives. This group has subsequently reported the development of a clinical Raman system and *in vivo* testing will be reported in the future. ⁴²

30.7.2 Cervix

The various gynecologic tissues differ both structurally and functionally^{67,70} from one another and they have been studied using Raman spectroscopy. Because of its well-characterized disease process and its significance, the cervix has been studied extensively in the development of spectroscopic detection. The cervix is the most inferior portion of the uterus, which typically measures 2.5 to 3.0 cm in diameter in

the human adult female. The cervix is covered by two types of epithelia. The multilayered squamous epithelium covers most of the ectocervix and is separated from the stroma by the basal layer; the columnar epithelium consists of a single layer of columnar cells and covers the surface of the endocervical canal. The interface of the two epithelia is called the squamo–columnar junction. Over time, the columnar epithelium is replaced by squamous epithelium, which causes the squamo–columnar junction to move toward the os. This transitional epithelium is termed squamous metaplasia.⁷⁰

Virtually all squamous cervical neoplasias (new growth) begin at the functional squamo–columnar junction and the extent and limit of their precursors coincide with the distribution of the transformation zone. Cervical intraepithelial neoplasia (CIN) refers to the precancerous stages of cervical carcinoma and is often also referred to as cervical dysplasia. Here we generally refer to them as "precancers." Other pathologies that affect the cervix include cervicitis or inflammation, which is usually the response of tissue to injury, and the human papilloma viral (HPV) infection. Similarities observed in the morphological changes of the epithelial cells between those induced by HPV and precancer have led to the suggestion that certain strains of HPV may be involved in the incipient stages of cervical precancer and other strains may aid in the progression of the disease. Thus, HPV is typically placed in the same category as mild precancers and is clinically treated as such. Endocervical cancers are typically adenocarcinomas, arising within the endocervix as opposed to cervical epithelial lesions, which arise in the squamo–columnar junction.

Cervical cancer is the second most common malignancy found in women worldwide. It was estimated that in 2001, 4100 deaths occurred in the United States from this disease and 13,000 new cases of invasive cervical cancer were diagnosed.⁶⁵ Although early detection of cervical precancer has played a central role in reducing the mortality associated with this disease over the last 50 years, the incidence of preinvasive squamous carcinoma of the cervix has risen dramatically, especially among women under the age of 50. The primary screening tool for cervical precancer is the Papanicolaou (Pap) smear, where scrapings from the walls of the ecto- and endocervix, which contain a variable number of cells, are examined and diagnosed.⁷⁰ Although the widespread application of the Pap smear as a screening tool has greatly decreased the incidence of cervical cancer,⁷² sampling and reading errors lead to high false-positive and -negative rates. Treatment ultimately relies on directed biopsies and subsequent pathological findings.

Alfano et al. were the first to report on the feasibility of using FT-Raman spectroscopy for detecting cancers from various gynecologic tissues. The canceristic Raman eatures of normal tissues and malignant tumors from the cervix, uterus, endometrium, and ovary were described. Three significant peaks were noted to differ in the Raman spectra of normal and benign cervix compared to cancerous lesions. In cancerous tissues, the intensity of the amide I stretching vibration band at 1657 cm⁻¹ is less than the intensity of the C–H bending vibrational band at 1445 cm⁻¹. The amide III band at 1262 cm⁻¹ is broadened in cancerous lesions. An additional unidentified peak at 934 cm⁻¹ is observed only in normal and benign cervical samples. A possible diagnostic algorithm could be based on the relative intensities of the two peaks where $I_{1657} > I_{1445}$ in normal and benign tissues and $I_{1657} < I_{1445}$ in cancerous samples. Alfano et al. attributed these peaks primarily to collagen and elastin.

The author has reported *in vitro* as well as *in vivo* studies on the application of Raman spectroscopy for cervical *precancer* detection.^{27,58} In her early work, Raman spectra of cervical tissues were measured to characterize the spectral signatures of the different cervical tissue types and to assess the feasibility of using Raman spectroscopy for cervical precancer diagnosis.⁵⁸ Primary tissue Raman peaks were observed at 626, 818, 978, 1070, 1246, 1330, 1454, and 1656 cm⁻¹ (±10 cm⁻¹), present in all samples. The peaks at 626, 818, and 1070 were attributed as primarily due to silica from the optics of the system. Both empirical and multivariate techniques were used to explore the diagnostic capability of NIR Raman spectra from cervical tissues. A multivariate discrimination algorithm developed using the entire Raman spectrum could differentiate cervical precancers from nonprecancers with a sensitivity and specificity of 91 and 90%, respectively.⁵⁸ A discrimination algorithm developed using intensities at just 8 Raman bands gave an unbiased estimate of the sensitivity and specificity as 82 and 92%, respectively.⁵⁸ Thus, the success of the *in vitro* Raman studies for precancerous cervical tissue recognition warranted the development of a clinical system.

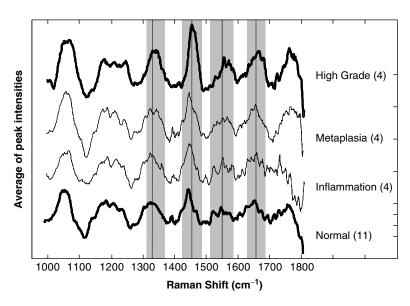

FIGURE 30.10 *In vivo* NIR Raman spectra for different types of cervical tissues. (Modified from Utzinger, U. et al., *Appl. Spectrosc.*, 55, 955, 2001.)

In a pilot clinical study approved by the IRB, NIR Raman spectra of the cervix were successfully measured *in vivo* from 24 sites (11 normal, 4 inflammation, 4 metaplasia, 1 low-grade, and 4 high-grade lesions) in 13 patients.²⁷ Raman spectra were measured from normal and abnormal areas of the cervix using the fiber probe described in Figure 30.5 and a Raman system similar to the one shown in Figure 30.3. Figure 30.10 shows typical Raman spectra of the different types of cervical tissues acquired *in vivo*.²⁷

Cervical tissue Raman spectra show peaks in the vicinity of 1070, 1180, 1210, 1245, 1270, 1330, 1400, 1454, 1580, and 1656 cm⁻¹. The ratio of intensities at 1454 to 1656 cm⁻¹ is greater for precancerous tissues than for all other tissue types, while the ratio of intensities at 1330 to 1454 cm⁻¹ is lower for samples with cervical precancer than for all other tissue types. A simple algorithm based on these two intensity ratios separates high-grade lesions from all others with a sensitivity of 100% and a specificity of 95%.²⁷ Preliminary results thus indicate that it is possible to measure Raman spectra *in vivo* and extract potentially diagnostically useful information.

In vivo Raman spectra, in general, appeared similar to *in vitro* Raman spectra previously obtained from cervical biopsies. Due to the small number of patients included, the number of samples within a particular category was small; only one of the investigated samples was histologically identified to be low grade. Thus, while promising results were obtained in discriminating high-grade lesions from all other tissue types, significant research still remains to be done to characterize the spectra of low-grade lesions and other tissue pathologies of the cervix before Raman spectroscopy can be validated as a viable method for the diagnosis and potential screening of cervical precancers.⁷³

30.7.3 Skin

The skin is the largest organ of the body and has many different functions. It is divided into two main regions: the epidermis and the dermis. The epidermis primarily consists of keratinocyctes and varies in thickness throughout the body. Melanocytes, the pigment-producing cells of the skin, are found throughout the epidermis. The dermis consists mostly of fibroblasts, which are responsible for secreting the collagen and elastin that give support and elasticity to the skin. There are two major groups of skin cancers: malignant melanoma and nonmelanoma skin cancers. Cancers that develop from melanocytes are called melanoma. Nonmelanoma skin cancers are the most common cancers of the skin. Two of the most common nonmelanoma types are basal cell carcinoma (BCC) and squamous cell carcinoma (SCC).

About 75% of all skin cancers are BCCs, which have a high likelihood of recurrence after treatment, either at the same site or elsewhere. 65 SCCs account for about 20% of all skin cancers; these carcinomas are more likely to invade tissues beneath the skin and distant parts of the body than are BCCs.

Although most people believe they are not at risk for skin cancer, cancers of the skin (including melanoma and nonmelanoma skin cancers) are the most common of all cancers and account for about half of all cases in the United States.⁶⁵ The American Cancer Society estimated approximately 9800 skin cancer deaths for 2002, 7800 from melanoma and 2000 from other skin cancers. Melanomas account for about 4% of skin cancer cases but cause about 77% of skin cancer deaths. The number of new cases of melanoma found in the United States is on the rise. The American Cancer Society predicted 53,600 new cases of melanoma in the United States in 2002. For most skin cancer patients (including melanoma and nonmelanoma skin cancer), early diagnosis and thorough treatment (i.e., complete resection) are critical for a favorable prognosis.

Current diagnostic methods for skin cancers rely on physical examination of the lesion in conjunction with skin biopsy. Suspicious areas are selected upon visual inspection by the clinician, after which those lesions are partially or wholly biopsied for complete histological evaluation.⁶⁵ The biopsy is then sectioned and stained for pathological investigation and diagnosis. This protocol for skin lesion diagnosis is accepted as the gold standard, but it is subjective, invasive, and time consuming; hence, there is considerable interest in developing a noninvasive diagnostic tool that can accurately detect skin lesions noninvasively in real time, especially in the early stages.

Previous studies on skin cancer detection using optical spectroscopy have been primarily limited to fluorescence and diffuse reflectance spectroscopy and have produced limited success. ^{74,75} The interference of skin pigment and external agents such as creams and soaps has been the major limitation to the success of these techniques. Despite the relative ease of studying the skin, the first published reports of skin Raman spectra appeared only in the early 1990s. These early studies, however, focused on characterizing skin components, and included research on skin hydration, skin aging, and the effect of UV radiation. ¹¹

Williams et al. utilized FT-Raman spectroscopy to examine a number of skin features and correlate the Raman spectra with the biochemical agents responsible. ^{76,77} Caspers et al. used confocal Raman microspectroscopy to ascertain the *in vivo* Raman signal characteristics emanating from each layer of normal human skin. They showed that each layer of the skin contained Raman features that could be highly correlated with the protein and chemical content of each respective layer. ⁶² A recent study has also shown that it is possible to extract carotenoid Raman spectra *in vivo* from various skin tissues. ⁷⁸ Gniadecka et al. utilized FT-Raman spectroscopy to successfully differentiate BCC from normal, healthy skin *in vitro* in 16 patients. ⁷⁹ Although promising results were reported, FT-Raman spectroscopy is not a feasible technique for clinical diagnosis.

A recent study exploring the use of confocal Raman microspectroscopy for skin cancer detection was also reported. Results from two pilot studies performed on a novel bench top confocal Raman microspectrometer were encouraging. In the first study, Raman spectra were acquired *in vitro* from normal and various types of malignant skin tissues obtained from human patients undergoing excision. Figure 30.11 shows the Raman spectra of normal skin, BCC, SCC, and melanoma tissues at a depth where optimal differences between the various tissue types were observed. Key differences in the spectra are observed at several Raman bands including those seen at 860, 940, 1120, 1220 to 1340, and 1550 cm⁻¹.

Another study assessed the capability of the confocal Raman system to acquire Raman spectra *in vivo* and the variability in the Raman spectra from various types of normal skin. Raman spectra were acquired from the dorsal area of the hand from volunteers of various ethnicity and skin color (white, African-American, east Asian, and south Asian) at various depths of tissue. Subsequent statistical analysis of the Raman spectra at various depths revealed significant variations of Raman signal in the upper strata of the skin, presumably due to differences in melanin content. However, Raman spectra from locations deeper in the skin (\sim 60 µm) showed much more similarity visually and statistically. These results indicate that confocal Raman spectroscopy can limit the measurement volume to specified depths of the skin,

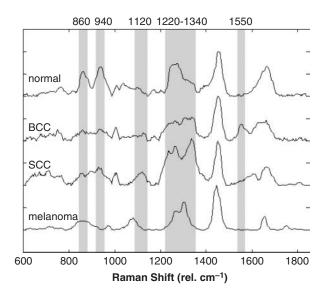

FIGURE 30.11 NIR Raman spectra of normal and cancerous skin lesions acquired *in vitro* using a confocal Raman microspectrometer.

which may circumvent the problems in skin color differences traditionally associated with optical measurement.

30.7.4 Other Applications

The preceding examples show the various stages of development in the implementation of Raman spectroscopy for disease detection *in vivo*. Additional applications of this versatile technique not specifically reported here include the detection of various pathologies in the brain⁸¹ and the GI tract, especially the esophagus,⁶³ ovary,⁵⁶ and colon.⁸² Raman spectroscopy has also been used to determine various analytes such as those in the blood. For example, studies have been reported on the determination of glucose concentration in diabetes patients.⁵⁹ A recent study reported the transdermal measurement of blood glucose using tissue modulation for signal extraction.⁸³ Researchers are using Raman spectroscopy in clinical settings and results appear promising. Raman spectroscopy is poised to move to the next level of implementation.

30.8 Future Perspectives

Recent technological developments have made clinical implementation of Raman spectroscopy feasible. Advances in diode laser technology and CCD detector technology have contributed tremendously to this process. However, the need still exists for compact Raman probes and integrated systems that would make this technique even more versatile. Currently, several integrated systems are available for the application of Raman spectroscopy in environmental and manufacturing processes. A similar advancement is required in the field of biomedicine. The introduction of micro-optics and microfabrication can further aid in the development of compact small-diameter probes.

This chapter presents a review of concepts, instrumentation, and sample applications of nonresonance Raman spectroscopy for disease detection *in vivo*. The success of the technique has led to the development of feasible clinical systems that can measure Raman signals from tissue with short collection times. Many of these systems have already undergone preliminary testing and several others are currently in the process of being tested. These studies clearly indicate that clinical application of Raman spectroscopy is imminent and may be expected to change the face of disease detection in the near future. While more extensive

studies are still needed to form a true assessment of the capability of Raman spectroscopy for disease detection, preliminary results are extremely encouraging. What makes this technique so invaluable is not only its use for disease classification, but also the possibility of evaluating the acquired spectra for biochemical composition. This technique is a viable clinical tool and an important research tool for furthering both the technology of patient care and the understanding of the disease process.

31.1 Introduction

Spectroscopic techniques examine different types of light–tissue interactions and provide biochemical and morphological information at the molecular, cell, and tissue levels in a noninvasive way. Because light delivery and collection are compatible with optical fibers and data analysis can be achieved in real time, spectroscopic information can serve as a powerful tool for assessing the state of tissue *in vivo* thus, guiding surgery or biopsy or monitoring the effects of treatment. Ultimately, optical techniques could eliminate the need for biopsy, at least in some cases, and allow for a single triage visit during which detection and treatment of a lesion could be combined. However, to optimize the use of optical methods in disease detection and treatment, it is important to understand and quantify the information provided by the detected optical signals. Spectroscopic techniques are ideal for this purpose.

Three different methods have been used to establish the presence of distinct spectral features for normal and diseased tissues *in vivo*. Empirical techniques use intensity information at specific wavelengths or

wavelengh ranges. Such techniques are easy to implement, but they do not use the characteristics of the full spectrum and lack quantitation. Statistical techniques, such as principal component analysis, are based on the analysis of the entire spectrum. However, this approach does not provide insights into the origins of the detected changes. In addition, statistical analysis methods usually assume a linear relationship between the components contributing to a given spectrum. Thus, extraction of quantitative information about the source of the spectroscopic signals is often difficult because of the turbid tissue nature or interference between different types of spectroscopic features (for example, fluorescence and Raman, or fluorescence, scattering, and absorption). Thus, it is necessary to develop models that take into account the optical, morphological, and biochemical properties of tissue in a quantitative way. Parameters extracted from model-based techniques can be used to classify tissue (e.g., normal vs. diseased) or to quantify tissue components (e.g., blood analyte concentrations).

In this chapter, we review how four spectroscopic techniques (fluorescence, diffuse reflectance, light scattering and Raman spectroscopy) can be used to extract quantitative information about tissue biochemistry, organization, morphology, and molecular composition and the corresponding changes that take place during the development of disease. In addition, we discuss the complementary character of these techniques and provide examples demonstrating the synergy and enhancement that can be achieved by combining spectroscopic information.

31.2 Characterization of Tissue Biochemistry Using Fluorescence Spectroscopy *in Vivo*

Fluorescence is one of the most widely used spectroscopic techniques at the clinical and the basic science levels.¹ It has been used as a tool for the detection of endogenous and exogenous chromophores as a means of localizing lesions and tailoring dosimetry for treatments such as photodynamic therapy.² In this section, we will focus on endogenous tissue fluorophores. Promising results have been reported on the use of steady-state and time-resolved fluorescence spectroscopy as a diagnostic modality in a number of tissues, including the gastrointestinal tract,^{3–5} the uterine cervix,^{6–8} the skin,^{6–9} the bladder,¹⁰ the oral cavity,^{10–12} and the lung.^{10–13}

For most epithelial tissues, a small number of endogenous fluorophores are present that can be excited in the 300- to 600-nm range. Among those, tryptophan, collagen, elastin, NAD(P)H, FAD, and porphyrins are the most prominent. Only two or three of these fluorophores are excited simultaneously for a specific excitation wavelength. Despite this fact, extraction of quantitative information about the fluorescence contributions of a specific chromophore is not trivial. Most of the difficulties are associated with the fact that measured tissue fluorescence can be highly distorted by tissue scattering and absorption.

In most cases, statistical or empirical algorithms are used to assess the sensitivity and specificity with which lesions can be distinguished from normal tissues based on their fluorescence characteristics. Empirical algorithms typically use the value or the ratio of the fluorescence intensity at specific excitation–emission wavelengths or wavelength ranges.³ This is the approach adopted by most fluorescence imaging diagnostic systems used clinically.^{13,14}

Principal component analysis is also a very useful statistical tool that is often used to decompose the spectra within a given data set into a linear combination of orthogonal basis spectra called principal components (PCs).¹⁵ The first PC accounts for the spectral features that vary the most, and subsequent PCs represent features with progressively smaller variance. To describe a specific spectrum, a linear combination of PCs is used, with each PC weighed by the appropriate PC score. Typically, the values of these PC scores are used to determine the spectral features that are different between normal and diseased tissues and to develop diagnostic algorithms. For example, the scores of selected PCs describing measured fluorescence spectra at 337-, 380-, and 460-nm excitation were used to separate cervical squamous intraepithelial lesions (SILs) from non-SILs with a sensitivity of 82% and a specificity of 68%.⁶ Statistical algorithms based on neural network nonlinear methods have also been developed and have shown, in some cases, superior diagnostic performance over multivariate statistical analysis-based algorithms.¹⁶

Such techniques are often useful in identifying spectral regions within which diagnostically useful fluorescence changes exist, and they can provide qualitative insights into the origins of these changes. However, in some cases subtle fluorescence differences can be masked by interferences introduced by tissue scattering and absorption. Thus, to acquire reliable quantitative information about the biochemical changes that take place during the development of disease and are represented in the tissue fluorescence, it is necessary to remove these distortions. Empirical and more theoretically rigorous models have been developed to achieve this.

An empirical model developed by Richards-Kortum et al.¹⁷ expressed the measured fluorescence as the product of two factors: (1) a linear combination of all the fluorophore contributions representing intrinsic fluorescence and (2) an attenuation factor representing broadband attenuation due to scattering, and oxyhemoglobin attenuation due to blood absorption. This model has been used to describe fluorescence excited at 476 nm from normal and diseased human arterial *ex vivo* tissues in terms of the intrinsic fluorescence from structural proteins (collagen and elastin) and ceroid, and the attenuation due to hemoglobin and structural proteins.¹⁷ Using the extracted fluorescence contributions for ceroid and structural proteins, diagnostic algorithms were developed that separated normal from diseased tissue with 91% sensitivity and 85% specificity.

This model has also been employed to describe measured fluorescence spectra excited at 337 nm and acquired *in vivo* from colposcopically normal and abnormal cervical tissues.¹⁸ In this case, the measured fluorescence was described in terms of the intrinsic fluorescence from collagen, elastin, NAD(P)H, and FAD, and attenuation due to oxyhemoglobin and scattering. The latter was represented by a constant. After normalizing the collagen contribution for each site of each patient to the average collagen contribution to the fluorescence of the normal sites of the same patient, a decrease was observed in the collagen fluorescence of precancerous tissues compared to colposcopically normal ones.

A trend toward elevated levels of the normalized relative NAD(P)H contributions was also reported for precancerous tissues when compared to normal tissues in the same patient. To observe this trend, spectra were normalized to their peak intensity prior to model analysis. The relative NAD(P)H fluorescence contribution of each site was then divided by the average NAD(P)H contribution to the normal sites in the same patient. This type of analysis provided useful information for understanding the origins of some of the observed measured fluorescence changes. However, because of the required normalizations, it was not very useful diagnostically in a clinical setting.

It has been recognized for some time that the diffuse reflectance spectrum, measured simultaneously with fluorescence, can also provide a means to remove absorption and scattering distortions in the measured tissue fluorescence spectrum, and thus to extract the intrinsic fluorescence. This was implemented in early fluorescence studies designed to monitor NAD(P)H in metabolically active tissues, such as the brain, heart and liver. The basic rationale behind this approach is that fluorescence and reflectance photons are distorted similarly by scattering and absorption. A comprehensive review of relevant work has been presented by Ince et al.¹⁹

Initial expressions involved linear^{20–24} or nonlinear^{25–27} combinations of the fluorescence and reflectance spectral features at specific wavelengths. Unfortunately, these models are applicable only for the particular wavelength regimes for which they were developed and tested, and are not sufficient to recover the entire intrinsic tissue fluorescence spectrum line shape and intensity. To achieve that, it is necessary to take into account the wavelength-dependent optical properties of tissue in a more rigorous manner. To this effect, an analytic model based on a photon migration picture developed from Monte Carlo simulations was introduced by Wu et al.²⁸ This model combines fluorescence and reflectance measurements acquired over the same wavelength range using identical light delivery and collection geometries. An empirical modification of this model that takes into account changes in the optical properties at the excitation wavelength has been reported recently by Finlay et al.²⁹ This expression was used to follow quantitatively the kinetics of protoporphyrin IX photobleaching and photoproduct formation in the normal rat skin *in vivo*. Gardner et al.³⁰ used Monte Carlo simulations to relate the propagation of laser excitation light and fluorescence to the diffuse reflectance. With these empirically obtained expressions, an expression for the intrinsic fluorescence was derived. Durkin et al.³¹ used Kubelka-Munk absorption and scattering coefficients

obtained from diffuse reflectance and transmittance experiments to predict the intrinsic fluorescence spectrum. Although such a model could be very useful for *ex vivo* studies, the acquisition of parameters from transmittance measurements renders this approach impractical for *in vivo* tissue measurements. Zhadin et al.³² expressed reflectance and fluorescence in terms of the medium's "darkness," a variable defined as the ratio of the absorption coefficient to the reduced scattering coefficient. The darkness parameter was extracted by inverting the reflectance and was used to extract the intrinsic fluorescence line shape from the measured fluorescence.

Most of these studies have been limited to wavelength ranges within which hemoglobin and water absorption are not very strong;^{28–30,32,33} however, a large number of fluorescence studies have been conducted in the 400-nm emission range,^{1,2} where important tissue chromophores, such as collagen and NAD(P)H, fluoresce strongly. Unfortunately, the Soret band of hemoglobin absorption is also in this spectral region, with a peak in tissue absorption at approximately 420 nm. This absorption can give rise to a dip in the measured bulk fluorescence that can be misinterpreted because the spectra are no longer simply a linear sum of spectral contributions from endogenous fluorophores such as collagen, NAD(P)H, elastin, etc. Such interference can not only lead to misinterpretation of the biochemical information conveyed by the measured fluorescence, but they can also mask small biochemical changes that take place in diseased tissue. Therefore, it is important to extract the tissue intrinsic fluorescence over a wide emission range that includes this important diagnostic region.

Recently, the photon-migration-based model developed by Wu et al.²⁸ was modified to extend its validity in regimes of significant absorption.³⁴ The ability of this model to recover the intrinsic fluorescence line shape *and* intensity has been validated using tissue phantoms with a wide range of physiologically relevant scattering and absorption properties.³⁵ This model has been used clinically to recover the intrinsic fluorescence of several types of tissue, including Barrett's esophagus,³⁶ the uterine cervix,⁸ and the oral cavity.¹²

For these studies, fluorescence and reflectance spectra were acquired using a FastEEM instrument, depicted schematically in Figure 31.1.³⁷ This instrument allows collection of 11 fluorescence emission spectra excited between 337 and 610 nm and a white light (350 to 750 nm) reflectance spectrum in less than 1 s. Light is delivered to the tissue via an optical fiber probe,³⁸ which consists of a central light delivery fiber surrounded by six light collection fibers (all fibers have a 200-µm core diameter and a numerical aperture (NA) of 0.22). At the tip of the probe, all fibers are fused together, creating an optical shield approximately 1.5 mm in diameter. The shield is beveled at a 17° angle to eliminate detection of specular reflections. In addition, the shield provides a fixed geometry for light delivery and collection, which are identical for the measured fluorescence and reflectance spectra.

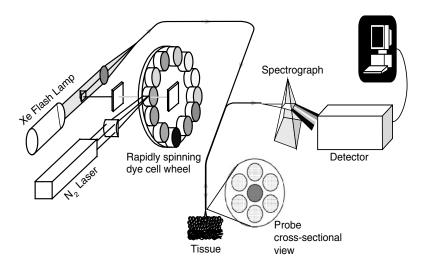

FIGURE 31.1 Schematic representation of FastEEM instrument used to acquire fluorescence and reflectance tissue spectra *in vivo*. (From Georgakoudi, I. et al., *Gastroenterology*, 120, 1620, 2001. With permission.)

Extraction of intrinsic fluorescence spectra for *in vivo* tissues has allowed minimization of the variations in line shape and intensity in measured fluorescence spectra that result from the presence of physiological blood content variations. ¹² In some cases, it is found that even significantly different measured fluorescence spectra correspond to similar intrinsic fluorescence spectra, mainly as a result of the removal of absorption distortions (Figure 31.2). Significant differences have been detected in the intrinsic fluorescence spectra of normal and diseased tissues in Barrett's esophagus, the uterine cervix, the oral cavity, and coronary arteries. Mean intrinsic fluorescence spectra for normal and diseased tissues based on the analysis of data from multiple patients are shown in Figure 31.3.

In contrast to the measured fluorescence spectra, which consist of nonlinear contributions from tissue fluorescence, scattering and absorption, intrinsic fluorescence spectra are composed of a linear combination of the fluorescence spectral features of the chromophores excited at a particular wavelength. Thus, once the component spectral features are identified, a simple linear decomposition can be performed to extract quantitative tissue biochemical information.

Biochemical decomposition of measured tissue fluorescence spectra has been performed previously using the spectral features of commercially available chromophores diluted in saline.^{5,18} However, because fluorescence is sensitive to the local environment of the chromophore, it does not necessarily follow that such spectra are an accurate representation of the chromophores' spectral features *in vivo*. To extract the fluorescence signatures of two of the major tissue chromophores, namely collagen and NAD(P)H, in an *in vivo* environment, fluorescence EEMs and reflectance spectra were acquired during asphyxiation (i.e., elimination of blood flow) of human esophageal tissue *in vivo*.³⁹ The changes in the tissue redox state that take place during loss of oxygen were evident in the measured tissue reflectance spectra, and they were accompanied by spectral changes in the intrinsic tissue fluorescence.

These changes were expected because the levels of NAD(P)H should increase as the levels of tissue oxygen decrease. The observed changes in intrinsic fluorescence during tissue deoxygenation could be described accurately by two spectral components extracted by analysis of the intrinsic fluorescence using a multivariate curve resolution (MCR) algorithm.³⁹ The fluorescence spectral features of these two components are consistent with those of collagen (commercially available collagen Type I) and NAD(P)H (from isolated cervical tissue epithelial cells).³⁹ Thus, it could be concluded that the MCR extracted fluorescence EEMs (Figure 31.4) represent the spectral signatures of collagen and NAD(P)H *in vivo*.

A linear combination of the *in vivo* NAD(P)H and collagen EEMs extracted from the tissue asphyxiation measurements was fit to intrinsic fluorescence excitation–emission matrices of normal and diseased tissues. This decomposition provided quantitative information about the biochemical make-up of tissue and the changes that take place during the development of disease. The results of this decomposition for Barrett's esophagus, cervical, oral, and coronary artery tissue sites are included in Figure 31.5. Note that no normalizations were performed prior to biochemical decomposition of these data sets.

Barrett's esophagus is defined as the replacement of normal squamous esophageal tissue by metaplastic columnar epithelium. Patients with Barrett's eosphagus are at higher risk for developing adenocarcinoma of the esophagus. As a result, they undergo regular endoscopic surveillance procedures in an attempt to detect changes at the precancerous or dysplastic stage when treatment can be effective. Unfortunately, dysplastic changes are endoscopically invisible. Thus, random biopsies are acquired, typically, one at each quadrant of the esophagus for every 2 cm of the Barrett's segment. A technique that would allow the physician to detect precancerous lesions or to serve as a guide to biopsy could improve significantly the clinical management of these patients.

When a linear combination of NAD(P)H and collagen fluorescence spectra was fit to *in vivo* fluorescence spectra from seven patients with Barrett's esophagus, it was found that high-grade dysplastic tissues have lower levels of collagen and increased levels of NAD(P)H when compared to nondysplastic tissues. This information is diagnostically useful, and it provides important insights about the biochemical changes that occur in tissue during the development of premalignancies. For example, the increase in NAD(P)H for high-grade tissues is consistent with cellular hyper-proliferation or increased metabolic activity.²³ The decrease in collagen fluorescence could be the result of degradation in the collagenous network of the connective tissue. This in turn could be the result of an increase in the activity of

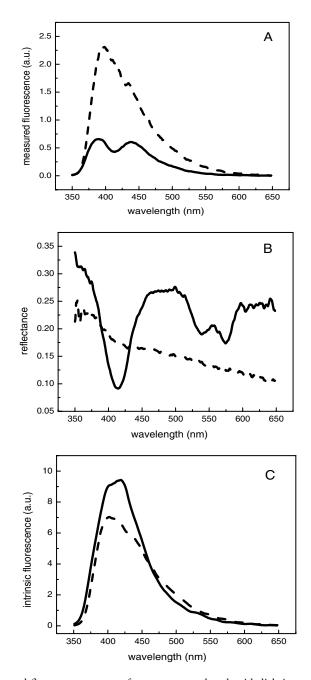

FIGURE 31.2 (A) Measured fluorescence spectra from two normal oral epithelial tissue sites, 337-nm excitation. (B) Corresponding measured reflectance spectra. (C) Corresponding intrinsic fluorescence spectra. Notice that the intrinsic fluorescence spectra exhibit much more similar spectral features than the corresponding measured spectra.

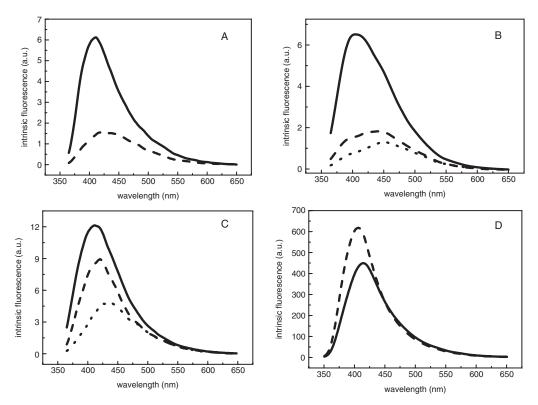

FIGURE 31.3 Mean intrinsic fluorescence spectra from (A) ten nondysplastic (solid line) and five high-grade dysplastic lesions (dashed line) in seven Barrett's esophagus patients. (B) 43 normal squamous (solid line), 12 biopsied squamous metaplastic (dashed line), and 10 biopsied high-grade squamous intraepithelial lesions (dotted line) of the cervix from 35 patients. (From Georgakoudi, I. et al., *Am. J. Obstet. Gynecol.*, 186, 374, 2002. With permission). (C) 28 normal (solid line), 8 dysplastic (dashed line), and 9 cancerous (dotted line) oral epithelial tissue sites from 15 patients. (D) 22 normal/intimal fibroplasia (solid line) and 88 atherosclerotic and atheromatous (dashed line) coronary artery tissue sites. All spectra were acquired *in vivo* with the exception of the coronary artery spectra. Excitation wavelength = 337 nm.

collagenases, enzymes that cleave collagen. Indeed, an increase in the level of serine and cysteine proteases has been found in gastric and colorectal cancerous and precancerous lesions. ⁴⁰ Such proteases are known to be activators of matrix metalloproteinases, a prominent class of tissue collagenases. ⁴¹ The decrease in collagen fluorescence could also be at least partially attributed to an increase in epithelial thickness, which would limit the amount of light that reaches the underlying stroma.

Similar differences are found in the NAD(P)H and collagen fluorescence levels of normal and precancerous uterine cervical tissue sites.^{8,39} During the normal reproductive life of a woman, squamous epithelium, the tissue type lining the ectocervix (i.e., the vaginal portion of the cervix), starts gradually to replace the columnar epithelium of the endocervix (i.e., the cervical canal that leads to the uterus). This replacement is known as squamous metaplasia and it takes place within the transformation zone. Most precancerous and cancerous cervical changes occur at the transformation zone. During colposcopy, the cervix is visualized under 6× or 15× magnification and colposcopically abnormal tissues are biopsied and examined histopathologically to determine the presence or absence of disease.

Although colposcopy and biopsy are highly sensitive techniques for detecting cervical cancerous and precancerous lesions known as SILs, they have very low specificity. That means that a significant number of tissue sites that appeared colposcopically abnormal are histopathologically normal and did not have to be biopsied. A technique that would improve upon the specificity of colposcopy would enhance its efficiency and have a significant impact on the time and resources dedicated to these procedures.

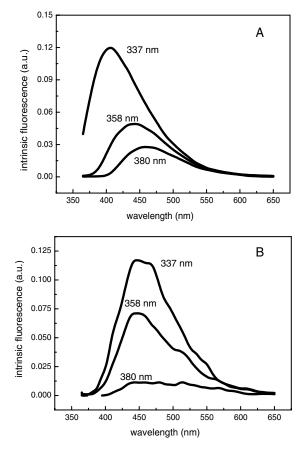

FIGURE 31.4 (A) Intrinsic fluorescence spectra of tissue collagen extracted for 337-, 358-, and 380-nm excitation from measured fluorescence and reflectance spectra acquired during asphyxiation of human esophageal tissue *in vivo*. (B) Corresponding tissue NAD(P)H intrinsic fluorescence spectra.

Especially in the case of the cervix, a tool that could provide a diagnosis in real time would potentially allow the combination of detection and treatment of a lesion during a single patient visit, providing a further positive economic and psychological impact.

Results of the analysis of intrinsic fluorescence spectra acquired *in vivo* from colposcopically normal and colposcopically abnormal cervical tissue sites from 35 patients are shown in Figure 31.5B. Colposcopically abnormal tissue sites were biopsied and classified either as squamous metaplastic (i.e., benign) or SIL (i.e., precancerous). A significant decrease in collagen fluorescence was present between colposcopically normal and abnormal tissues.^{8,39} As in the case of Barrett's esophagus, this decrease could be the result of collagenases. Indeed, it has been reported that differences can be found in the levels or patterns of expression of metalloproteinases in normal, squamous metaplastic and SIL cervical sites.⁴²

As mentioned previously, most of the colposcopically abnormal tissue sites are found within the transformation zone of the cervix, an area of constant dynamic change. Higher levels of collagenase expression have been reported for tissues undergoing architectural changes as in tissue regeneration and wound healing.⁴³ In addition, we find that among the colposcopically abnormal tissues, SILs tend to have higher NAD(P)H fluorescence than squamous metaplastic sites. This increase could be attributed to increases in epithelial thickness or metabolic activity, as in the case of Barrett's esophagus. As indicated by the diagnostic threshold lines drawn based on logistic regression analysis, the colposcopically abnormal but histopathologically benign squamous metaplastic tissue sites can be separated fairly well from the

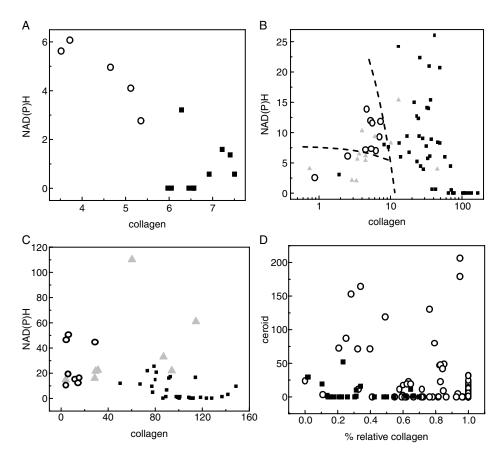

FIGURE 31.5 NAD(P)H and collagen fluorescence contributions to intrinsic tissue fluorescence excitation—emission matrices (excitation = 337 to 425 nm; emission = 375 to 700 nm) of the patient populations described in Figure 31.3. (A) Nondysplastic (squares) and high-grade dysplastic (circles) Barrett's esophagus. (B) Normal squamous epithelium (squares), colposcopically abnormal squamous metaplastic, i.e., benign (triangles) and high-grade SILs (circles) of the uterine cervix. (C) Normal squamous (squares), dysplastic (triangles), and cancerous (circles) nonkeratinizing oral epithelial tissues. (D) Ceroid fluorescence extracted from analysis of intrinsic fluorescence spectra excited at 480 nm shown as a function of the percentage of the relative collagen contribution with respect to the sum of the collagen and elastin fluorescence contributions to intrinsic fluorescence spectra excited at 337 nm for normal/intimal fibroplasia (squares) and atheromatous/atherosclerotic (circles) coronary artery. The decision lines in (B) were drawn based on logistic regression analysis. ([A] and [B] from Georgakoudi, I. et al., Cancer Res., 62, 682, 2002. With permission.)

histopathologically abnormal tissues, illustrating how quantitative biochemical information can be valuable in helping the physician decide which colposcopically abnormal tissue sites to biopsy.

A third tissue type for which intrinsic fluorescence spectra have been extracted and biochemically analyzed is oral squamous epithelium. Squamous cell carcinoma of the upper aerodigestive tract continues to be a major public health problem worldwide. In the U.S. alone, 40,000 new cases and 11,000 deaths were expected for the year 2000.⁴⁴ Despite advances in radiotherapy, chemotherapy, and surgery, patients' survival with oral cancer has not improved significantly. The entire oral cavity is lined with squamous epithelium; however, the detailed morphology and architecture of the tissue vary depending on its function. Initial studies indicate that it is diagnostically important to consider separately the intrinsic fluorescence properties of keratinized and nonkeratinized epithelia.¹² The NAD(P)H and collagen contributions to the intrinsic fluorescence of normal, dysplastic and cancerous nonkeratinized epithelial sites are shown in Figure 31.5C. A decrease in collagen and an increase in NAD(P)H fluorescence are observed

in dysplastic and cancerous oral tissues, consistent with the changes observed in cervical and Barrett's esophagus tissues.

Finally, intrinsic fluorescence of coronary artery, a nonepithelial tissue, has been extracted and decomposed into fluorescent biochemical constituents. Despite major improvements in diagnosis and treatment, coronary artery disease is still the most significant cause of death in the United States, and is responsible for more than 3 million hospital admissions every year. Coronary angiography, and more recently intravascular ultrasound, are the most widely used methods for invasive diagnosis of coronary artery disease. However, the sensitivity of these tools in identifying the morphological components of atherosclerotic plaques, and especially of necrotic core, is poor.

Laser-induced fluorescence (LIF) spectroscopy has been tested in the last decade in the *in vitro* diagnosis of atherosclerosis, with the purpose of improving the morphology-based diagnosis of the plaque. ^{17,46,47} Four chemical components with specific fluorescence spectral features have been identified in the human arterial wall: collagen, elastin, ceroid, and tryptophan. ^{17,46–48} Collagen and elastin are the structural proteins of normal and diseased arteries. An increase in the collagen content of atherosclerotic tissues has been reported. ^{49–51} Tryptophan is an amino acid present in the skeleton of numerous proteins in the intimal extracellular matrix that is increased in atherosclerotic plaques. Ceroid is an insoluble conglomerate with marked autofluorescence properties, present in the atherosclerotic macrophage cells and necrotic core. ⁵² Oxidized low-density lipoprotein is its main chemical component, which gives rise to a characteristic spectral fingerprint of the atherosclerotic lesion. ^{46,52,53}

After being harvested from cardiac transplant patients and postmortem autopsies, 110 coronary artery segments were investigated *ex vivo* with the FastEEM. While extracting the intrinsic fluorescence of normal and diseased coronary artery tissues, it was found that beta carotene, a second tissue absorber in addition to hemoglobin, was affecting significantly the line shapes of the measured reflectance and fluorescence spectra. Once beta carotene absorption was incorporated in the analysis of the fluorescence and reflectance spectra, intrinsic tissue fluorescence excited at 340 and 480 nm was extracted and decomposed biochemically into contributions from collagen, elastin, and ceroid. The basis spectra for these components were derived based on the fluorescence characteristics of commercially available elastin and collagen type I and MCR. A significant increase was found in the ceroid and collagen fluorescence of atheromatous and atherosclerotic specimens when compared to that of normal and intrimal fibroplasia tissues, consistent with the histopathological analysis of these specimens (Figure 31.5D).

In conclusion, in this section we summarized methodologies that can be used to extract quantitative tissue biochemical information based on fluorescence spectroscopic measurements. Removal of distortions introduced in measured tissue fluorescence by scattering and absorption is essential in achieving this goal. The extracted quantitative information can be diagnostically useful, providing important insights into the biochemical changes that take place *in vivo* during disease development. In addition, such information can be used to optimize the design of instruments to detect or monitor lesions based on fluorescence.

31.3 Characterization of Bulk Tissue Optical Properties Using Diffuse Reflectance Spectroscopy *in Vivo*

A diffuse reflectance spectrum arises from light that has been scattered multiple times within the sample of interest. The spectral features of light diffusely reflected from tissue depend on its scattering and absorption properties. Diffuse reflectance spectroscopy studies the changes in these optical properties associated with disease or therapy. Reflectance measurements can be performed with very short light pulses (time-domain), an intensity-modulated source (frequency-domain), or a steady-state broadband or monochromatic source. In this section, we will focus on the use of visible steady-state *in vivo* diffuse reflectance measurements to characterize tissue and provide clinically useful diagnostic information. A broad review of elastic light-scattering spectroscopy and diffuse reflectance is provided in Chapter 29 of this handbook.

A number of clinical studies performed with tissues such as colon,^{54,55} bladder,⁵⁶ breast,⁵⁷ ovary,⁵⁸ and skin^{59–63} demonstrate that diffuse reflectance spectra contain diagnostically useful information. Typically, an optical fiber probe is used to deliver white light from a high-power lamp onto the tissue and to collect the diffuse reflectance. Several algorithms have been developed based on statistical or on empirical approaches.

For example, the ratio of the area under the normalized reflectance curve between 540 and 580 nm to the area under the reflectance between 400 and 420 nm has been used to differentiate neoplastic from nonneoplastic colon tissues.⁶⁴ The slope of the reflectance in the 330- to 370-nm range was employed to distinguish between malignant and nonmalignant bladder tissues.⁵⁶ A combination of parameters related to the area under the reflectance curve, the reflectance slope and the mean intensity at specific wavelength bands were used by Wallace et al.⁶⁵ to distinguish between malignant melanoma and benign pigmented skin lesions. Such skin lesions were also separated with 80% sensitivity and 51% specificity using an imaging approach that combined reflectance-related parameters with morphological features of the lesion, such as dimension and roundness.⁶² Neural network-based pattern recognition algorithms have been also used to identify characteristic skin,⁶³ breast,⁵⁷ and colonic⁵⁴ neoplastic reflectance features.

A semiempirical model developed to describe skin optical properties based on specific features of the reflectance was reported by Dawson et al.⁶⁰ In this model, skin was treated as a four-layer system with absorption due to fibrous protein, melanin, and hemoglobin in the first three layers, respectively, and scattering due to collagen and fat in the fourth layer. By assuming that the amount of reflected light from the first three layers is minimal, they found that the logarithm of the inverse skin reflectance (LIR) is equal to the sum of the absorbances of the first three layers minus the log of the reflectance of the fourth layer. The effects of scattering were empirically accounted for in the LIR spectrum by subtracting a line connecting the LIR intensities at 510 and 610 nm. Using the LIR values at 510, 543, 560, 576, and 610 nm, an erythema index was defined that was proportional to the hemoblobin content of the skin sample. An approximate correction for melanin scattering had to be implemented to ensure that the erythema index was not correlated with the pigmentation or melanin content of the skin. The melanin index was characterized empirically by using the slope of the LIR spectrum between 650 and 700 nm. However, this erythema index was dependent on the oxygen saturation levels of hemoglobin.

Feather et al.⁶⁶ showed that the hemoglobin index, which depended on the gradients of the LIR values at four isosbestic points between 527.5 and 573 nm, was independent of oxygen saturation and, thus, a more suitable parameter for quantifying the amount of cutaneous hemoglobin. Skin oxygen saturation levels could be estimated by combining the hemoglobin index with the LIR intensity at 558.5 nm. These empirical expressions for hemoglobin content and oxygen saturation were validated with *in vitro* measurements of red cells in plasma. To perform similar measurements *in vivo*, it was necessary to remove significant contributions from specular reflections at the skin surface. This was achieved by using crossed linear polarizers for light delivery and detection.⁶¹ Further empirical modifications were also implemented to correct for hemoglobin absorption effects in the case of the melanin index, and for melanin absorption and scattering in the case of the hemoglobin index. The usefulness of these models for characterizing the optical properties of skin was illustrated by analyzing *in vivo* measurements performed with different skin colors and on a human forearm raised to different heights relative to the heart. However, there are no reports for this latter model being used clinically as an aid in detecting or treating skin lesions.

Another empirical model based on analysis of the LIR spectrum has been reported by Koenig et al. 67 and used to describe reflectance spectra collected from the bladder 67 and the colon. 54 First, measured reflectance spectra were converted into absorbance units using the expression, $A = -\log(R/Ro)$, where R and Ro were reflectance from tissue and a white reflectance standard, respectively. Then, a line was fit to the 640- to 820-nm range of the spectrum. This line was assumed to represent contributions from tissue scattering to the absorbance spectrum and was subtracted after it was extrapolated to cover the entire absorbance spectrum. Hemoglobin oxygen saturation was estimated based on the absorbance intensities at 555 and 577 nm, which are peak absorption wavelengths for deoxy- and oxyhemoglobin, respectively. The total amount of blood was estimated in the case of the bladder study based on these intensities and was found to be the most diagnostically useful parameter for discriminating neoplastic

from nonneoplastic bladder tissue with high sensitivity (91%), but low specificity (60%).⁶⁷ The high blood content of inflammed tissues was thought to be the reason for the low specificity results. This model was also used to interpret the success of statistically based algorithms designed to differentiate between neoplastic from neoplastic colon tissues, as well as between adenomatous and hyperplastic colon polyps, which is the more clinically relevant problem in the colon.⁵⁴ However, the extracted parameters were not used as the basis of a diagnostic algorithm.

Zonios et al.⁵⁵ have developed a more theoretically rigorous model describing the measured tissue reflectance as a function of the absorption and reduced scattering coefficients for a light delivery/collection geometry consistent with that of an optical fiber probe. This model is based on an expression developed by Farrell et al.,⁶⁸ which describes the diffuse reflectance from a narrow pencil beam of light incident on the surface of a semi-infinite turbid medium in terms of the reduced scattering (μ_s') and absorption (μ_a) coefficients and the source-collection fiber separation distance. The latter expression was derived using the diffusion approximation to the light transport equation. To acquire an analytical expression, Zonios et al. assumed point delivery of light and collection over a circular spot with an effective radius, extracted from the model, approximately equal to the radius of the optical fiber probe. This model is particularly appropriate for tissues that can be modeled by a single layer.

Some *a priori* knowledge with regard to the spectral features of the tissue's scattering and absorption is also required before using this model to describe tissue reflectance spectra. This is needed because the measurements employ a probe with a single source-collection fiber separation; hence, only a single piece of information is at each wavelength, insufficient to extract the diagnostic parameters, μ_s' and μ_a , independently. In particular, the identity of the absorbing tissue chromophores and their corresponding tissue spectra must be known. In most cases, this does not present a serious limitation. For example, in the case of most epithelial tissues, oxy- and deoxyhemoglobin, whose extinction coefficients have been studied widely, are the only significant absorbers in the visible region of the spectrum. In the case of other tissues such as breast and artery, additional absorbers, such as beta carotene, need to be included. Melanin absorption also needs to be included for tisssues such as skin. The level of agreement between the observed reflectance and the model fit can be used to ascertain whether all the absorbers have been accounted for.

This model has been used to describe, with good agreement, reflectance spectra acquired *in vivo* from tissues such as the colon,⁵⁵ Barrett's esophagus³⁶ (Figure 31.6A), the cervix,⁸ the oral cavity,¹² the artery (Figure 31.6B), and the breast. Notice the differences in the reflectance spectral features of Barrett's mucosa and coronary artery tissue, attributable mainly to the presence of beta carotene absorption in coronary artery. Based on this model analysis, quantitative information was extracted with regard to the bulk tissue scattering and absorption properties. For example, the extracted total hemoglobin concentration was significantly higher for adenomatous polyps than for normal colon mucosal tissues, while no significant changes in tissue oxygenation were detected.⁵⁵ Coronary artery tissue classified histopathologically as normal or as intimal fibroplasia exhibits consistently low levels of beta carotene absorption, in contrast to calcified and noncalcified atheromatous and atherosclerotic coronary arteries, which have varying amounts of beta carotene (Figure 31.6D).

In addition, the reduced scattering coefficient of colon polyps was generally lower and varied less as a function of wavelength than that of normal colon mucosa. This is a diagnostically useful trend that has also been detected between dysplastic and nondysplastic tissues such as Barrett's esophagus, ³⁶ the cervix, ⁸ and the oral cavity. ¹² To quantify these changes, the slope and intercept of a line fit to the wavelength-dependent μ_s was used. The gradual decrease in the slope and intensity of μ_s as Barrett's esophagus tissue is transformed from nondysplastic to low-grade and high-grade dysplasia is shown in Figure 31.6C. This decrease in the reduced scattering coefficient could be due to an increase in epithelial thickness, which in turn leads to less light reaching the highly scattering collagen fibers of the stroma; thus, less light is reflected within the collection angle of the fiber probe. In addition, changes in the density of the collagen fibers resulting from an increase in the activity of collagenases, as discussed in the fluorescence section, could also contribute to the observed decrease in the reduced scattering coefficient.

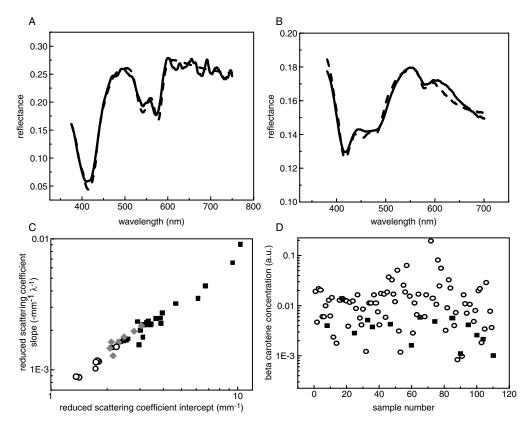

FIGURE 31.6 Measured reflectance spectra (solid lines) from a nondysplastic Barrett's esophagus tissue site (A) and an atheromatous coronary artery tissue sample (B) with corresponding fits (dashed lines). (C) Slope and intercept of line fit to the wavelength-dependent reduced scattering coefficient for nondysplastic (squares), low-grade (diamonds), and high-grade (circles) dysplastic Barrett's esophagus tissues. (D) Beta-carotene concentration extracted from the absorption coefficient of normal/intimal fibroplasia (squares) and atheromatous/atherosclerotic (circles) coronary artery. ([A] and [C] from Georgakoudi, I. et al., *Gastroenterology*, 120, 1620, 2001. With permission.)

These results demonstrate that diffuse reflectance spectroscopy is a promising tool that can be used clinically to detect and quantify changes in tissue biochemistry and morphology. Further improvements in the models used to describe measured tissue diffuse reflectance spectra, that would account more rigorously for the layered tissue architecture^{69,70} and small source-detector separations,^{71,72} could enhance the sensitivity of these measurements and allow the detection of more subtle changes with higher accuracy.

31.4 Characterization of Cellular and Subcellular Morphology Using Light-Scattering Spectroscopy

Light-scattering spectroscopy (LSS) is a novel optical technology for imaging and characterizing the morphology of subcellular organelles within the epithelial linings of the body.^{73,74} LSS is based on the fact that the spectral and angular distributions of light scattered by a particle depend on the size, shape, and internal structure of this particle. Thus, by analyzing light that has undergone a single backscattering event in tissue, we can extract quantitative morphological information about the scattering particle. As discussed next, the backscattering angle at which light is collected can be adjusted to gain some selectivity in terms of the size of the scattering particle that is characterized spectroscopically. For example, scattering in almost the exact backward direction provides detailed information about the cell nucleus.^{8,36,73–75} Changes in the morphology of the nucleus, such as enlargement, pleomorphism (variation in size and

shape), crowding (increase in the number of nuclei per unit area), and hyperchromatism (increase in chromatin content or nuclear material) comprise important histopathologic hallmarks for the diagnosis of precancerous and cancerous lesions; thus, this technique bears great promise as a noninvasive tool for characterizing important tissue morphological features and for detecting disease.

Light scattering measurements are performed routinely for extracting cell size in flow cytometry. Goniometric light scattering studies, i.e., studies that examine light scattering as a function of scattering angle, have also been performed in the 2- to 170°-range with suspensions of cells and subcellular organelles to characterize their scattering properties. Unfortunately, single scattering events are masked in biological tissue, because only a small portion of the light incident on tissue is returned after a single scattering. The rest enters the tissue and undergoes multiple scattering from a variety of tissue constituents. As a result, it becomes randomized in direction, producing a large background of diffusely scattered light. (This is the diffuse reflectance component discussed in the previous section.) This diffuse component is influenced significantly by hemoglobin absorption and scattering by cells, as well as by noncellular structures, such as collagen. As discussed earlier, important information can be obtained about the overall tissue optical properties from analysis of the diffuse reflectance spectra. In this section, we focus on the light representing single backscattering events. To study this, the diffusely scattered component must be removed from the overall reflected light.

Several approaches may be used to accomplish this. One employs a mathematical model to describe the diffusive background. Examples of such models were described in the previous section. The diffuse reflectance model fit is subtracted from the overall measured reflectance spectrum to obtain the single scattering component. Polarized light can be used to accomplish this as well.^{77,82} This approach uses the fact that incident light singly scattered in the backward direction retains its polarization, whereas multiply scattered light becomes depolarized. Thus, by using linearly polarized incident light, the contribution due to single scattering can be obtained as the difference between the components of light scattered from the tissue polarized parallel and perpendicular to the direction of polarization of the incident light.

Recent measurements on tissue phantoms consisting of water and polystyrene beads using a single 200-µm core diameter fiber for light delivery and collection indicate that such a probe geometry could also be sensitive to the size distribution and refractive index of the scattering particles near the surface of the sample. In addition, this study suggests that determination of the size and refractive index in this case could be achieved simply by studying the features of the intensity oscillations of the collected light (i.e., background removal would not be required).⁸³

The spectrum of the single scattering component can be analyzed to obtain information about the properties of the scatterers. 77,82,83 The origin of LSS signals depends on the geometry of collection. For example, particles that are large compared to the wavelength have strong scattering components in the near-exact forward and backward directions (even though backscattering is much weaker than forward scattering). 84 Cells and nuclei have the right size to exhibit this type of scattering behavior. Early light scattering measurements performed with suspensions of HeLa cells, Chinese hamster oocytes, and white blood cells indicated that the detected scattering patterns were in good agreement with Mie scattering from a dense sphere embedded within a larger softer sphere. 85 However, in tissue, because cells are adjacent to one another, there is index matching among the cell membranes of neighboring cells; thus, the nucleus becomes the major large size scatterer.

In addition, the intensity of the backscattered light from large particles oscillates in intensity as a function of wavenumber with a frequency characteristic of the particle size and relative refractive index.⁸⁴ Particles that are small compared to the wavelength, such as the tubules of the endoplasmic reticulum, scatter light in an approximately isotropic fashion over all angles. The light-scattering intensity as a function of wavelength also exhibits very broad features.⁸⁴ The angular and wavelength-dependent distributions of the light intensity scattered by particles whose size is comparable to the wavelength, such as mitochondria and lysosomes, exhibit significantly broader features than the corresponding spectra of large particles — but not as broad as those of small particles.⁸⁴ For cells with a high volume fraction of mitochondria, such as hepatocytes, the scattering properties are dominated by those of mitochondria, even in the exact backward direction.⁸⁶ When particles of several sizes are present, the resulting signal is

a superposition of these variations. Thus, the size distribution and refractive index of the scatterers can be determined from analysis of the spectrum of light backscattered by these particles. Once the size distribution and refractive index are known, quantitative measures characterizing alterations of morphology of the epithelial cells can be obtained, and corresponding diagnostic algorithms can be developed.

Preliminary *in vivo* studies have been performed to assess the potential of this technique as a tool for detecting precancerous and early cancerous changes in five different organs with three different types of epithelia: columnar epithelia of the colon and Barrett's esophagus, ^{36,73,75} transitional epithelium of the urinary bladder, ⁷³ and stratified squamous epithelium of the oral cavity ^{35,73} and the uterine cervix. ⁸ Reflectance spectra were collected using the FastEEM instrument described in Section 31.2. The diffuse background was subtracted from measured reflectance spectra using modeling. ⁵⁵ The light scattering spectra were analyzed based on the van de Hulst approximation for light scattering by particles that are large compared to the wavelength. ⁷⁴ The extracted size distributions were then used to obtain quantitative measures characterizing the degree of nuclear enlargement and crowding. Figure 31.7 displays these LSS parameters in binary plots to show the degree of correlation with histological diagnoses. In all five organs there is a clear distinction between dysplastic and nondysplastic epithelium. Both dysplasia and CIS exhibit a higher population density of nuclei than normal tissues and either a higher percentage of enlarged nuclei (Figure 31.7A through D) or a larger variation in the distribution of nuclear size. These features can be used as the basis for spectroscopic tissue diagnosis.

Studies of backscattering of linearly polarized light from cells, ^{77,82} ex vivo ^{77,82,87–90} and *in vivo* ⁷⁷ tissues have also shown great promise for characterizing cell and tissue morphology. Experiments have been performed during which the backscattered light collected from a small tissue area (approximately 3 mm²) was detected along the parallel and the perpendicular polarization relative to the propagation of the incident light. ⁸² The light-scattering spectrum extracted by subtraction of the perpendicular from the parallel polarized light was analyzed to provide information about the size distribution of cell nuclei from cell monolayers and ex vivo tissues. Significant differences were detected in the nuclear size distributions from normal and tumor colon tissues, consistent with the results of histopathology from corresponding thin tissue sections. ⁸² Further measurements with tissue phantoms and ex vivo and in vivo tissues have been performed with a probe with a linear pollarizer at its tip, which consisted of a central light delivery fiber and four light collection fibers positioned symmetrically around the light collection fiber. ⁷⁷ These studies concluded that the spectral features of backscattered light from a biological sample with the same polarization as the incident light are dependent on the internal morphology of the cell.

LSS measurements have also been performed in an imaging modality using polarization for background removal. Typically, the sample is illuminated with linearly polarized light, and the backscattered light is collected along the parallel and perpendicular polarizations. Jacques et al.⁸⁸ showed that, by combining the information in these two images, one can acquire an image sensitive only to the morphology of the upper few hundred micrometers of skin, where most skin cancers start to develop.

In a recent study by Gurjar et al.,⁹⁰ it was shown that, by imposing limitations on the angle of the backscattered light collected, quantitative information can be acquired about the size distribution and refractive index of epithelial cell nuclei (Figure 31.8). A 1.25 × 1.25-cm area was illuminated with narrowband collimated linearly polarized light. Light backscattered within one degree from the exact backward direction along the parallel and perpendicular polarizations with respect to the incident light was imaged onto a charge-coupled device (CCD) camera. By subtracting the perpendicular image from the parallel-polarized image pixel by pixel, the singly backscattered light intensity was extracted. A series of such images was acquired for 13 narrow wavelength bands, such that a light-scattering, wavelength-dependent spectrum could be constructed for each CCD pixel.

These spectra were analyzed using Mie scattering theory to determine the corresponding distributions of nuclear size and refractive index. While the spatial resolution of these images is limited by the CCD pixel size, the size distribution of the nuclei within that pixel can be determined with an accuracy of 0.1 µm, and the corresponding refractive index can be estimated with three-digit accuracy. LSS images representing distinct regions of nuclear enlargement within the physical outline of an adenomatous colon polyp are shown in Figure 31.9. Similar maps have been obtained to represent an increase in the relative

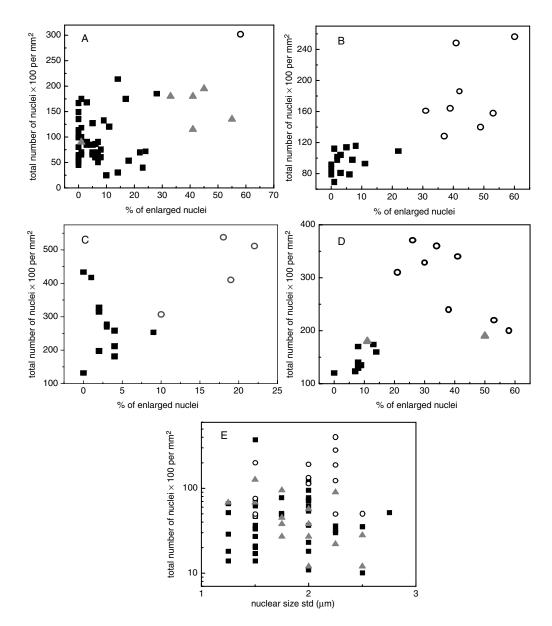

FIGURE 31.7 The population density of nuclei is plotted against the percentage of enlarged nuclei (i.e., nuclei larger than 10 μ m) for (A) Barrett's esophagus epithelium (squares, nondysplastic Barrett's mucosa; triangles, low-grade dysplasia; circles, high-grade dysplasia). (B) Colon epithelium (squares, normal colon mucosa; circles, adenomatous polyp). (C) Urinary bladder epithelium (squares, normal cells; circles, transitional cell carcinoma $in \, situ$). (D) Oral cavity epithelium (squares, normal cells; triangles, low-grade; circles, squamous cell carcinoma $in \, situ$). FIGURE 31.9 LSS image showing the spatial distribution of the percentage of enlarged nuclei, i.e., nuclei larger than 10 μm, for an adenomatous colon polyp. (From Gurjar, R. et al., *Nat. Med.*, 7, 1245, 2001. With permission.)

refractive index of cell nuclei (i.e., hyperchromatism) within the adenomatous polyp. 90 Results of nuclear morphometry acquired in this fashion are consistent with hematoxylin and eosin stained thin sections prepared from the same polyp following acquisition of the LSS images.

Wavelength-dependent, light-scattering spectra have also been collected as a function of angle (angular LSS) from monolayer cultures of benign mesothelial intestinal cells and T84 tumor colonic cells. ⁹¹ Analysis of these measurements using Mie theory shows that the cell nuclei scatter predominantly within a narrow cone (1 to 2°) near the exact backward direction, in agreement with previous results as well as theoretical calculations (Figure 31.10). Thus, the signal measured within a sufficiently narrow solid angle provides information about the size and refractive index of the cell nuclei. The signal scattered into larger scattering angles (>3°), particularly with 45° azimuth with respect to the polarization of the incident light, provides information about subcellular structure at the submicron scale (see Figure 31.10).

In this angular regime, the LSS signals could not be fitted under the assumption that the particles are normally distributed for any given mean size from 0.3 to 15 μ m. Moreover, other types of size distributions, such as top-hat, exponential, or skewed-normal could not fit the data. The spectra were found to be best described by an inverse power-law distribution for the number of particles, where the concentration N(d) of particles with a diameter d, was given by $N(d) \propto d^{-\beta}$ with the exponent β not dependent

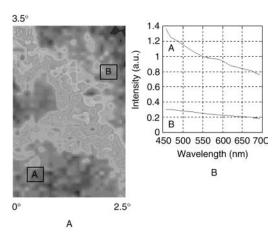

FIGURE 31.10 Experiments with two-layer tissue models with the upper layer formed by a monolayer of T84 colon tumor cells. (A) A/LSS contour map at $\lambda = 532$ nm. (B) Spectra of light scattered by cells in regions A and marked on map in (A). The analysis of these spectra enables extraction of quantitative characteristics of the size distributions of scattering particles responsible for the respective scattering spectra. (From Backman, V. et al., *IEEE J. Sel. Top. Quantum Electron.*, 7, 887, 2001. With permission.)

on d and characterizing the variations of refractive index inside the cells and, thus, the variations of intracellular density. To obtain the values of β , a Mie theory-based inversion procedure was used to fit the data. The sizes were assumed to be distributed between 0.01 and 1.5 μ m according to an inverse power law, with fitting parameter β . For T84 tumor cells, β was found to be approximately 2.2, whereas for normal mesothelial cells the best fit was obtained for β = 2.7. Thus, the size distribution of the T84 colon tumor cells is shifted with respect to that of the normal cells, with an increase in the relative number of large intracellular and intranuclear structures. We note that an inverse power-law distribution is a hallmark of fractal behavior. 92

Inverse power-law distributions have been used previously to describe refractive index variations in frozen tissue sections^{93,94} and have been associated with the fractal dimension of tissue. The smaller values of the size exponent for malignant cells can be correlated with certain alterations of normal cell structure associated with cancerous changes. For example, a smaller value of β in the size distribution of the intranuclear structure correlates with the visual perception of clumped and rough chromatin when a stained tissue sample is microscopically evaluated. Pathologists evaluating hematoxylin and eosin–stained samples of precancerous cells frequently observe such changes. Smaller values of β for malignant cells may also indicate higher structural entropy and, therefore, higher disorganization of the cell structure. Finally, a difference in β may be related to change in the fractal properties of the malignant cells. Thus, angular LSS studies can provide information about the organization and packing of subcellular and subnuclear structures at scales significantly more sensitive than conventional microscopic imaging.

These initial studies demonstrate that LSS can be used not only to detect changes in nuclear morphology that are well established hallmarks of precancerous and cancerous lesions but also to characterize subtle changes in the morphology and organization and packing of cells and tissues that have not been explored previously.

31.5 Characterization of Tissue Molecular Composition Using Near-Infrared Raman Spectroscopy

Near-infrared (NIR) Raman spectroscopy is well suited for probing the detailed biochemical and morphological composition of human tissue.^{95–97} Unlike fluorescence, reflectance, and NIR absorption spectroscopies, Raman spectroscopy provides narrow spectral bands with high information content that can

be assigned to specific molecular vibrations. Whereas relatively few endogenous biological fluorophores exist, many of whose spectra significantly overlap, there exist a multitude of Raman active chemicals in tissue that have unique spectra and can be specifically related to healthy and diseased conditions.

Several features of NIR Raman spectroscopy are especially important to the study of human tissue. NIR excitation wavelengths have relatively small extinction coefficients and large penetration depths in human tissue (approximately 1 mm), providing the opportunity to observe subsurface structures. The small absorption coefficient also precludes photolytic sample decomposition. Additionally, in contrast to vibrational spectra obtained via mid-IR absorption, water is a relatively weak absorber in the NIR, and water interference is not a problem in Raman experiments. Furthermore, the strong fluorescence interference from biological tissue samples encountered with visible excitation wavelengths is significantly reduced in the NIR region, rendering Raman features more easily accessible.

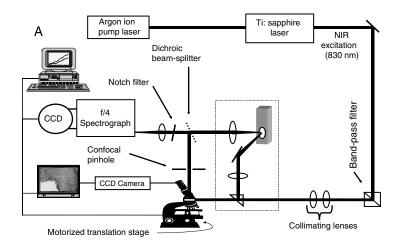

Most importantly, the sharp bands in the IR fingerprint region can be conveniently studied as Raman shifts and allow identification and quantification of the chemical species involved. Quantitative analysis is achieved by examining the intensities of molecular vibrational spectral bands because they provide a direct reflection of molecular concentrations. Such an analysis is possible because the intensity of the Raman bands for a given moiety is linearly related to its concentration.

Several groups have investigated methods to employ the technique and accurately extract chemical concentrations. 98–104 The ability to quantitatively probe biochemical features that characterize normal tissue and accompany disease progression is of substantial importance in the utility of Raman spectroscopy as a diagnostic aid. Furthermore, in several diseases, prognosis is directly related to the concentration of key chemical constituents in the tissue. Although it is often difficult to determine the spectra of all the components of a Raman spectrum from a biological sample, due to its complexity, spectral analysis techniques can still be used to extract quantitative information. These techniques are known as multivariate analysis methods, or chemometrics, and can be implemented to extract chemical concentrations, even without complete knowledge of the chemical's Raman spectrum or cross section. One Although chemometric techniques are powerful algorithms in spectral analysis, the accuracy of a model built depends on the quality of the spectral data set and the accuracy of the reference measurements.

Several geometries can be employed for quantitative Raman spectroscopy. These include direct back-scattering, excitation at various angles relative to the collection optics, microscopic illumination; they can include free-space optics, fiber optics, or a combination of the two. The particular geometry invoked depends on the nature of the sample and the conditions required for the particular application. The common overlying factor involved in Raman spectroscopy instrumentation is that the system must have a high throughput and efficiency because of the inherently weak nature of the Raman effect. Two specific instruments used in the development of quantitative spectroscopic models are presented here as examples. They have spectral resolutions of ~8 cm⁻¹, which is sufficient to resolve all relevant Raman bands.

The laboratory system used for studying biopsied biological tissue, shown in Figure 31.11A, is capable of collecting Raman and fluorescence spectra from macroscopic or from microscopic samples. ¹⁰⁷ NIR Raman excitation at 830 nm is provided by an argon ion laser-pumped Ti:sapphire laser. The excitation laser beam traverses a bandpass filter and can be focused onto a bulk sample (~1-mm diameter spot) or coupled into the confocal microscope (~2-µm diameter spot) via a prism that can be moved in and out of position. If bulk tissue is studied, the Raman-scattered light is collimated, filtered, and coupled into an imaging spectrograph attached to a CCD detector.

For microscopic measurements, an epi-illuminated microscope is used. The microscope objective focuses the excitation light and collects the Raman scattered light in a backscattering geometry. A dichroic beamsplitter and mirror combination redirect the Raman-scattered light to the spectrograph system along the same optical path used for the bulk tissue system, after passing through a confocal pinhole to increase axial resolution. A CCD camera atop the microscope allows for registration of the focused laser spot with a white-light transilluminated image. Typically, a 63× infinity-corrected water immersion objective (0.9 NA) is used. The detector and the microscope translation stages are computer controlled; therefore, spectral maps of the tissue can be created by raster-scanning the translation stage under the microscope objective.

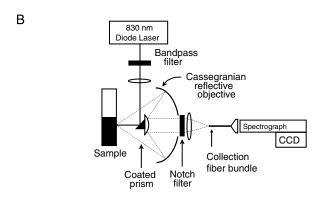

FIGURE 31.11 (A) Schematic diagram of instrument designed to acquire fluorescence and Raman spectroscopy maps of thin samples and thick tissue specimens. (B) Instrument designed to acquired Raman spectra from blood samples. (From Berger, A.J. et al., *Appl. Opt.*, 38, 2916, 1999. With permission.)

Simply by changing the excitation source, the filters/beamsplitters, and spectrograph grating, the system can be adapted for collecting fluorescence. Three additional wavelengths, 352, 477, and 647 nm, are delivered to the system via optical fibers. The switch between Raman and fluorescence can be made in less than 2 min, thereby allowing collection of complementary data of point measurements or spectral maps.

The experimental setup designed for the measurement of aqueous biological analytes using NIR Raman spectroscopy is shown in Figure 31.11B.¹⁰³ Excitation light, provided by an 830 nm diode laser, is bandpass filtered and delivered to the sample via a prism mounted in a Cassegrain microscope objective. The Cassegrain provides coaxial excitation with wide-angle collection and the backscattered Raman light from the sample is notch filtered and reimaged onto an optical fiber bundle. The circular collection fiber bundle is converted to a linear array and coupled directly into an imaging spectrograph. The light is dispersed onto a CCD detector and the fiber bundle image is binned to produce a spectrum.

Raman spectra are often analyzed by looking at markers such as the ratio of the intensities of two Raman bands. Such approaches have been useful in developing diagnostic algorithms for diseases such as breast cancer and cervical cancer. ^{108–110} However, because the amount of information contained in Raman spectra is large and relevant to disease diagnosis and to the study of disease progression, it is prudent to develop spectroscopic models that take full advantage of this content. Methods that use information about the entire spectrum can be statistical or based on physical models.

Statistical methods are used when the spectra of the individual tissue components are not accurately known. There are two distinct types of problems in Raman spectral diagnosis of biological tissue:

classification analysis ("Is this specimen in category A or B?") and quantitative analysis ("How much of C is present?"); statistical methods can be applied to both. In the case of classification, statistical analysis is useful for proof-of-principle studies to evaluate the diagnostic capabilities of Raman spectroscopy when a new disease is being approached, or when there is an incomplete understanding of the basic constituents comprising the Raman spectra of the tissue so that a more physical model cannot be constructed. In this case, principal components are used to characterize the Raman spectra of a "calibration set" of samples containing A and B, as determined by pathology. As mentioned earlier, the principal components constitute an orthogonal set of spectra, a linear combination of which can accurately characterize each of the spectra in the sample set. By correlating the fit coefficients ("scores") of the spectra in the data set with their known classifications, a diagnostic algorithm can be established. This approach has been shown to be effective in several tissue types, including atherosclerosis, breast cancer, and gastrointestinal cancers. [108,111,112] However, its drawback is that the principal components are mathematical constructs, without direct physical meaning.

In the case of quantitative analysis of biological samples the procedure is similar, except that the calibration data set is composed of samples with various values of C, as determined by a standard reference technique. A variety of techniques to correlate the fit coefficients with the reference values for this type of problem include principal component analysis and partial least squares (PLS) analysis. An example of the use of PLS in determining the concentration of blood analytes is discussed next.

Methods of analyzing tissue "statistically," without full knowledge of the constituent spectra, are called implicit methods. On the other hand, if the spectra of the tissue constituents are accurately known, physically based "explicit" models can be developed. These can be based on the known chemical moieties in the tissue, its morphological constituents, or a combination of both. 107,113,114 Even if this approach cannot provide a complete characterization of all the spectral features from a given tissue type, it can usually account for the majority of them and subsequently lead to identification of more subtle, and yet important, constituents.

The use of physical models is based on the linear nature of the Raman effect; this allows the least-squares minimization reconstruction of the complex Raman spectrum of a heterogeneous macroscopic (~1 mm³) sample from a set of "basis spectra" obtained separately from the individual chemical or morphological constituents. Such a model is mathematically described as follows:

$$R(\mathbf{v}) = \mathbf{K} \sum_{i} \rho_{i} r_{i}(\mathbf{v}), \tag{31.1}$$

where K is a constant that depends on the experimental system and collection geometry, R(v) is the Raman spectrum of the macroscopic sample, $r_i(v)$ is the Raman spectrum of a given basis spectrum, and ρ_i is the concentration of the corresponding chemical or morphological component.

If the basis spectra are of individual chemicals, they can be obtained microscopically or macroscopically, and the intensity of various spectral features can be directly related to concentrations by controlling the experimental conditions when the model is developed. If the basis spectra are of individual morphological features, a confocal microscope of the type described previously can be employed to collect spectra of various structures. The latter approach has the advantage that the spectra are observed in their native environment. Although the morphological approach can be quantitative, in practice quantification is difficult because concentrations cannot be directly measured. Several studies have used the morphological approach to date; 107,113,114 however, they are only semiquantitative.

Different methods are appropriate for different applications. For example, in the case of measuring blood analytes, when chemical concentrations are derived, implicit methods are most appropriate. In other cases, such as breast or artery tissue analysis, when morphologic structures are characterized, explicit methods are the most appropriate. Below, we give examples of both. Combination methods that introduce physical information into statistical techniques, such as hybrid linear analysis, 115 are also possible.

Statistical methods can be used to build an accurate quantitative spectroscopic model. One such example is the measurement of concentration of blood analytes, with an ultimate goal of obtaining

TABLE 31.1 Prediction Accuracy of Blood Analytes in Human Serum Using a PLS-Generated Algorithm

Analyte	Reference Error	RMSEP	\mathbf{r}^2	Integration Time (s)
Glucose	3 mg/dl	26 mg/dl	0.83	60
Cholesterol	4 mg/dl	12 mg/dl	0.83	60
Triglyceride	3 mg/dl	29 mg/dl	0.88	60
BUN (urea)	0.9 mg/dl	3.8 mg/dl	0.74	60
Total protein	0.1 g/dl	0.19 g/dl	0.77	10
Albumin	0.09 g/dl	0.12 g/dl	0.86	10

accurate transcutaneous measurements so that, for example, diabetic patients would not need to draw blood several times per day to monitor their blood glucose levels. The first step in such a study is to analyze human serum, thereby circumventing any complicating factors such as scattering from cells and absorption from hemoglobin.

Berger et al. have reported such a study where six analytes in serum could be predicted with clinical or near-clinical accuracy in less than 1 min.¹⁰³ The analytes studied include glucose, cholesterol, urea, total protein, albumin, and triglycerides. They also completed a preliminary study in whole blood that was able to predict hematocrit accurately as well. These studies used the implicit method of PLS analysis.

Berger et al. used the experimental setup shown in Figure 31.11B to collect Raman spectra of human serum. The experiment used 250 mW of excitation at 830 nm focused down to a 50-µm diameter spot; data were collected for 5 min at 10-s intervals. A total of 69 samples was analyzed over a 7-week period, and reference concentrations were provided by standard hospital chemical analysis methods. Data were analyzed with PLS in a leave-one-week-out cross validation manner. Accurate predictions were maintained for all analytes with 60-s integration times, and some predictions could be accurately made in 10 s. Accuracy for the spectroscopic analysis is reported as root mean square error of prediction (RMSEP) compared to the reference technique. The prediction accuracies, along with the reference errors, are shown in Table 31.1. As can be seen, there is good correlation for all six analytes; in fact the accuracy for some (total protein and albumin) is limited by the reference technique.

As an example of the use of explicit methods, we consider the analysis of coronary artery spectra. In such a case, one collects the Raman spectra of all of the chemical or morphological components individually, keeping track of the intensity of each Raman spectrum relative to its unit concentration. The composite tissue spectrum can then simply be reconstructed by summing the basis spectra with the appropriate weighting, thereby determining the abundance of each component in the tissue (Equation 31.1).

Using this approach, Brennan et al. have developed a quantitative model to characterize the relative amounts of chemical coronary artery tissue components. He model consisted of basis spectra from commercially available beta carotene, cholesterol and cholesterol linoleate, chemically extracted lipids from arterial adventitia (i.e., noncholesterol lipids), isolated mineralizations dissected from highly diseased tissue (i.e., calcium hydroxyapatite), and proteins, characterized by two different spectra collected from delipidized normal and diseased arterial tissues. Appropriate calibration measurements were performed to estimate the weightings of the individual basis spectra.

To study the accuracy of the model, coronary arteries were obtained from explanted hearts, and therefore a wide range of disease states were represented. Samples were frozen and ground into minces, which were combined in various mixtures to vary the distribution of chemical concentrations further. It was necessary to use homogenized minces so that the Raman spectra, which were obtained from a small volume (~1 mm³), were representative of the entire sample that was subjected to chemical analysis. Raman spectra were collected from 10 different sites from each mince using the laboratory system described above with 350 mW of excitation at 830 nm over a 100-µm diameter spot. The samples were then analyzed chemically to determine the amount of triglycerides, free cholesterol, cholesterol esters, phospholipids, and inorganic phosphorus (to characterize the calcium salts). Figure 31.12 shows examples

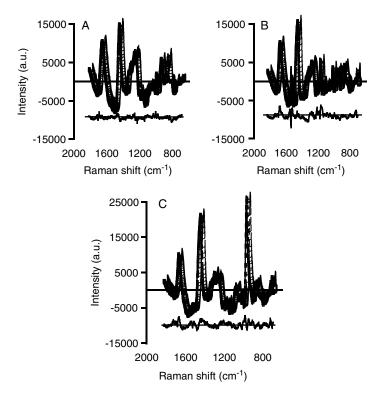

FIGURE 31.12 Comparison between the model (line) and spectra (dots) of coronary artery that exhibited (A) intimal fibroplasia, (B) noncalcified atheromatous plaque, and (C) calcified plaque. The differences between a spectrum and its model fit are displayed below each comparison (same scale). (From Brennan, J.F. et al., *Circulation*, 96, 99, 1997. With permission.)

of the model fits (line) to the data from macroscopic samples (dots) for three classes of artery. The small residuals, whose size is on the order of the noise, show that the model is relatively complete.

Despite all of the assumptions used in generating the basis spectra and calibrating the model, macroscopic spectra can be accurately reconstructed, and quantitative spectroscopic analysis correlates well with the chemical assay. Table 31.2 shows correlation coefficients between the chemical assay and the Raman analysis, the bias (mean difference between the two methods), and the standard deviation (σ) of the difference between the measurements. All correlation coefficients are >0.9, with the exception of free cholesterol, which is slightly lower.

The two examples discussed here show the potential for Raman spectroscopy not only for identifying the chemicals present in a sample, but also as a means for providing an optical quantitative assay. In addition to providing chemical information, it is also possible to take this information and develop diagnostic algorithms to determine disease states. 117 Also, utilizing this chemical information opens up

TABLE 31.2 Prediction Accuracy of Raman Artery Chemical Model Compared to Reference Chemical Assay

Component	r	Bias, %	σ, %
Total proteins	0.998	-0.7	2.6
Fats (noncholesterol)	0.999	1.6	2.1
Total cholesterol	0.951	-2.3	1.5
Free cholesterol	0.848	-2.2	1.4
Cholesterol esters	0.900	-0.0	1.4
Calcium salts	0.994	1.5	1.3

the potential for studying disease progression, regression, and etiology *in vivo*. Such an approach may lead to advances in future therapies.

31.6 Enhanced Tissue Characterization via Combined Use of Spectroscopic Techniques

The spectroscopic techniques described in the previous sections provide complementary information on different aspects of tissue composition, morphology, and biochemistry. Diagnostic algorithms that separate normal from diseased tissues based on specific quantitative changes that take place during disease development can be established based on each technique individually. However, medical decisions and diagnoses are generally not made on the basis of one measure. Experience has shown that the combined use of several measures provides more robust and reliable results. In the same way, it is reasonable to expect that by combining information from different spectroscopic techniques we can enhance our capability to classify tissue and our understanding of the processes that lead to the creation of a lesion. Indeed, this has been achieved in the following examples.

31.6.1 Tri-Modal Spectroscopy for Characterization and Detection of Precancerous Lesions in Vivo

Tri-modal spectroscopy, or TMS, refers to the combined use of intrinsic fluorescence, diffuse reflectance and light scattering spectroscopy as a quantitative tool for characterizing tissue morphology and biochemistry. The fluorescence and reflectance spectra required for the implementation of each one of these techniques are acquired simultaneously with the FastEEM instrument shown in Figure 31.1. Thus, the information extracted from IFS, DRS, and LSS characterizes the same tissue site. In this small data set, this information can be combined simply by assigning a classification to a particular tissue site consistent with the diagnostic algorithms developed for at least two of the three techniques. As a result, a significant enhancement is observed in the sensitivity and specificity with which we can separate dysplastic (low-and high-grade) lesions from nondysplastic Barrett's esophagus or high-grade from nonhigh-grade (low-grade and nondysplastic) Barrett's esophagus. Results are presented for spectra acquired from 16 patients, 26 nondysplastic, 7 low-grade, and 7 high-grade dysplastic tissue sites (Table 31.3).³⁶

A similar enhancement was observed when spectroscopic information from all three techniques was combined to separate colposcopically abnormal but histopathologically benign cervical tissues from histopathologically abnormal cervical lesions. The reported sensitivities and specificities were based on logistic regression and cross validation performed on a set of spectra from 44 patients including 50 colposcopically normal, 21 colposcopically abnormal but histopathologically benign and 13 colposcopically abnormal sites classified as low-grade (2) or high-grade (11) SILs (Table 31.4).⁸ A similar enhancement is also observed for detection of oral cavity lesions.³⁵ Ultimately, it is expected that dedicated TMS algorithms will be developed based on the weighted contributions of the individual pieces of information extracted from each technique.

TABLE 31.3 Accuracy of Spectroscopic Classification of Nondysplastic (NDB), Low-Grade (LGD) and High-Grade Dysplastic (HGD) Tissue in Barrett's Esophagus

	HGD vs. (LGD and NDB)		(LGD and HGD) vs. NDB	
	Sensitivity	Specificity	Sensitivity	Specificity
Intrinsic fluorescence (IF)	100%	97%	79%	88%
Diffuse reflectance (DR)	86%	100%	79%	88%
Light scattering (LS)	100%	91%	93%	96%
Combination of IF, DR, and LS	100%	100%	93%	100%

TABLE 31.4 Performance of Different Spectroscopic Techniques for Separating SILs from Non-SILs

	Biopsied Non-SILs ^a vs. SILs		Non-SILs ^b vs. SILs	
	Sensitivity	Specificity	Sensitivity	Specificity
IFS	62%	67%	62%	92%
DRS	69%	57%	62%	82%
LSS	77%	71%	77%	83%
TMS	92%	71%	92%	90%

^a Biopsied non-SILs include 21 colposcopically abnormal biopsied sites classified as mature squamous epithelium (5/21) or squamous metaplasia (16/21).

TABLE 31.5 Sensitivity, Specificity, and Positive Predictive Value of Three Different Diagnostic Algorithms for Coronary Atherosclerosis

	Sensitivity	Specificity	PPV*
ÌFS	90%	82%	95%
DRS	72%	68%	90%
BMS*	95%	91%	98%

^{*} PPV = positive predictive value; BMS = Bi-modal spectroscopy.

31.6.2 Bi-Modal Spectroscopy for Characterizing Atherosclerotic ex Vivo Lesions

Analysis of intrinsic fluorescence and diffuse reflectance spectra acquired using a FastEEM instrument from normal and diseased coronary artery *ex vivo* tissues indicates that significant changes can be detected in tissue composition during the development of atherosclerotic lesions. For example, analysis of intrinsic fluorescence spectra at several excitation wavelengths yields the fluorescence contributions of collagen/ elastin and ceroid. On the other hand, diffuse reflectance spectra convey important information about the levels of beta-carotene absorption. The combination of information concerning these important tissue constituents results in a significant enhancement in our ability to classify tissue spectroscopically in accordance with pathology (Table 31.5).

31.6.3 Fluorescence and Raman Spectroscopy for Characterizing Microscopic Ceroid Deposits in Coronary Artery Samples

Ceroid is postulated to be a complex of protein associated with oxidized lipids and may be responsible for causing irreversibility of certain atherosclerotic plaques. In small uncomplicated plaques, ceroid initially appears within the cytoplasm of superficial macrophage-like foam cells. It has therefore been suggested that macrophages might be responsible for lipid oxidation in the plaque, with potentially damaging consequences, such as cell injury and necrosis and the release of insoluble material into the extracellular space, ultimately causing the plaque to become irreversible. In advanced plaques, most of the ceroid is extracellular.

Ceroid is histochemically identified by insolubility in a variety of lipid solvents and the uptake of lipid dyes. In addition, ceroid is characterized by the emission of intense yellow autofluorescence when it is excited with ultraviolet (UV) light.^{53,120} However, the exact chemical composition of ceroid deposits in atherosclerotic plaques is not well defined, and may vary in different samples or tissues. Insight into the

b Non-SILs in this case include 50 colposcopically normal sites and 21 biopsied sites classified as squamous metaplasia or mature squamous epithelium.

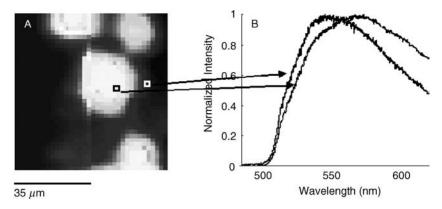

FIGURE 31.13 (A) Fluorescence map showing the distribution of ceroid at 565-nm excitation. (B) Fluorescence spectra of collagen/elastin and ceroid acquired at 476-nm excitation.

chemical composition of ceroid may provide a better understanding of the mechanism of its formation and suggest avenues to induce plaque regression with medical therapy.

By spatially monitoring tissue autofluorescence, the location of ceroid within an unstained thin tissue section can be identified spectroscopically; subsequently, Raman measurements can be acquired to ascertain more detailed information on the chemical composition of the deposit. Figure 31.13A shows a fluorescence map, 477-nm excitation, that pinpoints the location of several ceroid deposits in a sample of coronary artery. Although collagen and elastin also exhibit autofluoresce in the UV, it is typically less intense than the emission from ceroid and peaks around 530 nm. This is blue shifted compared to the ceroid fluorescence maximum that occurs between 550 to 580 nm. The normalized fluorescence spectra of ceroid and collagen are displayed in Figure 31.13B. The fluorescence map in Figure 31.13A was generated by plotting the fluorescence peak intensity at 565 nm for each pixel and thus bright regions are indicative of the presence of ceroid.

Following identification of ceroid deposits through their characteristic fluorescence emission, Raman spectroscopy was performed on the same region of tissue in order to elicit the chemical composition of the deposits. Due to its narrow and distinct spectral features, Raman spectroscopy is ideally suited to the study of complex chemical mixtures such as those occurring in the core of unstable atherosclerotic plaques. Figure 31.14A depicts a Raman map showing the distribution of cholesterol in the same ceroid deposit displayed in Figure 31.13A. In addition to cholesterol, several other chemical moieties, such as cholesterol esters, apoproteins, and triolene, have been identified in the deposits. After acquisition of the Raman data, the identical tissue section was lipid extracted and subsequently stained with oil red O as further confirmation of the identity of the deposit. A white light image of this stained tissue section is presented in Figure 31.14B. In this image, the deposit appears red, indicating that the substance is histochemically identified as ceroid.

By capitalizing on the well known fluorescence spectral profile of ceroid and the detailed chemical information provided by Raman spectroscopy, we were able to gain insight into the chemical composition of ceroid deposits. The combination of Raman and fluorescence spectroscopies provides a means to identify ceroid deposits and to probe their chemical composition. This might shed light on the process of lipoprotein degradation and deposition in atherosclerotic plaques.

31.7 Conclusion

In conclusion, the preceding examples illustrate that spectroscopy reveals biochemical and morphological information about the native tissue state, without the need for tissue removal. The extracted morphological information can be similar in nature to that obtained by histopathology, as in the characterization of cell nuclear morphology using LSS. In addition, spectroscopic techniques (such as intrinsic fluorescence

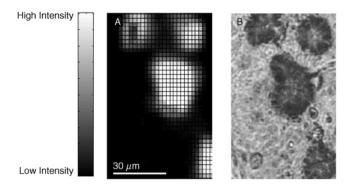

FIGURE 31.14 (A) Raman map and (B) phase contrast image of a ceroid deposit in a sample of human coronary artery.

and Raman) also provide information about tissue biochemistry which cannot be directly obtained otherwise, because tissue removal and processing necessarily alter its biochemistry. Methods such as angular LSS can be sensitive to morphological structures and structural changes that cannot be resolved using even invasive conventional microscopic techniques. Furthermore, analytical models can be used to describe measured tissue spectra and extract information in a quantitative manner. Based on all of these desirable features, it is evident that spectroscopy can be a powerful tool for understanding better some of the fundamental processes that take place very early in the development of disease.

The combination of information extracted from complementary spectroscopic techniques offers the opportunity to acquire a more accurate picture of the tissue state, which in turn enables more robust diagnosis of disease. The capability to perform measurements over small and wide tissue areas enhances the clinical applicability of these techniques. Based on the work already performed in this field, it is clear that spectroscopy is on the way to serving as an important adjunct to clinical and histopathological evaluation of disease.

Acknowledgments

The authors acknowledge contributions from Andrew Berger (now at the University of Rochester), Martin Hunter, Irving Itzkan, Maxim Kalashnikov, Tae-Woong Koo, Lev Perelman (now at Harvard Medical School), and Qingguo Zhang from the MIT Spectroscopy Laboratory; Jacques Van Dam (now at the Stanford University School of Medicine), Michael Wallace (now at the Medical University of South Carolina), Brian Jacobson, David Carr-Locke, Ellen Sheets, and Christopher Crum from the Brigham and Women's Hospital; Stanley Shapsay, Tulio Valdez, Cesar Fuentes, and Sandro Kabani from the Boston University Medical Center; John Kramer, Joseph Crowe, and Joseph Arendt from the Cleveland Clinic Foundation; Maryann Fitzmaurice from the Cleveland Clinic Foundation; and Gary Horowitz from Beth Israel/Deaconness Medical Center. 32.1 Introduction

Since both biological structures and systems of interest within the materials research community are chemically heterogeneous at the microscopic level, the spatial distribution of the underlying chemical species defining the molecular complex often determines the function and properties of the macroscopic assembly. As a corollary, changes in the microscopic molecular heterogeneity may alter significantly the chemical and physical attributes of a substance. While optical microscopy techniques may be employed to survey molecular heterogeneity, they provide little information on, for example, the chemical composition, molecular structure, or local packing characteristics. In contrast, microspectroscopic techniques,

such as those involving vibrational spectroscopy, afford potentially powerful complementary approaches for addressing these questions. Thus, a combination of microscopy methodologies and infrared spectroscopy, in particular, retains the spectroscopic advantages of experimental versatility and the availability of extensive databases, while introducing the spatial selectivity inherent in microscopic techniques. In particular, the mid-infrared spectral region (4000 to 400 cm⁻¹), which has been the focus of microspectroscopic examinations for many decades, has proved to be an invaluable source of compositional and structural information for a wide variety of materials. In this brief survey, we first review the instrumentation required for conducting mid-infrared microspectroscopy and then describe several examples illustrating recent developments in this area.

Infrared microspectroscopy involves the measurement of a vibrational spectral response from a prescribed, small region of an appropriately derived sample. Historically, attempts to harness infrared spectroscopy for microscopic measurements have been successful in various forms for more than 50 years. ^{1,2} In the last 20 years, a number of approaches have become commonly accepted, and numerous commercial instruments are now either available or being developed. Simultaneously, the growth in the number and variety of studies involving infrared microspectroscopy has been explosive. Although spectral specificity for this technique may be achieved in various ways, the most widely employed current methods involve infrared interferometry. In general, the three basic instrumental approaches for obtaining infrared microspectroscopic measurements are to (1) provide incident infrared radiation to a small area of the sample, (2) restrict detection of the signal from the sample to only a small spatial area, and (3) detect wide field signal radiation through the use of multichannel detectors. Based on integration of a single element or multichannel detector to an interferometer and microscope assembly, we divide our discussion into two parts: (1) single-element microscopy and (2) imaging using multichannel detectors.

32.2 Single-Element Detector FTIR Microspectroscopy

Fourier transform infrared (FTIR) spectroscopy became commercially viable approximately three decades ago, and within 10 years attempts were made to use interferometers for microscopic measurements. Specifically, the advantages of radiation throughput, spectral reproducibility, and time averaging afforded by FTIR spectroscopy were particularly conducive to examining small spatial regions. In addition, the development of stable, sensitive, fast-response cryogenic detectors allowed high-fidelity measurements of spectral intensities.³ Infrared interferometers coupled to infrared microscopes incorporating these sensitive detectors were introduced in the 1980s.⁴ Today, these systems and their advanced versions are used in microscopic infrared analyses in thousands of laboratory locations.

32.2.1 Instrumentation

In single-element microspectroscopic instrumentation,⁵ modulated radiation from an interferometer is diverted to a set of optics that condense light to a prescribed spatial area, allowing spectral information to be obtained from small samples. Using opaque apertures of controlled size, smaller and better-defined spatial areas can be imaged by restricting the region illuminated by the infrared beam. Subsequently, the radiation is collected by another set of optical components and focused onto a detector. In this manner, infrared spectra may be obtained from highly specified microscopic locations. To uniquely identify the sample area to be spectroscopically examined, a corresponding white light optical image is also acquired. Clearly, focusing the infrared beam for maximal throughput and minimal dispersion in the sample plane requires the optical and infrared paths to be parfocal and collinear. Hence, an optical microscope is integrated into the infrared microscope assembly. A schematic drawing of the system is shown in Figure 32.1.

Important differences exist between a microscope used for infrared spectroscopy and one used for optical microscopy. While optical microscopy is performed by employing high-quality refractive optics made of glass, infrared microscopes usually consist of all-reflective optics. Glass cannot be employed because it does not transmit radiation wavelengths in the mid-infrared spectrum longer than ~5 µm.

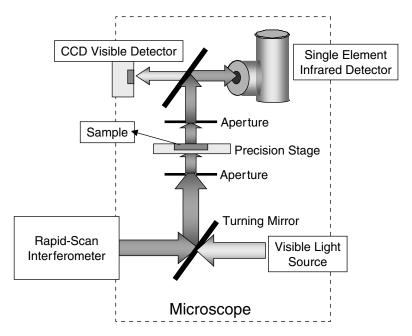

FIGURE 32.1 Schematic diagram of a mapping spectrometer incorporating a single element detector

Further, spectral fidelity is of paramount concern in the infrared spectral domain, where optical aberrations resulting in spectral nonlinearities must be minimized. The source of modulated radiation in the infrared spectral region is derived from an attached rapid-scan interferometer. In principle, any type of modulator may be employed (for example, step-scan interferometers); rapid-scan interferometers are generally used because they offer cost advantages. Radiation corresponding to small spatial areas is governed by carbon-black-coated metal apertures. In some later designs, specialty infrared absorbing glasses were used, allowing visible imaging while providing restricted infrared imaging.

The instrumentation described above permits the examination of either microscopic samples or narrowly defined regions within larger sample areas and is capable of routinely examining samples in the microgram range. This approach is appropriate particularly for studying small impurities or defects in samples but is of limited utility in obtaining quantitative information from large, heterogeneous materials for which information on the presence and distribution of specific chemical species is desired. By moving the sample, which is easier than moving the optics, different sample locations may be spectroscopically examined. Thus, the sequential movement of the sample in a predetermined manner allows a large sample area to be mapped point by point.⁶ Hence, this single-element infrared microspectroscopy using apertures is also referred to as "point mapping" or "point scanning" infrared spectroscopy. Clearly, a sample holder capable of precise microscopic movements must be employed, and for every spatial point a registration of the sample movement to the spectrum corresponding to each spatial index must be maintained. This is accomplished by an automated, programmable microscope stage and an attached computer, which can also be used to control the instrument and to synchronize the various events that are required to map large sample areas.

32.2.2 Capabilities and Limitations

While apertures permit infrared microspectroscopy, they also result in loss of light due to diffraction effects when the aperture is small. In practice, radiation transmitted through an aperture results in the formation of a diffraction pattern and can lead to the detector sampling light from outside the apertured region due to the secondary lobes of the diffraction pattern. The effects of this stray light may compromise the spectral content as far as $40~\mu m$ away from the points of interest in the sample.⁷ This problem may

be circumvented by employing a second aperture in tandem to reject radiation even further. However, this also results in loss of signal from the desired sample area under study, thus degrading the spectral signal-to-noise ratio (SNR) and necessitating larger data-acquisition times to improve data quality. Alternately, large apertures are required for permitting greater radiation throughput, which then incurs a tradeoff between the time required for accumulating data and the achieved spatial resolution. Thus, spatial fidelity and spectral quality are intimately linked in single-element systems incorporating apertures; a balance between the two is required to maximize the efficacy of the sampling protocol.

The design of infrared microscopes that employ apertures for mapping considers the largest aperture that may be employed during the course of experiments. Typically, the largest apertures are approximately on the order of $100 \times 100~\mu m$.² Thus, the spot size at the sample plane allowed by the optics is fixed at a larger spot size (hundreds of micrometers in diameter) to account for all aperture sizes that a user might utilize. The effective area available for light throughput is determined, however, by the area of the aperture opening. Thus, the flexibility to employ large aperture sizes implies that the efficiency of light utilization is anywhere from 0.25 to 100%.

32.2.3 Data Processing

Once the spectral response from a sample area is obtained, the absorbance magnitude of a specific vibrational mode is plotted to obtain a map of the distribution of that chemical species. Maps of the relative abundance of chemical species are variously termed "chemical maps" or "functional group maps." Clearly, both the large amount of time required to record data and the optical configuration of a single element detector are not suited either for high spatial resolution or for high spectral resolution mapping over large sample areas. Hence, the acquired data sets usually contain less than 1000 spectral resolution elements and hundreds of spatial resolution elements. Sophisticated spectral data processing may, however, be carried out readily in short time periods. Spatial data processing is of little use because small spatial features are usually below the resolution limit of the technique, and the small number of recorded spatial elements renders the results of many spatial processing routines meaningless. Thus, most data-processing strategies are usually extensions of those developed for a single spectrum acquired by conventional infrared spectrometers.

The usual baseline corrections, normalizations for thickness, and other such steps taken prior to plotting the data for a chemical map are routinely applied. Complex multivariate analyses may be implemented, and library matching of the entire data set is usually feasible. In general, even the most complex data-processing protocols are rapid due to the small data sizes and can be accomplished in a matter of minutes. Computation speeds and power requirements are moderate because less than 1000 spectra are usually processed. One common strategy for use in the spatial domain is to apply deconvolution methods after the point data are acquired, with the points of observation being separated by a distance smaller than the aperture dimension along the direction of separation. Since the collected spectra are often few in number, it is usually more effective to collect data for a longer time than to apply sophisticated techniques for improving the SNR ratio in order to extract molecular information.

32.3 FTIR Raster Imaging Using Multichannel Detectors

While single-element microspectroscopy provides the capability for obtaining spectra from small spatial regions, poor SNR characteristics, diffraction effects, and stray light issues resulting from the use of apertures limits the applicability of these methods. Further, the point-by-point mapping approach results in large collection times and poor utilization of the hundreds of focal plane spot sizes whose diameters measure in the micrometers. An approach to resolve some of these issues has recently been implemented⁸ in which, as an improvement over single element detectors, a linear array detector is employed to image an area corresponding to a rectangular spatial area on the sample. Unfortunately, the imaged area may not be sufficiently representative of the distribution of chemical species in the sample, and, hence, a technique to image larger areas is required. To compensate for this the linear array is moved precisely to

sequentially image a selected, relatively large spatial region of the sample. This is referred to as "push-broom" mapping or "raster scanning." The process is conceptually similar to point mapping but takes advantage of the multiple channels of detection. Imaging a large sample area is faster by a factor of m for a linear array containing m detector elements.

While detectors for point-by-point mapping are typically 100 to 250 µm in size, modern array detector pixels are sized in the tens of micrometers. Employment of a linear array thus eliminates the need for apertures because small array detectors directly image different spatial regions. The spatial resolution is determined by the optics; in one commercial implementation,⁸ the detectors are 25 µm in size, and the instrument can be operated at either a 1:1 magnification or 4:1 magnification to provide a 25-µm or 6.25-µm spatial resolution. Such magnification ratios can be readily achieved by employing available infrared optics that are expected to be relatively aberration-free. However, the optical and infrared paths must be collinear, and the visible image must be referenced to acquire infrared data. Further, a precision stage that reproducibly steps in small spatial increments is required for any mapping larger than that achieved by one row of detectors. Since a precision stage is an integral part of the instrument and a record of the visible image is required, the instrument does not require any visual observation accessories. Once the sample is manually positioned a visual image can be constructed by using the visible-light camera and by moving the sample stage. The sample area from which infrared spectroscopic data are to be determined is therefore delineated, and acquisition may then be initiated.

32.3.1 Instrumentation

The schematic diagram of the instrumentation, shown in Figure 32.2, is similar to that required for single-element infrared microscopy but incorporates several important changes. First, no apertures are required; consequently, the unavoidable deficiency in utilizing radiation in point mapping systems is mitigated. Second, the requirements for high-quality optics are simpler and not as stringent as those for the single-element microscope. Third, the spot size can be smaller and matched to the size of the detector array. Since the infrared radiation is more effectively utilized, a reduced intensity source can be employed. Further, the small number of detectors allows fast readout times, and, with the interferometer being operated in a continuous scan mode, instrumental costs decrease. By combining a small multichannel

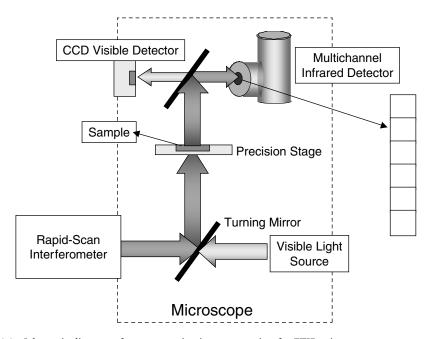

FIGURE 32.2 Schematic diagram of raster-scanning instrumentation for FTIR microspectroscopy.

detector with rapid-scan spectroscopy to allow mirror scanning in a favorable Fourier frequency regime, and by utilizing frequency domain filtering, higher SNR data can be obtained. Compared to single element detector systems, the removal of apertures allows for higher radiation throughput and provides additional increases in the SNR of data obtained. Hence, with respect to point mapping procedures, the performance of raster-scanning systems is enhanced for both the spatial and spectral domains.

32.3.2 Data and Data Processing

A data set from a raster-scanning system can be quite large compared to a single element detector system. For the same data-acquisition time the data set increases by at least the number of channels present in the detector. Further, as discussed above, the SNR per measurement time is higher; hence, in a given time, larger data sets are obtained. The spatial resolution of raster-scanning systems is essentially diffraction-limited, resulting in chemical concentration plots over the field of view being comparable to the visualization afforded by optical microscopy methods. Many data-processing techniques for enhancing visible images can be effectively applied to the infrared spectroscopic data. In addition, since large numbers of spectra are accumulated in each data set, multivariate methods allow statistically rigorous conclusions to be determined.

32.4 Global FTIR Spectroscopic Imaging

The state of the art in FTIR microspectroscopic instrumentation is the combination of a focal plane array (FPA) detector and an interferometer. 9,10 FPA detectors consist of thousands of individual detectors placed in a two-dimensional grid pattern. Compared to a linear array, the increase in the number of detectors increases the multichannel advantage; for example, a $p \times p$ pixel focal plane array detector provides a p^2 time savings compared to a single-element detector and a p^2/m time saving compared to a linear array detector, where m is the number of detector elements in the linear array detector. For a 256×256 element detector compared to the single-element case, the advantage is a factor of 65,536; in comparison to the 16-element detector, the multichannel advantage is a factor of 4,096. Further, the two-dimensional detectors are capable of imaging large spatial areas. An FPA matched to the characteristics of the optical system is capable of imaging the entire field of view afforded by the optics and of utilizing a large fraction of the infrared radiation spot size at the plane of the sample. Among the available various infrared microspectroscopic methods, FPA-based global imaging represents the most versatile approach toward viewing large sample areas and in recording spectral intensities.

Since the methodology of microspectroscopy employing FPA detectors is similar to the acquisition of images from an optical microscope, the technique has been termed "infrared spectroscopic imaging." FTIR coupled with an FPA detector provides spatially resolved images across a wide field of view in data-collection times comparable to the time required to record a single spectrum at a single spatial location using a single element detector. This enormous advantage in acquisition time allows both spatially and spectrally specific analyses. For example, a single spectrum from a small sample region, comparable to a single FPA pixel, may be examined or a spectroscopic signal from a spectral feature representative of the entire field of view can be imaged. Due to the considerable reduction in experimental recording times both the imaging of large areas of static samples¹¹ and the examination of dynamic processes are feasible and rapid.

32.4.1 Instrumentation

The schematic of a typical FTIR microimaging system shown in Figure 32.3 interfaces an interferometer to an infrared microscope, yielding a specified spot size at the sample plane. This spot, which is typically hundreds of micrometers in size, is magnified by the optical train and imaged onto a focal plane array that is tens of millimeters in diameter. The spatial resolution is thus determined both by the optics that determine magnification and the size of an individual detector element on the focal plane array. Even

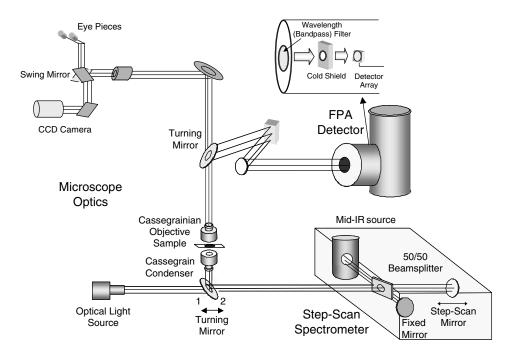

FIGURE 32.3 Schematic diagram of an FTIR imaging spectrometer incorporating a focal plane array detector.

though the nominal spatial resolution is determined by the optics and the detector, the actual resolution limit usually depends upon the diffraction limit of the wavelengths of interest incident upon the sample.

The first and, to date, most popular approach to FTIR microimaging spectrometers incorporates a step-scan interferometer, which provides a means for maintaining constant optical retardations for desired (often large) time periods. A constant retardation over extended time periods is employed both for signal averaging purposes and for computer storage of the acquired data. An initial small time delay prior to data acquisition allows for mirror stabilization at each interferometer step. The data-acquisition and readout formats may be spatially sequential (rolling mode) or simultaneous (snapshot) across the array. In either case, the signal is integrated for only a fraction of the time required for the collection of each frame. The integration time, number of frames coadded, and number of interferometer retardation steps, which is determined by the desired spectral resolution, determine the time required for the experiment. Since signal integration governs the data quality, efforts are made to increase the ratio of the integration time to the total data-acquisition time.

Imaging configurations utilizing a continuous scan¹² or rapid-scan¹³ interferometer have been proposed for small detector arrays. Since a large number of detector elements generally precludes regular rapid scanning velocities due to slow readout rates, many instrumental configurations employ a continuously-scanning interferometer at slow speeds. Some manufacturers employ fast step-scan modes where the mirror is partially stabilized to achieve the same retardation error as in continuous-scan spectroscopy; this approach is termed "slow-scan." While slow-scan approaches appear to be similar to rapid-scan methods, they do not have the advantage afforded by the coupled Fourier frequencies as in rapid scanning and merely delay FPA nonlinearity corrections until after the completion of the interferometer scan. We believe that the utility of these slow-scan methods is limited and of little consequence in acquiring high SNR data. A generalized data-acquisition scheme that permits true rapid-scan data acquisition for large arrays or higher mirror speed acquisitions from small arrays has been proposed.¹³ The integration time for individual frames collected by the FPA detector is small enough to be considered negligible on the time scale of interferogram collection. For most FPA detectors available today, however, the motion of the moving mirror in a continuous-scan mode does not allow the coaddition of frames per interferometer retardation step. Compared to step-scan approaches, rapid-scan data collection allows fast interferogram

acquisition because there is no requirement for mirror stabilization; however, the image stored per resolution element is noisier. Although random FPA noise is dominant, the error arising from the deviation in mirror position during frame collection is considered the next largest contributor. The advantage of continuous-scan interferometry lies in reduced instrumentation costs compared to step-scan units and more efficient data collection because mirror-stabilization times are eliminated.

32.4.2 Post-Collection Operations

The major difference between all other forms of FTIR spectroscopy and FTIR spectroscopic imaging is the extremely large volumes of data handled in the latter mode of operation. For a 256×256 element FPA, a user may acquire tens of gigabytes of data per hour. Further, the human comprehension of such a large volume of data in its entirety is not only impossible but also undesirable. Hence, the most common operation is to reduce the data in some manner to allow compact visualization of desired features. A number of analytical approaches have been suggested with the data presented in a variety of forms. Since the information content of the data decreases as the complexity of the representation decreases, the best data-extraction methods cannot be determined *a priori* but are implemented on a case-by-case basis. For example, the most common representations either visualize the two-dimensional distribution of the intensity of a specific vibrational mode over the field of view, project a limited number of spectra from any desired sample region or microdomain, or present statistical distributions of a chemical species. Often, several data-analysis approaches are employed in tandem to provide an effective visualization of the distribution of chemical species.

Another facet of data processing not commonly encountered in conventional infrared spectroscopy is the need to reduce noise in the data set. The low SNR in FTIR images arises both from the characteristics of the FPA and from data-acquisition schemes. While efforts to improve FPAs for spectroscopic imaging have been suggested and advances are constantly being made, the modification of data-acquisition methods is an area of considerable attention. A common data-acquisition approach has been to coadd as many frames as possible during the available experimental time. While this approach results in significant gains, as expected, the SNR, as a function of coadded frames, achieves a plateau. Thus, after the coaddition of a limited number of frames, the benefits are relatively minor compared to the large increase in experimental time expenditures. The coaddition of complete image data sets was shown to be effective in increasing the fidelity of the data, with an optimum sampling strategy being derived by combining both frame and image data-set coaddition. While image coaddition results in improved SNR characteristics, the process involves a $2n^2$ increase in collection time for an SNR improvement factor of n. This rules out image coaddition as a technique to increase the SNR for either real-time imaging of rapidly changing systems or for the expeditious examination of large numbers of samples.

A low-noise, single-beam background ratioed to a single-sample, single-beam image was shown to exhibit lower noise characteristics, allowing for imaging measurements of dynamic systems. ¹⁵ This method, termed "pseudo coaddition," is also limited in achievable benefits because noise from the sample's single beam tends to dominate the resultant spectra. Spectra from sample areas with the same true absorbances can be coadded in a similar statistical manner to yield low-noise-average spectra. ¹⁵ Mathematical noise reduction, using, for example, the minimum noise fraction (MNF) transform, is an alternate pathway toward obtaining higher-fidelity images after data acquisition. ¹⁶ The transformation and inverse transformation after eliminating components due to noise is computationally intensive but does not result in loss of image content or affect image-collection times. The gain in the SNR depends on the SNR characteristics of the original data. Noise is reduced by a factor greater than five if the noise in the initial data is sufficiently low.

32.5 Applications

A recent survey of FTIR techniques, including microspectroscopy, extended to biological materials has been compiled.¹⁷ Although examples of global FTIR imaging applied to biological systems have been

discussed elsewhere,18 we include here several specific studies to illustrate the range of applications and to outline potential future directions. Since FTIR imaging is a noninvasive, nondestructive technique, analyses of intact cells or biopsied tissues are not only a relatively straightforward process but are also of enormous contemporary interest. Conventional cell and tissue examinations are conducted using visible microscopy at various magnification levels. To assist in discrimination between different constituent morphological features of the specimen, samples are stained with reagents responsive to specific chemical components. Although staining methods are generally useful for visualizing tissue structure, they are relatively nonspecific for obtaining detailed chemical information. Moreover, the choice of a specific staining protocol or application of other immunohistochemical techniques often depends on a preliminary biochemical knowledge of the system or disease under scrutiny. FTIR imaging presents, however, an opportunity to directly visualize detailed chemical and morphological characteristics without concern for sample history or disease etiology. As inherent chemical properties of the molecular composition dictate contrast between various components, no sample staining is required. In contrast to conventional IR microscopic methods, the large numbers of spectral data that are obtained through global imaging allow quantitative analyses based on statistical techniques. From the simple demonstration of imaging a lipid [C(16)-lysophosphatidylcholine] distribution in a KBr disk, 19 FTIR imaging applications have grown to include, for example, various tissue sections, single cells, pharmaceutical devices, and food grains.

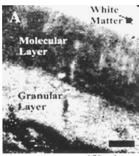

32.5.1 Human and Animal Tissue Sections

32.5.1.1 Brain

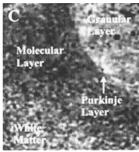

Concentration distributions of various components in thin monkey brain sections²⁰ revealed specific lipid/protein distributions corresponding to morphological features. Concentration abundance images constructed from spectral data indicated that a greater proportion of lipids occurred in white-matter regions relative to the lipid proportion in gray-matter areas. Since visualization of the entire data set is difficult, a number of statistical methodologies, including scatter plots, histograms, and profile matching, were suggested for data analysis to extract the desired information. These techniques, based on a statistically significant number of observations (spectra), can then be employed to characterize different regions of the tissue. Once the characteristic spectral features of specific regions of a tissue and their inherent variations are known, significant deviations from these may be used to characterize biochemical imbalances, even in cases where morphological changes may be small or nonexistent. This is the fundamental philosophy of employing imaging for biomedical analyses.

Neurotoxic effects of an antineoplastic drug (cytarabine [Ara-C]) on Purkinje cells, which are cells in rat cerebella that have been shown to strongly influence motor coordination and memory processes, were visualized using FTIR imaging.^{21,22} Based on the total absorbance inherent in the IR brightfield images, it was observed that the IR images contained more contrast compared to the visible microscopy images. The packing properties of the tissue influenced the refractive index in the infrared spectral region, resulting in better contrast. An analysis of the spectroscopic image from rat cerebella revealed a chemical basis for contrast between different parts of the tissue. This contrast was characterized by a ratio of the lipid-to-protein concentration. The relative lipid concentration exhibited significant differences among sample regions and could be employed as an index to characterize subtle structural changes. The higher protein-packing density of the Purkinje layer was shown to possess increased fractions of disordered lipid acyl chains. Hence, spatially resolved structural changes are determinable based on the molecular information contained in the vibrational spectra. Changes in these measures can be employed to detect and to quantify effects that result from diseases and the effects of drugs or foreign agents. The infrared spectroscopic images reflecting various tissue regions are shown in Figure 32.4.

Neuropathologic effects of a genetic lipid storage disease, Niemann–Pick type C, were investigated by examining sections of control and affected mice cerebella in an effort to understand the chemical basis of the observed morphological changes and to relate these changes to disease pathology.²³ By employing infrared imaging, various cellular layers were readily identified, and the diseased and control samples were distinguished without external, histological staining on the basis of spectral features

150 microns

FIGURE 32.4 Infrared spectroscopic images of thin cerebellar sections from a control and Ara-C-treated animal. Spectroscopic image showing the spatial distribution of lipid/protein ratios in a rat treated with (A) saline and (B) cytarabine rat. (C) Spectroscopic image depicting the distribution of phosphatidylcholine in a cerebellar section from a cytarabine treated animal. The image is derived from the intensity of a vibrational absorption band centered at approximately 3060 cm⁻¹, assigned to the methyl (CH₃) stretching vibration of the lipid choline headgroup (From Lester, D.S. et al., *Cell. Mol. Biol.*, 44, 29, 1998. With permission.)

characteristic of each layer. Lipid depletion was found in diseased samples in comparison to control tissue sections; other molecular differences were discerned in the granular-layer region of the tissue. The observed chemical changes were consistent with demyelination within the cerebellum of the diseased animal. In this manner, morphology and underlying chemical changes are readily correlated. Of particular interest is that separate analyses for each constituent chemical are not required. Instead, a single spectroscopic experiment yields information on the many types of chemical species that are present and their relative concentrations.

32.5.1.2 Bone

As opposed to grinding bone for average spectroscopic analyses, which destroys local structure and may introduce artificial changes, spatially resolved measurements have been carried out on bone-related systems since the 1980s using point mapping. Spatially resolved FTIR imaging²⁴ has recently allowed the examination of bone in a nondestructive manner, where the advent of imaging allows the rapid characterization of different structures.²⁵ The spatial variations of chemical components representing the main structural ingredients in bone formation can be easily monitored. For example, hydroxyapatite and protein distributions, as shown in Figure 32.5, illustrate the morphological distributions of these chemicals. Not only can the two-dimensional structure of a thin section be observed, but FTIR imaging also allows the three-dimensional structure of bone, as shown in Figure 32.5, to be visualized in terms of the distribution of its chemical constituents.²⁶

The nondestructive nature of the two-dimensional infrared imaging technique also allows the determination of molecular orientation in addition to simple concentration analyses.²⁴ Chemical-composition data from FTIR imaging and morphology were correlated for human iliac crest biopsies.²⁷ The known developmental processes in bone were related to observed gradients in mineral levels by examining spatial profiles from the middle of the osteon to the periphery. The observations were found to be consistent with the models for structure development in the Haversian model of bone development. Protein content, which could be readily monitored using the Amide I contour (1620 to 1680 cm⁻¹), revealed nonmineralized, high-protein-content regions, namely, the osteoid. A measure of crystallinity and bone maturity was determined using the phosphate V₁, V₃ contour and was found to increase away from the osteonal center. Due to the design of experiments, sample-selection limitations, and the myriad approaches for characterizing extracted chemicals, the available databases are often contradictory and often lead researchers to accept the historical understanding of osteoporosis as a mass deficiency of otherwise healthy bone materials. Using imaging techniques investigators have shown from their examination of spectral data from known, localized sites of mineralized tissue that the conventional view of the disease is not entirely correct. When imaging data from normal and osteoporotic human iliac crest biopsies were compared,²⁸

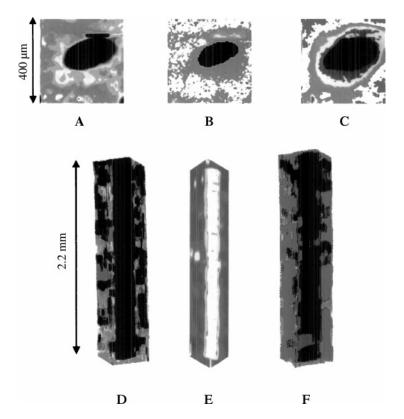

FIGURE 32.5 (Color figure follows p. 28-30.) (A–C) 2D images of three IR parameters for the cortical bone section (human tibia) shown as follows: (A) nonreducible/reducible collagen crosslinks, measured by the 1660/1690 peak height ratio in the amide I spectral region; (B) hydroxyapatite crystallinity index, measured by shape changes in PO_4^{3-} v_1 , v_3 mode and quantitated by the 1030/1020 peak height ratio; (C) mineral-to-matrix ratio, measured by the phosphate v_1 , v_3 /amide I area ratio. Black and blue indicate low numerical values while green, yellow, and red indicate progressively increasing numerical values of the particular parameter. The dimensions of each image are $400 \times 400 \ \mu m$. (D–F) 3D reconstructed views of three IR parameters for the cortical bone section (human tibia), as follows: (D) view of the collagen crosslink parameter measured as the 1660/1690 height ratio in the amide I spectral region; (E) PMMA distribution in a cortical bone section. The relative concentration of PMMA is determined from the integrated intensity of the C=O stretching mode; (F) 3D reconstructed oblique view of the relative amounts of mineral-to-matrix as measured by the phosphate v_1 , v_3 /amide I area ratio. The dimensions represented in each image are $400 \times 400 \ \mu m \times 2.2 \ mm$. (From Ou-Yang, H. et al., *Appl. Spectrosc.*, 56, 419, 2002. With permission.)

two spectral parameters were found useful in characterizing the biochemical changes. The first, which is indicative of the extent of mineral (hydroxyapatite) formation in the tissue, was obtained using a ratio of the integrated areas of the phosphate contour and the amide I peak. This parameter also served to normalize any thickness variations arising from the sample preparation process. The second parameter, indicative of the size and perfection of the crystals, was obtained by taking a ratio of absorbance at 1030 cm⁻¹ to the absorbance at 1020 cm⁻¹. It was shown that the average mineral levels in osteoporotic samples are considerably reduced compared to normal bone and that the crystal size and crystal perfection were substantially degraded.

The analysis protocol was applied to examine the effects of estrogen therapy on fracture healing in rat femurs. The mineral content per unit matrix in the estrogen-treated samples was found to be higher, demonstrating the effectiveness of the treatment. Similarly, the crystal sizes and perfection ratios were also found to be elevated in the treated samples. When healing bone was monitored, it was found that several sites along the fracture contained a disproportionately large protein content, indicating that these were sites for the formation of new mineral. In addition, cellular activity was detected at the fracture

sites by signals corresponding to cellular-membrane fatty acids. It is clear that FTIR imaging may be employed to detect and monitor normal structure, structure development, and pathological changes in bone through the chemical alterations reflected by localized spectral changes.^{24–28}

32.5.1.3 Prostate

Prostate cancer, specifically prostatic adenocarcinoma originating in the epithelial regions of the prostate gland, is prevalent in the western world. In the United States, almost 180,000 men are diagnosed with prostate cancer each year. Similarly, cancer of the prostate is the most common male cancer affecting British men, with the average lifetime risk of development approximately 1 in 13, with nearly 21,000 men diagnosed with prostate cancer every year in the U.K. Early detection and correct diagnoses may increase considerably the number of treatment options available for this disease. We have attempted to discern chemical markers of the onset of prostatic adenocarcinoma before it becomes apparent in morphological changes, which are typically profound for late-stage cancers but extremely subtle and often difficult to discern in the early phases of the disease. The chemical specificity of FTIR spectroscopy is particularly useful in the study of this disease because it can be combined with the spatial selectivity afforded by imaging when analyzing tissue. For prostatic adenocarcinoma, it is particularly important to assess spectral changes in small (5 to 20 µm wide), localized regions around prostatic ducts, or lumens. A comparison of a stained visible image, as employed for conventional morphological analyses, and an infrared spectroscopic image of the distribution of chemical components is shown in Figure 32.6. Preliminary studies indicate that the analysis of localized spectral changes is an attractive means for char-

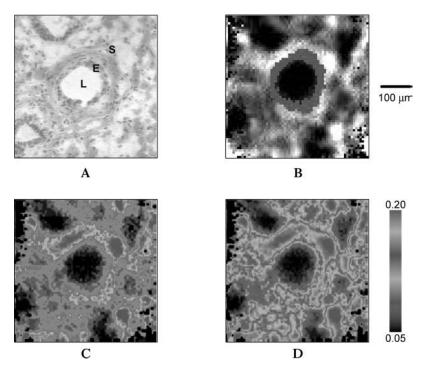

FIGURE 32.6 (Color figure follows p. 28-30.) (A) H&E stained section corresponding to the unstained section used to obtain spectroscopic images. The circular lumen (L) of prostatic gland in the center is lined by a double layer of epithelial cells (E) and supported by a smooth muscular and fibrocollagenous stroma (S). (B) Unstained section with the epithelial regions highlighted in red. Images of the distribution of absorbance obtained by applying (C) no gain ranging at a gain setting of one and (D) gain ranging for gains one and ten with a gain ranging radius of ten points. The images represent a sample area of 500 μ m \times 500 μ m as indicated by the size bar. The color-coded images show the distribution of the absorbance at 1245 cm⁻¹ between the indicated limits. (From Bhargava, R. et al. *Appl. Spectrosc.*, 55, 1580, 2001. With permission.)

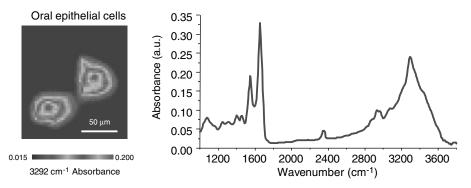

FIGURE 32.7 (Color figure follows p. 28-30.) IR spectroscopic image of single oral epithelial cells (left) and the corresponding spectrum from a part of the cell. The high signal-to-noise ratio of the data allows for detailed analysis of subtle chemical changes.

acterizing spectral changes for disease diagnosis and for monitoring its progression. Since the spectral changes involved are subtle, large numbers of samples must be examined, and FTIR imaging techniques that provide superior data quality, as indicated in Figure 32.6,²⁹ must be employed.

32.5.1.4 Breast

Silicone breast implants, consisting of an elastomeric shell filled with silicone gel material, are used extensively for breast enhancement procedures. The silicone gel may leak from the implant due either to material failure as a consequence of aging or to a rupture in the casing. Among the complications arising from this leakage are capsular contracture, calcification, and connective tissue disorders. To reliably assess any histopathological changes it is first necessary to confirm the presence of implant material in the breast tissue. Since silicone gel differs in chemical composition from surrounding tissue, it is easily detected in tissue sections using FTIR spectroscopic imaging.³⁰ The presence of an inclusion was revealed by monitoring the Si-CH₃ characteristic stretching vibrations, which are normally absent in human tissue. Silicone gel contaminations in regions as small as ~10 μ m could be observed even for inclusions where conventional optical microscopy contrast was poor and chemical specificity was lacking. Dacron, a commercial name for poly(ethylene terepthalate), threads due to fixative patches were also distinguished. In particular, the rapid analysis and minimal sample preparation allowed the detection of contamination within minutes of sectioning the tissue.³⁰ These advantages imply that FTIR imaging may potentially be useful in settings requiring real-time analysis, for example, in surgical facilities.

32.5.2 Single Cells

The high spatial resolution of infrared imaging, which has allowed the examination of small morphological features in tissues, may also be employed to image single biological cells.³¹ An example of single-cell imaging and the associated spectral data that are collected are shown in Figure 32.7. It is expected that in the future the spatial-resolution limits and spectral SNR that can be obtained will allow relatively complete chemical characterizations of single cells and their intracellular components. In particular, the monitoring of biochemical changes within single cellular assemblies that have either been modified in a specific manner or harvested from specific types of tissue will make more detailed approaches to biomedical analyses achievable.

32.6 Summary

FTIR spectroscopic imaging employing an infrared interferometer and infrared-sensitive multichannel detectors have considerably enhanced the ability to rapidly acquire high-fidelity, spatially resolved data at unprecedented levels of spatial resolution and chemical detectivity. These approaches are particularly

suited to detailed biochemical and biological studies in which localized chemical signatures combined with large numbers of recorded data points lead to robust characterization protocols for biomedical analyses. An increase in the number and sophistication of available chemometric tools coupled to this powerful technique undoubtedly will contribute to an explosive growth in the acceptance and use of FTIR spectroscopic imaging in biomedical venues. Significant efforts in the authors' laboratory are under way to demonstrate fully the utility of infrared vibrational spectroscopic imaging for disease detection and diagnosis.

33.1 Introduction

Most radiation-based spectroscopic and imaging techniques typically depend on evaluation of a non-scattered or singly scattered signal for retrieval of quantitative information. For example, absorption spectroscopy depends on the survival of unscattered light across a known pathlength, L; dynamic-light scattering or photon-correlation spectroscopy, because of its scatter by Brownian motion out of the optical path, requires the fluctuation of light intensity; x-ray and computed x-ray tomography depend on the straight-line path of nonabsorbed x-rays; and so forth. Yet most systems of interest multiply scatter radiation of low energy and require diluted suspensions or nonscattering media when dealing with optical interrogation. Hence, optical techniques developed for imaging and spectroscopy are usually plagued by scatter influence. To expand the quantitative applicability of optical techniques to these real systems new techniques have been developed that focus on coherence properties, temporal and spatial correlation, and other properties; these allow for the extraction of nonscattered or singly scattered light from a multiply scattered signal. Yet these approaches neglect the scattered signal, which is the largest portion of the signal, in favor of that portion that possesses the smallest signal-to-noise ratio (SNR).

In this chapter, we first review continuous-wave and time-resolved techniques along with the associated diffusion equation for quantitative absorption, scattering, and fluorescence spectroscopy using multiply scattered light. In addition, since in the wavelength window of 600 to 900 nm light is multiply scattered by most biological tissues, we then focus on the development of these optical techniques for biomedical spectroscopy and imaging, i.e., optical tomography. Because of the limitations imposed by endogenous chromophores on tissues in this wavelength regime, we provide a comprehensive review of fluorescence-enhanced optical spectroscopy and imaging methods including measurement methods, solutions to forward- and inverse-imaging problems, and attributes of clinical and sensing fluorophore development.

33.2 Background: Probing Random Media with Multiply Scattered Light

Before presenting the measurement methods and analysis for probing random media with multiply scattered light, we will first consider traditional light-spectroscopy techniques that depend on monitoring light transmitted across a known pathlength, *L*.

33.2.1 Beer-Lambert Relation for Absorption and Turbidity Spectroscopy

Absorption and turbidity measurements consist of monitoring the attenuation of light intensity $I(\lambda)$ at wavelength λ , given incident-light intensity $I_o(\lambda)$, to determine the absorption or scattering coefficients (μ_a [cm⁻¹] or μ_s [cm⁻¹], respectively):

$$\log \frac{I(\lambda)}{I_a(\lambda)} = -\mu_a(\lambda)L \quad \text{or} \quad -\mu_s(\lambda)L \tag{33.1}$$

where the absorption coefficient is provided by the product of the concentration of light-absorbing species, $[C_i]$ [mM], and its extinction coefficient at wavelength λ , ε_i^{λ} [cm⁻¹ mM⁻¹]:

$$\mu_a(\lambda) = 2.303 \sum_{i=1}^{N} \varepsilon_i^{\lambda} [C_i]$$
(33.2)

and the scattering coefficient can be predicted from:

$$\mu_{s}(\lambda) = \int_{0}^{\pi} \frac{12\phi}{k^{2}} \int_{0}^{\infty} \frac{f(x_{i})}{x_{i}^{3}} \int_{0}^{\infty} \frac{f(x_{j})}{x_{i}^{3}} F_{i,j}(n, x_{i}, x_{j}, \lambda, \theta) \cdot S_{i,j}(x_{i}, x_{j}, q, \phi) \sin\theta dx_{j} dx_{i} d\theta$$
(33.3)

where $F_{i,j}$ is the binary form factor between the particles with different sizes x_i and x_j ; $S_{i,j}$ is the corresponding partial structure factor, which describes the correction factor of coherent scattering due to particle interactions of particles i and j; n is the relative refractive index of the particles to the medium; λ is wavelength; θ is the scattering angle; ϕ is the volume fraction of particles in the suspension; f(x) is the particle-size distribution; and q is the magnitude of the wave vector, $q = 2k \sin(\theta/2)$, where k is given by $2\pi m/\lambda$ and m is the refractive index of the medium. The structure factor is a direct measure of the local ordering of colloidal particles, and the values of $S_{i,j}$ are equal to unity in the absence of particle interactions (e.g., in a dilute suspension).

Determination of absorption and scattering coefficients through the Beer–Lambert relationship in Equation 33.1 assumes that light is absorbed or scattered *out of the path* and that no light scattered is back *into the path*. Absorption and scattering mechanisms can be considered simultaneously in dilute suspensions as an effective absorption cross section:

$$\mu_{eff} = \mu_a + \mu_s \tag{33.4}$$

33.2.2 Fluorescence Spectroscopy and Fluorescence-Lifetime Spectroscopy

Fluorescence spectroscopy, whether measured using time-resolved or continuous-wave (CW) techniques, is based on the absorption of excitation light at λ_x across path length L by fluorophores of concentration $[C_i]$. Quantum efficiency, α , describes the fraction number of emission photons at fluorescence wave length λ_m emitted for each excitation photon absorbed by the fluorophore; it is typically described as the rate of radiative decay, Γ , relative to the sum of radiative and nonradiative decay rates $(\Gamma + k_{nr})$. In other words, $\alpha = \Gamma/(\Gamma + k_{nr})$. The intensity of detected fluorescence light, I_m , in response to a constant intensity of incident excitation light, $I_n^{\lambda_x}$, can be expressed as:

$$I_{m} \propto I_{o}^{\lambda_{x}} \alpha \left[\varepsilon_{i}^{\lambda_{x}} [C_{i}] \right] \cdot \int_{0}^{\infty} g(t) dt$$
 (33.5)

Here g(t) represents the time-dependent fluorescence decay that describes the process of radiative and nonradiative relaxation of the activated fluorophore elevated to an excited state by absorption of excitation light. For most laser dyes the relaxation is a first-order process described by a mean lifetime, τ , of the activated state. Consequently, the time-invariant emission intensity predicted by Equation 33.5 can be rewritten as:

$$I_{m} \propto I_{o}^{\lambda_{x}} \alpha \left[\varepsilon_{i}^{\lambda_{x}} [C_{i}] \right] \cdot \int_{0}^{\infty} \exp \left[-\frac{t}{\tau} \right] dt \propto I_{o}^{\lambda_{x}} \alpha \left[\varepsilon_{i}^{\lambda_{x}} [C_{i}] \right] \tau$$
 (33.6)

where the fluorescence lifetime, τ , is influenced by the relative rates of radiative and nonradiative decay [i.e., $\tau = 1/(\Gamma + k_{nr})$].

Ratiometric fluorescent probes, in which re-emission is monitored across two or more wavelengths (such as *bis*-carboxyethyl carboxyfluorescein [BCECF] or seminaphthofluorescein [SNAFL]), also provide a means to monitor changes in decay kinetics using CW methods. The ratio of the emission intensities at λ_{m1} and λ_{m2} following excitation at a single excitation wavelength is independent of the concentration of fluorophore available and depends only on the decay kinetics probed at the two emission wavelengths:

$$\frac{I_m(\lambda_{m1})}{I_m(\lambda_{m2})} = \frac{I_o^{\lambda_x} \alpha^{\lambda_{m1}} \left[\boldsymbol{\varepsilon}_i^{\lambda_x} \left[\boldsymbol{C}_i \right] \right] \boldsymbol{\tau}^{\lambda_{m1}}}{I_o^{\lambda_x} \alpha^{\lambda_{m2}} \left[\boldsymbol{\varepsilon}_i^{\lambda_x} \left[\boldsymbol{C}_i \right] \right] \boldsymbol{\tau}^{\lambda_{m2}}} = \frac{\alpha^{\lambda_{m1}}}{\alpha^{\lambda_{m2}}} \cdot \frac{\boldsymbol{\tau}^{\lambda_{m1}}}{\boldsymbol{\tau}^{\lambda_{m2}}}$$
(33.7)

In time-domain measurements, where an incident impulse of excitation light is used to excite the sample, the resulting time-dependent emission intensity can be predicted by:

$$I_{m}(t) \propto I_{o}^{\lambda_{x}}(\delta) \alpha \left[\varepsilon_{i}^{\lambda_{x}}[C_{i}] \right] \cdot \int_{0}^{t} \exp \left[-\frac{t'}{\tau} \right] dt'$$
 (33.8)

Thus, when a dilute fluorescence sample is excited with an impulse of excitation light and the emission intensity is monitored as a function of time, the lifetime or decay kinetics that govern the relaxation of the activated state to the ground state can be quantitated independently of the concentration of fluorophore present. The measurement of the time-dependent emission light following activation in a diluted, nonscattering suspension with an incident impulse of excitation light also serves as the basis of the time-domain measurements described below for random media.

Above, CW and time-domain analyses were presented for fluorophores exhibiting first-order decay kinetics in which the form of the decay kinetics, g(t), is given by:

$$g(t) = \exp(-\frac{t}{\tau}) \tag{33.9}$$

However, most analyte fluorophores exhibit more complex decay kinetics such as multiexponential decays:

$$g(t) = \sum_{i=1}^{N} a_i \exp\left[\frac{-t}{\tau_i}\right]$$
 (33.10)

or stretched-exponential decay kinetics, which indicates collisional quenching among species j:

$$g(t) = \sum_{i=1}^{N} a_{j} \exp\left[-\alpha_{j} \cdot t - \beta_{j} \sqrt{t}\right]$$
(33.11)

By monitoring the time dependence of the emitted fluorescence light as a function of time following excitation, the decay kinetics can best be ascertained and correlated with the local environment that impacts the relaxation process. For example, the Stern–Volmer equation relates the quencher concentration, [Q], and fluorescence-intensity measurements made in the absence and presence of the quenchers I_m^o and I_m , respectively:

$$\frac{I_m^o}{I_m} = 1 + K[Q] = 1 + \left(k_q \tau_o\right)[Q]$$
 (33.12)

where K is the Stern–Volmer constant, and k_q and τ_o are the bimolecular quenching constant and the lifetime of the fluorophore in the absence of quencher.

The decay kinetics of many analyte-sensing fluorophores can be used to assess concentrations of analytes such as H⁺ and Ca²⁺, which may have no appreciable absorption cross section at the emission and excitation wavelengths used. Consequently, fluorescence-lifetime spectroscopy broadens the applicability of absorption spectroscopy, provided a fluorophore with analyte-sensitive decay kinetics can be identified.

While time-dependent techniques are the best way to assess fluorescence-decay kinetics, their need for Dirac pulses of excitation light complicates instrumentation and limits quantitation. Frequency-domain approaches provide an alternative approach to the impulse function by exciting with an intensity-modulated excitation light modulated at MHz–GHz modulation frequencies, ω . Activation of the fluorophore creates

isotropic, intensity-modulated fluorescent light that is both phase delayed and amplitude attenuated relative to the incident light owing to the kinetics of the relaxation process. For a simple, first-order system the decay kinetics, the phase delay, $\theta(\omega)$, and the modulation ratio, $M(\omega)$, at modulation frequency ω can be predicted from:

$$M(\omega)\exp(-i\theta(\omega)) = \int_{0}^{\infty} g(t)\exp[-i\omega t]dt = \int_{0}^{\infty} \exp\left[-\frac{t}{\tau}\right]\exp[-i\omega t]dt$$

$$M(\omega) = \frac{I_{AC}(\omega)}{I_{DC}(\omega)} = \frac{\mu_{a}\alpha}{\sqrt{1+(\omega\tau)^{2}}}; \quad \theta(\omega) = \tan^{-1}[\omega\tau]$$
(33.13)

where the amplitude and average of the modulated emission light is given by $I_{AC}(\omega)$ and $I_{DC}(\omega)$. In dilute, nonscattering media, the fluorescent emission is collected at right angles to the excitation illumination to avoid inadvertently collecting excitation light.

It has been proposed that absorption and scattering spectroscopy employing the Beer–Lambert relationship as well as the CW, time-domain, and frequency-domain fluorescence-spectroscopy approaches for quantitative spectroscopy when scattered back into the optical path do not corrupt attenuation or intensity measurements. However, most systems are comprised of random media, i.e., those that absorb, multiply scatter, and fluoresce. The techniques of CW, time and frequency domain, and associated approaches to performing quantitative spectroscopy and imaging in random media are outlined in the next section.

33.2.3 Measurement Approaches for Quantitative Spectroscopy and Imaging in Random Media

Here we restrict our discussion to quantitative spectroscopy and imaging in random media in which the diffusion approximation to the radiative transport equation holds. The conditions are (1) the source of incident (excitation) light is isotropic; (2) the scattering capacity of the tissue exceeds that of its absorption capacity, i.e., $\mu_a << (1-g)\mu_s$, where g is the mean cosine of angular scatter of the medium; and (3) the light that is collected has been multiply scattered. When referring to measurements of multiply scattered light, i.e., light that has traveled a distribution of pathlengths or "times of flight," we term them photon-migration measurements.

33.2.3.1 CW and Time-Resolved-Measurement Approaches

CW measurements employ a light source whose intensity nominally does not vary with time. The constantpower, isotropic source illuminates the random medium with light whose intensity becomes exponentially attenuated with increasing distance from the tissue surface. Increased absorption or scattering properties of the medium result in increased light attenuation as the light propagates deeper into the random medium. In CW measurements, the time-invariant intensity is measured as a function of distance from the incident source and is primarily a function of the product $\mu_{\nu}\mu'_{\nu}$ or $\mu_{\nu}\mu_{\nu}(1-g)$. The amount of generated fluorescent light at any position \bar{r} is proportional to the product of the concentration of fluorophore, $[C_i]$, and the local excitation fluence, $\Phi_{v}(r)$, which is the concentration of excitation photons times the speed of light within the medium. Thus, the origin of emission light predominates from the region in which the excitation fluence, Φ_v , is greatest. For time-invariant CW measurements, the region with the greatest excitation fluence always remains close to the point of incident-excitation illumination. Consequently, the origin of fluorescence is mainly from the surface or subsurface regions. For determination of fluorescent optical properties in a uniform medium with CW techniques, fluorescence spectroscopy may not be impacted by the confinement of the origin of emission light if the random medium is indeed homogeneous. However, in imaging scenarios where concentration of fluorophore is nonuniform, CW techniques will undoubtedly emphasize surface and subsurface regions. In imaging cases where the fluorescent dye acts as a contrast agent and has "perfect uptake," (i.e., partitioning of the dye occurs exclusively in the tissue of interest without any residual

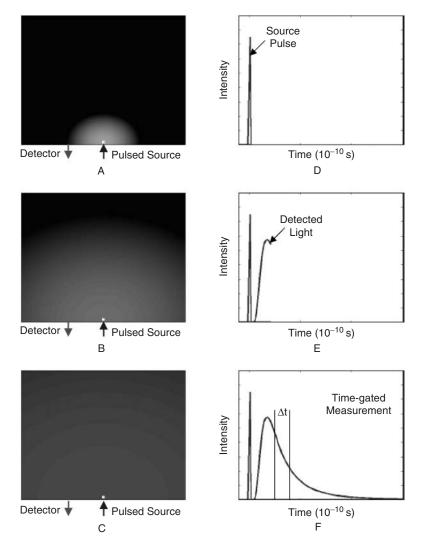

FIGURE 33.1 Schematic of time-domain photon-migration (TDPM) measurement approach used in NIR optical spectroscopy and tomography. TDPM imaging approaches use an incident impulse of light that results in the propagation of the pulse, which attenuates as a function of distance from the source and time following its delivery. The detected pulse is measured as intensity vs. time, which represents the photon "time of flight." Panel (A) illustrates the light distribution in tissue from a pulse point source after 1×10^{-10} s, (B) 25×10^{-10} s, and (C) 150×10^{-10} s following the incident impulse. The corresponding recorded data during the time intervals at the detector are illustrated in panels (D) through (F). A time-gated illumination measurement is shown in panel (F) in which the integrated intensity measured within a specified window is measured. (From Hawrysz, D.J. and Sevick-Muraca, E.M., *Neoplasia*, 2(5), 388, 2000. With permission.)

dye in the intervening tissues between the target and the surface), then CW techniques may be appropriate. However, the elusive "holy grail" of contrast-based imaging for all medical-imaging modalities is to develop agents that maximize their partitioning in the target region of interest. Near-infrared (NIR) techniques involving fluorescent contrast agents for clinical imaging will likely not involve CW measurement despite the simplicity of its instrumentation.

Time-domain photon-migration (TDPM) measurements employ a light source that delivers a pulse of excitation light that broadens and attenuates as it propagates through the random medium, as shown in Figure 33.1. TDPM techniques employ single-photon counting (sometimes called time-correlated counting) or gated integration measurements to acquire the emitted pulse broadened by as much as

several nanoseconds of photon time of flight. As the absorption properties of the random media increase, the broadening of the excitation pulse lessens and greater attenuation occurs. In the case of increased scattering properties, the excitation pulse increasingly broadens and attenuates during its propagation away from the incident point source. Clearly the impact of absorption and scattering has differing effects on the photon time of flight: increased absorption decreases the path and travel time of migrating photons, while increased scattering enhances it. When fluorophores are excited within the random medium, a propagating excitation pulse generates a propagating emission pulse that is further broadened owing to the decay kinetics of the dye.

Since the region of highest excitation fluence is not stationary and propagates away from its incidence with time following delivery to the surface, the origin of fluorescent signals activated by the propagating excitation pulse may not be restricted to surface or subsurface tissues as in the case of CW measurements. If the time constant of the dye's decay kinetics is less than or comparable to the detected excitation photon time of flight, then the fluorescence measured at a distance away from the incident excitation source may originate deeply within the random medium. On the other hand, if the time constant of the dye's decay kinetics is greater than the detected excitation photon times of flight, then the fluorescence will originate from shallow locations within the random medium.²

The phenomenon can be explained by the fact that at the medium surface, the position of maximum excitation fluence travels from its point of incidence to deep within the medium and exponentially attenuates as it penetrates. Consider a fluorophore that has an instantaneous rate of radiative relaxation. The maximum emission fluence will likewise follow the trend of the propagating excitation pulse: at time t = 0 when the excitation pulse is launched, the emission fluence will be greatest at the point of incidence, and as time progresses the point of greatest emission fluence will propagate into the medium, attenuating as it does so. The emission light that reaches the surface will initially originate from regions closest to the incident source and then from deeper within the random medium with increased time after the initial impulse of excitation light. However, in the case of a phosphorescent agent with a slow radiative relaxation rate and an effective lifetime on the order of milliseconds (much larger that the measured photonmigration times of flight), the greatest concentration of activated fluorophore will reside close to the incident point of excitation illumination; while the pulse of excitation fluence transits deeper within the random medium, the slow decay of the activated fluorophore closest to the point of incident of excitation will result in a pulse of emission fluence that does not propagate spatially with time into the random medium and away from the point of the incident-excitation illumination. Consequently, for imaging and spectroscopic-imaging applications where information from within the random medium is desired, longlived fluorophores cannot be employed.

The qualitative CW and TDPM measurements for fluorescence spectroscopy and imaging are described above. Quantitative prediction is also possible with the radiative transport equation, Monte Carlo, and diffusion equations, provided the proper model for fluorescent decay is incorporated. Here we restrict our analysis to media in which the diffusion approximation to the radiative-transfer equation applies. The photon-diffusion equation may be written to predict CW and TDPM measurements of excitation (subscript x) and emission (subscript m) fluence, $\Phi_{x,m}(\vec{r})$ and $\Phi_{x,m}(\vec{r},t)$, respectively:^{3,4}

$$\vec{\nabla} \cdot \left(D_{x,m} \vec{\nabla} \Phi_{x,m}(\vec{r},t) \right) - \mu_{ax,m} \Phi_{x,m}(\vec{r},t) = \frac{1}{c} \frac{\partial \Phi_{x,m}(\vec{r},t)}{\partial t} - S_{x,m}(\vec{r},t)$$
(33.14)

where $D_{x,m}$ is the optical-diffusion coefficient at the excitation or emission wavelength in centimeters [cm] given by:

$$D_{x,m} = \frac{1}{3[\mu_{a_{x,m}} + \mu'_{s_{x,m}}]}$$
 (33.15)

and $\mu'_{s_{x,m}}$ is the isotroptic scattering coefficient given by $(1-g)\mu_{s_{x,m}}$. The excitation or emission fluence, $\Phi_{x,m}(\vec{r},t)$ [W/m²], is the angle-integrated scalar flux of photons and is defined as the power incident on an

infinitesimally small sphere divided by its area. Again, it can also be thought of as the local concentration of photons times the speed of light, c, at a given position \bar{r} and (for time-dependent cases) at time t. For continuous-wave spectroscopy or imaging there is no time dependence, and the source term, $S_x(\bar{r},t)$, becomes time invariant. Assuming the source is isotropic, this term is equivalent to the power deposited over its area. For TDPM measurements the source, $S_x(\bar{r},0)$ is assumed to be a Dirac delta function, assuming a finite value at time zero, but zero at all other times. For both CW and TDPM measurements Equation 33.14 can be solved to predict the excitation fluence, $\Phi_x(\bar{r})$ or $\Phi_x(\bar{r},t)$, in response to the known spatial distribution of absorption and scattering properties, $\mu_{ax}(\bar{r})$ and $\mu'_{sx}(\bar{r})$, of the media volume at the excitation wavelength. Here the absorption coefficient at the excitation wavelength is comprised of contributions from the endogenous chromophores ($\mu_{ax\to 0}(\bar{r})$) as well as the exogenous fluorophores ($\mu_{ax\to 0}(\bar{r})$).

Since a closed-form solution for $\Phi_x(\vec{r},t)$ exists only for simple geometries such as infinite and semi-infinite media of uniform optical properties, the solutions are otherwise developed numerically using finite-difference or finite-element methods.

Of the three boundary conditions commonly used, the partial-current condition is the most rigorous.^{5,6} It states that a photon leaving a tissue never returns and uses a reflectance parameter to account for Fresnel reflection at the tissue–air surface. If the boundary condition is perfectly transmitting (thereby exhibiting no Fresnel reflection), then the fluence evaluated at the boundary must fall to zero, creating a discontinuity that violates the diffusion approximation that assumes isotropic radiance. When the Fresnel reflection is considered at the boundary, this violation is eased by modeling a portion of the photons to be reflected back into the medium. The partial-current-boundary condition can be expressed in terms of the fluence and its gradient normal to the boundary:

$$\Phi_{x,m}(\vec{r},t) = 2 \cdot \frac{1 + R_{eff_{x,m}}}{1 - R_{eff_{x,m}}} \cdot D_{x,m} \vec{\nabla}_n \Phi_{x,m}(\vec{r},t)$$
(33.16)

where R_{eff} is the effective reflection coefficient whose quantity predicts the amount of light reflection and degree of anisotropy at the boundary.

A slightly simpler condition, the extrapolated-boundary condition, is an approximation of the partial-current condition and yields solutions similar to those of the diffusion equation.^{7,8} In this case, the fluence is set to zero at an extrapolated boundary located at a specified distance outside the medium to account for Fresnel reflection at the surface.

The third boundary condition, the zero condition, merely sets the fluence to zero on the boundary and is used for its simplicity. In a homogeneous scattering medium, the zero-boundary condition results in an analytical solution to the diffusion equation in terms of the absorption and scattering coefficients.^{8,9}

The measured flux or photon current in CW or TDPM measurements, $J_{x,m}(\vec{r})$ or $J_{x,m}(\vec{r},t)$, is then determined by the gradient of fluence, $\vec{\nabla}\Phi_{x,m}(\vec{r})$ and $\vec{\nabla}\Phi_{x,m}(\vec{r},t)$, at the surface (also known as Fick's law):

$$J_{x,m}(\vec{r},t) = -D_{x,m} \nabla \Phi_{x,m}(\vec{r},t)$$
 (33.17)

As a result of combining Fick's law and the partial-current- or extrapolated-boundary conditions, the measured flux or photon density is simply proportional to the fluence at the surface.

Since red light multiply scatters as it transits tissues, it can excite exogenous fluorescent agents that, in turn, act as uniformly distributed sources of fluorescent light. The fluence at the emission wavelength, $\Phi_m(\vec{r})$ or $\Phi_m(\vec{r},t)$, is generated and propagates within the multiply scattering medium; it can also be described by Equation 33.14, provided that its source-emission kinetics are properly modeled in the source term, $S_m(\vec{r})$ or $S_m(\vec{r},t)$. The isotropic scattering coefficient at the emission wavelength, μ'_{s_m} , may be considered to be different than that at the excitation wavelength. The absorption coefficient at the emission wavelength, $\mu_{a_m}(\vec{r})$, is due to both endogenous chromophores and, if reabsorption of the emission light from the fluorophore occurs, the reabsorption of fluorescent light by the exogenous agent. While including secondary reabsorption and photobleaching effects is relatively straightforward, when

the excitation and emission spectra are well separated and the fluorophore is in dilute concentrations, we neglect this contribution to absorption at the emission wavelength. The general form for the emission source, $S_m(\vec{r},t)$, is:

$$S_{m}(\vec{r},t) = \mu_{a_{x \to m}}(\vec{r}) \alpha \Xi_{m} \int_{0}^{t} \Phi_{x}(\vec{r},t') \cdot g(t') dt'$$
 (33.18)

where $\Phi_x(\vec{r},t)$, α , and Ξ_m are, respectively, excitation photon density, quantum efficiency of the fluorophore, and the detection efficiency factor of the system at the emission wavelength (which contains the system-spectral response and the fluorophore spectral-emission efficiency¹⁰). The time-invariant source of CW measurements, $S_m(\vec{r})$, is described by Equation 33.18, with the upper limit of the time integral equal to infinity. The source of emission light from a mixture of fluorophores undergoing various decay kinetics is simply a combination of the above expressions.

If the solution for the excitation fluence, $\Phi_x(\vec{r})$ or $\Phi_x(\vec{r},t)$, is first obtained, and the decay kinetics and optical properties at the emission wavelength are known, the emission fluence, $\Phi_m(\vec{r})$ or $\Phi_m(\vec{r},t)$, can then be solved using one of the three commonly used boundary conditions described above. The measured flux or photon current in CW or TDPM measurements is then determined from the gradient of the emission fluence.

While CW measurements can be limited in information content regarding decay kinetics and spatial discrimination, TDPM measurements are tedious in that they require an incident Dirac pulse or convolution/deconvolution of the pulse, suffer from low SNR, and mathematically require the solution of an integral-differential equation for spectroscopy and imaging applications. Indeed, the large dynamic range of SNR over the entire distribution of photon times of flight in TDPM approaches can require significant data-acquisition times to resolve or reduce uncertainty in the resulting images. However, some developers prefer to employ TDPM measurements to construct optical property maps since their information content is the richest.¹¹ Frequency-domain approaches sidestep these issues with the use of an easily achievable sinusoidally modulated light source, measurements possessing high SNR, and, as shown in the next section, a more tractable set of equations for solution of the spectroscopy and imaging-inverse problems.

33.2.3.2 Frequency-Domain Measurement Approaches

Frequency-domain measurements in random media are similar to those described in the previous section. An intensity-modulated point source of excitation light is launched into a scattering medium, and the propagating "photon-density wave" is attenuated and phase delayed relative to the incident source as it propagates through the random medium, as shown in Figure 33.2. The detected phase delay and amplitude attenuation measured at the excitation wavelength can be used to determine the optical properties of the random medium, whether they are uniform (for solution of the inverse-spectroscopy problem) or nonuniform (for solution of the inverse-imaging problem). The diffusion equation for solution of the forward problem of predicting measurements also applies, with the difference that the equation is cast in the frequency domain rather than in the time domain:

$$\vec{\nabla} \cdot \left(D_{x,m} \overline{\nabla} \Phi_{x,m}(\vec{r}, \omega) \right) - \left[\mu_{ax \to m} + \frac{i\omega}{c} \right] \Phi_{x,m}(\vec{r}, \omega) + S_{x,m}(\vec{r}, \omega) = 0$$
(33.19)

Here the fluence, $\Phi_{x,m}(\vec{r},\omega)$, is now a complex number describing the characteristics of the photon-density wave at position \vec{r} and modulated at angular frequency ω . Moreover, the fluence is comprised of alternating, $\Phi_{AC_{x,m}}(\vec{r},\omega)$, and nonalternating, $\Phi_{DC_{x,m}}(\vec{r},0)$, components, of which the former provides an accurate description of the phase delay, $\theta_{x,m}$, and amplitude, $I_{AC_{x,m}}$, of the wave at position \vec{r} :

$$\Phi_{x,m}(\vec{r},\omega) = \Phi_{AC_{x,m}}(\vec{r},\omega) + \Phi_{DC_{x,m}}(\vec{r},0)
= I_{AC_{x,m}} \exp(i\theta_{x,m}) + I_{DC_{x,m}}(\vec{r},0)$$
(33.20)

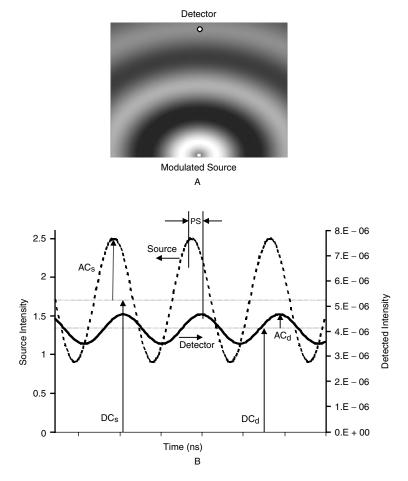

FIGURE 33.2 Schematic of the frequency-domain photon-migration (FDPM) measurements used in NIR optical spectroscopy and tomography. FDPM traditionally consists of an incident, intensity-modulated light source that creates a "photon-density wave" that spherically propagates continuously throughout the tissue. Panel (A) shows light distribution in tissue due to a modulated source (exaggerated for purposes of illustration), and panel (B) illustrates the detected signal (solid line) in response to the source illumination (dotted line). The typical frequency domain data, where the measurable quantities are the phase shift θ, the amplitude of each wave I_{AC} and the average value I_{DC} of intensity. As shown in (B), the intensity wave that is detected some distance away from the source is amplitude-attenuated and phase-delayed relative to the source. (From Hawrysz, D.J. and Sevick-Muraca, E.M., Neoplasia, 2(5), 388, 2000. With permission.)

The nonalternating component of the fluence, $\Phi_{DC_{x,m}}(\bar{r},0)$, is simply the fluence that is measured when using a CW source ($\omega=0$). The pre-exponential factor, $I_{AC_{x,m}}$, is the amplitude of the photon-density wave, and $\theta_{x,m}$, is the phase delay of the wave relative to the incident source. At larger modulation frequencies the photon-density wave attenuates more rapidly during its propagation and experiences greater phase lag. Consequently, the amplitude decreases with increasing modulation frequency, while the phase delay increases with modulation frequency. Often the amplitude or modulation ratio is reported as a measurement. The modulation ratio is simply the amplitude of the wave normalized by $I_{DC_{x,m}}(\bar{r},0)$.

For the solution of the excitation fluence via Equation 33.19 the source function is either a point source (as shown in Figure 33.2) or a plane source of modulated light:

$$S_{x}(\vec{r}, \omega) = S(\vec{r}, \omega) \exp(i\theta_{x}(\vec{r}, \omega))$$
(33.21)

where the strength (or amplitude) of the excitation source at its position of incidence, $\vec{r_s}$, is $S(\vec{r_s}, \omega)$, and its absolute phase is $\theta_s(\vec{r_s}, \omega)$. Typically, frequency-domain photon-migration (FDPM) measurements are conducted between a point source of illumination, and the amplitude and the phase of the detected light (also collected at a point) is determined relative to the source. Consequently, in most cases in the literature, the source strength is designated as unity, and the phase of the incident source is taken as zero. As described in the next section, emission fluence in response to incident-planar-wave excitation can be employed and predicted by the diffusion equation, provided that the spatial phase, $\theta_s(\vec{r_s}, \omega)$, and amplitude, $S(\vec{r_s}, \omega)$, of the source are properly accounted for.¹²

The boundary conditions for frequency-domain measurements in random media are identical to those described above for CW and TDPM techniques, and the partial-current-boundary condition is similarly written:

$$\Phi_{x,m}(\vec{r},\omega) = 2 \cdot \frac{1 + R_{eff_{x,m}}}{1 - R_{eff_{x,m}}} \cdot D_{x,m} \vec{\nabla}_n \Phi_{x,m}(\vec{r},\omega)$$
(33.22)

The measured flux or photon current in frequency-domain measurements, $J_{x,m}(\vec{r},\omega)$, is then determined by Fick's law:

$$J_{x,m}(\vec{r},\omega) = -D_{x,m}\nabla\Phi_{x,m}(\vec{r},\omega)$$
(33.23)

The result of combining Fick's law and the partial-current- or extrapolated-boundary conditions is that the measured flux or photon density of the wave (now a complex number) is simply proportional to the fluence at the surface. Consequently, the measured phase, $\theta_{x,m}$ and amplitude, $I_{AC_{x,m}}$, are predicted from the fluence, $\Phi_{AC_{x,m}} = I_{AC_{x,m}} \exp(i\theta_{x,m})$.

As with CW and TDPM methods, the radiative relaxation of the activated fluorophore serves as a distributed source of emission light within the random medium. The emission source, $S_m(\vec{r},\omega)$, for single-exponential-decay kinetics is:

$$S_{m}(\vec{r},\omega) = \mu_{a_{x\to m}} \left(\frac{1}{1-i\omega\tau}\right) \Phi_{x}(\vec{r},\omega) \alpha \Xi_{m}$$
 (33.24)

and for any arbitrary-decay kinetics expressed by g(t), the source term can be generally derived from:

$$S_{m}(\vec{r}, \omega) = \mu_{a_{x \to m}} \Phi_{x}(\vec{r}, \omega) \alpha \Xi_{m} \int_{0}^{\infty} \left(g(t) e^{(i\omega t)} dt \right)$$
(33.25)

The solution of Equation 33.19 describes the propagation of excitation light; from this the excitation fluence, $\Phi_x(\vec{r},\omega)$, can be directly obtained and used as input for the source term to solve Equation 33.19 for the emission fluence, $\Phi_m(\vec{r},\omega)$.¹³ Thus, the solution of the coupled equations with the specified boundary conditions, the phase and amplitude of the detected emission wave relative to the incident excitation source, can be directly determined.

As with TDPM measurements, the ability to use fluorescence to interrogate random media is afforded by FDPM measurements when the lifetime of the fluorescent agent is small when compared to the photon time-of-flights. As with TDPM approaches, effective contrasts for FDPM approaches are limited to fluorescence rather than phosphorescent or long-lived compounds. This was demonstrated in the Photon-Migration Laboratory (PML) by comparing FDPM contrast offered by tris (2,2'-bipyridyl) dichlororuthenium (II) Ru(bpy) $^{3+}_{3}$ with a lifetime of 600 ns and ICG with a lifetime of 0.56 ns. In this case, the FDPM contrast was defined as the change in the phase and amplitude of the emission light as the position of the target changed relative to the position of the point of excitation illumination and emission detection. Using a single target with 100-fold greater concentration than the background in a phantom (see Figure 33.3 for measurement geometry of the phantom), the phase and amplitude modulation contrast at each of the

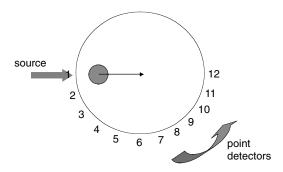

FIGURE 33.3 Schematic of the phantom tests showing the change in emission-phase measurements as a fluorescent and phosphorescently tagged, 10-mm-diameter target was moved from the periphery toward the center of a 100-mm-diameter cylindrical vessel.

detectors could be seen when ICG was used (Figure 33.4A); however, no contrast was measured when ruthenium dye, Ru(bpy)₃²⁺, was used as the contrast agent (Figure 33.4B). These results confirm computational predictions that effective contrast agents must possess shorter lifetimes than the time of flight of photon propagation.¹⁴

Consequently, in order to develop fluorescence-lifetime spectroscopy and imaging techniques, the time dependence of the photon-migration process must be accounted for in order to obtain lifetime information. Whether imaging or spectroscopy is used, the inverse problem becomes one of separating photon migration from fluorescence-decay kinetics. Some investigators have sought to avoid the problem by employing phosphorescent dyes wherein the photon migration times of flight of picoseconds to nanoseconds are insignificant compared to lifetimes on the order of micro- to milliseconds. Nonetheless, time-dependent emission measurements will be unable to interrogate beyond the surfaces or subsurfaces when long-lived dyes are employed. When used as contrast agents for imaging, these long-lived dyes do have utility, but only if their partitioning within the target is perfect and there is no residual dye in the background.

Finally, since the amplitude of the detected fluorescence, I_{AC_m} , is insensitive to the intensity due to the ambient light, the frequency-domain approach has clear advantages for application in environments that are not light tight. In addition, since frequency-domain approaches offer steady-state measurement of a time-dependent light-propagation process, they have comparatively high SNRs with respect to time-domain approaches and retain lifetime-dependent signals, which is otherwise missing in CW measurements. Due to the ease of instrumentation of frequency-domain over time-domain approaches, and due to the superior information of time-dependent techniques over CW measurements, the remainder of this chapter will focus on FDPM measurements, but studies conducted using CW and TDPM techniques will be cited.

33.3 Frequency-Domain Photon Migration (FDPM) Measurement Approaches

Two approaches have been employed in spectroscopy and imaging of random media: (1) point detection and point illumination and (2) area detection and area illumination. Point-detection schemes typically employ heterodyne or I and Q mixing techniques, which employ signal mixing at the photodetector following point detection to extract signals of phase and amplitude modulation at a single point. To conduct FDPM measurements among a number of sources and detectors, either scanning of the source/ detector or transmitter/receiver pair or replication of the receiver/transmitter circuitry is required. Consequently, this restricts FDPM imaging and spectroscopy to sparse data sets for solving the inverse-spectroscopy and imaging problems. While sufficient for solving the problem of inverse spectroscopy (as discussed in Section 33.4), point illumination and point detection provide sparse sets for optical tomography or solution of the inverse-imaging problem (as discussed in Section 33.5). The use of an incident point of excitation light delivered by a fiber optic requires a number of measurements as its position is scanned or replicated along the surface for imaging purposes (Figure 33.5). Since excitation fluence

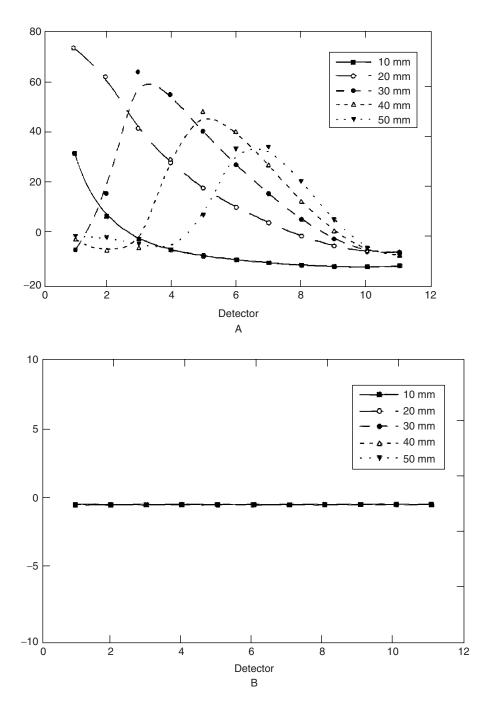

FIGURE 33.4 The phase contrast in degrees (determined from the phase measured in the presence and absence of a target) measured at the emission light for a 100:1 target-to-background ratio for (A) phosphorescent dye with lifetime of 1 ms and (B) fluorescent dye with lifetime of 1 ns. The phase contrast is predicted from simulation of the target moving from the perimeter (10 mm) toward the center (50 mm) of a 10-cm-diameter cylinder under conditions of maximum phase contrast, i.e., $\omega \tau = 1$ and uniform lifetime. The detectors are located around half of the perimeter of the cylinder, as described in Figure 33.3.

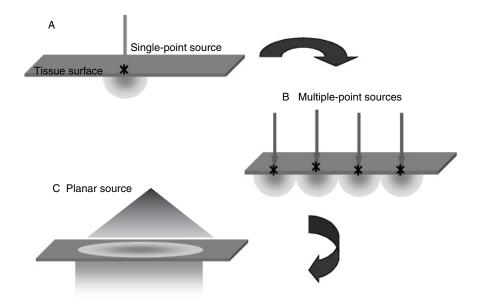

FIGURE 33.5 Illustration of different geometries for illumination of deep tissues. (A) Single-point source of excitation-light delivery. (B) Multiple-point sources, which in the extreme of high density of simultaneous sources is representative of (C). (C) Planar source of excitation light with illumination spread over an area of the tissue surface.

attenuates rapidly, each point-source illumination will not necessarily probe significant volumes and may "miss" the fluorescent target region of interest. Consequently, a high density of measurements is typically required for a relatively confined volume for imaging purposes, and area-illumination and area-detection schemes may become pertinent for imaging. However, for optical-tomography work employing endogenous contrast, measurement geometries are necessarily restricted to point illumination and point detection. The general principles of frequency-domain measurements of fluorescence in random media using heterodyne point measurements and homodyning area measurements, challenges for fluorescence spectroscopy and imaging in random media, and, finally, measurements geometries are discussed below.

33.3.1 Heterodyne Mixing for Frequency-Domain Photon Migration

Point-illumination and point-detection measurements are most common because of their prevalence in frequency-domain spectrometers for measurement of decay kinetics in nonscattering diluted samples. For imaging systems the point-source and point-detection schemes and tomographic approaches are developed exclusively for this geometry. The heterodyned point-illumination and point-detection measurements consist of three parts: (1) the modulated source; (2) the detector, which may also act as the mixer; and (3) the electronics to accomplish mixing. A schematic of the system is illustrated in Figure 33.6.

The modulated source can be either a coherent light source that is externally modulated via an electrooptic modulator, a laser diode modulated by use of a radio frequency (RF) signal via a bias tee, or, which
is more complicated, a pulsed source with a constant and known pulse-repetition rate. A master oscillator
drives the source, which is focused to illuminate a point on the surface of the random medium or coupled
to the surface through the use of fiber optics. Modulation frequencies are typically on the order of 30 to
500 MHz. A fast detector — i.e., silicon photodiode, avalanche photodiode, or fast photomultiplier —
is required to detect the amplitude and phase delay of the detected photon-density wave at excitation
and emission wavelengths. To acquire the signal for standard data acquisition, the signal, L, of frequency ω is "mixed down" to a more manageable frequency, $\Delta\omega$, by mixing with another signal of frequency, $\omega + \Delta\omega$. For example, the mixing can be accomplished through direct-gain modulation of the photomultiplier tube or at a mixer, which receives the photomultiplier signal. (Figure 33.7). Consider the signal

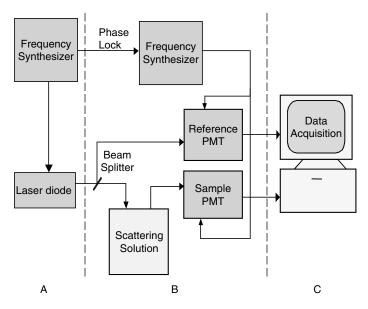

FIGURE 33.6 Schematic of heterodyned FDPM system that consists of three parts: (A) the modulated source (shown as laser diode), (B) the detector (PMT), which also acts as the mixer, and (C) the data-acquisition hardware and software to accomplish mixing.

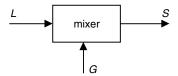

FIGURE 33.7 Schematic of mixer for heterodyne and homodyne detection of $I_{AC_{v,m}}$ and $\theta_{x,m}$ for FDPM.

representing the detected light, L, which has propagated to a position and experienced phase delay θ and has amplitude L_{AC} and average signal L_{DC} .

$$L = L_{DC} + L_{AC} \cdot \cos[\omega t + \theta]$$
 (33.26)

Assume the signal G generated by a slave oscillator is in phase with the master oscillator (i.e., there is no phase delay relative to the incident light) and has amplitude G_{AC} and average signal level G_{DC} .

$$G = G_{DC} + G_{AC} \cdot \cos[(\omega + \Delta\omega)t + \theta_{inst}]$$
(33.27)

where θ_{inst} represents the phase delay introduced into the signal due to instrumentation rather than light propagation. Upon mixing the signals, one obtains S, which consists of high- $(2\omega + \Delta\omega, \omega + \Delta\omega, \omega)$ and low-frequency $(\Delta\omega)$ components:

$$\begin{split} S &= L \times G \\ S &= L_{DC} \cdot G_{DC} + L_{DC} \cdot G_{AC} \cdot \cos \left[\left(\omega + \Delta \omega \right) t + \theta_{inst} \right] \\ &+ G_{DC} \cdot L_{AC} \cdot \cos \left[\omega t + \theta \right] \\ &+ \frac{L_{AC} \cdot G_{AC}}{2} \cdot \cos \left[\Delta \omega t - \theta + \theta_{inst} \right] \\ &+ \frac{L_{AC} \cdot G_{AC}}{2} \cdot \cos \left[\left(2\omega + \Delta \omega \right) t + \theta + \theta_{inst} \right] \end{split}$$

When the mixed signal is filtered with a low-bandpass filter, the final detected signal is:

$$S = L_{DC} \cdot G_{DC} + \frac{L_{AC} \cdot G_{AC}}{2} \cos[\Delta \omega t - \theta + \theta_{inst}]$$
 (33.29)

whereby the information of signal L is preserved in the low-frequency signal, where $\Delta \omega$ is typically in the hundreds of hertz or kilohertz. Following subtraction of the average of the signal, $L_{DC} \cdot G_{DC}$, Fourier analysis of the mixed signal at frequency $\Delta \omega$ yields the phase information, $[-\theta + \theta_{inst}]$, as well as the product of $L_{AC} \cdot G_{AC}$. To solve the inverse spectroscopy or imaging problem, accurate assessment of L_{AC} and θ must be determined using a referencing approach to eliminate θ_{inst} , G_{AC} , and G_{DC} .

When using external-cavity or laser-diode modulation, the modulation frequencies can be swept continuously, providing a frequency spectrum of $\Phi_{x,m}(\omega)$ or $\theta_{x,m}(\omega)$ and $I_{AC_{x,m}}(\omega)$. However, in the case of a pulsed light source, such as a Ti:sapphire picosecond or femtosecond laser, the master oscillator is set by the length of the laser cavity, which sets the laser repetition rate, $1/\omega$, and the signal G is swept across the harmonics of the laser-repetition frequency plus a small offset, $n\omega + \Delta\omega$, $n = 1, 2, \ldots$. Thus, pulsed sources provide a frequency spectrum of $\Phi_{x,m}(n\omega)$ or $\theta_{x,m}(n\omega)$ and $I_{AC_{x,m}}(n\omega)$ where $n = 1, 2, \ldots$. See Reference 16 for more information about frequency-domain measurements with pulsed laser sources.

33.3.2 Homodyne Mixing for Frequency-Domain Photon Migration

The homodyne approach is similar to the heterodyne approach described above except that the signal, L, of frequency ω is mixed down to DC signal through mixing with another signal of identical frequency. Consider the signal G generated by the master oscillator with an introduced phase delay, η , with amplitude G_{AC} and average signal level G_{DC} :

$$G = G_{DC} + G_{AC} \cdot \cos[(\omega)t + \theta_{inst} + \eta]$$
(33.30)

where θ_{inst} represents the phase delay introduced into the signal due to instrumentation rather than light propagation.

The mixing of signals L and G produces S, which consists of a high-frequency component (2 ω , ω) and a DC component:

$$\begin{split} S &= L \times G \\ S &= L_{DC} \cdot G_{DC} + L_{DC} \cdot G_{AC} \cdot \cos[(\omega)t + \theta_{inst} + \eta] \\ &+ G_{DC} \cdot L_{AC} \cdot \cos[\omega t + \theta] \\ &+ \frac{L_{AC} \cdot G_{AC}}{2} \cdot \cos[-\theta + \theta_{inst} + \eta] \\ &+ \frac{L_{AC} \cdot G_{AC}}{2} \cdot \cos[(2\omega)t + \theta + \theta_{inst} + \eta] \end{split}$$

$$(33.31)$$

When the mixed signal is filtered with a low-bandpass filter, the final detected DC signal is:

$$S = L_{DC} \cdot G_{DC} + \frac{L_{AC} \cdot G_{AC}}{2} \cos[-\theta + \theta_{inst} + \eta]$$
(33.32)

When the phase delay η is changed by known values, it is possible to evaluate $L_{DC} \cdot G_{DC}$, $\frac{L_{AC} \cdot G_{AC}}{2}$,

 $\left[-\theta + \theta_{inst}\right]$ and, by proper referencing, determine those quantities that define signal L and the light propagation within the random medium.

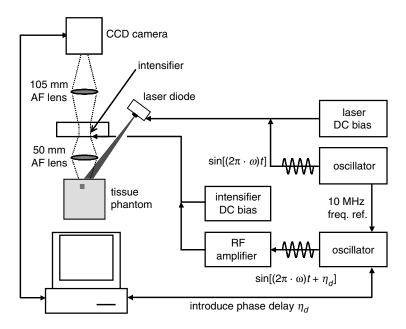

FIGURE 33.8 Schematic of ICCD homodyne FDPM system in the Photon-Migration Laboratory (PML).

Because image intensifiers used in area-detection schemes have slow response times, the homodyne approach is typically used. Figure 33.8 illustrates the image-intensified charge-coupled device (ICCD) homodyne FDPM system consisting of three major components: (1) a CCD camera, which houses a multipixel array of photosensitive detectors; (2) a gain-modulated image intensifier, which acts as the mixer (see below); and (3) oscillators that sinusoidally modulate the laser-diode light source and the image intensifier's photocathode gain at the same frequency, ω . A 10-MHz reference signal between the oscillators ensures that they operate at the same frequency with a constant phase difference. Emitted light from the tissue or phantom surface is imaged via a lens onto the photocathode of the image intensifier. As before, the light (L) that reaches the photocathode of the image intensifier has a phase delay, $\theta(r)$, average intensity, $L_{DC}(r)$, and amplitude intensity, $L_{AC}(r)$, that may vary as a function of position on the sample and, consequently, across the photocathode face.

The gain of the image intensifier has an average, G_{DC} a possible phase delay due to the instrument response time, θ_{inst} , and an amplitude, G_{AC} at the modulation frequency. The modulated gain is accomplished by modulating the potential between the photocathode, which converts the NIR photons into electrons, and the multichannel plate (MCP), which multiplies the electrons before they are focused onto the phosphor screen (Figure 33.9). The resulting signal at the phosphor screen is a mixed homodyne signal (S) containing all the amplitude, DC, and phase information of the optical signal collected by the detector. Yet since the phosphor screen has response times on the order of submilliseconds, it acts as a low-pass filter so that the image transferred to the CCD camera is simply the homodyne signal represented in Equation 33.32. The time-invariant but phase-sensitive image on the phosphor screen is then imaged onto the CCD using a lens or fiber coupling. $^{12,17-19}$

Rapid multipixel FDPM data acquisition proceeds as follows. The phase of the photocathode modulation is stepped, or delayed, at regular intervals between 0 and 360° relative to the phase of the laser-diode modulation. At each phase delay η_a , the CCD camera acquires a phase-sensitive image for a given exposure time (see Figure 33.10), which is on the order of milliseconds. A computer program then arranges the phase-sensitive images in the order acquired and performs a fast Fourier transform (FFT) to calculate modulation amplitude, I_{AC} , and phase, θ , at each CCD pixel (i,j) using the following relationships:

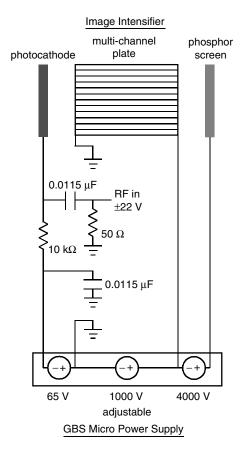

FIGURE 33.9 Schematic of the image-intensifier circuit and system used in the homodyne ICCD system. (From Thompson, A.B. and Sevick-Muraca, E.M., *J. Biomed. Opt.*, 8, 111, 2003. With permission.)

$$I_{AC}(i,j) = \frac{\left[\left\{IMAG[I(f_{\text{max}})_{ij}]\right\}^2 + \left\{REAL[I(f_{\text{max}})_{ij}]\right\}^2\right]^{1/2}}{N/2}$$
(33.33)

$$\theta(i, j) = \arctan\left(\frac{IMAG[I(f_{\text{max}})_{ij}]}{REAL[I(f_{\text{max}})_{ij}]}\right)$$
(33.34)

I(f) is the Fourier transform of the phase-sensitive intensity data and $I(\eta_d)$. $IMAG[I(f_{max})]$ and $REAL[I(f_{max})]$ symbolize, respectively, the imaginary and real components in the digital-frequency spectrum that best describe the sinusoidal data. N relates the number of phase delays between the gain modulation of the image intensifier and the incident-light source.

Area illumination is accomplished simply by expanding a modulated laser-diode beam onto the surface of the phantom or tissue to be imaged. To date there has been no attempt to use area illumination and area detection for tomographic reconstructions because all formulations are based on the propagation of light from a point-excitation source to a point on the medium's surface. Yet despite its current lack of acceptance by the tomographic community (see Section 33.5), planar-wave illumination is by far the most common means of illuminating photodynamic therapy (PDT) agents for assessing therapeutic drug distribution and providing excitation for assessing diagnostic fluorochrome distribution in s.c. tumor-bearing rodents. Typically, CW light from a xenon or tungsten lamp, laser, or laser diode is expanded to

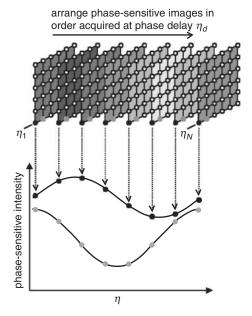

FIGURE 33.10 The process in which the phase delay between the image intensifier and laser-diode modulation is adjusted between 0 and 360° yielding phase-sensitive yet constant-intensity images at the phosphor screen. When the intensities are compiled at each pixel, the sine wave is reconstructed and the phase and amplitude attenutation are obtained from simple FFT. (From Thompson, A.B. and Sevick-Muraca, E.M., *J. Biomed. Opt.*, 8, 111, 2003. With permission.)

illuminate an entire animal or portion of the animal. Incident powers range from μ W/cm² to mW/cm², and area detection can be accomplished using a CCD with or without an image-intensifer coupling and with or without a spectrograph for spectral discrimination. Typically, CW measurements are conducted in mice and rats of small tissue volumes, while the frequency-domain measurements of fluorescence-enhanced contrast have been performed in canines (see Section 33.5).

In addition to the area measurements, the ICCD can be employed to rapidly conduct single-pixel measurements for tomographic reconstructions by simply using the ICCD to simultaneously measure the phase and amplitude of light collected by a number of fibers whose ends are affixed onto an interfacing plate focused on the photocathode of the image intensifier via a lens (Figure 33.11).

33.3.3 Homodyne I and Q

Another homodyning method for frequency-domain measurements that does not depend on conducting successive measurements at varying phase delays, η , imposed on signal G employs I and Q demodulation.²⁰ The technique depends on mixing signal L with two signals, G_1 and G_2 , at the same frequency G0, but phase shifting it by 90° (Figure 33.12):

$$G_1 = G_{AC}\cos(\omega t); \quad G_2 = G_{AC}\sin(\omega t) \tag{33.35}$$

When L is mixed with G_1 , the signal output, S_1 , is given by:

$$S_{1} = L_{DC} \cdot G_{AC} \cdot \cos(\omega t) + \frac{L_{AC} \cdot G_{AC}}{2} \cdot \left[\cos(2\omega t + \theta + \theta_{inst} + \frac{\pi}{2}) + \cos(\theta + \theta_{inst} + \frac{\pi}{2}) \right]$$
(33.36)

When L is mixed with G_2 , the signal output, S_2 , is given by:

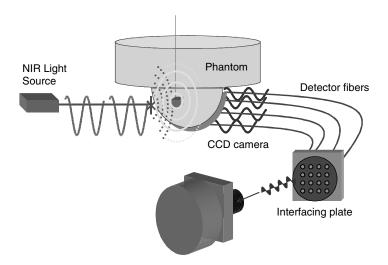

FIGURE 33.11 The adaptation of a number of single fibers collecting detected light for imaging by the ICCD system, which is depicted in Figure 33.9.

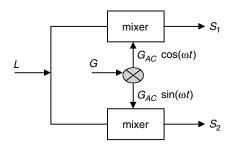

FIGURE 33.12 Illustration of the homodyne FDPM detection employing the mixing of L, G_1 , and G_2 , where G_2 is phase shifted by 90° relative to G_1 .

$$S_2 = L_{DC} \cdot G_{AC} \cdot \sin(\omega t) + \frac{L_{AC} \cdot G_{AC}}{2} \cdot \left[\sin(2\omega t + \theta + \theta_{inst} + \frac{\pi}{2}) - \sin(\theta + \theta_{inst} + \frac{\pi}{2}) \right]$$
(33.37)

Upon passing through a low-pass filter, the high-frequency components at ω and 2ω can be eliminated, leaving two DC signals:

$$S_{1} = \frac{L_{AC} \cdot G_{AC}}{2} \cdot \left[\cos(\theta + \theta_{inst} + \frac{\pi}{2}) \right]$$

$$S_{2} = \frac{L_{AC} \cdot G_{AC}}{2} \cdot \left[-\sin(\theta + \theta_{inst} + \frac{\pi}{2}) \right]$$
(33.38)

When the two signals are combined, the quantities of $\frac{L_{AC} \cdot G_{AC}}{2}$, $\left[-\theta + \theta_{inst}\right]$ can be determined, and by proper referencing the AC and phase delay associated with signal L and with the light propagation within the random medium can be determined.

33.3.4 Excitation-Light Rejection Considerations

Regardless of the measurement method (i.e., CW, time-domain, or frequency-domain), and regardless of the measurement geometry (point or area illumination and detection), one of the greatest and largely unrecognized challenges in fluorescence spectroscopy and imaging in random media is the importance of excitation-light rejection. In fluorescence spectroscopy of dilute, nonscattering samples, the isotropic emission light is collected at right angles to the incident excitation light to avoid corruption of excitation light in the fluorescence measurements (see Section 33.4). Yet in random media, the excitation light is propagated isotropically, potentially corrupting measurements in random media. Generally, the Stoke's shift associated with many fluorophores is small; in the case of indocyanine green (ICG), an FDAapproved agent, it is 50 nm. The wavelength sensitivity at the photocathode does not discriminate between excitation and emission wavelengths requiring a mechanism for excitation-light rejection and passage of emission light only for accurate spectroscopy and imaging data. The excitation light reaching a detector at a location on the surface is the predominant signal and can be as little as 103 times greater than the emission fluence when the fluorophore concentration is high and significantly greater as the fluorophore concentration is reduced to nanomolar and femtomolar levels, as might be expected in fluorescent contrast-agent identification of small cancer metastases. For planar-wave illumination, specularly reflected excitation light would create an even greater portion of the signal, further compounding the discrimination of the weak fluorescent signal emitted from the tissue surface (Figure 33.5). Generally, investigators employ interference filters with a rejection capability of OD 3 for excitation light, which generally sets the noise floor of the fluorescent measurement and limits the smallest amount of detectable fluorophore. When interference and bandpass filters for emission-light passage and holographic filters for excitation-light rejection are stacked, the noise floor can be reduced as much as nine orders of magnitude.²¹ Clearly, the sensitivity of fluorescence spectroscopy and imaging in random media hinges on the success of excitation-light rejection.

The forward-spectroscopy and imaging problems consist of using the diffusion model to predict light propagation, fluorescence generation, and the resulting measurements at the medium–air interface given the spatial distribution of optical properties within the entire volume. To solve the inverse-spectroscopy problem we assume a uniform distribution of optical properties with the unknowns being (1) the optical properties at the excitation and emission wavelengths, (i.e., $\mu_{a_{x,m}}$, $\mu'_{s_{x,m}}$) and (2) the optical properties associated with the fluorescent agent (i.e., $\alpha\mu_{a_{x\to m}}$, τ), which experiences first-order decay kinetics. Section 33.4 further develops the inverse solution to the imaging problem for tomographic imaging.

33.4 Fluorescence Spectroscopy in Random Media

Fluorescence-lifetime spectroscopy is advantageous for quantitative spectroscopy of analytes and metabolites because the measurement of fluorescence-decay kinetics (rather than fluorescence intensity) obviates the need to know the concentration of the sensing fluorophore.¹ As described in Section 33.1, frequency-domain techniques provide measurement of fluorescence lifetime (τ) using simple relationships of the phase delay (θ) and modulation ratio (M) of the re-emitted fluorescence as a function of the modulation frequency relative to the incident intensity-modulated excitation light. However, the development of fluorescence-lifetime spectroscopy for NIR biomedical tissue diagnostics for sensing through the use of systematically administered dyes^{22,23} or implantable devices^{24,25} requires deconvolving the influence of multiple scatter upon the measured emission phase delay and amplitude attenuation. As shown below, the addition of scatter increases the sensitivity of fluorescence-lifetime spectroscopy over traditional methods that focus on isotropic emission-light generation across a fixed path length, L.

Approaches to suitable modeling of multiply scattering of NIR excitation and fluorescence photons and to the use of diffusion models for quantitative spectroscopy have been previously demonstrated^{10,26,27} for dyes exhibiting single-exponential-decay kinetics. Failure to properly account for multiply scattered excitation and emission-light propagation in random media can result in incorrect decay kinetics. For example, when conducting phase-modulation measurements on a solution of Intralipid® containing the NIR-excitable fluorophore ICG, Lakowicz et al.²⁸ did not incorporate the propagation of light into their

calculations, yet they attribute multiexponential decay kinetics to this dye, which typically exhibits single-exponential decay kinetics.

33.4.1 Single-Exponential-Decay Spectroscopy

There are generally six unknowns to be solved for a uniform medium of unknown optical properties containing a fluorophore exhibiting a first-order radiative relaxation process: $\mu_{a_{\lambda_x}}, \mu_{a_{\lambda_m}}, \mu'_{s_{\lambda_x}}, \mu'_{s_{\lambda_m}}, \alpha \mu_{a_{x\to m}}, \tau$ with the subscripts altered slightly from the past nomenclature to emphasize the optical properties at two separate wavelengths, λ_x and λ_m .

33.4.1.1 Optical Property Determination

For a uniform random medium, the optical properties can be accurately determined from multidistance frequency-domain measurements.^{29,30} The analytical solution to the diffusion equation with point-source illumination at wavelength λ ,

$$\vec{\nabla} \cdot \left(D_{\lambda} \vec{\nabla} \Phi_{\lambda}(\vec{r}, \omega) \right) - \left[\mu_{a\lambda} + \frac{i\omega}{c} \right] \Phi_{\lambda}(\vec{r}, \omega) + S_{\lambda}(\vec{r}, \omega) = 0$$
(33.39)

in an infinite medium provides three equations for $I_{AC_{\lambda}}$, θ_{λ} , and $I_{DC_{\lambda}}$ as a function of modulation frequency, ω , distance away from the source, r, in terms of the optical properties μ_{a_1}, μ'_{s_1} .

When FDPM measurements are conducted as a function of modulation frequency, nonlinear regression can be performed to arrive at the optical properties of the medium. Conversely, when referencing the measurements of $I_{AC_{\lambda}}$, θ_{λ} , and $I_{DC_{\lambda}}$ at position r to a "reference" position r_0 , linear regression of the following equations:

$$DC_{rel} = \frac{DC(r)}{DC(r_0)} = \frac{r_0}{r} \exp\left[-(r - r_0)(\frac{\mu_a}{D})^{1/2}\right]$$
 (33.40)

$$AC_{rel} = \frac{AC(r)}{AC(r_0)} = \frac{r_0}{r} \exp\{-(r - r_0)(\frac{c^2 \mu_a^2 + \omega^2}{c^2 D^2})^{1/4} \cos[\frac{1}{2} \tan^{-1}(\frac{\omega}{c \mu_a})]\}$$
(33.41)

$$\theta_{rel} = \theta(r) - \theta(r_0) = (r - r_0) \left(\frac{c^2 \mu_a^2 + \omega^2}{c^2 D^2} \right)^{1/4} \sin\left[\frac{1}{2} \tan^{-1} \left(\frac{\omega}{c \mu_a} \right) \right]$$
 (33.42)

enables accurate estimation of the optical properties at a single modulation frequency using a single detector. Frequency-domain measurements must be referenced to eliminate contributions of G_{AC} , G_{DC} and θ_{inst} , as denoted in Equation 33.29, before data are regressed to Equations 33.40 through 33.42.

An alternative referencing method was devised by Mayer et al.²⁷ that involved measurement of modulation and phase delay at two positions, r_1 and r_2 , using two unmatched detectors. Unlike traditional fluorescence-spectroscopy measurement across a known pathlength, L, the instrument-response function for frequency-domain measurements in scattering media can be corrected without the use of reference dyes. The correction can be obtained by multiplexing two unmatched detectors at two different positions in the sample.²⁷ The two fibers leading to the unmatched detectors shown in Figure 33.13 are of the same length, which ensures equal optical pathlengths of the two received signals, L_pL_2 .

The measured relative phase shift between detector 1 and detector 2, $\theta_{rel_{1,2}}$, and measured modulation ratio, $M_{rel_{1,2}}$, between the two detectors reflect light propagation (and fluorescence generation, in the case of fluorescence measurements) in the sample between the incident source and the two detectors, (i.e.,

$$\theta_{\scriptscriptstyle 1}, \theta_{\scriptscriptstyle 2}, \begin{pmatrix} L_{\scriptscriptstyle AC_1} \\ L_{\scriptscriptstyle DC_1} \end{pmatrix} \begin{pmatrix} L_{\scriptscriptstyle AC_2} \\ L_{\scriptscriptstyle DC_2} \end{pmatrix}) \text{ as well as the instrument function (} \theta_{\scriptscriptstyle inst_1}, \theta_{\scriptscriptstyle inst_2}, \begin{pmatrix} G_{\scriptscriptstyle AC_1} \\ G_{\scriptscriptstyle DC_1} \end{pmatrix} \begin{pmatrix} G_{\scriptscriptstyle AC_2} \\ G_{\scriptscriptstyle DC_2} \end{pmatrix}) :$$

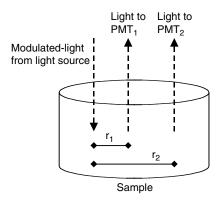

FIGURE 33.13 Schematic of fiber optically coupled source and detector placement for fluorescence measurements in scattering media. The two detector fibers are of the same length to ensure equal optical pathlengths.

$$\theta_{rel_{1,2}} = \left(-\theta_1 + \theta_{inst_1}\right) - \left(-\theta_2 + \theta_{inst_2}\right) \tag{33.43}$$

$$M_{rel_{1,2}} = \frac{L_{AC_1}G_{AC_1}}{L_{AC_2}G_{AC_2}} \cdot \frac{L_{DC_2}G_{DC_2}}{L_{DC_1}G_{DC_1}}$$
(33.44)

After multiplexing, the measured relative phase shift between detector 2 and detector 1, $\theta_{rel_{2,1}}$, and measured modulation ratio, $M_{rel_{2,1}}$, between the two detectors continue to reflect light propagation (and

fluorescence generation, in the case of fluorescence measurements) in the sample $(\theta_1, \theta_2, \begin{pmatrix} L_{AC_1} \\ L_{DC_2} \end{pmatrix})$

$$\begin{pmatrix} L_{AC_2} \\ L_{DC_2} \end{pmatrix} \text{ as well as the instrument function (} \theta_{\textit{inst}_1}, \theta_{\textit{inst}_2}, \begin{pmatrix} G_{AC_1} \\ G_{DC_1} \end{pmatrix}, \begin{pmatrix} G_{AC_2} \\ G_{DC_2} \end{pmatrix}) :$$

$$\theta_{rel_{2,1}} = -\left(-\theta_1 + \theta_{inst_1}\right) + \left(-\theta_2 + \theta_{inst_2}\right)$$
 (33.45)

$$M_{rel_{2,1}} = \frac{L_{AC_2}G_{AC_2}}{L_{AC_1}G_{AC_1}} \cdot \frac{L_{DC_1}G_{DC_1}}{L_{DC_2}G_{DC_2}}$$
(33.46)

where subscript 12 denotes the relative value of the signal detected at detector 1 to the signal detected at detector 2, and subscript 21 denotes the converse.

Combining Equations 33.43 and 33.45 and Equations 33.44 and 33.46 gives phase-shift and modulation ratios that are devoid of instrument function:

$$\Delta\theta = \theta_2 - \theta_1 = \frac{1}{2} \left(\theta_{rel_{1,2}} - \theta_{rel_{2,1}} \right) \tag{33.47}$$

$$M = \left(\frac{M_{rel_{1,2}}}{M_{rel_{2,1}}}\right)^{1/2} = \left(\frac{\frac{L_{AC_1}G_{AC_1}}{L_{AC_2}G_{AC_2}} \cdot \frac{L_{DC_2}G_{DC_2}}{L_{DC_1}G_{DC_1}}}{\frac{L_{AC_2}G_{AC_2}}{L_{AC_1}G_{AC_1}} \cdot \frac{L_{DC_1}G_{DC_1}}{L_{DC_2}G_{DC_2}}}\right)^{1/2} = \left(\frac{L_{AC_1}/L_{AC_2}}{L_{DC_2}/L_{DC_1}} \frac{G_{AC_1}/G_{AC_2}}{G_{DC_2}/G_{DC_1}}\right)$$
(33.48)

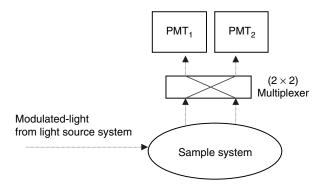

FIGURE 33.14 Illustration of multiplexing system for the two-channel frequency-domain detection apparatus.

For matched detectors, $\left(\frac{G_{AC_1}/G_{AC_2}}{G_{DC_2}/G_{DC_1}}\right)$ is unity. For unmatched detectors, the ratio must be experimentally determined.³¹

Figure 33.14 illustrates the multiplexing system for the conventional two-channel frequency-domain system developed for fluorescence-lifetime spectroscopy.

The multiplexing method described above can be used for measurements performed with sources at the excitation and emission wavelengths, and hence single-distance (multifrequency) nonlinear regression²⁹ can be performed to obtain optical properties of the medium without corruption from the instrument functions. In a recent study, we showed that measurements made at multiple distances enable linear regression of parameters²⁹ and result in the most precise optical property estimation.³⁰ Regardless of whether from referenced or multiplexed frequency-domain measurements conducted with point-source illumination at wavelengths λ_x and λ_m , the optical properties of $\mu_{a_{\lambda_x}}, \mu_{a_{\lambda_m}}, \mu'_{s_{\lambda_x}}, \mu'_{s_{\lambda_m}}$ can be accurately obtained.

33.4.1.2 Determination of Single-Exponential-Decay Lifetime

After the optical properties are estimated from frequency-domain measurements employing the two wavelength sources, the emission fluence is measured in response to point-source illumination at the excitation wavelength using excitation-light-rejection filters to reduce the noise floor. From the referenced measurement used to arrive at $\Phi_m(\vec{r},\omega) = I_{AC_m} \exp(i\theta_m)$, the fluorescent properties of $\alpha\mu_{a_{x\to m}}$ and τ are determined from the solution to Equations 33.19 and 33.24 for an infinite medium:

$$\Phi_{m}(\vec{r},\omega)_{ac} = \frac{\alpha\mu_{a_{x\to m}}\Xi_{m}(SA)}{4\pi c D_{x} D_{m} r} \frac{1}{\left[1 + (\omega\tau)^{2}\right]} \left\{ \left[\psi - \kappa\omega\tau\right] + i\left[\kappa + \psi\omega\tau\right] \right\}$$
(33.49)

where *r* is the distance to the excitation point source, *SA* is the complex fluence of the source describing its modulation depth and phase, and the terms ψ and κ are functions of optical properties (μ_a and μ'_s), c, and ω .^{10,27}

$$\psi(\vec{r},\omega) = \frac{\delta(\vec{r},\omega)\xi + \zeta(\vec{r},\omega)\rho(\omega)}{\xi^2 + \rho(\omega)^2}$$
(33.50)

$$\kappa(\vec{r},\omega) = \frac{\zeta(\vec{r},\omega)\xi - \delta(\vec{r},\omega)\rho(\omega)}{\xi^2 + \rho(\omega)^2}$$
(33.51)

$$\delta(\vec{r}, \omega) = \exp[-\beta_{x}(\omega)r)]\cos[\gamma_{x}(\omega)r] - \exp[-\beta_{m}(\omega)r)]\cos[\gamma_{m}(\omega)r]$$
(33.52)

$$\zeta(\vec{r}, \omega) = \exp[-\beta_x(\omega)r]\sin[\gamma_x(\omega)r] - \exp[-\beta_m(\omega)r]\sin[\gamma_m(\omega)r]$$
(33.53)

$$\xi = \frac{\mu_{a_m}}{D_m} - \frac{\mu_{a_x}}{D_x} \tag{33.54}$$

$$\rho(\omega) = \frac{\omega}{c} \left[\frac{1}{D_x} - \frac{1}{D_m} \right]$$
 (33.55)

Frequency-domain photon-migration measurements at both the excitation and emission wavelengths have demonstrated experimentally the ability to measure the single exponential lifetimes of ICG and 3,3'-diethylthiatricarbocyanine iodide (DTTCI),²⁷ rhodamine B,¹⁰ and mixtures of ICG and DTTCI¹³ in tissue-like scattering media of Intralipid.

Yet most analyte-sensing fluorphores exhibit multiexponential decays or stretched-exponential-decay kinetics, increasing the number of unknowns from two $(\alpha\mu_{a_x\to m}, \tau)$ to 2j+1 for a fluorophore experiencing j-activated states (Equation 33.10): $(\mu_{a_x\to m}, \tau_j, a_j)$ and to 3j+1 for a fluorophore undergoing collisional quenching (Equation 33.11): $(\mu_{a_x\to m}, \tau_j, a_j, \alpha_j, \beta_j)$.

33.4.2 Multiexponential-Decay Kinetics

In general, the solution for the emission fluence in an infinite medium of uniform optical properties is given by:

$$\Phi_{m}(\vec{r},\omega) = \frac{\alpha \mu_{a_{x \to m}} \Xi_{m}(SA)}{4\pi c D_{x} D_{m} r} \left\{ \left(\psi - i\kappa \right) \left(g(t) e^{(i\omega t)} dt \right) \right\}$$
(33.56)

Generally, frequency-domain measurements are insensitive to the form of the decay kinetics used to describe the relaxation process. As an example, Figure 33.15 illustrates the phase and modulation ratio measured in a dilute, nonscattering sample using traditional fluorescence-lifetime-spectroscopy techniques. The emitted fluorescence results from a combination of two dyes, ICG and DTTCI, that individually exhibit first-order relaxation kinetics. The frequency-domain data are equally well fit using a singleexponential-decay (which represents the average of the decay times), a two-exponential-decay, and a stretched-exponential-decay model, indicating that the data at these modulation frequencies are insufficient to discern the relaxation processes. Typically, differences in decay kinetics are manifested at higher modulation frequencies, which unfortunately suffer from a small-instrument response function and low SNR. However, when predicting the phase-delay and modulation ratio from the solution to the diffusion equation for infinite media employing the various kinetic models for radiative relaxation, significant differences in frequency-domain data taken at modulation frequencies below 150 MHz (Figure 33.16) become apparent. Figure 33.16 shows model predictions for the two dyes within a scattering medium experiencing different relaxation mechanisms along with the data, indicating the potential for enhanced sensitivity of fluorescence-lifetime spectroscopy in random or multiply scattering media. Note that the phase-delay and modulation ratios in Figures 33.15 and 33.16 span a larger range in scattering media than in nonscattering media.

In summary, challenges remain in connection with solving the inverse-fluorescence-spectroscopy problem when it comes to extracting parameters that accurately predict changes in both decay kinetics and, therefore, analyte of metabolite concentrations. While a few studies in the literature indicate that the inverse-spectroscopy problem for fluorescence lifetime in random media can be solved, to date the inverse problem of multiexponential-decay functions that exist for analyte-sensing fluorophores has not been solved. However, as long as the number of unknown parameters remains smaller than the number of measurements, the solution to the inverse-spectroscopy problem entails a straightforward least-squares-minimization problem. In contrast to the inverse-spectroscopy problem, the inverse-imaging

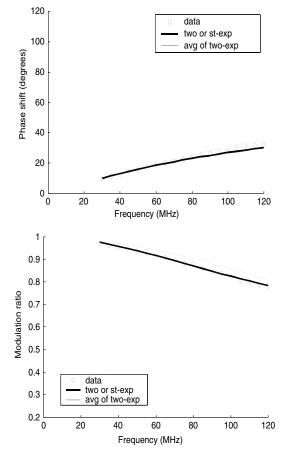

FIGURE 33.15 The plot of fluorescence phase shift (top) and modulation ratio (bottom) as a function of modulation frequency on ICG–DTTCI mixture (ICG:DTTCI = 0.15 mM: 0.5 mM, in a dilute nonscattering medium) for corrected experimental measurements (\diamondsuit), and that predicted by incorporating two-exponential-decay kinetics or stretched-exponential-decay kinetics (bold line) and average of two-exponential-decay kinetics (thin gray line).

problem entails a smaller number of measurements than unknown parameters, necessitating optimization approaches.

33.5 Fluorescence FDPM for Optical Tomography¹⁵

The solution to the inverse-imaging problem, known as optical tomography, has been motivated over the past decade by optical mammography, i.e., the use of deeply penetrating NIR light for detecting breast cancer on the basis of endogenous optical property contrast between normal and diseased tissues. It has been proposed that the optical property contrast in scattering and absorption is due to the increased size and density of neoplastic cells in a tumor region and the increased vascular blood supply (as a result of angiogenesis) that locally increases hemoglobin, a primary chromophore in tissues. While optical mammography has seen many advances in recent years, most notably in the application of FDPM, ^{32,33} TDPM, ¹¹ and continuous-wave³⁴ measurements (see also Reference 22), the need for angiogenesis-mediated absorption contrast for diagnostic optical mammography limits the potential applications of optical mammography. Since the endogenous contrast from angiogenesis can be expected to be low in small lesions and non-specific to cancer, NIR detection of nonpalpable disease in dense breast tissue is limited without the addition of contrast. Hence, moderately resolved, biochemical molecular imaging within tissues using

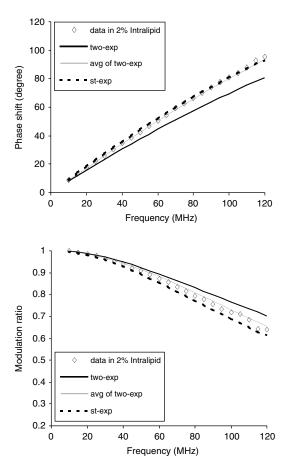

FIGURE 33.16 The plot of fluorescence phase shift (top) and modulation ratio as (bottom) a function of modulation frequency on ICG–DTTCI mixture (ICG:DTTCI = 0.15 mM: 0.5 mM, in 2% Intralipid® solution) for corrected experimental measurements (♦) and that predicted by the propagation model incorporating two-exponential-decay kinetics (bold line), average of two-exponential-decay kinetics (thin gray line), and the stretched-exponential-decay kinetics (dashed line).

unassisted NIR optical techniques is somewhat limited in scope and can be expanded through the use of contrast-enhancing agents.

Fluorescent contrast agents have been proposed and independently confirmed as the most efficient means for inducing optical contrast when time-dependent measurements (i.e., TDPM or FDPM) are conducted.^{35,36} Furthermore, in the near future these agents may offer a host of opportunities for molecular imaging that are limited only by synthetic design. The basic principles behind fluorescence-enhanced NIR optical tomography stem first from the kinetics of fluorescence generation. It is the kinetics of the fluorescence-decay process that imparts the superior contrast of fluorescence over absorbance when TDPM or FDPM measurements are made.

Figure 33.17 provides a simple schematic describing in physical terms why contrast by fluorescence is greater than contrast by absorption for FDPM imaging. Consider a tissue volume illuminated by an intensity-modulated light source at source position r_s . The propagating wave is denoted by dotted lines. As the propagating excitation wave transits through the tissue, it is attenuated and phase delayed due to the tissue optical properties. If the wave encounters a light-absorbing heterogeneity, such as a highly vascularized tumor, a portion of the intensity wave is reflected. The strength of the "reflected wave" (or dotted line) depends on the absorption contrast and the size and depth of the heterogeneity. This reflected wave makes a small contribution to the wave that ultimately is detected at detector position r_d . It is this

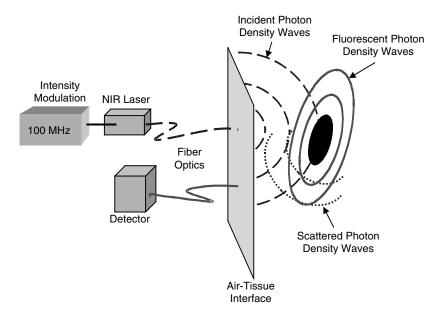

FIGURE 33.17 Schematic detailing the propagation of excitation photon-density waves (solid lines) and their perturbation by absorbing heterogeneities (dotted lines) and the generation of emission photon-density waves (solid gray lines) within the tissues. Fluorescence contrast-enhance optical tomography provides greater localization capability because the detected emission waves act as "beacons" providing information regarding the tagged heterogeneity. (From Hawrysz, D.J. and Sevick-Muraca, E.M., *Neoplasia*, 2(5), 388, 2000. With permission.)

small, added contribution that is used to detect the heterogeneity when endogenous contrast is employed. If the added contribution is not within the measurement noise, then it provides information for image recovery in one of the inversion strategies outlined below. However, if the heterogeneity is contrasted by fluorescence, then upon reaching the heterogeneity the excitation wave generates an emission wave (solid lines). The emission wave then acts as a beacon, and, when appropriate filters are used to reject the excitation light, it can be measured to directly locate the heterogeneity. In small tissue volumes, such as the mouse or rat, inversion algorithms may not be required to detect the fluorescent heterogeneity, as shown in the literature results summarized in Section 33.6. However, in larger tissue volumes, the forward-and inverse-imaging problems require solution for effective image recovery. Most importantly, since a phase delay and amplitude attenuation occur between the activating excitation wave and the re-emitted fluorescent wave associated with the fluorescence-decay kinetics, the fluorescence decay increases the contrast or phase-delay and amplitude-attenuation change associated with the detected signal. Finally, since a fluorescent probe can be "tuned" to exhibit differing fluorescence-decay characteristics that depend on the probe's local environment, the re-emitted signal can contain diagnostic information about the tissue of interest.

Few studies have successfully inverted NIR tissue optical measurements to render images of exogenously contrasted tissues or tissue-mimicking phantoms. Table 33.1 outlines several investigations that have employed "synthetic" data sets and phantoms.^{37–57} The approaches are basically similar to those used in NIR optical-tomography work, with the following three exceptions: (1) because of the low quantum yield of fluorescent dyes, the SNR for CW, TDPM, and FDPM measurements is inarguably lower, potentially making it more difficult to successfully reconstruct images; (2) due to the fluorescence-lifetime delay, both TDPM and FDPM approaches have additional contrast in the time-dependent photon-migration characteristics; and, finally, (3) because the fluorescence-kinetic parameters of fluorescence lifetime and quantum efficiency can be directly inverted, the technique can be used to perform quantitative imaging via dyes that report cancer.

CCD = charge-coupled device; CGD = conjugate gradient descent; CW = continuous-wave imaging; FD = finite difference; FDPM = frequency-domain photon migration; FEM = finite-element method; MFD = multigrid finite difference; N/A = not applicable; NS = not specified; POCS = projection onto convex sets; SART/SIRT = simultaneous algebraic reconstruction techniques; TDPM = time-domain photon migration; ϕ , τ = quantum efficiency and lifetime of contrast agent.

The latter characteristic of fluorescence-lifetime imaging reveals its similarity to magnetic resonance imaging (MRI). In MRI, imaging is accomplished by monitoring the RF signal arising from the relaxation of a magnetic dipole perturbed from its aligned state using a pulsed magnetic field. In fluorescence-contrast-enhanced optical tomography, imaging is accomplished by monitoring the emission signal arising from the electronic relaxation from an optically activated state to its ground state. Unfortunately, the emission light is multiply scattered; hence, the resolution afforded by MRI is unlikely to be matched by contrast-enhanced optical tomography. Unlike contrast agents for conventional imaging modalities, optical contrast, due to fluorescent agents, may be achieved in two ways: (1) through increased target:background concentration ratios and (2) through alteration in the fluorescence-decay kinetics upon partitioning within tissue regions of interest.⁵⁸ Section 33.6 summarizes the literature on fluorescent contrast agents and their development over the past decade. The approaches for solving the inverse-imaging problem are presented in the next section.

33.5.1 Approaches to the Inverse-Imaging Problem

Attempts to solve the fluorescence-enhanced optical-imaging problem have been made both by solving a formal inverse problem and by taking a less rigorous model-based approach. For example, localization of a fluorescent target has been demonstrated using localization techniques in which the strength of reradiating target is used to ascertain its central position within a background containing no fluorophore. Through the use of FDPM measurements between a point source and detector as the pair was scanned over the phantom surface, the center of a single fluorescent target could be accurately identified.³⁷ In yet another approach, an analytical solution to the spherical propagation of emission light in uniform scattering media was used to determine the *x,y,z* position of the point source of fluorescence in an otherwise nonfluorescent background probed by CW measurements.⁴⁸ Using time-domain measurements, Wu et al.^{38,42} developed a system for assessing the position of a fluorescent target in turbid media by evaluating early-arriving photons to determine the origin of the fluorescence generation. Hull et al. similarly used spatially resolved CW measurements to determine the location of the fluorescent target in scattering media.⁴⁵ Unlike the studies described above, when there is presence of background signal or if the goal of reporting fluorescence-decay kinetics prevents a localization approach, then a solution to the full inverse-imaging problem is required.

The solution of a formal inverse problem requires the use of the appropriate mathematical models described above in Section 33.2. Specifically, a guess of the interior optical or fluorescence properties is iteratively updated until the predicted measurements given by the solution of the forward problem match the actual measurements. Since the number of unknowns (or optical and fluorescent contrast-agent properties) is greater than the number of measurements, the problem is underdetermined and especially difficult. This inverse problem is unavoidably "ill-posed," which generally means that the solutions are nonunique and unstable in the presence of measurement error. In addition, the optical-tomography problem is generally highly nonlinear, and attempts to linearize it result in solution instabilities and often intractably long computational times if the update step is to remain within the range of accuracy of the linearization. The solution of the inverse problem is an intensive area of research in itself that is motivated by several different research areas including biomedical NIR optical tomography based on endogenous contrast.

To assess the performance of an inverse-problem algorithm, the achieved solution must be compared to the known distribution of optical properties. As a consequence, studies investigating the inverse optical-tomography problem are performed using either (1) "synthetic" measurements, i.e., measurements that are predicted by the forward problem to which artificial random "noise" is added to simulate measurement error; or (2) phantom studies in which tissue-mimicking scattering media of known optical properties are used to collect experimental CW, time, or frequency-domain measurements that are used for the inverse solution. In the following sections, we briefly review the methods used to solve fluorescence-enhanced optical-tomography problems, broadly classified into categories of integral and differential

approaches and employing a number of parameter-updating schemes. Finally, sample reconstructions from actual experimental data are presented.

33.5.2 Integral Formulation of the Inverse Problem

One of the more common methods of formulating the inverse problem is by integral treatment. Since the emission diffusion equation is in the form of an nonhomogeneous differential equation, Green's function is used to obtain the analytical solution of the emission fluence $\Phi_m(\vec{r},\omega)$. Equation 33.19 can be rewritten to account for variation in the endogenous and exogenous optical properties including the absorption due to fluorophore, $\mu_{a_{v\rightarrow m}}(\vec{r})$, and the optical-diffusion coefficient, $D_m(\vec{r})$:

$$\vec{\nabla}^2 \Phi_m(\vec{r}, \omega) + k_m^2(\vec{r}) \Phi_m(\vec{r}, \omega) = -\frac{S_m(\vec{r})}{D_m(\vec{r})} - \frac{\vec{\nabla} D_m(\vec{r}) \cdot \vec{\nabla} \Phi_m(\vec{r}, \omega)}{D_m(\vec{r})}$$
(33.57)

where the complex diffusion wave number can be expressed as:

$$k_m^2(\vec{r}) = \frac{1}{D_m(\vec{r})} \left(-\mu_{a_m}(\vec{r}) + i\frac{\omega}{c} \right)$$
 (33.58)

The term $\left[\vec{\nabla}D_m(\vec{r})/D_m(\vec{r})\right]\cdot\vec{\nabla}\Phi_m(\vec{r})$ in Equation 33.57 accounts for the discontinuity in $D_m(\vec{r})$. However, since there is little or no variation in the isotropic scattering coefficient (the component that constitutes the overwhelming contribution to $D_m(\vec{r})$ at the emission wavelength, λ_m) the above term is insignificant. The Green's function corresponding to Equation 33.57 consequently satisfies

$$\vec{\nabla}^{2}G_{f}(\vec{r},\vec{r}') + k_{m}^{2}(\vec{r})G_{f}(\vec{r},\vec{r}') = -\delta(\vec{r} - \vec{r}')$$
(33.59)

by manipulating Equations 33.57 and 33.19 (at the excitation wavelength), and with the use of Green's theorem, $\int_{v} (U\vec{\nabla}^2 G - G\vec{\nabla}^2 U) d^3 r = \oint_{S} (U\vec{\nabla} G - G\vec{\nabla} U) \cdot dS$, one can obtain the expression of the emission fluence measured at r_d following point excitation at r_s , $\Phi_m(r_d, r_s)$, which arises due to $S_m(r', r_s)$, the emission generation at point r' following the incident illumination of excitation light at r_s , and due to the propagation of the emission light from position r' to detector point r_d as predicted from the Green's solution, $G_f(r_d, r_s)$:

$$\tilde{\Phi}_{m}(\vec{r}_{d}, \vec{r}_{s}) = \int_{\Omega} G_{f}(\vec{r}_{d}, \vec{r}') S_{m}(\vec{r}', \vec{r}_{s}) d\Omega = \int_{\Omega} G_{f}(\vec{r}_{d}, \vec{r}') \frac{\alpha \mu_{a_{x \to m}}(\vec{r}')}{D_{m}(\vec{r})(1 + i\omega\tau)} \Phi_{x}(\vec{r}', \vec{r}_{s}) d\Omega$$
(33.60)

where Ω is the volume of integration, $\vec{r_d}$ is the point-detector location, and $\vec{r_s}$ is the point-source location. To reconstruct the spatial map of $\mu_{a_{x\rightarrow m}}(\vec{r})$ detailing the heterogeneity, Equation 33.60 is discretized into a series of equations in terms of $G_p \Phi_x(\vec{r}',\vec{r_s})$, and the vector of measurements of $\Phi_m(\vec{r_d},\vec{r_s})$. We consider the excitation source to be amplitude-modulated by a frequency of ω . Measurements of phase shift, θ_m , and amplitude of AC component I_{AC} (or $\Phi_m(\vec{r_d},\vec{r_s}) = I_{AC_m}e^{-i\theta_m}$) are obtained at detector positions $\vec{r_d}$ in response to the excitation source at $\vec{r_s}$. [Note: It is assumed that the phase shift and the AC component are predicted relative to the incident excitation light at $\vec{r_s}$. In addition, it is assumed that absolute measurements of I_{AC_m} and θ_m are used as inputs.] Discretizing Equation 33.60 yields:

$$\tilde{\Phi}_{m}(\vec{r}_{d}, \vec{r}_{s}) = \sum_{i=1}^{N} G_{f}(\vec{r}_{j}, \vec{r}_{d}) \Phi_{x}(\vec{r}_{j}, \vec{r}_{s}) \frac{\alpha \mu_{a_{x \to m}}(\vec{r}_{j}) \Delta}{D_{m}(\vec{r})(1 + i\omega \tau)}$$
(33.61)

where *N* is the total number of cells in the domain, and Δ is the area or volume of the pixel or voxel. If there are *K* sources and *L* detectors, then $\tilde{\Phi}_m = FX$ can be denoted as:

$$\begin{pmatrix} \tilde{\Phi}_{m}(\vec{r}_{d}, \vec{r}_{s})_{1} \\ \tilde{\Phi}_{m}(\vec{r}_{d}, \vec{r}_{s})_{2} \\ \vdots \\ \tilde{\Phi}_{m}(\vec{r}_{d}, \vec{r}_{s})_{M} \end{pmatrix} = \begin{pmatrix} F_{11} & \cdots & F_{1N} \\ F_{21} & \cdots & F_{2N} \\ \vdots & \ddots & \vdots \\ \vdots & \ddots & \vdots \\ F_{M1} & \cdots & F_{MN} \end{pmatrix} \begin{pmatrix} X(\vec{r}_{1}) \\ X(\vec{r}_{2}) \\ \vdots \\ X(\vec{r}_{N}) \end{pmatrix}$$

$$(33.62)$$

$$F_{ij} = \frac{G_f(\vec{r}_{di}, \vec{r}_j) \Phi_x(\vec{r}_{si}, \vec{r}_j) \alpha \Delta}{D_m(\vec{r}) (1 + i\omega \tau)}$$
(33.63)

$$X(\vec{r}_j) = \mu_{a_{x \to m}}(\vec{r}_j) \tag{33.64}$$

where $F \in C^{M \times N}$, $X \in \Re^N$, $\tilde{\Phi}_m \in C^M$, and $M = K^*L$.

Equation 33.64 is also appropriate if imaging is performed on the basis of a fluorophore-absorption cross section with a constant lifetime τ . The problem formulated in Equations 33.62 through 33.64 is nonlinear in $\mu_{a_{n,m}}$ since the excitation fluence, $\Phi_x(\vec{r})$, is also a function of absorption.

However, if tomographic reconstruction on lifetime were pursued, the problem would become linear, and Equations 33.63 and 33.64 would be rewritten as:

$$F_{i,j} = \frac{G_f(\vec{r}_{di}, \vec{r}_j) \Phi_x(\vec{r}_{si}, \vec{r}_j) \Delta}{D_m(\vec{r})}$$
(33.65)

$$X(\vec{r_j}) = \frac{\alpha \mu_{a_{x \to m}}(\vec{r_j})}{(1+i\alpha\tau)} \tag{33.66}$$

where the vector X represents the sources of fluorescence within the random medium.

The formulation of the inverse-lifetime problem is called fluorescence-lifetime imaging^{40,41,59} and has been the subject of tomographic reconstructions from synthetic measurements. Fluorescence-lifetime imaging is not possible for CW measurements ($\omega = 0$). To date fluorescence-lifetime imaging has been accomplished using actual experimental measurements only in limited works,⁵¹ probably because few contrast agents exist that are designed with "tuneable" lifetimes.

Nonetheless, the opportunity for lifetime imaging is clearly evidenced by ICCD measurements using the instrumentation depicted in Figure 33.8. Two fluorescent targets were positioned 0.5 cm from the imaged surface of a tissue-simulating phantom and embedded in $10 \times 10 \times 10$ cm³ of 0.5% Intralipid. The first target encapsulated a 1- μ M solution of ICG, and the second encapsulated a 1.42- μ M solution of 3,3′-DTTCI. These solution concentrations were chosen to equilibrate the number of fluorescent photons emitted from each target because an equivalent number of excitation photons encounter each target. Figures 33.18A and 33.18B confirm this equilibration, as it is difficult to differentiate the targets from the DC and AC measurements. However, Figures 33.18C and 33.18D plot the phase delay and the modulation ratio (I_{AC}/I_{DC}) and provide differentiation of the two volumes. The differentiation, which results from a disparity in lifetime (0.62 ns) between the two fluorescent agents, demonstrates the potential of fluorescence-lifetime imaging. While these images present raw data, quantitative tomographic recovery of fluorescence lifetime is possible with solution to the inverse-imaging problem.

The inverse-imaging problem can be approximated as a linear problem and iteratively solved using the Gauss–Newton method:

$$\Phi_m^{meas}(\vec{r}_d, \vec{r}_s) - \Phi_m^{comp}(\vec{r}_d, \vec{r}_s) = F \cdot \Delta X(\vec{r})$$
(33.67)

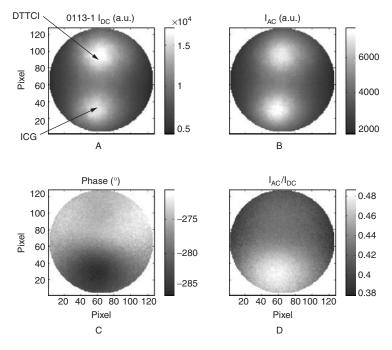

FIGURE 33.18 The (A) I_{DC} (B) I_{AC} (C) phase, and (D) I_{AC}/I_{DC} modulation ratio of two submerged targets of differing fluorescent lifetimes showing that I_{DC} cannot distinguish the difference in fluorescence-decay kinetics.

Regardless of whether absorption or fluorescence-lifetime imaging is to be performed, parameter updating can be accomplished by noting that **F** is simply the Jacobian, **J**, and the difference between the measurement and the model-predicted fluence, $\Phi^{meas} - \Phi^{comp} = \Delta \Phi$, can be used to update the optical property map, $\Delta X(\vec{r})$, by the relationship specified above, or alternatively by:

$$\Delta \Phi = \mathbf{J} \cdot \Delta \mathbf{X} \tag{33.68}$$

While a number of investigators report reconstructions based on the integral approaches using frequency-domain or CW ($\omega = 0$) approaches, all assume that the measurements can be accurately measured relative to the incident light. Yet in practice, it is nearly impossible to perform such a measurement. Typically, a portion of the incident light is split for simultaneous measurement at a reference detector that cannot report the source strength or the phase delay of light that is incident on the medium surface. Calibration of the source via a "reference" phantom may also be conducted if a three-dimensional (3D) model can be used to predict the measurements and if the source strength can be accurately recovered from the measurements and model. Yet such a procedure is cumbersome and susceptible to errors and increases the challenges for incorporation into medical imaging in clinical situations. A method to eliminate "calibration" against an external standard would eliminate the number of measurements as well as improve measurement accuracy. The following sections present three general approaches to reference measurements for the recovery of optical properties in light of image-reconstruction formalisms: (1) emission measurements at detector position r_d referenced to the background emission wave, $\Phi^b_n(ec r_i,ec r_d)$; (2) emission measurements at detector position r_d referenced to the detected emission wave at a single reference position r_r , $\Phi_m(\vec{r}_s, \vec{r}_r)$; and (3) emission measurements at detector position r_d referenced to the detected excitation wave at a single reference position r_r , $\Phi_x(\vec{r}_s, \vec{r}_r)$.

33.5.2.1 Measurement Referenced to the Background Emission Wave $\Phi_m^b(\vec{r}_s,\vec{r}_r)$

In this approach, calibration of the detection system is achieved by normalizing the measurement in the presence of the heterogeneity with that measured or predicted in its absence. Typically, the "absence" case consists of a uniform medium with constant and known optical properties. In this case, the main

problem associated with matching experimental data to the solution of Equation 33.57 has been the unknown source strength, the unknown phase delay from the timing characteristics of various components of the detection system, and the amplitude gain or loss. The advantage of using background or a well-defined reference phantom is that it allows for the elimination of the most systematic errors common to both background and actual measurement data sets. This approach has been widely employed in both frequency^{60,61} and time-domain^{62,63} photon-migration measurements. However, this is an unrealistic approach in a clinical sense because, unlike phantom studies, the absence case and "background" fluence measurements are impossible in clinical applications. For contrast-enhanced imaging, "absence" may be achieved prior to the administration of a contrast agent or activation-induced contrast such as that resulting from blood flow. Yet when the agent is fluorescent, there is no emission signal to measure the absence scenario; hence, the "absence" scenario is unrealistic in fluorescence imaging.

For heterodyne FDPM measurements the referenced measurements enable elimination of instrument responses. For example, an emission measurement referenced to the background case in which the target,

$$\frac{\Phi_{AC_m}(r_d, r_s)}{\Phi^b_{AC_m}(r_d, r_s)} = \frac{L_{AC_m}G_{AC}\exp(i(-\theta_m + \theta_{instr}))}{L^b_{AC_m}G_{AC}\exp(i(-\theta_m^b + \theta_{instr}))} = \frac{L_{AC_m}}{L^b_{AC_m}}\exp\left[i(\theta_m^b - \theta_m)\right]$$

successfully eliminates the instrument response, and the background optical properties are known.

The mechanics of inverting data referenced to the background absence case may be illustrated by the following equation, which shows the relationship between the measurement and the inversion algorithm for a source-detector pair when a Born-type inversion scheme is used for fluorescent measurements,

where the referenced measurement is represented by $\frac{\Phi_{AC_m}(\vec{r_s},\vec{r_d})}{\Phi^b_{AC_m}(\vec{r_s},\vec{r_d})}\Big]_{\rm exp}$:

$$\frac{\Phi_{AC_m}(\vec{r}_s, \vec{r}_d)}{\Phi_{AC_m}^b(\vec{r}_s, \vec{r}_d)} = \frac{1}{\left[\Phi_{AC_m}^b(\vec{r}_s, \vec{r}_d)\right]_{a \text{ priori}}} \int_{\Omega} \frac{\alpha}{D_m (1 + i\omega\tau)} G_f(\vec{r}_d, \vec{r}) \Phi_x(\vec{r}_s, \vec{r}) \mu_{a_{x \to m}}(\vec{r}) d\Omega$$
(33.69)

Here, $\left[\Phi^b_{AC_m}(\vec{r}_s,\vec{r}_d)\right]_{a\ priori}$ is the background emission wave detected at the same detector position, \vec{r}_d , as in the presence of the heterogeneity case in response to excitation from the source position, \vec{r}_s . $\Phi^b_{AC_m}(\vec{r}_s,\vec{r}_r)$ is computed from the known optical properties of the assumed uniform background case or measured in the case of an absent heterogeneity.

In contrast to the absolute-measurement case, where the matrix, \mathbf{F} , is itself the Jacobian matrix (Equation 33.63), relative-measurement schemes have the added complication of calculating the Jacobian matrix by using the integral equation. However, in this case, the $\Phi^b_{AC_m}(\vec{r_s},\vec{r_d})$ stays constant throughout the iteration due to its homogeneous nature, the inversion problem remains linear, and the calculation of the Jacobian matrix is straightforward. As a result, the reconstruction remains stable during the iterative process, while the source strength dependency and other calibration problems are eliminated. Even though the reference to the background-emission-fluence approach is relatively easy to implement in phantom studies and is a good benchmark to test the inversion algorithms, it can be difficult in actual application to clinical trials where a true absence condition does not occur or where the spatially distributed optical properties are not known.

33.5.2.2 Measurement Referenced to the Emission Wave $\Phi_m(\vec{r}_r,\vec{r}_r)$

Because of the unrealistic nature of referencing to the background emission wave, the inversion scheme uses the emission fluence at the reference point on the tissue surface. This approach involves the measurements of the emission fluence relative to one another, where the referenced measurement is repre-

sented by
$$\frac{\Phi_m(\vec{r}_s,\vec{r}_d)}{\Phi_m(\vec{r}_s,\vec{r}_r)}$$
 and

$$\frac{\Phi_{AC_{m}}(r_{d}, r_{s})}{\Phi_{AC_{m}}(r_{d}, r_{r})} = \frac{L_{AC_{m}}(r_{d}) \ G_{AC} \exp(i(-\theta_{m} + \theta_{instr}))}{L_{AC_{m}}(r_{r}) \ G_{AC} \exp(i(-\theta_{m}(r_{r}) + \theta_{instr}))} = \frac{L_{AC_{m}}(r_{d})}{L_{AC_{m}}(r_{r})} \exp\left[i\left(\theta_{m}(r_{r}) - \theta_{m}(r_{d})\right)\right]$$

and the Fredholm's equation to be solved is written:

$$\frac{\Phi_{m}(\vec{r}_{s},\vec{r}_{d})}{\Phi_{m}(\vec{r}_{s},\vec{r}_{r})} = \frac{1}{\Phi_{m}(\vec{r}_{s},\vec{r}_{r})} \int_{\Omega} \frac{\alpha}{D_{m}(1+i\omega\tau)} G_{f}(\vec{r}_{d},\vec{r}) \Phi_{x}(\vec{r}_{s},\vec{r}) \mu_{a_{x}\to m}(\vec{r}) d\Omega$$
(33.70)

Here $\Phi_m(\vec{r_s},\vec{r_r})$ is the emission wave detected at the reference position, $\vec{r_r}$, in response to excitation from the source position, $\vec{r_s}$. This referencing approach is the most reasonable method for matching the actual measurement data with simulation data because it does not require the separate measurement of a homogeneous background wave. Also, this referencing approach has merit in that, unlike the method described below, it uses the measurements at the same wavelength.

While referencing to the emission wave, $\Phi_m(\vec{r_s},\vec{r_r})$, is more practical than referencing to the background emission wave, $\Phi_{AC_m}^b(\vec{r_s},\vec{r_d})$, normalization by $\Phi_m(\vec{r_s},\vec{r_r})$ renders the inversion algorithm using the Borntype integral approach highly nonlinear. This nonlinearity is absent when referencing to the background emission wave. Consequently, the calculation of the Jacobian matrix is not as straightforward as with the background emission wave (for details see Reference 57).

Hence, the formulated inverse-imaging problem is inherently unstable due to its nonlinear nature. Using the Marquardt-Levenberg regularization, Lee and Sevick-Muraca⁵⁷ were unable to recover optical property maps in two-dimensional (2D) or 3D synthetic data. In contrast, through the use of the approximate extended Kalman filter for nonlinear systems, ^{64–66} 3D reconstructions from sparse experimental measurements were possible in a large 256-cm³ volume.⁵³

33.5.2.3 Measurement Referenced to the Excitation Wave $\Phi_{x}(\vec{r},\vec{r}_r)$

Another practical referencing scheme utilizes measurements of excitation fluence at fixed reference positions to be used as the normalization factors; these would, in turn, eliminate the source strength dependency. This approach is more realistic than measurements referenced to the background-emission case because it does not require separate and impractical measurements with and without heterogeneity.

The relationship between the experimental measurements and the simulation for a given source and detector pair is represented by:

$$\frac{\Phi_{AC_m}(r_d, r_s)}{\Phi_{AC_x}^b(r_d, r_r)} = \frac{L_{AC_m}(r_d) G_{AC_m} \exp(i(-\theta_m(r_d) + \theta^m_{instr}))}{L_{AC_x}(r_r) G_{AC_x} \exp(i(-\theta_x(r_r) + \theta^m_{instr}))} \approx \frac{L_{AC_m}(r_d)}{L_{AC_x}(r_r)} \exp\left[i(\theta_x(r_r) - \theta_m(r_d)\right]$$

and described by the following integral equation:

$$\frac{\Phi_{AC_m}(\vec{r}_s, \vec{r}_d)}{\Phi_{AC_n}(\vec{r}_s, \vec{r}_r)} = \frac{1}{\Phi_{AC_n}(\vec{r}_s, \vec{r}_r)} \int_{\Omega} \frac{\alpha}{D_m(1 + i\omega\tau)} G_f(\vec{r}_d, \vec{r}) \Phi_x(\vec{r}_s, \vec{r}) \mu_{a_{x \to m}}(\vec{r}) d\Omega$$
(33.71)

where the referenced measurement is represented by $\frac{\Phi_{AC_m}(\vec{r}_s,\vec{r}_d)}{\Phi_{AC_x}(\vec{r}_s,\vec{r}_r)}\Big|_{\text{even}}$

Here $\Phi_{AC_x}(\vec{r_s},\vec{r_r})$, represents the excitation fluence detected at a fixed reference position, $\vec{r_r}$, in response to excitation from the source position, $\vec{r_r}$.

Even though the excitation fluence, $\Phi_{AC_x}(\vec{r_s},\vec{r_r})$, is updated during the iteration, the Jacobian matrix can be directly calculated from Equation 33.71, and the change in $\Phi_x(\vec{r_s},\vec{r_r})$ is small compared to the change in $\Phi_m(\vec{r_s},\vec{r_r})$. As the source term of the emission-diffusion equation is modified after each iteration

(Equation 33.57), changes in the emission fluence are greater than those in the excitation fluence. The same consequence can be inferred from the integral equation (Equation 33.71). Moreover, the phase of the emission fluence is greater than that of the excitation fluence, and the normalized fluence, Φ_m/Φ_x , maintains a high phase contrast.

Due to noise and the ill condition of the Jacobian matrix for inverting systems of equations, updating can be accomplished using Newton's method⁶⁷ with Marquardt–Levenberg parameters λ :

$$(\mathbf{J}^{T}\mathbf{J} + \lambda \mathbf{I})\Delta X = \mathbf{J}^{T} \left[\frac{\Phi_{AC_{m}}(\vec{r}_{s}, \vec{r}_{d})}{\Phi_{AC_{x}}(\vec{r}_{s}, \vec{r}_{r})} \right]^{meas} - \left[\frac{\Phi_{AC_{m}}(\vec{r}_{s}, \vec{r}_{d})}{\Phi_{AC_{x}}(\vec{r}_{s}, \vec{r}_{r})} \right]^{comp}$$
(33.72)

Using excitation referencing at a single reference point, Lee and Sevick-Muraca⁵⁷ reconstructed an $8 \times 4 \times 8$ cm³ phantom containing a $1 \times 1 \times 1$ cm³ target with 100-fold greater ICG concentration by using 8 excitation sources, 24 detection fibers for collecting excitation light, and 2 reference detection fibers (one on either side of the reflectance and transillumination measurements) for collecting excitation light. Figure 33.19A is the original map containing 2D slices that demark the heterogeneity placement, while Figure 33.19B is the 3D reconstructed image.

While the results in Figure 33.19 represent reconstructions based on emission FDPM measurements relative to excitation FDPM measurements at a fixed reference position, Ntziachristos and Weissleder⁵⁶ successfully reconstructed two fluorescent targets in a 2.5-cm-diameter, 2.5-cm-long cylindrical vessel containing ICG and Cy5.5 dyes. In addition, they used CW emission measurements referenced to excitation measurements at each of the 36 detector fibers as a result of point excitation at 24 source fibers. The high density of measurements for reconstruction of the small simulated tissue volume is troublesome for validity of the diffusion equation used in the forward solver but is similar to that demonstrated by Yang et al.,⁵¹ who reconstructed ICG and DTTCI in similarly sized phantoms and mice, presumably from absolute FDPM measurements at the emission wavelength alone.

The studies of the reconstruction presented above assumed that the absorption and scattering properties were known *a priori*. However, using a differential approach coupled with Bayesian reconstruction approaches (see below), Eppstein et al.⁶⁸ were able to demonstrate the insensitivity of reconstructions to changes in endogenous optical properties. Using a synthetic 256-cm³ volume containing 0.125-cm³ targets with 10:1 contrast in absorption due to fluorophore and surrounded on four sides by 68 sources and 408 detection fibers, Eppstein was able to show that when the absorption cross section at the excitation wavelength, $\mu_{a_{xi}}$, varied as much as 90% and was unmodeled, while the scattering coefficient, $\mu_{s_{xi}}$, varied 10% or less and was also unmodeled, the impact on the reconstruction was minimal or negligible. Recently, Roy et al.⁶⁹ produced similar results when they demonstrated unmodeled variations in all endogenous optical properties by as much as 50%, which did not impact reconstructions when emission FDPM measurements were individually self-referenced to excitation FDPM measurements, as was done with the CW measurements of Ntziachristos and Weissleder.⁵⁶ While it appears promising that fluorescence-enhanced optical tomography can be accomplished without much *a priori* information about the endogenous optical properties, these results nonetheless pertain to synthetic studies and must be conducted on actual tissues of substantive and clinically relevant volumes for validation.

33.5.3 Differential Formulation of the Inverse Problem

A second approach to the full-inverse-imaging problem may be the differential formulation, but this time it is rewritten for measurement $Z(\vec{r}_d, \vec{r}_s)$, whether absolute, relative to a reference measurement at the emission or excitation wavelength, or self-referenced relative to the excitation wavelength at each detector position, \vec{r}_d . We term this approach the differential formulation because a small change in the predicted measurements is directly expressed in terms of a small change in the optical properties, ΔX , using a Jacobian matrix, \mathbf{J} , $\partial(\Delta Z_i)/\partial X_i$. Consider a number of detectors, M; the error function is then

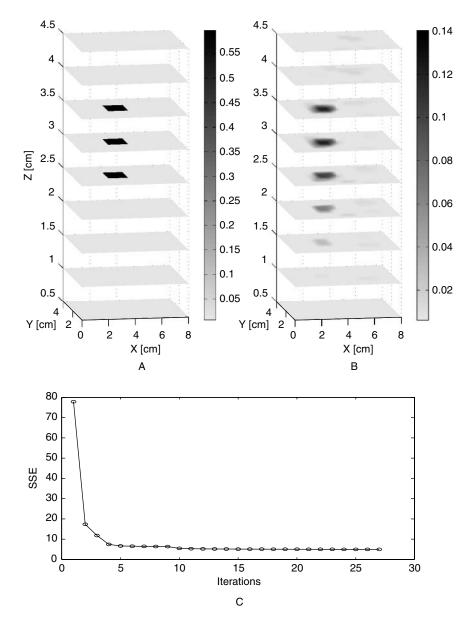

FIGURE 33.19 The reconstruction of $\mu_{a\to m}$ using the excitation wave as a reference using the integral approach and Marquardt–Levenberg reconstruction. The image was required after 27 iterations with regularization parameters for I_{AC} ratio (ACR), $\lambda_{AC} = 1.0$, and for relative phase shift (RPS), $\lambda_{\theta} = 0.02$. (A) Optical property maps of true $\mu_{a\to m}$ distribution and (B) reconstructed $\mu_{a\to m}$ distribution. Peak values of $\mu_{a\to m}$ reached 0.1205 cm⁻¹. (C) Iteration vs. SSE.

defined as the sum of the square of errors between the measured and calculated values at detector i = 1...M:

$$F(\mathbf{X}) = \sum_{i=1}^{M} \left[\left(Z_i \right)^{(m)} - \left(Z_i \right)^{(c)} \right]^2 = \sum_{i=1}^{M} \left[f_i(X) \right]^2$$
 (33.73)

We refer to each f_i as a residual and the gradients of the error function with respect to the property, X:

$$\nabla F(\mathbf{X}) = 2\mathbf{J}^T f(X) \tag{33.74}$$

$$\nabla^{2} F(\mathbf{X}) = 2 \left[\mathbf{J}^{T} \mathbf{J} + \sum_{i=1}^{M} f_{i}(X) \nabla^{2} f_{i}(X) \right]$$
 (33.75)

Consider the Taylor's expansion of function F around a small perturbation of optical properties, ΔX :

$$F(\mathbf{X} + \Delta \mathbf{X}) = F(\mathbf{X}) + \nabla F(\mathbf{X}) \cdot \Delta \mathbf{X} + \frac{1}{2} \Delta \mathbf{X}^{T} \cdot \nabla^{2} F(\mathbf{X}) \cdot \Delta(\mathbf{X})$$
(33.76)

which can be expressed as:

$$F(\mathbf{X} + \Delta \mathbf{X}) = F(\mathbf{X}) + 2\mathbf{J}^{T} f(\mathbf{X}) \cdot \Delta \mathbf{X} + 2 \cdot \Delta \mathbf{X}^{T} \left[\mathbf{J}^{T} \mathbf{J} + \sum_{i=1}^{M} f_{i}(X) \nabla^{2} f_{i}(X) \right] \cdot \Delta \mathbf{X}$$
(33.77)

and the function to be minimized, $\Phi(\Delta X)$, can be explicitly written:

$$\Phi(\Delta \mathbf{X}) = F(\mathbf{X} + \Delta \mathbf{X}) - F(\mathbf{X}) = 2\mathbf{J}^T f(\mathbf{X}) \cdot \Delta \mathbf{X} + 2 \cdot \Delta \mathbf{X}^T \left[\mathbf{J}^T \mathbf{J} + \sum_{i=1}^M f_i(\mathbf{X}) \nabla^2 f_i(\mathbf{X}) \right] \cdot \Delta \mathbf{X}$$
(33.78)

For first-order Newton's methods, the term $2 \cdot \Delta \mathbf{X}^T \left[\sum_{i=1}^M f_i(X) \nabla^2 f_i(X) \right] \cdot \Delta \mathbf{X}$ is neglected, and the Gauss–Newton method becomes one of minimizing:

$$\nabla \Phi(\Delta \mathbf{X}) \Rightarrow 0 = \mathbf{J}^T \mathbf{J} \cdot \Delta \mathbf{X} + \mathbf{J}^T f(\mathbf{X})$$
 (33.79)

$$\mathbf{J}^T \mathbf{J} \cdot \Delta \mathbf{X} = -\mathbf{J}^T f(\mathbf{X}) \tag{33.80}$$

The Levenberg-Marquardt method of optimization becomes⁴⁹

$$\left[\mathbf{J}^{T}\mathbf{J} + \lambda \mathbf{I}\right] \cdot \Delta \mathbf{X} = -\mathbf{J}^{T} f(\mathbf{X}) \tag{33.81}$$

The gradient-based truncated Newton's method is based on retaining the second-order terms such that Equation 33.78 becomes⁴⁹

$$\nabla \Phi(\Delta \mathbf{X}) \Rightarrow 0 = \mathbf{J}^T f(\mathbf{X}) + \left[\mathbf{J}^T \mathbf{J} + \sum_{i=1}^M f_i(X) \nabla^2 f_i(X) \right] \cdot \Delta \mathbf{X}$$
 (33.82)

or alternatively,

$$\Phi'(\Delta X) \Rightarrow 0 = \nabla F(X) + \nabla^2 F(X) \cdot \Delta X \tag{33.83}$$

Typically, the first-order Newton's methods were employed, with the exception of the work by Roy.⁷⁰ In the Newton's methods, it is assumed that $\Delta \Phi = \mathbf{J} \cdot \Delta \mathbf{X}$, and the solution is found using one of the several optimization approaches. The Jacobian matrix can be computed either directly from the stiffness matrices of the finite element formulation or simply, but more computationally time-consuming, from backward, forward, or central differencing approaches that compute the differences in the values of $Z(\vec{r_d}, \vec{r_s})$, with small differences in the parameter to be updated, $X(\vec{r_j})$. The Gauss–Newton and the Levenberg–Marquardt algorithms performed poorly in a large residual problem. Since the inverse is highly nonlinear and ill conditioned due to the error in measurement data, the residual at the solution will be large. It seems reasonable, therefore, to consider the truncated Newton's method.

For the truncated Newton's method, the additional computational cost of computing the Hessian [associated with $\nabla^2 F(\mathbf{X})$] is assisted by reverse automatic differentiation.^{49,70} Using synthetic data, Roy has shown the feasibility of using the technique for 3D reconstruction of lifetime, τ , and absorption-coefficient $\mu_{\alpha_{x \to m}}$ changes in frustrum and slab geometries from synthetic data containing noise that mimics experimental data.⁵⁴

33.5.4 Regularization and Other Approaches to Parameter Updating

In both the integral and differential formulations of the inverse problem, the tissue to be imaged must be mathematically discretized into a series of nodes or volume elements (voxels) in order to solve these inverse problems. The unknowns of the inverse problems are then comprised of the optical properties at each node or voxel. The final image resolution is naturally related to the density nodes or voxels. However, the dimensionality of the imaging problem is directly related to the number of nodes and can easily exceed 10,000 unknowns for a 3D image. In a problem of this scale, the calculation of Jacobian matrices and matrix inversions involved in updating the optical property map are computationally intensive and contribute to the long computing times required to reconstruct the image. The instability arises because the measurement noise in the data or errors associated with the validity of the diffusion approximation can result in large errors in the reconstructed image.

One of the greatest challenges associated with fluorescence-enhanced tomography is the propagation of error. In comparison with absorption imaging based on measurements of excitation light, fluorescence measurements have a reduced signal level and SNR. Lee and Sevick-Muraca⁷¹ measured the SNR for single-pixel excitation and the emission-frequency domain at 100 MHz and found them to be 55 and 35 dB, respectively. In addition to the reduced signal, the noise floor of emission measurements can be expected to be elevated when excitation-light leakage constitutes an increased proportion of the detected signal. Consequently, for emission-tomography measurements, excitation-light leakage is crucial, and interference filters that attenuate excitation light four orders of magnitude (i.e., filters of OD 4) may be clearly insufficient. Excitation-light leakage will be a significant problem when emission measurements are conducted in tissue regions where the target is absent and fluorescent contrast agents are not activated. Unfortunately, this type of error is not present in synthetic studies and is undoubtedly underestimated in the vast proportion of tomography investigations to date.

33.5.4.1 Regularization

Regularization is a mathematical tool used to stabilize the solution of the Newton's inverse problem and to make it more tolerant to measurement error. Regularization approaches will play an important role in the development of suitable algorithms for actual clinical screening. For example, when discretized, the differential and integral general formulations result in a set of linear Newton's equations generally denoted by AY = Z, where Y is the unknown optical properties and Z is the measurements. This system is commonly solved in the least-squares sense where the object function $Q = ||AY - Z||^2 + \lambda ||Y||^2$ is minimized and λ is called the regularization parameter. The minimization of this function results in $Y = (A^TA + \lambda I)^{-1}A^TZ$. The regularization parameter is generally chosen either arbitrarily or by a Levenberg–Marquardt algorithm so that the object function is minimized.⁷² Thus, the choice of regularization parameter is through a priori information and adds another degree of freedom to the inverse-problem solution. Finally, in a recent work, Pogue et al.⁶⁰ present a physically based rationale for empirically choosing a spatially varying regularization parameter to improve image reconstruction.

33.5.4.2 Bayesian Regularization

Eppstein et al.^{46,47,52,68} used actual measurement-error statistics to govern the choice of varying regularization parameters in their Kalman filter implementation in optical tomography. In their work, they developed a novel Bayesian reconstruction technique, called APPRIZE (automatic progressive parameter-reducing inverse zonation and estimation), specifically for groundwater problems and adapted them to fluorescence-enhanced optical tomography.^{64–66} Unique components of the APPRIZE method are an approximate extended Kalman filter (AEKF), which employs measurement error and parameter uncertainty to

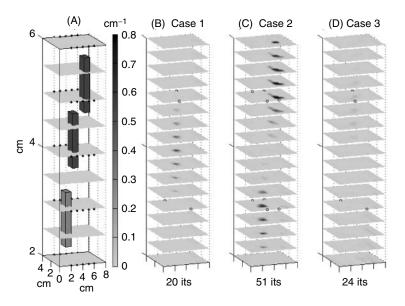

FIGURE 33.20 Image reconstruction with APPRIZE. (A) The initial homogeneous estimate discretized onto the $9 \times 17 \times 17$ grid used for the initial inversion iteration and shown with the true locations of the 3 heterogeneities and 50 detectors (small dots). (B) Case 1: the reconstructed absorption due to the middle fluorescing heterogeneity, interpolated onto the $17 \times 33 \times 33$ grid used for prediction and shown with the locations of the four sources used (open circles). (C) Case 2: the reconstructed absorption due to the top and bottom fluorescing heterogeneities shown with the locations of the eight sources used (open circles). (D) Case 3: the reconstructed absorption of a homogeneous phantom shown with the locations of the four sources used (open circles). Although the phantoms and reconstructions were actually 8 cm in the vertical dimension, only the center four vertical centimeters are shown here. (From Eppstein, M.J. et al., *Proc. Natl. Acad. Sci. U.S.A.*, 99, 9619, 2002. With permission.)

regularize the inversion and compensate for spatial variability in SNR, and a unique approach to stabilizing and accelerating convergence called data-driven zonation (DDZ). Using the notation (ΔX , f(X)) as described in Section 33.5.3, the Newton's solution is formulated here as:⁵²

$$\Delta \mathbf{X} = \left[\left[\mathbf{J}^{T} (\mathbf{Q} + \mathbf{R})^{-1} \mathbf{J} + \mathbf{P}_{xx}^{-1} \right]^{-1} \cdot \mathbf{J}^{T} (\mathbf{Q} + \mathbf{R})^{-1} \right] \cdot f(\mathbf{X})$$
 (33.84)

where Q is the system-noise covariance, which describes the inherent model mismatch between the forward model (the diffusion equation) and the actual physics of the problem; R is the covariance of the measurement error that is actually acquired in the measurement set; and P_{xx} is the recursively updated error covariance of the parameters, X, and is estimated from the measurement error, f(X). The use of this spatially and dynamically variant covariance matrix results in the minimization of the variance of the estimated parameters, taking into account the measurement and system error.

The novel Bayesian minimum-variance reconstruction algorithm compensates for the spatial variability in SNR that must be expected to occur in actual NIR contrast-enhanced diagnostic medical imaging. Figure 33.20 illustrates the image reconstruction of 256-cm³ tissue-mimicking phantoms containing none, one, or two 1-cm³ heterogeneities with 50- to 100-fold greater concentration of ICG dye over background levels. The spatial-parameter estimate of absorption from the dye was reconstructed from only 160 to 296 surface reference measurements of emission light at 830 nm in response to incident 785-nm excitation light modulated at 100 MHz. Measurement error of acquired fluence at fluorescent emission wavelengths is shown to be highly variable.

Another important feature of the Bayesian APPRIZE algorithm is the use of DZZ. With DDZ, spatially adjacent voxels with similarly updated estimates are identified through cluster analysis and merged into

larger stochastic parameter "zones" via random field union.⁷³ Thus, as the iterative process proceeds, the number of unknown parameters, *X*, decreases dramatically, and the size, shape, value, and covariance of the different "parameter zones" are simultaneously determined in a data-driven fashion. Other approaches to reducing the dimensionality of the problems involve concurrent NIR optical imaging with MRI^{74–76} and ultrasound⁷⁷ to compartmentalize tissue volumes and to reduce the number of parameters to be recovered in the optical-image reconstruction.

33.5.4.3 Simply Bounded Constrained Optimization

Imposing restrictions on the ill-posed problem can transform it to a well-posed problem, as discussed above. Regularization is one method for reducing the ill-posedness of the problem. In the optical-tomography problem, its solution, i.e., the optical properties of tissue, must satisfy certain constraints, and imposing these conditions can in itself regularize or stabilize the problem. Imposing these constraints also explicitly restricts the solution sets and can restore uniqueness.

Provencher and Vogel⁷⁸ have suggested two techniques, prior knowledge and parsimony, for making the problem well posed. The first condition requires that all prior physical knowledge about the solution be included in the model. The second condition protects against the introduction of nonphysical phenomena. Tikhonov and Arsenin⁷⁹ also suggested that, to obtain a unique and stable solution from the data, supplementary information should be used so that the inverse problem becomes well posed. The basic principle of using *a priori* knowledge of the properties of the inverse problem is to restrict the space of possible solutions so that the data uniquely determine a stable solution.

Roy and Sevick-Muraca showed that the constrained optimization technique, which places simple bounds on a physical parameter to be estimated, might be more appropriate for solving the fluorescenceenhanced optical-tomography problem.⁵⁰ That is, a range of fluorescent optical properties is physically defined for the problem, and the recovered parameter, X, must always be positive. Specifically, Roy demonstrated the use of the bounding parameter, ε , both as a means of regularizing and accelerating convergence and as a means of setting the level of optical property contrast to be reconstructed using referenced emission measurements.⁶⁹ Here, the possible values of parameter estimates are stated to lie between an upper and lower bound. In the first pass of the iterative solution, the optical property map is recovered, and parameter estimates that lie within the upper and lower bounds plus and minus a small bounding parameter, E, are recovered and held constant for the next iteration. Thus, the number of unknowns decreases with each iteration. Indeed, the value of the bounding parameter can be used to set the resolution and the performance of the tomographic image. For example, if the bounding parameter is large, then the tomographic image will "filter out" artifacts not associated with the target; but if the bounding parameter is small, the tomographic image may sensitively capture artifacts and heterogeneity that are not necessarily associated with the target. Figure 33.21 illustrates the reconstruction using the simply bounded truncated Newton's method, which shows that as the bounding parameter is increased, the recovered image becomes less sensitive to the background "noise." This approach may have significant application for increasing the target to background signals, an issue related to nuclear imaging that impairs tomographic reconstructions.

33.6 Fluorescent Contrast Agents for Optical Tomography¹⁵

Table 33.2 provides a chronological listing of studies reported in the literature over the past decade that involve a number of different fluorescent-contrast agents.^{23,51,80–116} While the studies have progressed from using photodynamic agents; freely-diffusable agents, such as ICG; fluorochromes conjugated to monoclonal antibodies (MAb) and their fragments; small-peptide targeting agents similar to those employed in nuclear imaging; and, finally, activatable and "reporting agents." Unfortunately, the translation of these agents to human clinical studies has been limited. Furthermore, investigations have been largely confined to superficial or subcutaneous tumors, where the true advantages of NIR fluorescent agents, that is, deeptissue penetration and optical tomography, cannot be aptly demonstrated. Nonetheless, the strategies for

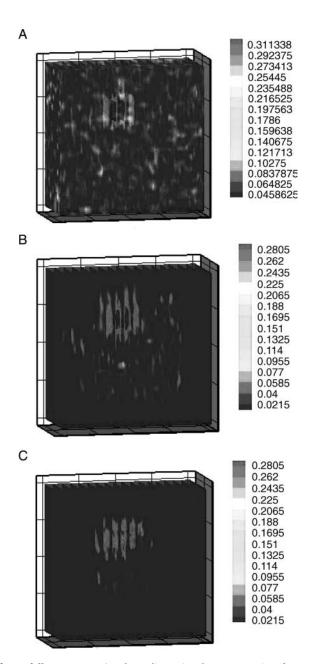

FIGURE 33.21 (Color figure follows p. 28-30.) Three-dimensional reconstruction from simply bound truncated Newton's method. (A) Actual distribution of fluorophore-absorption coefficient of background tissue variability of endogenous (50%) and exogenous (50%) properties. (B) Reconstructed fluorophore-absorption coefficient of background tissue variability of endogenous (50%) and exogenous (500%) properties using relative measurement of the emission fluence with respect to the excitation fluence at the same detector point, $\varepsilon = 0.0001$. (C) Reconstructed fluorophore absorption coefficient of background tissue variability of endogenous (50%) and exogenous (500%) properties using relative measurement of the emission fluence with respect to the excitation fluence at the same detector point. (From Roy, R., Godavarty, A., and Sevick-Muraca, E.M., *IEEE Trans. Med. Imaging*, in press. With permission.)

NIR fluorescent-contrast agents have been impressive and have included using simple blood-pooling agents to highlight hypervascularity, employing contrast provided by pharmacokinetic model-parameter estimates of uptake, and designing agents that specifically target membrane receptors of cells lining

 Fluorescence-Enhanced Contrast Imaging: Literature of Agent Studies

Ref.	Imaging System (incident fluence)	Animal Model	Dose	Contrast Agent	λ Excitation/Emission	Comments
Biolo et al., 1991 ⁸⁰	Spectrograph for point detection of fluorescence following surface illumination	Mouse	0.12mg/kg bw ~0.24 μmol/kg bw	ZnPc (phthalocyanine) in liposomes, spectral detection of fluorescence at λ	600 nm	Provide measurements for assessing pharmacokinetics of PDT agent
Pelegrin et al., 1991 ⁸¹	Area illumination with area (133 mW/cm²) detection using photography	Mouse, deceased	100 μg/animal ~600 pmol/kg bw	Fluorescein isothiocyanate (FITC) coupled to MAb	488 nm Kodak Wratten filter #12 for excitation light rejection	Study the localization of dye targeted to human colon carcinoma in mice after coupling to MAb
Straight et al., 199182	Interstitial illumination (20 mW) with area detection using CCD camera	Mouse	20 mg/kg bw ~70 μmol/kg bw	Photofrin II	514.5/spectral discrimination 585–730 nm	Validate CCD technology for imaging drug distribution in tumors
Folli et al., 1992 ⁸³	Fiber through endoscope illumination (10 mW/ cm²) with area detection using photography	Human	0.1–0.28 mg/patient ~0.1 nmol to 0.28 nmol/patient	Fluorescein isothiocyanate (FITC) coupled to MAb	488 nm Kodak Wratten filter #12 for excitation light rejection	Study immunophotodiagnosis in colon carcinoma patients
Cubeddu et al., 1993, 1997 ^{84–85}	Area illumination (75 μW/cm²) with pulsed dye laser with gated CCD video camera	Mouse	5–25 mg/kg bw ~17–87 μmol/kg bw, 1993 0.1 mg/kg ~0.35 μmol/kg bw, 1997	HpD (hematopor-phyrin derivative)	405 nm/>560 nm	Demonstrate the use of time- dependent measurements to identify HpD distinct from native fluorescence based upon long fluorescent lifetimes
Kohl et al., 1993 ⁸⁶	Intensified CCD	Mouse	0.2–1 mg/kg bw ~0.7–3.5 μmol/kg bw	Porphyrin-based photosensitizers		Demonstrate the ability to image s.c. tumor
Folli et al., 1994 ⁸⁷	Area illumination with area (13 mW/cm²) detection using photography	Mouse, deceased	100 μg/animal ~600 pmol/kg bw ^a	Indopentamethine-cyanine coupled to MAb directed against squamous cell carcinoma	640 nm Kodak Wratten filter #70 for excitation light rejection	Show the ability to detect indocyanine dye targeted to squamous cell carcinoma in the upper respiratory tract through MAb E48 without removing skin, as was necessary when fluorescein was employed
Haglund et al., 1994 ⁸⁸	Area illumination (100-W tungsten-halogen bulb) and area detection with CCD camera	Rat	1.0 mg/kg bw 1.3 μmol/kg bw	ICG	780/830	Distinguish rat gliomas from normal brain tissue through free-agent fluorophore imaging with CCD camera

Mordon et al., 1994 ⁸⁹	Area illumination (150W Xenon lamp, 2.5 mW/cm²) with area detection using intensified CCD	Mouse	5 mg/kg bw (~13 μmol)	5,6-CF carboxyfluorescein (BCECF)	465 nm/490 and 515 nm	Show the use of dual-wavelength measurements of a ratiometric dye to provide a 2D pH image of tumor tissues
Ballou et al., 1995 ⁹⁰	Area illumination with area detection using intensified video camera or cooled CCD	Mouse	10–100 μg/animal ~40 pmol to 6 nmol/ animal	Cyanine fluorochromes coupled to MAb	550–674 nm/565–694 nm	Demonstrate the use of tumor- targeting antibodies using Cy3.18, Cy5.18, and Cy5.5.18 cyanine fluorochromes
Devoisselle et al., 1995 ⁹¹	Area (50 mm²) illumination (Xe lamp) with point detection using fiber optics and spectrograph	Mouse	7.5 mg/kg bw ~10 μmol/kg bw	ICG emulsion	720 nm/spectra discrimination of fluorescence	Demonstrate the use of emulsion preparation to alter the pharmacokinetics of ICG
Rokahr et al., 1995 ⁹²	N ₂ laser pulsed through fiber and detected with fiber to spectrometer	Human undergoing urinary- bladder cytoscopy	50 mg/patient (ALA induces fluorescence)	Protoporphyrin IX	337 and 405/380 through 685 spectral discrimination	Discriminate malignant and normal bladder tissue with ALA-induced protoporphyrin imaging
Haglund et al., 1996 ⁹³	Area illumination with photography lights and area detection with CCD camera	Human (open brain)	1 mg/kg bw ~1.3 mmol/kg bw	ICG	790/805 nm	Study detection of human glioma with ICG imaging
Sakatani et al., 1997 ⁹⁴	Cooled CCD camera, 100-mW laser diode	Rat	554 pmol/rat	ICG-lipoprotein	790 nm/840 nm	Conduct cerebrospinal imaging with ICG bound to lipoprotein, injected intracranially
Neri, 1997 ⁹⁵	Method similar to Folli et al. (1994); 100-W tungsten lamp for area illumination with detection via an 8-bit CCD in a light-tight box	Mouse	100 μl/mouse of a concentrated antibody solution of 1 mg/ml with dye:MAb ratio of 1:1	Fragments of human antibodies directed against oncofetal fibronectin (B-FN) and labeled with Cy7	673–748 nm/765–855 nm	Demonstrate the use of B-FN targeting for providing diagnostic imaging and therapy of cancer targeting angiogenic vessels
Ballou et al., 1998%	Area illumination and area detection via CCD	Mouse	50 µg/animal MAb:dye (1:2) ~600pmol/animal	Cy3, Cy5, Cy5.5, and Cy7 labeled antibodies against human nucleolin and stage-specific embryonic antigen-1		Demonstrate the ability to penetrate more deeply with Cy7 dye

^a Molecular weight of proteins are estimated on the order of 10⁶ g/mol.

neovasculatures as well as the neoplastic cells that the vasculature feeds. Strategies that focus on lysosomal activity and enzyme cleavage for fluorochrome activation and mediation of fluorescence decay as well as for fluorochrome accumulation specific to cancer cells have also been demonstrated. Table 33.1 outlines these fluorochromes used in *in vivo* studies. When available, the chronological listing also notes the excitation and emission wavelengths used, the incident illumination, the measurement geometry, and the type as well as number of fluorochrome molecules used to detect a signal. The fluorophores are broadly classified into PDT agents, nontargeting blood-pooling agents, agents that "report" or sense, targeting agents based on immunodiagnostics and small-peptide conjugation, and activatable agents.

33.6.1 Photodynamic Therapy Agents

Starting with the area of photodynamic imaging, the early studies relating to fluorescence-enhanced imaging date back to 1991 and focused on evaluating the spatial distribution as well as the pharmacokinetics of PDT agents for dosimetry purposes. Measurements were typically conducted in tumor-bearing mice with total agent administration between 0.1 and 90 μM/kg bw using area illumination and CCD camera detection. PDT agents are likely candidates for fluorescent-enhanced imaging, more than likely due to their existing Food and Drug Administration investigational-new-drug (IND) applications for therapeutic use. The ability to obtain an IND for a diagnostic agent previously approved for therapeutic use enhances the opportunity for fluorescence-enhanced optical imaging. Yet despite the attractiveness for their current and pending INDs, photodynamic agents do not possess the excitation and emission spectra favorable for fluorescent contrast agents for imaging deep tissues. First, to maximize penetration depth into tissues, excitation must be between 750 and 800 nm, and the Stokes shift must be significant (~50 nm) to enable discrimination of the small fluorescent component from the overwhelming large component of excitation light. An insufficient Stokes shift of 10 nm or less complicates the process of rejecting multiply scattered light as the efficiency of filters cannot be guaranteed. Next, the fluorochrome for systemic administration should not experience a net lifetime or long-lived decay kinetics that exceed the photon time of flight, as described in Section 33.2.3. For these reasons, the usefulness of PDT agents for contrast (and for therapy) is largely limited to epithelial linings of accessible tissues and not for deep tissues. However, one notable use of a PDT agent for contrast-enhanced surface imaging involves the use of its metabolic by product. Using exogenous δ aminolevulinic acid (ALA) for natural production of protoporphryin IX, Ecker et al.⁹⁷ showed the ability to detect adenomatous polyps of the colon in humans and provided evidence to suggest the ability to discriminate between hyperplastic and adenomatous polyps. While excitation at 337, 405, and 436 nm does not classify this agent as an NIR probe for deeptissue penetration, this study is nonetheless significant in that it employs a natural "reporting" mechanism in which the nonfluorescent ALA is hypermetabolized in diseased tissue to the fluorescent porphyrin form.

33.6.2 Nontargeting Blood-Pooling Agents

ICG, with its 778-/830-nm excitation/emission maxima was an early contrast agent choice used as a blood-pooling agent for assessing hypervascularity and "leaky" angiogenic vessels of high permeability. While many advances in dye development have accelerated within the past 2 years, the majority of studies investigating NIR fluorescent-contrast agents have been limited to ICG, a compound with FDA approval for systemic administration for investigating hepatic function¹¹⁷ and retinal angiography.¹¹⁸ ICG is excited at 780 nm and emits at 830 nm. It has an extinction coefficient of 130,000 M⁻¹cm⁻¹, a fluorescent lifetime of 0.56 ns, and a quantum efficiency of 0.016 for the 780-/830-nm excitation/emission wavelengths in water.³⁵ These values are not necessarily what will be observed *in vivo*.

When dissolved in blood, ICG binds to proteins such as albumin and lipoproteins. The absorption maximum shifts up to 805 nm, but the wavelength of maximum fluorescence is stable near 830 nm, and the fluorescent intensity depends on its concentration. ICG is a nonspecific agent and is cleared rapidly from the blood, but it tends to collect in regions of dense vascularity through extravasation.

FIGURE 33.22 Use of an incident-expanded beam on the mammary chain of the canine to excite systemically administered fluorophore and to collect the emission of generated light from the tissue surface. (From Hawrysz, D.J. and Sevick-Muraca, E.M., *Neoplasia*, 2(5), 388, 2000. With permission.)

Devoisselle et al. 91 demonstrated the use of ICG in an emulsion preparation at an administration of 10 μ mol/kg bw in a tumor-bearing rat to measure its prolonged pharmacokinetics, while Reynolds et al. 98 used free ICG (1.3 μ mol/kg bw) as a fluorescent agent in canines to image spontaneous mammary disease on a veterinary-outpatient basis.

In a study by Reynolds et al.,⁹⁸ frequency-domain approaches were employed whereby the canine mammary chain area was illuminated with intensity-modulated light, and the resulting amplitude of the generated fluorescent light that propagated to the surface was imaged by a gain-modulated image-intensified camera. The approach enabled rejection of room light and provided the first demonstration of fluorescence-enhanced imaging in a spontaneous tumor as in a large animal (Figure 33.22). Since the canine is the only species other than the human to naturally encounter mammary and prostate cancer,¹²¹ this is an excellent animal model in which to assess the potential of detecting diseased tissue via a contrast agent. However, penetration depths are nonetheless limited to 0.5 to 2 cm, still not meeting the deep imaging potential of fluorescence-enhanced optical imaging.

In measurements of the canine mammary chain, also by Reynolds et al., a homodyned, gain-modulated image intensifier was used as described in Section 33.3.2. Excitation was accomplished by illuminating the tissue surface with a 4-cm-diameter expanded beam of a 20-mW, 780-nm laser, which was modulated at 100 MHz. Figure 33.23 shows the DC, amplitude, phase, and modulation ratio (I_{AC}/I_{DC}) of an 830-nm wavelength emitted from the left fourth mammary gland with a palpable 1.2-cm (longitudinal) by 0.5-cm (axial) papillary adenoma located approximately 1 cm deep within the mammary tissue. The image was acquired 23 min following i.v. injection of l mg/kg ICG. The diseased region is clearly shown in the raw, unprocessed DC, amplitude, phase, and modulation images.

The use of ICG for optical tomography has already been identified by the Chance group at the University of Pennsylvania. In a combined time-domain and MRI-imaging study of 11 patients, Ntziachristos et al.⁷⁴ administered 0.2 mg/kg ICG i.v. and conducted measurements in response to pulsed excitation at 780 nm. Their time-domain system involved pulsed laser diodes at 780 and 830 nm multiplexed into 24 source fibers and collected at 8 detection points. ¹²² Using the MRI images to validate their integral inversion results, they were able to reconstruct images of an infiltrating ductal carcinoma due to the enhanced signature from the vascular blood pooling of ICG. Unfortunately, fluorescence signals were not acquired, possibly due to the low SNR available with TDPM measurements, and the images were reconstructed from signals at the incident wavelength.

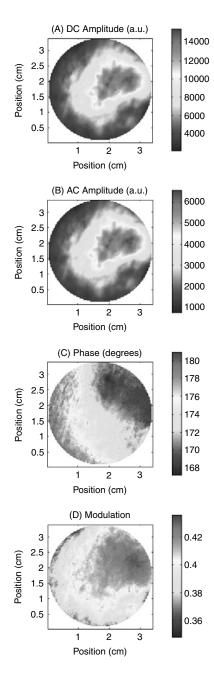

FIGURE 33.23 (Color figure follows p. 28-30.) The 128×128 pixel-based imaging of 830-nm fluorescence of (A) CW I_{DC} , (B) amplitude I_{AC} , (C) phase delay, and (D) modulation ratio of the detected fluorescence generated from the area cranial of the left fourth mammary gland of a canine. Illumination was accomplished with an expanded 780-nm laser diode. Modulation frequency was 100 MHz. (From Reynolds, J.S. et al., *Photochem. Photobiol.*, 70, 87, 1999. With permission.)

Later, using the modulated ICCD system Gurfinkel et al.¹⁰² used FDPM measurements with ICG as a blood-pooling agent as well as with a photodynamic agent, carotene-conjugated 2-devinyl-2-(1-hexyloxyethyl) pyropheophorbide (HPPH-car), to provide the difference in pharmacokinetics. The time course of images was clearly able to discriminate between the nonselective uptake of the ICG blood-pooling agent, whose contrast was due mainly to the density of the microvasculature associated with the disease,

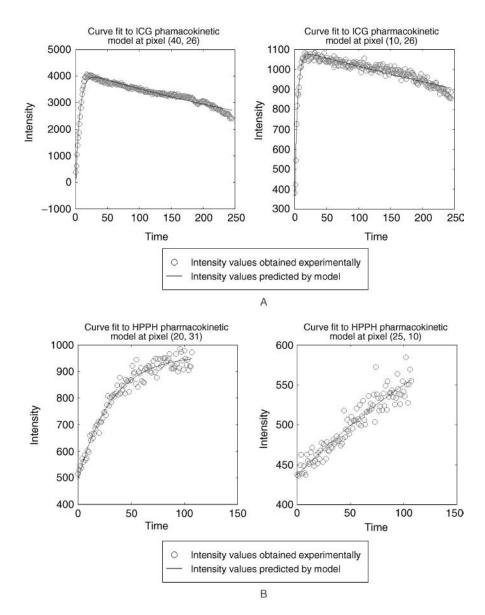

FIGURE 33.24 AC fluorescent intensity as a function of time illustrating typical curve fits using (A) the ICG pharmacokinetic model and (B) the HPPH-car pharmacokinetic model. The symbols denote actual measurements, while the solid curve denotes the model fit. (From Gurfinkel, M. et al., *Photochem. Photobiol.*, 72, 94, 2000. With permission.)

and the specific uptake of the HPPH agent, whose uptake is hypothesized to be mediated with the enhanced overexpression of low-density lipoprotein (LDL) receptors on the surface of cancer cells and the association of HPPH and LDL in the blood compartment. Figure 33.24 represents the values of the AC intensity as a function of time at a single point in the area detection corresponding to the s.c. tumor following i.v. injection of ICG as well as HPPH-car. Upon fitting the time course of AC-intensity measurements with pharmacokinetic models, a map of uptake parameters shown in Figure 33.25 demonstrates the ability to enhance optical contrast based on pharmacokinetics, as is currently done in MRI. In an effort to tune the pharmacokinetics of cyanine dyes by changing the level of hydrophobicity/philicity, Licha et al.¹⁰³ and Ebert et al.¹¹² showed that a hydrophilic derivative of cyanine dyes could enhance

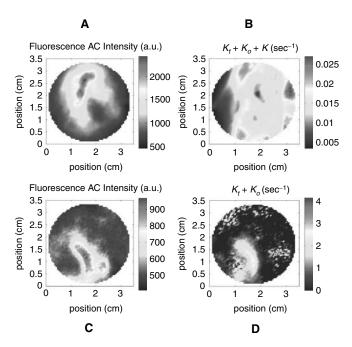

FIGURE 33.25 (Color figure follows p. 28-30.) (A) Fluorescence I_{AC} intensity map from ICG delineating diseased tissue and (B) map of pharmacokinetic uptake parameters obtained from fitting the time sequences of fluorescence-intensity images showing no specific uptake of ICG in diseased tissue. (C) Fluorescence AC intensity map from HPPH-car delineating diseased tissue and (D) map of pharmacokinetic uptake parameters obtained from fitting the time sequences of fluorescence-intensity images showing specific uptake of HPPH-car in diseased tissue. (From Gurfinkel, M. et al., *Photochem. Photobiol.*, 72, 94, 2000. With permission.)

uptake and be detected using single-point illumination and detection at the excitation wavelength $(0.5 \, \mu \text{mol/kg bw})$ and area illumination and detection at the emission wavelength $(2 \, \mu \text{mol/kg bw})$.

In addition to using ICG as a means for assessing hypervascularity associated with cancer, ICG may also be used to assess lymph flow. Figure 33.26 is an *in vivo* ICCD image of a canine made cranial to the nipple of the left fifth gland 30 min after ICG injection. While the imaged area was not associated with a palpable nodule, pathologic examination confirmed that the fluorescence was attributed to a blood vessel that bifurcated approximately 1 cm below the tissue surface in an area cranial to a regional lymph node. Figure 33.27 represents the *in vivo* FDPM images of the fluorescence generated from the area of the right fifth mammary gland 43 min after injection of the ICG. Pathologic examination showed that the fluorescent source in this image corresponded to the regional lymph node.

The ability to detect fluorescence signals originating from regional lymph nodes suggests that FDPM fluorescence imaging coupled with improved fluorescent dyes could provide a valuable diagnostic method for assessing regional lymph-node status in breast cancer patients. Lymph-node status in breast cancer patients can be a powerful predictor of recurrence and survival, and the number of lymph nodes with metastases provides crucial prognostic information regarding the choice of adjuvant therapy. ¹²³ Currently, lymph-node involvement is assessed by dissection and subsequent pathologic examination, but researchers are investigating the use of other diagnostic modalities including MRI, x-ray-computed tomography, and sonography. ¹²³ More recently, nuclear imaging of a technetium-99 sulfur colloid injected into the tissue area of a known breast tumor has been used to identify the sentinel lymph nodes. With the simultaneous or sequential injection of a blue dye to visually aid in its location, the sentinel lymph node can then be surgically removed. ^{123,124} Moreover, with NIR fluorescent agents, sentinel-lymph-node mapping could possibly be achieved without the use of the radionucleotide or with the introduction of a second dye to aid in surgical incision. Furthermore, the development of peptide-, protein-, or antibody-conjugated fluorescent dye (see below) makes possible nonsurgical, optical diagnosis of nodal involvement.

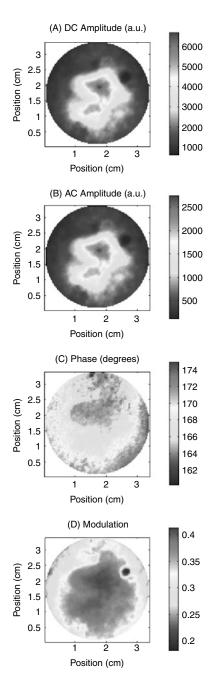

FIGURE 33.26 (Color figure follows p. 28-30.) The 128×128 pixel-based imaging of 830-nm fluorescence of (A) CW I_{DC} , (B) amplitude I_{AC} , (C) phase delay, and (D) modulatio0n ratio of the detected fluorescence generated from the area cranial of the left fifth mammary gland of a canine. Illumination was accomplished with an expanded 780-nm laser diode. Modulation frequency was 100 MHz. (From Reynolds, J.S. et al., *Photochem. Photobiol.*, 70, 87, 1999. With permission.)

Using intracranial injection of ICG bound to lipoprotein, Sakatani et al.⁹⁴ also showed the use of ICG in mapping the cerebrospinal fluid pathways in rats. Area illumination using a 100-mW laser diode and area detection with a cooled CCD camera was sufficient to detect meaningful images of fluid pathways following injection of 554 pmol ICG.

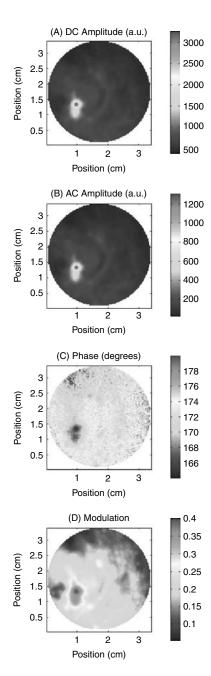

FIGURE 33.27 (Color figure follows p. 28-30.) The 128×128 pixel-based imaging of 830-nm fluorescence of (A) CW I_{DC} , (B) amplitude I_{AC} , (C) phase delay, and (D) modulation ratio of the detected fluorescence generated from a lymph node in the area of the right fifth mammary gland of a canine. Illumination was accomplished with an expanded 780-nm laser diode. Modulation frequency was 100 MHz. (From Reynolds, J.S. et al., *Photochem. Photobiol.*, 70, 87, 1999. With permission.)

33.6.3 Nontargeting Contrast Agents That "Report" or Sense Environment

While not employing the favorable excitation/emission characteristics, the studies of Mordon et al.⁸⁹ are especially intriguing because they are the first studies to employ a "reporting" dye, or a dye whose emission characteristics varied with tissue milieu. Specifically, they employed the pH-sensitive dye of 5,6 CF

carboxyfluorescence (BCECF), which is a ratiometric dye sensitive to pH. Using CW, spectrally resolved measurements of fluorescence resulting from area illumination with excitation light at 465 and 490 nm, they employed area detection using an intensified CCD camera to determine changes in fluorescence with changes in wavelength of the excitation light. Using an *in vitro* calibration of the ratiomeric dye, Mordon et al. were able to correlate the 2D fluorescent images to provide 2D images of tumor pH in a s.c. mouse model. While CW measurements are not time-dependent methods, this study did not directly measure changes in the fluorescence-decay kinetics but rather used spectral ratiometric changes to demark the change in the radiative relaxation rates that arose owing to acidotic tissue conditions.

33.6.4 Targeting, Contrast Agents: Immunophotodiagnosis

Folli et al.87 were the first to demonstrate the use of NIR targeting agents by coupling an indopentamethinecyanine dye coupled to a MAb E48 for targeting squamous cell carcinoma in the upper respiratory tract in mice. Approximately 600 pmol conjugated dye molecules were injected into mice and imaged postmortem using simple planar illumination and photography. This was the first demonstration of NIR immunophotodiagnosis that followed prior work to employ non-NIR, fluorescein-labeled antibodies targeted against carcinomembryonic antigen (CEA) in mouse⁸¹ and clinical studies.⁸³ The study was repeated by Neri,95 who used generated antibodies targeted to oncofetal fibronectin (B-FN), which is present in the angiogenic vessels of neoplasms but not in mature vessels. Further emphasizing the use of NIR fluorochromes in deep-tissue penetration for photoimmunodiagnosis, Ballou et al. 90,96 conjugated the cyanine dye class of Cy3, Cy5, Cy5.5, and Cy7 fluorochromes and not unsurprisingly found they could probe more deeply with the Cy7-conjugated MAbs in living tumor-bearing mice. They were able to image targeted delivery of fluorochromes of 40 pmol to 6 nmol/kg bw, and 600 pmol/animal using area illumination and an intensified or cooled CCD camera. More recently, Soukos et al. 115 used a 7,12dimethylbenz(a)anthracene (DMBA)-induced tumor in the hamster-cheek-pouch model and showed the ability to target cyanine dye to express endothelial growth factor receptor using the antiendothelial growth factor receptor (EGFR) MAb (C225) in surface illumination and detection. Approximately 3.3 nmol fluorochrome was used in each animal.

33.6.5 Targeting Contrast Agents: Small-Peptide Conjugations

A significant advancement in the design of optical contrast agents mimicked those used in other medical imaging modalities, Achilefu et al. 107-109 and Bugaj et al. 106 used area illumination and area CCD detection in tumor-bearing rats in order to detect ~6 to 7 µmol/kg bw of cyanine dye conjugated to small peptides for targeting somatostatin and bombesin receptors. One commercial nuclear diagnostic agent, Octreoscan®, is based on targeting the somatostatin receptor, which is overexpressed in neuroendocrine tumors. Bugaj et al. showed that the optical imaging using cytate, the derivatized and peptide-conjugated ICG, is similar to the radiolabeled peptide analog for somatostatin. Similar results were reported from using the peptide-conjugated derivative of ICG, cybesin, which is similar to the radiolabeled peptide analog for bombesin. Becker et al.¹¹⁰ reported similar work in tumor-bearing mice with detection limits reduced to 0.02 µmol/kg bw using a similar targeting construct. In their work, they conjugated the indodicarbocyanine dyes and the indotricarbocyanine (ITCC) dyes with analogs of somatostatin, somatostatin-14, and octreotate. In another approach, Becker et al. 99,101 followed the targeting approach previously used for methotrexate and PDT therapies, MRI gadolinium and magnetic-particle contrast, with human serum albumin (HSA) and transferrin (Tf) coupled to indotricarbocyanine dyes. While Tf binds to specific cell-surface receptors, HSA binds nonspecifically. Their studies show the contrast enhancement of targeting specificity using the Tf-ITCC.

In another study involving peptide conjugation, Zaheer et al.¹¹⁶ conjugated a bisphosphonate derivative, pamidronate, which exhibits specific binding to hydroxyapatite to an indocyanine dye to image bone structure in hairless mouse. The system may be capable of NIR detection of osteoblastic activity, enabling NIR imaging of skeletal development, coronary atherosclerosis, and other diseases.

33.6.6 Reporting or Sensing Contrast Agents

A novel "reporting" optical-contrast design was reported by Weissleder et al., 23 who employed fluorophore Cy5.5 loaded onto a polylysine backbone with methoxypolyethylene glycol polymer. When conjugated to the polymer backbone in high concentration, the fluorochrome tends to quench itself. However, when the polymer backbone is cleaved by cathespin B or H, lysosomal proteases whose activity may be enhanced in cancer cells, the fluorochromes become free and radiatively relax to produce fluorescence. In contrast to the small-peptide-conjugated dyes, this system requires fluorochrome internalization. The pioneering work enabled detection of 10 µmol of agent or 250 pmol of fluorochrome administered per tumorbearing animal and represented the first time an optical-contrast agent based on an internalization construct had been demonstrated. Along the same lines, another agent that reported on the basis of protease activity was developed using the same design principles. Bremer et al.111 coupled matrix metalloproteinase-2 (MMP-2) peptide substrates onto a poly-L-lysine polymer backbone and onto the peptides further conjugated with Cy5.5. The fluorochromes were sufficiently packed to be quenched upon activation. Upon action of the proteinase on the peptide, the Cv5.5 was freed and able to radiatively relax, reporting proteinase activity. MMPs are overexpressed in cancers, and MMP-2 in particular has been identified as the cause of collagen IV degradation. (Collagen IV is the major component of basement membranes.) The MMP-2 activity is thought to be responsible for the pathogenesis of cancer, including spread, metastasis, and angiogenesis, Using area illumination and detection, as little as 167 pmol per animal resulted in detected fluorescence to measure MMP activity in vivo for directing the therapeutic use of proteinase activity.

33.6.7 Combined Targeting and Reporting Dyes

Finally, Licha et al. ¹²⁵ sought to combine fluorochrome targeting using membrane receptors, such as transferrin, or the somatostatin and bombesin receptors with acid-cleavable constructs that would enable internalization of the fluorochromes in the lysosomal compartments and recycling of the receptors. Such constructs to augment the accumulation and, therefore, concentrate the signal from the targeting fluorochrome would be enhanced only if the contrast agent had a long half-life in the circulation. Coupling these cyanine dyes to different acid-cleavable hydrazone links that were bound to peptides, proteins, and antibodies, Licha et al. furthermore sought to develop a pH-sensitive contrast agent whose fluorescence is mediated by tumor acidosis.

In another innovative development, Huber et al.¹²⁶ synthesized bifunctional contrast agents containing a metal chelator for binding of a paramagnetic ion such as gadolinium and a conjugated fluorescent dye such as tetramethylrhodamine to combine optical imaging and MRI of experimental animals. While rhodamine excites within the visible with maximum absorbance at 547 nm and emission at 572 nm, the approach was successful for imaging of *Xenopus laevis* embryos. With the conjugation of an NIR-excitable dye, the potential to develop bifunctional contrast agents for deep-tissue medical imaging could also be realized. Again the reader is urged to be cautious in assessing contrast-agent studies conducted in mice and rats. These tissue volumes are not comparable to those in humans, and it is unlikely that emission signals at these wavelengths can be detected with sufficient SNR for image reconstruction in large volumes.

33.6.8 **Summary**

In summary, the approaches for fluorescent contrast-agent development have to date focused on:

- · Blood-pooling agents specific to increased microvessel density in neovascularized tumors
- · Targeting agents based on:
 - Immunophotodiagnosis
 - Small-peptide conjugations targeting overexpressed receptors whose location of action is directed to:
 - · Membrane receptors of endothelial cells that line angiogenic vessels of tumors
 - Membrane receptors of cancer cells

- Reporting agents that change their fluorescence-decay kinetics either through self-quenching or through environmental changes associated with:
 - · Interstitial pH
 - Membrane associated proteases and receptors
 - · Lysosomal, enzymatic degradation

In addition, the summary of the literature reports presented in Table 33.1 leads to the following conclusions:

- Fluorescence-enhanced optical imaging has not been demonstrated on large tissue volumes that are scalable to the clinic.
- The minimum number of fluorochrome molecules reported detected in a mouse or rat is 167 pmol.
- Favorable excitation and emission spectra are currently achievable using only the cyanine dye family.

Table 33.2 also contains limited references to endogenous fluorescence-enhanced contrast owing to green-fluorescence-protein-expressing tumors. In these systems, the green fluorescent protein has been transduced into cancer-cell lines to "report" tumors and metastases as well as their response to therapy. While the approach uses similar detection technology, it is not subject to the excitation-light-rejection issues that can plague fluorescence-enhanced contrast imaging. We present literature in this area for completeness.

In the following section, we summarize the theory and mathematics that enable us to predict the success of optical imaging using CW and time- and frequency-domain approaches as well as to develop the tomographic algorithms for fluorescence-enhanced optical tomography.

33.7 Challenges for NIR Fluorescence-Enhanced Imaging and Tomography

The preceding discussion presented an overview of the status of fluorescence-enhanced optical imaging. The opportunity to develop an emission-based tomographic imaging modality similar to that provided by nuclear imaging but without the use of radionucleotides is offered by NIR fluorescent agents. Yet the added challenge for NIR fluorescence-enhanced imaging over nuclear imaging is that, unlike nuclear techniques, an activating or excitation signal must first be delivered to the contrast agent before registration of the emission signal from the tissue. Preliminary data from animals (Table 33.2) and phantoms (not presented here) suggests that penetration depth and sensitivity may be comparable to nuclear techniques. A side-by-side comparison of NIR fluorescence-enhanced imaging with nuclear imaging is needed before the comparative performance can be ascertained.

Another opportunity for optical imaging is the ability for tomographic reconstruction and additional diagnostic information based on the fluorescence-decay kinetics of smartly designed probes. Tomography of large tissue-simulating volume has been demonstrated from experimental data as well as synthetic data (Table 33.1), albeit with the rather inconvenient point-source and point-detector geometries. The single-point-source and detector geometry is a throwback to NIR optical tomography from endogenous contrast studies and may not be the appropriate geometry for fluorescence-enhanced optical imaging, especially when transillumination through large tissues is required. Nonetheless, the tomographic algorithms as reviewed in Section 33.5 are already established for these systems. The challenge for the future is to develop tomographic algorithms for illumination and detection that are clinically feasible and adaptable for hybrid nuclear imaging.

While the field of NIR fluorescence-enhanced optical imaging is less than a decade old, the coming decade holds great promise for exciting new developments and, it is hoped, will result in an adjuvant tomographic imaging modality for nuclear imaging.

34.1 Definition of Optoacoustic Tomography

Optoacoustic tomography (OAT) is a method of image reconstruction based on time-resolved detection of acoustic-pressure profiles induced in tissue through absorption of optical pulses under irradiation conditions of temporal pressure confinement during optical-energy deposition.^{1,2} The phrase "irradiation conditions of temporal pressure confinement" means that optical energy (or other heat-generating energy) must be delivered to tissue faster than the resulting acoustic wave can propagate the distance in tissue equal to the desirable spatial resolution. For example, to achieve a resolution of optoacoustic images

- ** Moscow State University, Moscow, Russia

of 15 μ m with a speed of sound propagation in tissue of 1.5 mm per microsecond, optical pulses shorter than 0.01 μ sec are required. Thus, the use of short (nanosecond) optical pulses represents a necessary (but not sufficient) condition for achieving the desired spatial (axial) resolution of OAT.^{3,4} Achievement of the desired spatial resolution requires acoustic-wave detectors that have a temporal response function not slower than the optical-pulse duration.

Irradiation conditions of temporal pressure confinement must also be satisfied if optoacoustic signals are to accurately resemble profiles of absorbed optical energy in tissue.⁵ The distribution of absorbed optical energy can be used to visualize and quantitatively characterize various tissue structures and their physiological functions based on variations in tissue optical properties. To relate tissue structure to optoacoustic images the acoustic detectors must be capable of resolving rapid changes in optoacoustic signals associated with sharp edges and boundaries in tissues and reproducing slow changes associated with smooth variation in optical properties within one type of tissue. In other words, acoustic detectors must detect both high and low ultrasonic frequencies of acoustic pressure at once. These types of acoustic detectors are called ultrawide-band acoustic transducers.^{6,7} These transducers have relatively equal detection sensitivity over the entire ultrasonic range from 20 kHz to 20 MHz (and in some cases even higher up to 100 MHz).⁸ The ultrasonic detection bandwidth of acoustic transducers defines the limits of depth resolution. The lateral resolution of OAT, on the other hand, is defined by the dimensions of each acoustic transducer and the dimensions and geometry of the acoustic transducers in an array.^{9,10} Only an array of transducers provides lateral resolution of optoacoustic images. The array can be simulated by scanning a single transducer along tissue surface.¹¹

In this chapter we will elaborate on every aspect given in the definition of OAT including an explanation of optoacoustic profiles, ultrawide-band acoustic transducers, algorithms of optoacoustic image reconstruction, and medical applications of OAT. The chapter provides introductory and background information for students, scientists, engineers, and medical professionals interested in imaging methods that use light and ultrasound. Space limitations do not allow either a comprehensive theoretical treatment of optoacoustic phenomena in biological tissue or a detailed description of optoacoustic imaging technology.

34.2 History of Development

Theoretical and experimental optoacoustic studies from the 1970s and early 1980s conducted with nonbiological media created a theoretical and experimental background for the development of biomedical optoacoustics. 12 The initial idea driving advances in laser optoacoustics was the well-known exceptional sensitivity of piezoelectric detection. 13 Optoacoustic-signal profiles were first studied with temporal resolution after successful development of acoustic transducers with fast (nanosecond) response times.¹⁴ The first proposed optoacoustic applications aimed at sensitive detection of lesions in biological tissue based on measurements of arrival time of acoustic signals with no regard for information contained in the profile of optoacoustic signals.¹⁵ Later it was realized that the optoacoustic method with temporal resolution could be applied to monitoring laser-energy deposition in optically absorbing media during the ablation process. 16-18 The lack of a theoretical basis, however, prevented researchers from achieving quantitative results at that time. Developing an optoacoustic method suitable for applications in biological tissue was challenging due to its complex heterogeneous structure and optical properties, which were determined by three parameters: absorption coefficient, scattering coefficient, and scattering anisotropy. Rapid progress in the area of biomedical optoacoustics came with the understanding that under irradiation conditions of temporal pressure confinement the profile of laser-induced pressure transients accurately replicates the distribution of absorbed optical energy in the irradiated volume of tissue.^{3,4} In other words, under experimental conditions, when laser energy is deposited faster than the propagation of acoustic waves along the volume of tissue with characteristic dimensions of desirable spatial resolution, quantitative information on tissue optical properties can be obtained from time-resolved profiles of laserinduced pressure. It was then realized that a time-resolved optoacoustic profile would allow visualization of the distribution of absorbed optical energy in two and three dimensions inside opaque highly scattering media such as biological tissue.¹⁹⁻²² The imaging technology is now known as OAT.^{23,24}

Thermal pulses of microwave radiation can also be used instead of optical energy for generating acoustic transients in tissue. This type of imaging technology, called thermoacoustic computed tomography, provides deeper penetration of excitation energy in tissue but at the expense of lower tissue contrast.^{25,26} Initial experiments on optoacoustic imaging of gelatin phantoms resembling tissue optical properties were performed less than a decade ago.^{23,24,27–37} Those first experiments were followed by studies on human tissues *in vitro*.^{38–40} Recently OAT was established as a new method of medical imaging after being successfully used for two-dimensional (2D) OAT of tissues *in vivo*, mainly for noninvasive detection of breast cancer with submillimeter resolution^{41–43} and early detection of microscopic superficial lesions of oral cancer.^{44–46}

Advancement of the time-resolved stress-detection (TRSD) method was made possible after the development of sensitive piezoelectric detectors with an ultrawide ultrasonic detection band of up to 100 MHz.^{6–8,11} Piezoelectric transducers are the ultrasonic detectors of choice, especially when low thermal noise and sensitive detection is required within a very wide frequency band.⁸ Ultrawide-band piezoelectric detectors can be miniaturized for use in various medical applications including image-guided biopsy of prostate cancer and optoacoustic endoscopy. Optical oblique incidence reflectance and interferometric techniques can also be applied to detect wide-band acoustic signals.^{47–49} Optical detection has two main advantages over other methods; it (1) has the potential for remote (noncontact) optoacoustic detection^{50,51} and (2) provides rapid monitoring of large areas.⁵² The disadvantage of this method relative to piezoelectric detection is a lower sensitivity and high noise level in the range of acoustic frequencies greater than 1 MHz.⁸

34.3 Laser Generation of Optoacoustic Transients

The generation of acoustic waves by the consecutive transformation of optical energy into heat and then to mechanical stress is known as the thermooptical mechanism of stress generation. ¹² Short laser pulses allow the most efficient induction of the thermooptical stress. Absorption of laser radiation in a medium followed by a fast nonradiative relaxation of the excited states converts laser energy into heat. Subsequently, thermal expansion of the tissue heated under irradiation conditions of temporal pressure confinement causes a pressure rise, ΔP_2 in the irradiated volume: ^{5,12}

$$\Delta P = \frac{1}{\gamma} \frac{\Delta V}{V} = \frac{1}{\gamma} \beta \Delta T = \frac{1}{\gamma} \frac{\beta E_a(z)}{\rho C_V} = \frac{\beta c_0^2}{C_p} \mu_a F(z) = \Gamma \mu_a F(z)$$
 (34.1)

where γ [bar⁻¹] is the thermodynamic coefficient of isothermal compressibility (4.59 \times 10⁻⁵ bar⁻¹ for water):

$$\gamma = \frac{1}{\rho c_0^2} \frac{C_p}{C_V} \tag{34.2}$$

where c_0 [m/sec] is the sound velocity in tissue, ΔV [cm³] is the volume increase caused by the thermal expansion, V is the laser-irradiated volume initially at room temperature, ρ [g/cm³] is the density of a medium, C_p [J/gK] is the heat capacity at constant pressure, and C_v is the heat capacity at constant volume. The pressure increase is proportional to the thermal coefficient of volume expansion, β [K⁻¹], of the given medium and the absorbed energy density, E_a [J/cm³], which in turn equals the product of the laser fluence, F(z) [J/cm²], and the absorption coefficient of tissue, μ_a [cm⁻¹]. Pressure measured in [J/cm³] can be equally expressed in [MPa] or decabar (see SI and CGS units). The expression ($\beta c_s^2/C_p$) in Equation 34.1 represents thermoacoustic efficiency, often called Grüneisen parameter, Γ , which equals 0.1 for water and aqueous solutions at room temperature, T = 20°C. In comparison, $\Gamma = 12.7$ for fats, lipids, and oils, the most efficient biological media for generation of optoacoustic pressure (data from References 53 through 55). The Grüneisen parameter is a dimensionless, temperature-dependent factor proportional to the fraction of thermal energy converted into mechanical stress. For liquid water within a temperature range of 4 to 100°C, Γ can be expressed by the following empirical formula:^{5,56}

$$\beta(T) = -0.033 + 0.007T - 0.0000236T^2$$
(34.3)

where temperature, T, is measured in degrees Celsius.

Equation 34.1 is valid only when the heating process is much faster than the medium expansion and conditions of temporal pressure confinement are satisfied. When the laser pulse does not satisfy the conditions of temporal pressure confinement, optoacoustic imaging will lose both sensitivity and resolution.

34.4 Optoacoustic Profiles and Detection Geometry

34.4.1 Two Modes of Optoacoustic Detection

Unlike the majority of optical imaging technologies, where image information is obtained through measurements of the signal amplitude, OAT is based on measurements and analysis of optoacoustic-signal profiles. Optoacoustic profiles generated under irradiation conditions of temporal pressure confinement replicate axial profiles of the absorbed optical energy (where the axis crosses the centers of the acoustic transducer and irradiated volume). Irradiation of tissue in OAT is generally performed through an optically and acoustically transparent medium (optoacoustic buffer) designed to provide coupling of both the incident light from the laser source into the tissue and the resulting ultrasonic waves from the tissue into the acoustic detector.

The two modes of optoacoustic detection schematically depicted in Figure 34.1A and B are known as optoacoustic "forward" and "backward" modes. 4,56 Pulsed laser heating of the absorbing tissue under planar wave geometry results in generation of two ultrasonic transients being launched in opposite directions — forward into the volume of irradiated medium and backward into the transparent medium. The temporal optoacoustic profile depends on the position of the acoustic transducer relative to the irradiated tissue and on the ratio of acoustic impedances of the absorbing and transparent media. 5,12 In the forward detection mode, the optoacoustic signal propagated forward along the laser beam into absorbing medium is detected at the rear surface of the irradiated medium (Figure 34.1A). In the backward mode, the optoacoustic transient, propagated backward in the opposite direction of the incident laser beam, is detected at the site of laser irradiation. The two detection modes enable measurements of optical absorption and scattering over a wide range of tissue optical properties and ultrasonic absorption and scattering over a wide ultrasonic frequency range.

Each detection mode has its advantages and disadvantages. Both detection modes allow a certain amount of flexibility for *in vivo* and *in vitro* measurements with OAT. The forward detection mode provides signals that are easy to interpret. Possible medical applications of optoacoustic detection in the forward mode are, however, limited by applications in human organs with free access to the two opposite surfaces (such as breast). For various medical applications with only one tissue-surface access (such as skin or internal hollow organs), the backward detection mode is often the only choice. At the same time,

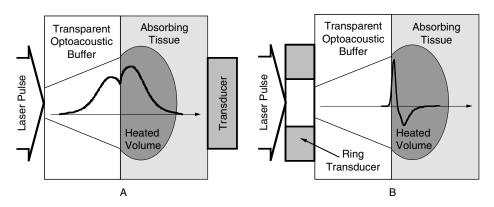

FIGURE 34.1 Forward (A) and backward (B) modes of the optoacoustic signal detection.

the backward detection mode, which uses solid optically and acoustically transparent material (such as fused silica, see Figure 34.1B) placed on the irradiated surface of tissue for optoacoustic coupling, provides the tissue-surface flatness that is required for generation (and detection) of an ultrawide ultrasonic frequency band in tissue, which in turn provides high spatial resolution of optoacoustic images. On the other hand, the detection of laser-induced transient pressure at the front-irradiated surface makes the design of the piezoelectric detector more complex. Different designs of optoacoustic transducers operating in the backward mode permit tissue irradiation from either the top or the side of the transparent medium coupled to the absorbing tissue. 6,7,56 An ultrawide-band acoustic transducer coupled to the top surface of the optoacoustic transparent medium can detect optoacoustic signals with high temporal resolution sufficient for medical purposes (up to $10 \mu m$). That is why the backward mode enables measurements of optical absorption distribution for a variety of tissues and over the entire optical spectral range.

34.4.2 One-Dimensional Optoacoustic Profiles

34.4.2.1 Depth Profiles in Plane-Wave Geometry

The optoacoustic profile generated in absorbing tissue, propagated through this tissue to the acoustic detector and detected with temporal resolution, is well established and has been quantitatively investigated theoretically and experimentally.⁵⁶ Figure 34.2A and B shows typical optoacoustic profiles detected in forward- (A) and backward- (B) mode geometries. The temporal profiles of the detected optoacoustic (pressure) signals can be presented as a solution:

$$p^{tr}\left(\tau^{tr} = t + \frac{z}{c_0^{tr}}\right) = T_{\alpha c} \frac{c_0^2 \beta}{2c_p} \int_0^{+\infty} \left(\tau^{tr} - \theta\right) Q(c_0 \theta) d\theta$$
 (34.4)

$$p'\left(\tau = t - \frac{z}{c_0}\right) = T_{\alpha c} \frac{c_0^2 \beta}{2c_p} \int_{-\infty}^{+\infty} (\tau^{tr} - \theta) Q^{tr}(-c_0 \theta) d\theta$$
 (34.5)

of the nonstationary thermal-wave equation:12

$$\frac{\partial^2 \rho'}{\partial t^2} - c_0^2 \Delta p' = \rho c_0^2 \beta \frac{\partial^2 T'}{\partial t^2}$$
 (34.6)

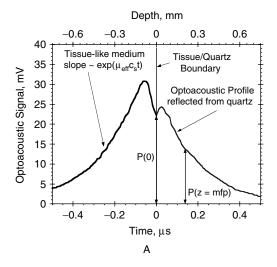

Here we used the following terms: c_0 , c_0^{tr} is the speed of sound in tissue and in the transparent optoacoustic buffer, β is the thermal-expansion coefficient for tissue, and Q(z) and $Q^{tr}(z)$ represent distributions of absorbed optical (thermal) energy in tissue (the zone of positive z) and in optoacoustic buffer (the zone of negative z) that also accounts for reflection of acoustic waves from the boundary.

$$Q = \mu_a F(z), \quad Q^{tr}(z) = \begin{cases} Q(z), & z > 0; \\ R_{ac} Q(-z), & z < 0; \end{cases}$$
(34.7)

Coefficients of acoustic transmission and reflection from the boundary are defined by the acoustic impedances of the transparent buffer, $z_b = \rho^b c_0^b$, and the absorbing tissue, $z_t = \rho^t c_0^t$, as follows:

$$T_{ac} = \frac{2z_b}{z_b + z_t}, \ R_{ac} = \frac{z_b - z_t}{z_b + z_t},$$
 (34.8)

where ρ^b, ρ^t [g/m³] are the densities, and c_0^b, c_0^t [m/sec] are the velocities of ultrasound waves in the buffer and in tissue.

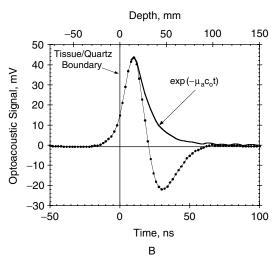

FIGURE 34.2 Optoacoustic profiles generated in optically absorbing and scattering tissue-like medium covered by an optically transparent window with significantly higher acoustic impedance (quartz). (A) Optoacoustic profile detected in forward mode. (B) Optoacoustic profile detected in backward mode and the same profile corrected for acoustic diffraction. The detection bandwidth of acoustic transducer was approximately 80 MHz.

Therefore, the reflected profile can either be in phase with the original profile ($z_b > z_t$, as at the quartz–tissue boundary) or in contraphase with the original profile ($z_b < z_t$, as at the air–tissue boundary). The optoacoustic profile in the forward mode is described by convolution of the spatial distribution of laser-induced acoustic sources and the temporal shape of the laser pulse. 12,56 Therefore, for sufficiently

short laser pulses, $\mu_{eff}c_0\tau_L << 1$ (where μ_{eff} is the effective optical attenuation in tissue and $\tau_L = \int_{-\infty}^{+\infty} f(t)dt$

is the laser-pulse duration), the optoacoustic profiles replicate the distribution profile of the absorbed laser energy:

$$p^{tr} \left(\tau^{tr} = t + \frac{z}{c_0^{tr}} \right) = \begin{cases} 0, & \tau^{tr} < 0; \\ T_{ac} \frac{c_0^2 \beta \tau_L}{2c_p} Q(c_0 \tau^{tr}), & \tau^{tr} > 0; \end{cases}$$
(34.9)

$$p\left(\tau = t - \frac{z}{c_0}\right) = \begin{cases} \frac{c_0^2 \beta \tau_L}{2c_p} Q(-c_0 \tau), & \tau < 0; \\ R_{ac} \frac{c_0^2 \beta \tau_L}{2c_p} Q(c_0 \tau), & \tau > 0; \end{cases}$$
(34.10)

The temporal profile of optoacoustic transients generated under irradiation conditions of temporal pressure confinement and detected in the forward mode without signal distortion replicates the profile of the spatial distribution of absorbed optical energy (Figure 34.2A). The signals from acoustic sources generated by laser pulses deep in the tissue are the first to arrive at the transducer (detector) placed at the rear surface of tissue. These signals from deep inside the tissue are followed by signals from sources located closer to the irradiated surface. A plane-wave optoacoustic profile generated in the tissue by a wide laser beam propagates in two opposite directions. Therefore, the temporal profile consists of two components moving with the speed of sound: the rising (original) spatial profile followed by a falling profile that corresponds to the reflection from the tissue–quartz boundary with acoustic reflection coefficient, R_{ac} . Depending on the sign of R_{ac} , the falling slope could be either a compressive ($z_b > z_p$ as in the case of rigid quartz–tissue) or tensile ($z_b < z_p$ as in the case of free air–tissue) boundary. The transition zone at the boundary has a duration equal to that of the laser pulse.

With the backward detection mode (see Figure 34.2B) the profile consists of a sharp rising front at τ_{tr} = 0 with the duration of the integrated laser pulse followed by an exponential trailing slope. The trailing slope resembles the profile of absorbed optical energy in tissue, which is determined by the optical attenuation coefficient and the speed of sound. This optoacoustic profile can be represented either by a compression transient wave (when $\beta > 0$, as in tissue at room temperature) or by a tensile transient wave (when $\beta < 0$, as in water in the temperature range of 0 to 4°C). However, due to acoustic diffraction in the quartz optoacoustic buffer, the signal detected in the backward mode is described by the bipolar derivative of the original laser-induced optoacoustic profile, as shown in Figure 34.2B.

The finite duration of laser pulses leads to a widening of all components of the optoacoustic profile. Initially the pulse duration extends the central transition zone of the optoacoustic transients detected in the forward mode and the front of the optoacoustic profile detected in the backward mode. Further increase in the pulse duration results in an optoacoustic profile that does not resemble the distribution of laser-induced acoustic sources and, instead, in most cases replicates the shape of the laser pulse. The optoacoustic profile detected in the forward mode from tissue having a free irradiated surface (free acoustic boundary produced between tissue and air) represents the exception, when the optoacoustic profile follows the derivative of the laser pulse. 12,56

34.4.2.2 Optoacoustic Profiles from an Absorbing Sphere

Spherical objects in tissue irradiated with near-infrared (NIR) light may be considered optically semi-transparent, which means that the effective optical penetration depth in tissue is greater than the linear dimensions (radius, a) of the absorbing objects (such as tumors). Furthermore, when $\mu_{eff} << 1/a$, distribution of optical energy inside spherical objects may be considered homogeneous.

For the sake of simplicity, let us consider a spherical object in tissue with optical properties dominated by optical absorption (scattering is apparent but may be neglected). In the spherical coordinates whose center coincides with the center of the object, the radial distribution of thermal energy in and around this object could be approximated by the following function:

$$Q(r) = \begin{cases} \mu_{\alpha} F_{\sigma} ch(\mu_{\alpha} r) / ch(\mu_{\alpha} r), & 0 \le r \le a; \\ 0, & a < r. \end{cases}$$
(34.11)

where F_o is the laser fluence at the surface of the absorbing sphere, which depends on the effective optical attenuation by absorption and scattering in tissue:

$$F_o = F_0 \exp(-\mu_{eff} z)$$
 (34.12)

The transient acoustic wave resulting from laser heating of the spherical object will have spherical symmetry and can be given by the following equation:

$$\frac{\partial^2 (rp')}{\partial t^2} - c_0^2 \frac{\partial^2 (rp')}{\partial r^2} = \frac{c_0^2 \beta}{c_p} r Q(r) \frac{df}{dt}$$
(34.13)

with the boundary condition associated with the finite pressure in the center of the sphere:

$$(rp')|_{r=0} = 0.$$
 (34.14)

The reflection of the acoustic wave from the center of the sphere occurs in the contraphase. The system of Equations 34.13 and 39.14 is similar to the planar case with a free (air–tissue) boundary, Equation 34.6. Therefore, Equation 34.5, with a reflection coefficient $R_{ac} = -1$, can be used here:

$$p'\left(\tau = t - \frac{r}{c_0}\right) = \frac{\mu_{\alpha} F_o c_0^2 \beta}{2rC_p} \int_{-\alpha/c_0}^{+\alpha/c_0} f(\tau - \theta) \left(-c_0 \theta\right) \frac{ch(\mu_{\alpha} c_0 \theta)}{ch(\mu_{\alpha} a)} d\theta.$$
(34.15)

As with planar acoustic waves, the optoacoustic profile of a spherical acoustic wave can be expressed as the convolution of the temporal profile of the laser pulse with the depth profile of the absorbed optical energy modified for the contraphase reflection of the acoustic wave from the center of the sphere. Under irradiation conditions of temporal pressure confinement (short laser pulses), so that $\mu_{\alpha}c_0\tau_L << 1$ and for relatively large dimensions of the absorbing sphere, $c_0\tau_L << a$, the optoacoustic profile replicates that of the absorbed (thermal) energy distribution:

$$p'\left(\tau = t - \frac{r}{c_0}\right) = \frac{\mu_{\alpha}F_{o}c_0^2\beta}{2rc_p} \begin{cases} \left(-c_0\tau\right)ch(\mu_{\alpha}c_0\tau)/ch(\mu_{\alpha}c_0\tau), & |\tau| < a/c_0; \\ 0, & |\tau| > a/c_0. \end{cases}$$
(34.16)

The optoacoustic profile for relatively weakly absorbing objects, $\mu_{\alpha} a < 1$, possesses a so-called N-shape, with duration $\tau_N = 2a/c_0$ associated with sound propagation through the object. The optoacoustic profile detected from a strongly absorbing object, $\mu_{\alpha} a >> 1$, can be described by two short pulses, where a tensile pulse follows the leading compression pulse with a delay equal to the time of sound propagation through the object.

Figure 34.3 shows a typical optoacoustic profile detected in forward mode from absorbing spheres inside a bulk tissue-like phantom irradiated with NIR laser pulses. A wide laser beam was used for illumination of this phantom, which resulted in a planar acoustic wave with a profile resembling depth (axial) distribution of the absorbed optical energy. On the background of the main exponential trend, which is due to the effective optical attenuation, this optoacoustic profile contains two N-shaped wavelets resulting from spherical acoustic waves from the two absorbing spheres. Since both spheres were positioned on one axis with the irradiation-detection system, the pressure profile in Figure 34.3 includes signals simultaneously recorded from both spheres. These phantom studies demonstrated that the accuracy of localization and the accuracy of "tumor" dimension measurements could be greater than 0.5 mm.

In the case of microscopic absorbing objects in tissue ($c_0\tau_L >> a$, Equation 34.15 can be transformed into the following expression for the optoacoustic profile that replicates the derivative of the laser pulse:

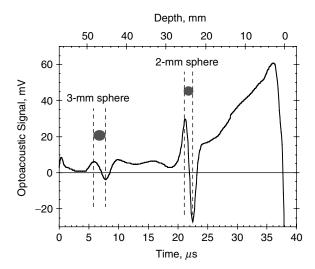

FIGURE 34.3 Laser-induced optoacoustic profile measured with a wide-band acoustic transducer along the axis with two gel spheres 2 and 3 mm in diameter colored with hemoglobin of blood. Two N-shaped signals are shown. The signal at t = 0 representing the transducer response to direct illumination was used for calibration of the time scale. Optical attenuation of the bulk phantom was $\mu_{eff} = 1.4 \text{ cm}^{-1}$.

$$p'\left(\tau = t - \frac{r}{c_0}\right) = \frac{\beta F_0 4\pi a^2}{4\pi r c_p} \left[th\left(\mu_{\alpha} a\right) - \frac{2\left(\mu_{\alpha} a - th\left(\mu_{\alpha} a\right)\right)}{\left(\mu_{\alpha} a\right)^2} \right] \frac{df}{d\tau}.$$
 (34.17)

If small (microscopic) structures in tissue also possess a relatively small optical absorbance, i.e., $\mu_a a << 1$, then the optoacoustic amplitude linearly increases with the absorption coefficient:

$$p'\left(\tau = t - \frac{r}{c_0}\right) = \frac{\beta I_s 4\pi a^2}{4\pi r c_p} \frac{\mu_{\alpha} a}{3} \frac{df}{d\tau}.$$
 (34.18)

If those microspheres possess strong absorption, then the optoacoustic amplitude saturates:

$$p'\left(\tau = t - \frac{r}{c_0}\right) = \frac{\beta I_s 4\pi a^2}{4\pi r c_p} \frac{df}{d\tau}.$$
 (34.19)

This type of behavior is explained by the fact that the optoacoustic signal amplitude is determined by the total absorbed optical energy.

34.4.3 Acoustic Diffraction and Other Factors of Signal Distortion

The optoacoustic profile can be altered in the course of propagation to the transducer through tissue and a transparent optoacoustic buffer. The main phenomena that contribute to the distortion of original optoacoustic profile are acoustic diffraction, acoustic attenuation, and the detector response dependent on the ultrasonic frequency of the detected signals.^{5,12,36} Additional distortion can occur due to roughness of the irradiated tissue surface and oblique incidence of the acoustic wave to the transducer aperture.¹⁰

The equations for planar (34.3 and 34.4) and spherical (34.15) optoacoustic profiles did not include acoustic diffraction. Generally, acoustic diffraction must be included, so that the optoacoustic profile is described by the following equation based on Equation 34.18:

$$p'(t,\mathbf{r}) = \frac{\beta}{4\pi c_p} \frac{\partial}{\partial t} \int \frac{Q(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|} f(t - c_0^{-1} |\mathbf{r} - \mathbf{r}'|) dV'$$
(34.20)

which considers the divergent acoustic wave only outside the volume occupied with laser-induced acoustic sources, Q(r). The solution (Equation 34.20) represents the main expression for OAT, whose goal is to invert Equation 34.20 to image the spatial distribution of the acoustic sources, Q(r).

The acoustic diffraction of the optoacoustic profiles can be described by the following parabolic equation: 12,57

$$\frac{\partial^2 p'}{\partial \tau \partial z} = \frac{c_0}{2} \Delta_{\perp} p', \tag{34.21}$$

where Δ_{\perp} is the Laplasian in the transversal coordinates $\{x,y\}$, and z is the depth coordinate. The boundary conditions for Equation 34.21 in the case of wide laser beams (commonly used in OAT) can be taken in the form of solutions (Equations 34.4 and 39.5) obtained upon consideration of planar acoustic waves.

Since optical illumination usually has a Gaussian cross-sectional profile, the first approximation for the distribution of laser-induced acoustic sources in the plane perpendicular to the axis of optical illumination may also be taken as Gaussian:

$$p'(z=0,\tau,\mathbf{r}_{\perp}) = p_0(\tau) \exp(-\mathbf{r}_{\perp}^2/a_0^2),$$
 (34.22)

where $p_0(\tau)$ is the temporal profile of the optoacoustic signal at the irradiated tissue surface.

A specific feature of optoacoustic signals is their ultrawide range of ultrasonic frequencies. The effective length, L_D , of the acoustic diffraction depends on the ultrasonic frequency (acoustic wavelength). The acoustic-beam cross section, πa_0^2 , doubles after propagation of a distance equal to the effective diffraction length:

$$L_{D} = \pi \, a_{0}^{2} / \lambda_{ac} = a_{0}^{2} \omega_{ac} / c_{0}$$
 (34.23)

where λ_{ac} is the wavelength of the acoustic wave with ultrasonic frequency, ω_{ac} . Therefore, different spectral components of the optoacoustic profiles undergo different degrees of acoustic diffraction; the lower ultrasonic frequencies contribute the most pronounced changes in the optoacoustic profile. The higher frequencies undergo minimal acoustic diffraction, thereby propagating mainly along the axis perpendicular to the acoustic front. Considering the importance of the effective diffraction length as a function of ultrasound frequency, the solution for the system of Equations 34.21 and 34.22 can be found in the spectral domain:

$$p'\left(z,\tau=t-\frac{z}{c_0},\mathbf{r}_\perp\right) = \int_{-\infty}^{\infty} \exp\left(-i\omega\left(\tau-t\right) - \frac{\mathbf{r}_\perp^2}{a_0^2} \frac{\omega}{\omega + i\frac{2c_0z}{a_0^2}}\right) \left(\omega + i\frac{2c_0z}{a_0^2}\right)^{-1} \omega d\omega. \tag{34.24}$$

Since high ultrasonic frequencies concentrate near the axis of acoustic beam, the highest resolution in OAT can be obtained by detecting optoacoustic profiles propagating along the axis of the laser beam. The optoacoustic profile at axis $\mathbf{r}_{\perp} = 0$ can be obtained from Equation 34.24 and expressed as:

$$p'(z,\tau,\mathbf{r}_{\perp}=0) = p_0(\tau) - \int_{-\infty}^{\tau} \omega_D \exp(-\omega_D(\tau-t)) p_0(t) dt, \qquad (34.25)$$

where $\omega_D = 2c_0 z/a_0^2$ is the characteristic frequency of acoustic diffraction defined as the frequency at which the characteristic diffraction length is equal to the length of propagation, z. The first item in equation 34.24 replicates the optoacoustic profile at the irradiated tissue surface, and the second item describes the influence of the limited radial dimensions of the acoustic wave. In the far diffraction zone $(z \to \infty)$, the solution (Equation 34.24) can be simplified as:

$$p'(z,\tau,\mathbf{r}_{\perp}=0) = \frac{a_0^2}{2c_0 z} \frac{dp_0}{d\tau}.$$
 (34.26)

The effect of the acoustic diffraction is to produce a derivative of the original optoacoustic profile in the far zone. The task of OAT is to use optoacoustic profiles at the irradiated surface for image reconstruction. Thus, for the purposes of OAT Equation 34.25 must be inverted, which yields the following result:

$$p'(\tau,z=0,\mathbf{r}_{\perp}=0) = p'(\tau,z,\mathbf{r}_{\perp}=0) + \omega_D \int_{-\tau}^{\tau} p'(\vartheta,z,\mathbf{r}_{\perp}=0) d\vartheta.$$
 (34.27)

Acoustic diffraction is most prominent in the backward detection mode, where a quartz acoustic buffer (with high acoustic impedance) is placed between the tissue and the transducer. The influence of acoustic diffraction can be compensated for, and the original laser-induced profile can be reconstructed with a procedure that convolves the detected optoacoustic profile and the reference profile detected from a highly absorbing medium (with $\mu_{eff} > \Delta f_{at}/c_0$, where Δf_{at} is the ultrasonic detection bandwidth of the acoustic transducer).³⁶ The detected reference signal replicates the profile of the laser pulse, with the Fourier spectrum altered by the signal-transmission path and the detection system, which include all distortion factors including acoustic diffraction, acoustic attenuation, and the sensitivity response of the acoustic transducer.

34.5 Two-Dimensional Imaging with Array vs. Scanning Mode

Two-dimensional optoacoustic images can be acquired either by using a stationary array of acoustic transducers or by scanning a single transducer along the tissue surface. Figure 34.4 depicts schematic diagrams of the two image-acquisition modes. One mode may have better lateral resolution for a specific clinical application. Stationary arrays of acoustic transducers allow real-time imaging deep inside tissue within a large field of view. On the other hand, all arrays have a limited zone where all transducers perform equally. Therefore, transducer arrays yield much better lateral resolution when imaging large tissue volumes in the far zone of the detector, especially in human organs that can be surrounded by the array (such as breast).

Figure 34.4A shows an array of acoustic transducers employed for breast imaging in the forward mode. Optical pulses can be delivered to the tissue surface with one or more optical fibers, as shown in the drawing. As an alternative, a wide laser beam can be used to illuminate the entire volume of the breast. Breast tumors having stronger optical absorption (primarily due to enhanced blood content) and greater optical scattering (primarily due to enlarged cell nuclei) produce a larger amplitude of optoacoustic signals in response to laser heating. The resulting acoustic waves propagate in tissue in all directions and can be detected with an array of acoustic transducers. The product of the temporal width of the optoacoustic signal produced in a tumor and the speed of sound yields tumor dimensions in the direction of the axis between the tumor and the detector. The product of the speed of sound in the tissue and the delay time between the laser pulse and the arrival of the transient pressure wave at the transducer is equal to the distance between the tumor and the transducer. A linear or arc-shaped array of acoustic transducers permits reconstruction of 2D images of optically heterogeneous structures located in the breast.

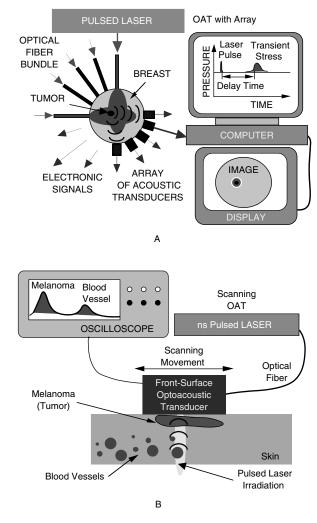

FIGURE 34.4 Schematic diagrams of optoacoustic tomography. (A) Forward mode imaging with an array of optoacoustic transducers. (B) Backward mode imaging by scanning a single transducer.

Figure 34.4B shows scanning of a single acoustic transducer along the skin surface for acquisition of 2D images of subsurface layers. Laser pulses are delivered to the tissue surface with a single optical fiber. Scanning a single transducer is most appropriate for the backward mode of acoustic detection at the site of optical irradiation. Translation of a single transducer along straight lines can produce 2D images with high lateral resolution defined by the resolution of a single transducer. The scanning mode is the only way to produce 2D imaging in the near zone of subsurface tissue volume because only one transducer with finite dimensions can image tissue located underneath that transducer. Acoustic transducers for the scanning mode must be designed with a very narrow angle of acceptance to provide lateral resolution. The best lateral resolution can be obtained with confocal optoacoustic transducers.

34.6 The Laser Optoacoustic Imaging System

The laser optoacoustic imaging system (LOIS) was developed for OAT of tissue structures located at a depth of up to 6 to 7 cm. LOIS combines the most compelling features of optical and ultrasound imaging systems, pronounced optical contrast, and high resolution of ultrawide-band ultrasound detection,

yielding a more sensitive imaging modality with substantially improved accuracy of the localization (<1 mm). The hybrid of optical and acoustic technologies overcomes the problems of pure optical imaging associated with the loss of resolution and sensitivity due to strong light scattering as well as problems of pure ultrasound imaging associated with poor tissue contrast and low signal-to-noise ratio (SNR).

34.6.1 Arc-Array of Ultrawide-Band Piezoelectric Transducers

The heart of LOIS is an array of ultrawide-band acoustic transducers. The greater the distance between the end elements in the array and the smaller the individual elements, the better spatial resolution can be achieved. 57,58 The first LOIS had only 12 relatively wide piezoelectric elements in a relatively short linear array, which provided very limited spatial resolution. 39 Advances in OAT over last 3 years have resulted in the design and development of longer transducer arrays that have a larger number of smaller-dimension piezoelectric transducers and are shaped like an arc to improve spatial (lateral) resolution. The array employed in experiments described in this chapter had 32 rectangular piezoelectric transducers measuring 1 mm \times 12.5 mm and a distance of 3.85 mm between the transducers (Figure 34.5). 40 The 110- μ m-thick piezoelectric polymer PVDF was used to make the transducer. Low acoustic impedance and an ability to operate in a wide ultrasonic-frequency band are the advantages of PVDF for detecting optoacoustic profiles. Alternatively, piezoceramic materials, such as PZT-5H or composite polymer-ceramic materials, can be used.

The transducers were located on the arc surface with a radius of 60 mm. Such geometry provided optimal resolution in the entire 60-mm × 60-mm field of view within the image plane. The shape and length of individual piezoelectric elements determine spatial resolution of this array in the plane perpendicular to the image plane. Flat elements provide a resolution equal to the linear size of the element. Backing polymer material with acoustic impedance similar to that of PVDF was used for mechanical matching of the piezoelectric material and damping reverberations after detection. OAT requires that the piezoelectric element not vibrate at its thickness-related resonance frequency after detecting an optoacoustic signal, and the frequency band of ultrasonic detection is widened in the range defined by the application. The front surface of the transducer array was covered by an aluminum film to reduce external electric noise. The thickness of the aluminum layer was such that the balance between ultrasound penetration and electric-noise reduction was optimized. The transducer-array housing was also made of aluminum. Acoustic insulating material was placed between the piezoelectric elements and the housing to prevent ringing of the housing that follows the vibration of the piezoelectric elements themselves.

34.6.2 Sensitivity of Detection

The theoretical absolute sensitivity of transducers, $S = 19.8 \mu V/Pa$, can be calculated on the basis of piezoelectric properties of the PVDF material used:

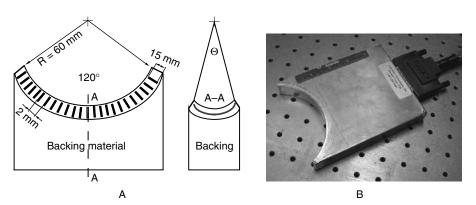

FIGURE 34.5 Schematic diagram (A) and photograph (B) of the arc-shaped transducer array.

$$S = g_{33}d [V/Pa].$$
 (34.28)

where $g_{33} = 0.18$ V m/N is the piezoelectric pressure modulus of the transducer material, and d = 110 μ m is the thickness of the piezoelectric element. Some portion of acoustic energy, however, can be lost due to reflection at the boundary of the shielding layer and the piezoelectric film. The defects of bonding of these two layers cause additional losses.

Detection of the optoacoustic signal obliquely incident on a piezoelectric transducer with finite dimensions can alter its profile. Therefore, an ideal piezoelectric element would have dimensions significantly smaller than the shortest detected acoustic wavelength, λ_{ac} . However, small dimensions yield a small value of electric capacitance of the transducer piezoelement, C_{pe} , which can be derived from the following formula:

$$C_{\rm pe} = \frac{\varepsilon \varepsilon_0 A}{d} \tag{34.29}$$

where A is the surface area of the piezoelement, and ε_0 is the dielectric permittivity of the transducer material. To avoid the shunting effect of the electronic circuitry, the capacitance of each transducer element should not be lowered to a level comparable to the stray capacitance of the connecting wires and input capacitance of the electronic preamplifier. The shunting effect can potentially be the source of significant losses of sensitivity in the detection system.

The ratio of the absolute sensitivity and the minimal detectable pressure dependent on thermal noise in the piezoelectric element defines the detection capability of the acoustic transducer. The minimally detectable pressure of the ultrawide-band ultrasonic transducer can be derived from the following expression:⁸

$$p_{\min} = \frac{M f_{\max}}{g_{33} c_1} \sqrt{\frac{kT_0}{C_{\text{pe}}}}$$
 (34.30)

where f_{max} is the upper ultrasonic frequency of the transducer detection band, c_l is the longitudinal speed of sound in the piezoelectric element, and kT_0 is the product of the Boltzmann constant $(1.38 \cdot 10^{-23} \text{ J/K})$ and ambient temperature (300 K). The numerical coefficient, M, in the numerator depends on whether the transducer operates in an open (M = 4.6) or short (M = 6.5) electrical circuit.⁸

Minimally detectable pressure is presented in Figure 34.6 as a function of the transducer capacitance, the main variable parameter for the PVDF material of the piezoelectric element operating in the open

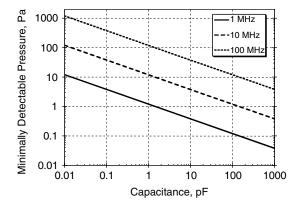

FIGURE 34.6 Acoustic pressure generated by thermal noise as a function of capacitance of acoustic transducer made of PVDF film and operating in the open circuit mode. Three curves for three values of upper ultrasonic frequency (1, 10, and 100 MHz) of the transducer detection band are shown.

circuit. This plot demonstrates that pressures in the range of 1 Pa can be detected with LOIS. It is difficult to calculate all possible losses of acoustic energy. Therefore, direct sensitivity measurement for all transducers in an array is very important. The experimental variability of the sensitivity between array elements is usually about 10 to 15% and must be taken into account in LOIS calibrations.

34.6.3 Spatial Resolution

The axial (depth) resolution of a pulsed optoacoustic system operating under irradiation conditions of temporal pressure confinement is directly defined by the detection bandwidth of ultrasonic transducers. The temporal response time of an ultrawide-band acoustic transducer is defined as $1.5/f_{\rm max}$, where $f_{\rm max}$ is the upper frequency limit of the piezoelectric element. The coefficient 1.5 accounts for the fact that for resolved detection of a sphere with diameter $2a_{\rm min}$ at least three data samples must be recorded. According to Sparrow's criteria, two coherently emitting identical spherical acoustic sources with radius $a_{\rm min}$ will be detected as separate objects if the space between their centers is equal to or greater than $\delta_z = 2a_{\rm min}$. The use of this transducer for imaging in tissue where the speed of sound equals c_0 makes it possible to obtain spatial resolution of:

$$\delta_z = 2a_{\min} = 3\frac{c_0}{f_{\max}}.$$
 (34.31)

The upper frequency limit of the ultrasonic detection band, $f_{\text{max}} = c_1/2d$, is defined by the transducer thickness and the frequency bandwidth of the preamplifier used. In LOIS design using a 110-µm-thick PVDF film, the upper frequency limit was 4 MHz, which provided 1.1-mm axial (depth) resolution.

The arc geometry of the transducer array provides enhanced lateral resolution of the area near the center of the arc curvature. This array geometry is the most beneficial for imaging within a circular field of view. In this area, the lateral resolution can be estimated as the width of the synthetic directivity pattern produced by the entire aperture of the array (see diagram in Figure 34.7):

$$\delta_l = 1.22 \frac{\lambda_{ac}}{\arcsin(r/R)} \approx c_0 \tau_a / 2 \sin \theta , \qquad (34.32)$$

where $\theta = \arcsin(r/R)$ is the angular aperture of the array, R is the radius of the arc curvature, r is the aperture radius, and $\tau_a = 2a_{\min}/c_0$ is the duration of the acoustic pulse from the minimally detectable sphere. If optoacoustic transients are detected, the spatial pulse duration $c_0\tau_a$ should be used as the equivalent of the shortest detectable acoustic wavelength, λ_{ac} . Equation 34.32 is equivalent to the equation for the waist size of a focused transducer with the same configuration obtained for harmonic-wave radiation. This formula works well as long as all transducers in the array make equal contributions to the formation of the synthetic aperture. Diffraction can reduce the sensitivity of some transducers when

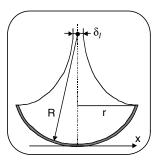

FIGURE 34.7 Schematic diagram of directivity of acoustic detection for an arc-shaped array of piezoelectric transducers.

they receive acoustic transients from points outside the central zone. The acoustic diffraction can, therefore, reduce the lateral resolution, which depends on the position of the acoustic source relative to the array.

With the 32-element arc-shaped array depicted in Figure 34.5, lateral resolution of 1 mm can be obtained. In the entire field of view, the lateral resolution is in the range of 1 mm < δ_l < 2 mm. For the arc-shaped transducer array described above, the ratio r/R equals approximately 0.87; therefore, Equation 34.32 can be simplified, yielding $\delta_l \approx 1.22 \lambda_{ac}$. This estimation is valid for monofrequency acoustic waves. With ultrawide-band detection, the detection-frequency spectrum must be accounted for and the correct value of the effective λ_{ac} selected.

34.6.4 Signal Processing in Optoacoustic Tomography

The signal-processing algorithm realized in LOIS is shown schematically in Figure 34.8. Each signal detected by acoustic transducers in the array consists of three components: (1) a sharp peak produced at the very surface of the medium under investigation, (2) a low-frequency, smoothly ascending exponential slope produced by the attenuation of optical intensity inside the tissue, and (3) a short N-shaped pulse generated by a small absorbing object (tumor). We assumed here that the tumor had a spherical shape with radius *a*. The duration of the N-shaped pulse is defined by the time of sound propagation through the sphere diameter. The delay in time of signal arrival depends on tumor location relative to the transducer. Therefore, the position of the tumor and its dimensions can be determined from the optoacoustic signal.

Before the signal can be used for image reconstruction, its low-frequency component associated with the effective optical attenuation inside the tissue must be completely eliminated because the high amplitude of the optoacoustic signal at the irradiated surface can significantly decrease image contrast. The removal of the smooth (exponential) trend in the optoacoustic profile can be achieved with either wavelet filtering⁶⁰ or a high-pass numeric hyper-Gaussian filter, which performs better than a simple set of resistor-capacitor (RC) cells.^{40,42} The imaging operator can conveniently vary the cut-off frequency and the slope of the filter transfer function.

The signal generated by laser pulses in the subsurface layer (very close to the surface) possesses maximum amplitude over the entire detected course. Therefore, the signal gradient is maximal at the tissue surface, which yields high ultrasound frequencies. High ultrasound frequencies that fall near the

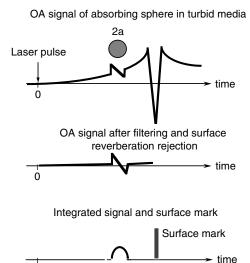

FIGURE 34.8 Optoacoustic signal processing. Top: Detected optoacoustic profile. Center: Exponential trend caused by effective optical attenuation is removed. Bottom: Original signal from an absorbing sphere restored.

resonance frequency, f_{max} , of piezoelements can induce significant reverberation in the transducer. The transducers used in LOIS are designed to dampen resonance frequencies and widen the range of detectable frequencies. Nevertheless, a strong reverberation takes place after the arrival of the signal from the tissue surface. These reverberations, however, do not affect the useful part of the optoacoustic profile. Besides, it is convenient to use a sharp high-gradient (derivative) peak for automatic determination of the tissue surface. The position of the irradiated tissue surface was considered to be the position of absolute minimum in the signal. The controlling computer generated the numerical signal at the surface position determined for each transducer and stored these data in a separate file. All data samples were cut off from the signal after arrival of the signal generated at the tissue surface. Integrated signals were used as input data for the image-reconstruction code. The computer-generated surface marks were used for surface visualization, so that the location of internal tissue structures could be related to the irradiated surface of tissue.

34.6.5 Algorithm of Image Reconstruction

A radial back-projection algorithm, presented schematically in Figure 34.9, was developed for optoacoustic imaging with an array of ultrawide-band transducers. 40,42,61 For the reconstruction of 2D optoacoustic images we used signal integrals projected back onto the 2D grid, taking into account the directivity pattern (angle of acceptance) of each transducer in the array. The image represents the distribution of a product of thermoacoustic efficiency, optical absorption coefficient, and effective laser fluence in tissue.

Consider a pulsed laser excitation of acoustic waves in a homogeneous medium with optical-absorption coefficient μ_a . The temporal integral of acoustic pressure detected by the transducer located at point r can be expressed in the following form:⁵⁸

$$u(\vec{r},t) = \int_{-\infty}^{t} p(\vec{r},t')dt' = \frac{\beta}{4\pi C_{p}} \int_{V} \frac{\mu_{a}(\vec{r}')I(\vec{r}')L(t - \frac{|\vec{r} - \vec{r}'|}{c_{s}})}{|\vec{r} - \vec{r}'|} d\vec{r}'.$$
 (34.33)

where β is the thermal coefficient of volume expansion, C_p is the specific heat capacity of the medium, and L is the laser pulse temporal profile. All other notations used in Equation 34.33 are shown in Figure 34.9.

The integral in Equation 34.33 is calculated over the entire space. This means that the acoustic pressure $p(\vec{r},t)$ at the time moment t and at point r is determined by the acoustic sources located in the spherical shell with radius $|\vec{r} - \vec{r}'|$ and thickness $d\vec{r}'$. Acoustic waves arrive at measurement point \vec{r} , with time delay $|\vec{r} - \vec{r}'|/c_s$. If the laser pulses are sufficiently short, then generation of thermal sources may be considered instantaneous, and the laser waveform function can be expressed as $L(t) = \tau_L \delta(t)$, where τ_L is the laser-pulse duration, and $\delta(t)$ is the delta function. Equation 34.33 for short laser pulses can be written as follows:

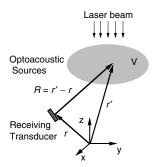

FIGURE 34.9 Geometry of the optoacoustic detection.

$$u(\vec{r},t) = \frac{\beta}{4\pi C_p} \int_{C_p} \frac{\mu_a(\vec{r}')F(\vec{r}')\delta(t - \frac{|\vec{r} - \vec{r}'|}{c_s})}{|\vec{r} - \vec{r}'|} d\vec{r}'$$
(34.34)

where F is the laser fluence. Let surface Σ be the spherical surface of radius, R, with its origin at the position of the receiving transducer. The radius of the sphere is defined by the time of sound propagation from the surface to the transducer. Vector \vec{R} can be presented as $\vec{R} = c_s t \vec{n}$, where \vec{n} is the unit vector of the surface element $d\Sigma$. Thus, the temporal integral of acoustic pressure can be expressed as:

$$u(\vec{r},t) = \frac{\beta}{4\pi C_p c_s t} \int_{\Sigma} Q(\vec{r} + c_s t \vec{n}) d\Sigma$$
 (34.35)

where function $Q(r) = \mu_a(r)F(r)$ describes the spatial distribution of absorbed optical energy.

Equation 34.35 can be considered fundamental for OAT. The temporal integral of the pressure profile detected by transducer at time t is the superposition of the laser-induced acoustic sources located on the sphere of radius $R = c_s t$. The product of the optical absorption coefficient and the effective optical fluence at this spherical surface determines the optoacoustic amplitude. The back-projected images acquired with a limited number of detectors display artifacts associated with image reconstruction using an incomplete data set. The contrast of these images can be improved through the image-filtration procedure applied to the entire 2D image. However, unprocessed optoacoustic images contain quantitative information about the distribution of absorbed optical energy in tissue. This quantitative information may be used for functional imaging and measurements of tissue optical properties.

34.6.6 Image Processing

OAT adopted the radial back-projection algorithm, earlier developed for ultrasound imaging.⁶² For the reconstruction of 2D optoacoustic images LOIS calculates integrals of the optoacoustic signals and projects them back onto the 2D grid, taking into account the directivity pattern (angle of acceptance) of each acoustic transducer. The field of view that results from the radial back-projection algorithm can be expressed in the following form:

$$\xi(\vec{r}) = \sum_{n=1}^{m} u_n(|\vec{r} - \vec{r}_n|/c_s) |\vec{r} - \vec{r}_n|$$
 (34.36)

where u_n is the integrated optoacoustic signal of the nth transducer, \vec{r}_n is the radius vector of the nth transducer, and m is the number of transducers in the array. The image represents the distribution of a product of thermoacoustic efficiency, optical absorption, and laser fluence. The back-projected images of very small or low-contrast objects might be noisy and their brightness sometimes may be insufficient for object recognition. Therefore, an image-filtration procedure was employed:

$$\xi_{2}(\vec{r}) = \frac{1}{4\pi^{2}} \int F_{\xi}(\vec{\omega}) H(\vec{\omega}) e^{i\vec{\omega}\vec{r}} d\vec{\omega}$$
 (34.37)

where $F_{\xi}(\vec{\omega}) = \int \xi(\vec{r}) e^{-i\vec{\omega}\vec{r}} d\vec{\omega}$ is the 2D Fourier spectrum of the back-projected image, $H(\vec{\omega}) = |\vec{\omega}| e^{-(|\vec{\omega}|/\sigma)^2}$ is the filter-transfer function, and $\vec{\omega} = \left\{\omega_x, \omega_y\right\}$ is the vector of spatial frequencies. Parameter σ permits variation of the filter bandwidth and the steepness of the filter characteristics. Optimization of σ can be achieved manually by operator or automatically. In the automatic procedure, parameter σ can be chosen from the analysis of image quality based on the contrast–dimension relationship. The filter parameter, σ , can be further optimized by employing contrast loss in the resulting image.

An image-reconstruction algorithm based on the Radon transform with a limited data set was proposed for OAT.⁶¹ If used directly, this method does not yield satisfactory resolution, even when a significant number of transducers is used. However, use of the Radon transform is possible if the integrals along the arcs are substituted by the integrals along the straight lines tangential to the corresponding arcs in limited areas containing suspicious objects inside the total field of view and using an iterative approach for the solution of the inverse problem.⁶³

34.7 Application of LOIS to Detection of Breast Cancer

At present, detection of breast cancer is the main biomedical application for OAT. LOIS combines advantages of pronounced optical contrast and sensitive, high-resolution ultrasonic detection, resulting in a more advanced imaging system for breast cancer. 1,19,21,42 As discovered by Folkman, rapidly growing cancer cells need additional blood supply and gradually develop a dense microvascular network inside and especially around tumors required for tumor growth. 64,65 Solid tumors require enhanced energy and oxygen supply through the microvascular network. Tumor-associated neovascularization allows tumor cells to express their critical growth advantage. Rapid tumor growth, bleeding, and metastasis usually follow this new vascular phase of growth.

Malignant breast tumors (carcinoma) have enhanced blood content and contain noticeably hypoxic blood.^{66,67} In contrast, benign tumors have a relatively normal level of blood oxygenation. Spectroscopic imaging, i.e., optical imaging using several optical wavelengths, allows for noninvasive *in vivo* imaging and quantification of oxygenated and deoxygenated hemoglobin, which reflects the physiologic functions of tumors.^{68,69}

Strong absorption of pulsed laser radiation leads to preferential energy deposition in tumors compared with normal tissue. The absorbed laser energy yields a temperature rise and a simultaneous pressure jump in the irradiated volume, thereby converting heated tumors into sources of ultrasonic waves. Shortpulse (nanosecond) energy deposition results in high thermoacoustic efficiency of pressure generation (up to 0.8) in live tissues and enables a superior spatial resolution of 0.5 mm and a field of view extending to a depth of up to 60 mm.⁴² The optically generated pressure profile resembles the distribution of absorbed energy in the irradiated tissue. The signal generated by the optoacoustic imaging system is initially a spatial replicate of the tumor in the direction of detection. This signal mimics the spatial distribution of optical absorption, creating an ultrasonic wave that mimics the shape of the object. The propagation of this signal to the surface follows the rules of ultrasound transmission, but the signal itself is distinct from typical ultrasound. Tumors measuring 1 to 10 mm and irradiated with laser pulses represent sources of pressure waves with an ultrawide ultrasonic frequency range of 150 kHz to 1.5 MHz. Such ultrasonic waves can propagate in tissues with insignificant attenuation and deliver spatially resolved information to the surface of tissue.^{6,21}

In contrast to pure optical tomography, where diagnostic information about tissue structure is integrated over the entire optical path, optoacoustic imaging permits direct reconstruction of the absorbed energy distribution from the profile of laser-induced pressure. 1.5,36,43 The sensitive time-resolved piezoelectric detection and analysis of the laser-induced ultrasonic profiles offer a unique opportunity to visualize objects at substantial depth in optically turbid and opaque tissues and to provide quantitative information about tissue structure with high-resolution ultrasound. Unlike pure ultrasonic imaging, where ultrasonic waves are delivered to tissue from outside and only a fraction of the total ultrasonic energy is reflected back from tissue boundaries, optoacoustic imaging converts tumors into bright acoustic sources standing out on a dark (low absorbing) background of normal tissues and detects 100% of the ultrasonic energy emitted by tumors. Thus, LOIS, which uses sensitive detection of laser-induced ultrasonic waves instead of detecting scattered photons, is free of the limitations associated with pure optical and pure ultrasound technologies.

34.7.1 Sensitivity of LOIS for Small-Tumor Detection

One of the important parameters of LOIS is its ability to detect small (early) tumors in the breast. Consider a tumor as a sphere of radius a with optical absorption coefficient μ_a . Let this tumor be located

at such a depth where the energy of laser pulses exponentially attenuated in the normal breast tissue can generate optoacoustic signals with a SNR of 1. The maximum depth of the tumor detection can be evaluated as:^{40,42}

$$z_{\text{max}} = -\frac{1}{\mu_{\text{eff}}} \ln \left(\frac{2p_{\text{noise}}r}{\Gamma \mu_a a F_0} \right)$$
 (34.38)

where μ_{eff} is the effective optical-attenuation coefficient in breast tissue, and r is the distance between the tumor and the transducer.

Fluence, F_0 , of laser pulses at the breast surface must be less than 40 mJ/cm² due to safety requirements for medical laser procedures with repetitive pulses. The increase in effective optical fluence in scattering tissues relative to incident fluence makes it possible to use several-fold-lower pulsed energy to achieve the projected sensitivity. Parameter Γ characterizes the efficiency of thermoacoustic excitation in the media. For live biological tissues at 37°C this parameter varies from 0.40 to 0.85 and is maximal in fatty tissues. The effective noise pressure, p_N , is calculated for a SNR equal to 1, according to Equation 34.30. The root mean square of noise voltage U_{RMS} produced by the transducer is defined by the thermal noise of the transducer capacitance and the input noise of the preamplifiers. For LOIS, the anticipated value of U_{RMS} will be about 10 μ V. The noise voltage is reduced \sqrt{N} times if the procedure of averaging by N pulses is used. The optimal number of acquisitions for optoacoustic signal averaging is N=16, which should yield an effective noise pressure of less than 0.5 Pa.

Using the experimental data obtained in the course of preliminary studies we were able to calculate the minimum diameter of spherical tumors with various blood content detectable inside the breast by the current system. $^{26,39-42}$ The radius of the minimum detectable spherical tumor is plotted in Figure 34.10A as a function of depth from the irradiated surface for optical absorption coefficient $\mu_a = 1 \text{ cm}^{-1}$ (at $\lambda = 757 \text{ nm}$) corresponding to the pathologically average blood content in tumors of 12%. Figure 34.10A shows that a 2-mm tumor can be detected under the current system at a depth of 6 cm. Substituting the noise pressure p_N characteristic of LOIS in Equation 34.38 yields a maximum depth of tumor detection of about 6 cm, assuming the tumor is a sphere 2 mm in diameter with $\mu_a = 0.6 \text{ cm}^{-1}$, or a greater depth for tumors with an absorption of 1 cm $^{-1}$.

Figure 34.10B depicts an optoacoustic image of two 7-mm spheres colored with hemoglobin (with an effective optical absorption of 12% of blood) and embedded in a gel phantom with optical attenuation of $\mu_{eff} = 1.2~\text{cm}^{-1}$. The anticipated blood content in actively growing small tumors is about 8 to 20%. ⁶⁵⁻⁶⁷ The area above the curve in Figure 34.10A represents the range beyond the limit of detection for these transducers, and all tumors with a combination of absorption—diameter below the curve can be detected by ultrawide-band acoustic transducers made of piezoelectric polymer materials (sensitivity >1 V/bar) designed and fabricated in collaboration with LaserSonix Technologies, Inc. (Houston, TX) and used in the experiments described in this chapter. The detection limits of LOIS may be further improved with advances in the piezoelectric transducer arrays supported by advanced electronics and image-processing algorithms.

The 2D image of blood-colored spheres differs from the correct circular shape, presenting them as ellipses. This fact has a simple explanation. When the angle of acceptance of these objects by the transducer array was about 120°, only one third of the data needed for complete image reconstruction was collected and used in image reconstruction. This factor limited lateral resolution in the far zone of the images presented in Figure 34.10B. An increase in the acceptance angle for the absorbing volumes located farther from the irradiation site but closer to the detector array results in an enhanced lateral resolution in general and better reproduction of spherical objects. The angle of acceptance in the case of the near zone may be over 180°, and, as a consequence, the shape of imaged objects would highly correlate with their real shapes (see Figure 34.11).

As depicted in the optoacoustic image in Figure 34.11, an artificial blood vessel (polyethylene tubing shaped as a loop) was placed at the substantial depth of 60 mm in the phantom with optical absorption

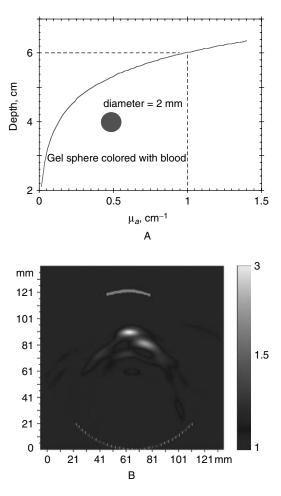

FIGURE 34.10 (Color figure follows p. 28-30.) (A) Minimally detectable tumor radius as a function of tumor depth in the bulk of normal tissue. Optical absorption coefficient of 1 cm⁻¹ corresponds to relative blood content of 12% in the tumor. (B) Optoacoustic image of two small spheres colored with hemoglobin in gelatin phantom resembling optical properties of breast tissue. An arc above the spheres indicates positions of optical fiber for delivery of laser pulses.

and scattering properties mimicking the breast tissues. The transducer array was at the bottom of the phantom, so that the field of view of the array overlapped with the blood-vessel loop. A single fiber was used for irradiation at only one location on the phantom surface, as depicted in the top portion of Figure 34.11. The phantom surface position is visible as a white dash with the conic divergent optical beam spreading into the depth. This optoacoustic image has a relatively dark background with some lighter structures due to the heterogeneity of the phantom. The optoacoustic contrast (\sim 500%) on the image in Figure 34.11 corresponds to the difference in both background optical absorption and blood at λ = 1064 nm. An experiment with a blood vessel embedded inside a gel phantom demonstrated that LOIS could image small-diameter vessels with sufficient resolution. In addition, this image gives evidence for the utility of optoacoustic imaging in the quantitative monitoring of blood in tumors.

34.7.2 In Vitro Imaging of Breast Cancer (Mastectomy Specimens)

Before optoacoustic imaging was applied in patients, extensive studies were conducted *in vitro* in mastectomy specimens.^{39,40} Breast specimens were obtained after radical mastectomy and examined within the first 10 min after surgical excision. It provided specimens that underwent minimal alterations of

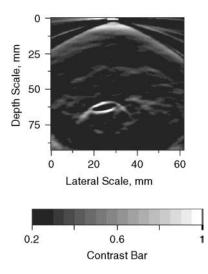

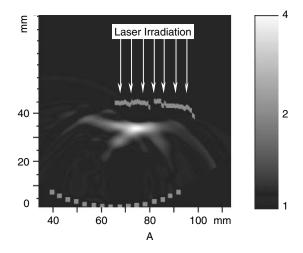

FIGURE 34.11 Optoacoustic image of artificial "blood vessel" loop in a milky phantom. Optical properties of this phantom were similar to the optical properties of the breast with real arteries at the wavelength of 1064 nm.

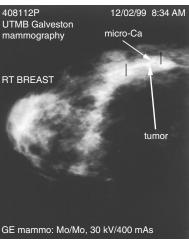

tissue optical properties, except that some blood was drained from the specimens. After optoacoustic imaging, a pathologist examined the mastectomy specimens to determine tumor location and geometry. The location of tumors was not known before the optoacoustic imaging procedure was performed.

Optical fiber was scanned along the surface of the radical mastectomy specimen with a 3.5-mm interval. Optoacoustic signals (from an array of 32 ultrawide-band piezodetectors) were employed for data collection and subsequent image reconstruction. One scan passed directly over the tumor. A 2D optoacoustic image of part of a breast with carcinoma is presented in Figure 34.12A. The field of view was about 36 cm². The optoacoustic image shows clearly the tumor core, horizontal tail, and small sprouts (confirmed by subsequent pathological examination). The dimension of a tumor core can be estimated as 10 \times 7 mm. A tumor was detected 11 mm from the surface, and skin was removed from most of the specimen; thus, the irradiated surface is depicted in Figure 34.12A as a rough line. Optoacoustic contrast between the tumor and surrounding normal tissues in this image exceeds 3.5-fold, making surrounding normal tissue look dark on the image. The x-ray mammography image of the same tumor, in a wider field of view, is also presented in Figure 34.12B. The core of the tumor and its long tail are also visible in this image. However, small sprouts are not visible due to limited radiographic contrast. Note that the x-ray image reveals two suspicious areas in the breast, only one of which was proven cancerous. The optoacoustic imaging system visualized only one bright object in the breast — a malignant tumor. The results presented in Figure 34.12 indicate that LOIS has a potential for early detection of cancerous tumors. A greater challenge for LOIS is to provide noninvasive differentiation of malignant and benign tumors. Therefore, the next series of studies were devoted to imaging blood with two colors of NIR light to compare blood-oxygenation levels in benign and malignant tumors.

67.7.3 Diagnostic Imaging in a Breast Cancer Patient

An eligible patient was chosen from a group of patients with breast tumors detected by x-ray mammography in both breasts, and one or more breast tumors were suspected of being cancerous. Two-dimensional optoacoustic images were acquired in several locations on each breast. Two images at two laser wavelengths of 1064 and 757 nm were acquired in succession. Each image required irradiation with 16 100-nsec pulses performed over the course of 0.8 sec, and collection of the imaging information was done on a 32-element array of acoustic transducers. Image reconstruction took about 1 sec on a 700-MHz PC. Laser pulses were delivered at one site of the breast surface, and the optoacoustic transducer array was placed on the opposite side of the breast approximately beneath the point of irradiation. The

В

FIGURE 34.12 Optoacoustic image (A) and x-ray mammography image (B) of a malignant tumor in the breast of UTMB Patient #40811. Note the two major suspicious areas in x-ray mammography image, only one of which proved cancerous. Note also the improved contrast in optoacoustic image. The rough line in (A) represents points on the breast surface illuminated with laser pulses. In order to display detailed structure of the breast tumor, 12 points of the breast surface were irradiated with laser pulses at 1064 nm.

irradiation point was placed approximately in the center of the imaging field suspected of having a tumor. The exact location of tumors was not known prior to optoacoustic imaging; however, the approximate location could be determined from the mammogram. One tumor (in the left breast) was not palpable; however, at least one tumor in the right breast was palpable. Tumors in both breasts were located several centimeters deep within the breast.

Optoacoustic images of breast ductal-lobular carcinoma and benign fibroadenoma obtained prior to biopsy are presented in Figure 34.13A and B, respectively. Optoacoustic images depict the dimensions, shape, location, and structure of the tumor angiogenesis network of microscopic blood vessels with enhanced optical absorption. However, the optical scattering and thermoelastic properties of the tumors might also have contributed to the optoacoustic contrast. The location of the tumors inside the breast and the tumor dimensions could be accurately determined from the optoacoustic images. However, direct comparison with x-ray mammography or ultrasound images based on tissue density was not appropriate.

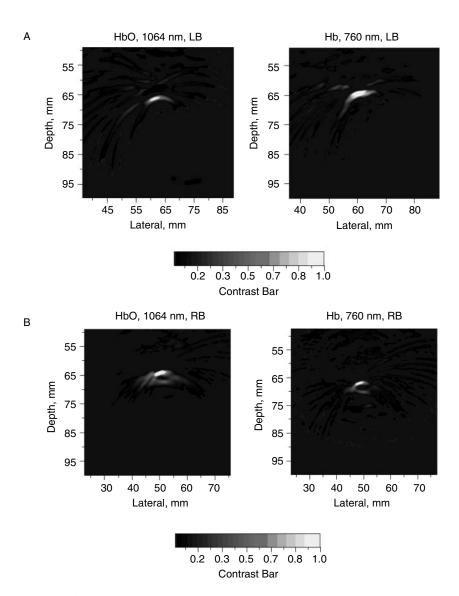

FIGURE 34.13 (Color figure follows p. 28-30.) (A) Two-dimensional optoacoustic *in vivo* images of a ductal-lobular carcinoma in the left breast (LB). Laser pulses were delivered to a single point on the skin surface above the tumor. Location of the piezoelectric detector array was at the bottom of the imaging field presented. Contrast between a tumor and surrounding normal tissue strongly depends on the laser wavelength. At the wavelength of 1064 nm the image brightness is significantly lower than the brightness at the wavelength of 757 nm, indicating tumor with reduced level of blood oxygenation. (B) Two-dimensional optoacoustic *in vivo* images of a benign fibroadenoma in the right breast (RB). Laser pulses were delivered to a single point on the skin surface above the tumor. Location of the piezoelectric detector array was at the bottom of the imaging field presented. Contrast between a tumor and surrounding normal tissue strongly depends on the laser wavelength. At the wavelength of 1064 nm the image brightness is significantly higher than the brightness at the wavelength of 757 nm, indicating tumor with normal level of blood oxygenation.

Note that LOIS provided only a small amount of light through a single optical fiber, which limited significantly the field of view on the optoacoustic images. Resolution of the image visualization with LOIS (~1 mm along the depth axis and 1.5 mm in lateral dimension) was comparable to that of x-ray mammography and ultrasound.

Two main conclusions may be drawn from clinical experiments on breast cancer patients. First, OAT substantially enhances the contrast between normal tissues and tumors. Second, the optoacoustic contrast

correlates to the level of oxygen saturation of hemoglobin in the tumor microcirculation. The tissue contrast was naturally variable; however, no tumors examined had a contrast of less than twofold relative to the background in normal glandular or fatty tissue. Since optoacoustic contrast in breast tumors is angiogenesis dependent; it may potentially serve as a means for noninvasive diagnosis of malignancy. A correlation between microvessel density in tumor angiogenesis (i.e., total concentration of hemoglobin) and brightness of tumors on optoacoustic images is currently being studied with the help of immunohistology.

34.7.4 Advantages and Limitations of LOIS

Five major characteristics of laser OAT that make it attractive for diagnostic imaging of breast cancer are: (1) high detection sensitivity, which results from efficient generation of acoustic sources in tumors by short laser pulses (thermoacoustic efficiency of ~0.7 to 0.8), and sensitive detection of acoustic waves with piezoelectric transducers; (2) high in-depth resolution of ~0.5 to 1.0 mm, which results from short-pulse laser excitation and fast time-resolved detection (ultrawide-band ultrasound detection); (3) high (submillimeter) lateral resolution that results from the geometry of the detection array; (4) high optical contrast (up to sixfold) between tumors and normal tissues, which most likely results from enhanced concentration of blood in malignant tissues due to angiogenesis and a laser wavelength correctly selected for its ability to penetrate tissue and target tumors; and (5) substantial depth of imaging without noticeable loss of resolution (up to 7 cm), which results from an optimal laser-excitation wavelength and efficient conversion of laser energy into ultrasonic waves propagating in soft tissues with insignificant attenuation and minimal distortion.

The two main limitations of the current design of LOIS are (1) limited field of view dictated by the limited number of acoustic transducers in an array that, in turn, was limited by the number (32) of electronic channels of data acquisition and processing and (2) inability to perform imaging in very large breasts.

34.7.5 Three-Dimensional Optoacoustic Imaging

One of the merits of OAT is its real-time performance. Three-dimensional (3D) optoacoustic images may be beneficial for some clinical applications. However, for real-time 3D imaging LOIS seems unreasonably expensive due to the large number (over 10³) of electronic channels that must operate in parallel to acquire data from a large organ such as breast. The real-time imaging capability of LOIS is very important for enabling functional imaging with high spatial resolution. The laser-pulse-repetition rate cannot be increased much over 100 Hz due to thermal superheating of tissue (especially blood vessels). Therefore, the only realistic approach to 3D imaging is the one currently being developed by LaserSonix Technologies, Inc. The system shown in Figure 34.14 has a bifocal array of 64 piezoelectric transducers

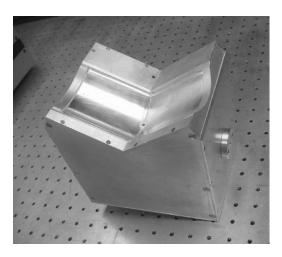

FIGURE 34.14 Bifocal array of 64 acoustic transducers.

and 64 data-acquisition channels. With a laser-pulse-repetition rate of 32 Hz, only half a second is required to produce a 2D image with an average of 16 signals from each transducer. Data-transmission time using a high-speed interface and 2D image reconstruction takes another half second with a 2-GHz pentium computer. This corresponds to close-to-real-time image acquisition and processing in LOIS. An optimal curvature and length of arc-shaped elements provide a resolution of about 3 mm in the plane perpendicular to the image plane, so that thin frontal slices of the breast can be visualized. Full-field-of-view 3D images can be reconstructed by fusing 60 2D slices.

34.8 High-Resolution Subsurface Imaging in Scanning Mode

In a continuous effort to develop an imaging modality with better spatial resolution applicable to sensitive detection of a variety of cancerous lesions, we have designed the optoacoustic front-surface transducer (OAFST), which operates in the backward mode, i.e., detects acoustic profiles at the site of laser irradiation.^{6,11,30,36} A feasibility study characterizing tissue structure performed with an OAFST confirmed its utility for *in vivo* imaging of various skin lesions and cancer staging in oral cavity.^{38,44–46} An ultrawide band of ultrasonic detection realized in an OAFST yields an in-depth resolution of about 15 µm. A focused OAFST was developed to achieve lateral resolution using an OAFST comparable to an in-depth resolution.⁴⁶ The new transducer design is known as the confocal optoacoustic transducer (COAT). The performance of the COAT was initially tested in optically homogeneous and heterogeneous phantoms.⁴³ Experiments *in vivo* were also performed demonstrating the developed transducer's ability to image and distinguish early stages of squamous-cell carcinoma in oral mucous of golden hamsters.^{43–46}

34.8.1 Confocal Optoacoustic Transducer

The COAT provides sharp focusing of the incident optical beam and a narrow, long waist of acoustic focus in the ultrasonic detection system. The distribution of focused light and the caustic of the ultrasonic detection form the volume of monitoring for the COAT. A schematic diagram of the COAT is presented in Figure 34.15. Pulsed laser radiation was delivered to the COAT via optical fiber focused by a lens onto the tissue surface through an optoacoustic lens. Ultrasonic waves induced in tissue by laser pulses and propagating backward through the optoacoustic lens were focused with the optoacoustic lens on the ring-shaped piezoelectric detector. The combination of a flat piezoelectric transducer and an optoacoustic lens is aimed at obtaining a focused receiving ultrasonic transducer with a narrow, long waist of the focal zone directly under the irradiated tissue surface. The shape of the lens curvature allows for the transformation of a spherical acoustic wave from tissue into a planar acoustic wave without phase distortion. A charge preamplifier was used to transform acoustic transducer signals into amplified electronic signals for further data acquisition and processing.

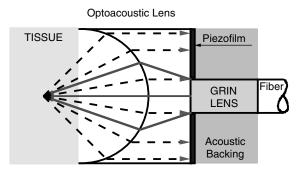

FIGURE 34.15 Principle schematic diagram of confocal optoacoustic transducer.

Laser pulses from a Q-switched Nd:YAG laser operating at the fundamental (λ = 1.064 µm) and second (λ = 0.532 µm) harmonics were used in studies of light-absorption distribution in phantoms and tissues. The temporal shape of laser pulses was close to Gaussian with full width at the max/e level $2\tau_L$ = 12 ns for λ = 532 nm. The energy of each laser pulse was measured with a calibrated Joulemeter (ED-200, GenTec, Canada). The sensitivity of the COAT permitted detection of ultrasonic waves with a SNR of 1 in tissues with an absorption of 20 cm⁻¹ while using incident laser fluence of F_0 < 1 mJ/cm², suitable for safe application in medical imaging.⁴⁵

34.8.2 Test Experiments in Tissue Phantoms

Optoacoustic imaging of human hair was carried out to demonstrate the spatial resolution of the COAT. Human hair with a diameter of 80 μ m was placed in water and irradiated with laser pulses at 532 nm. Scanning across the hair axis was performed with a lateral step of 25.4 μ m. The signals obtained were processed using absorption reconstruction, and the resulting image was created. The image is presented in Figure 34.16. The image shows the hair as a bright strip with a thickness corresponding to the thickness of the hair. The in-depth resolution was high, yielding correct reproduction of the hair thickness on the optoacoustic image. The width of the hair as defined by the optoacoustic image is several times greater than its thickness due to the relatively low angular aperture of the transducer. One may conclude from this that in confocal laser optoacoustic microscopy, the size of the image in the lateral direction will be greater than the in-depth dimension according to the angular aperture of the optoacoustic lens.

34.8.3 Noninvasive Detection of Oral Cancer in Vivo

A well-established animal model of 9,10-dimethyl-1,2-benzanthracene (DMBA)-induced squamous-cell carcinoma in oral cavity was provided for this study by Dr. M. Motamedi.⁷¹ Syrian golden hamsters weighing ~200 g were employed. The motivation for using hamster models was the development of a hamster buccal pouch carcinoma comparable to human oral cancer, as shown in References 72 and 73. DMBA solution

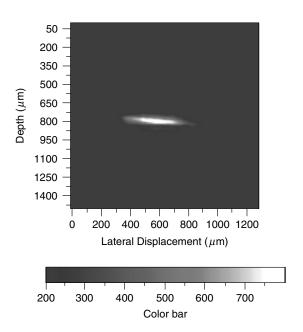

FIGURE 34.16 (Color figure follows p. 28-30.) Optoacoustic image of a human hair.

(0.5% of 9,10-dimethyl-1,2-benzanthracene dissolved in mineral oil) was applied twice a week onto the buccal mucosa of the left cheek pouch using a small brush until the first lesion was visible to the naked eye. Hamsters were euthanized and their pouches cut, stretched, and fixed with pins on a flat cork and then embedded in paraffin. Tissue sections were stained with hematoxylin-eosin (H&E). Histological sections were used as a gold standard to compare with optoacoustic images of different types of lesions and stages of squamous-cell carcinoma (from dysplasia to carcinoma *in situ* to invasive malignant lesion).

The optoacoustic-imaging procedure consisted of translating the transducer along the wet surface of pouch mucosa. Slight pressure was applied for better acoustic contact; this resulted in flattening of the irradiated tissue surface. A COAT was applied to the pouch surface with a thin water layer to provide acoustic coupling between the transducer and the tissue.

The main goal of this study was to test the feasibility of the COAT in the detection and staging of cancer in oral mucosa. ^{43–46} Previous studies performed with well-defined models of animal oral carcinoma consistently reported the following sequence of histological changes that occur in the affected pouch mucosa: (1) hyperplasia, (2) dysplasia, (3) carcinoma *in situ*, and (4) invasive carcinoma. Images presented in Figures 34.17 through 34.19 show a thin (10- to 30-µm) water layer as the top layer, so that the first mucosal surface is located at a depth of about 10 to 30 µm. The recorded signals were processed using the procedure described in Section 34.7, which converted optoacoustic signals into profiles of the absorbed optical energy and plotted on the 2D plane as 25-µm-wide columns. Thus, reconstruction of 2D images was made in hamsters in various stages of cancer development. Optoacoustic images were compared with histological microscopic sections stained with H&E.

Histological H&E sections of normal hamster cheek pouch have been described previously in the literature.^{72,73} A normal cheek pouch has several distinct layers. Figure 34.17 shows a microscopic histology section (A) and the corresponding optoacoustic image of a normal hamster cheek pouch (B). Both the histology and the OAT display distinct layers that correspond to keratinized stratified squamous epithelium (E), a very thin basal membrane separating the epithelium from mucosa of lamina propria (L), muscle-fiber mucosa (M), and submucosa connective tissue (S).

The process of cancer development leads to the gradual destruction in a layered structure of mucosa. Precancer in mucosa is characterized by hyperplasia and irregularly increased thickness of epithelium

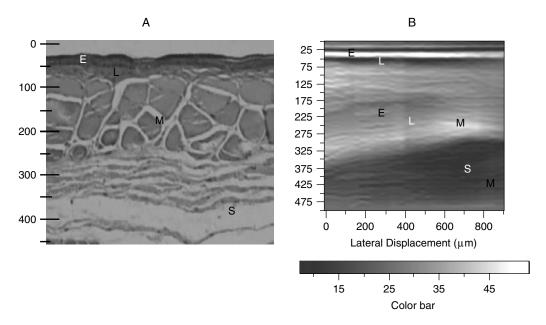

FIGURE 34.17 Histological section (A) and optoacoustic image (B) of hamster normal cheek pouch. Normal buccal mucosa pouch is characterized layered structure with distinct layers: keratin on top of epithelium (E), lamina propria (L) muscle fiber mucosa (M), and submucosa connective tissue (S).

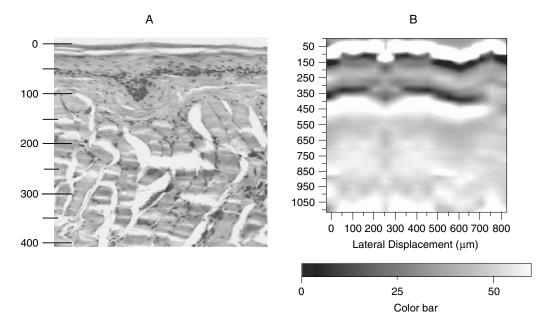

FIGURE 34.18 Histology section (A) and corresponding optoacoustic image (B) of microscopic tumor dysplasia in a hamster cheek pouch.

without, however, the layered structure being compromised. An early stage of cancer, dysplasia, is characterized by a more prominent thickening of the epithelium layer with rare and irregular breaks in the layered structure, formed by the local accumulation of epithelial cells with larger nuclei and a higher concentration of nuclei. These abnormal epithelial cells start proliferating into deeper mucosal layers. A histological section of dysplasia is depicted in Figure 34.18A. The optoacoustic image presented in Figure 34.18B shows a focal point of dysplasia. The epithelium layer looks normal around the microscopic region with dysplasia.

Figure 34.19A presents a histological section and optoacoustic image of a hamster pouch treated with DMBA for 6 weeks. At this time microscopic malignant lesions proliferating into deeper layers as fingers could be found throughout the treated area. The optoacoustic image in Figure 34.19B shows partial loss of the layered tissue structure with local invasions of epithelial cells into deeper mucosa and irregularly shaped areas in mucosa of lamina propria. Further progression of carcinoma development was observed in all animals by the presence of invasive carcinoma, which was detectable by the naked eye.

34.8.4 Advantages and Limitations of the Confocal Optical Transducer

The COAT represents a new technology for 2D imaging of layered tissue structure *in vivo*. This transducer combines a focused optical system for laser irradiation of tissue and a focused piezoelectric detection system operating in the ultrasonic band of 1 MHz to 100 MHz. The axial (depth) resolution of the transducer is 18 μ m for biological tissue. Lateral resolution is not worse than 60 μ m at a depth of up to 600 μ m. The major advantage of the COAT over the OAFST is improved lateral resolution over the range of depths in tissue from 0 to 1.5 mm. A deconvolution procedure for reconstruction of absorbed-energy distribution was developed and tested yielding a satisfactory accuracy of quantitative analysis.

Confocal optoacoustic imaging is sufficiently sensitive to depict structural changes in mucosa tissues much earlier than any changes could be detected on the tissue surface with the naked eye. Furthermore, optoacoustic images yield information on subsurface tissue structure that closely resembles structures provided by the optical microscopy of histology sections. Microscopic dysplasia can be differentiated from normal mucosa, and carcinoma *in situ* can be differentiated from dysplasia. Changes associated

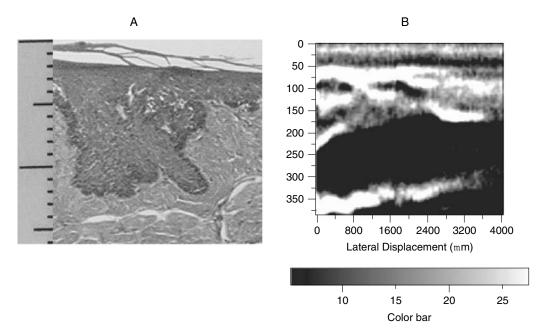

FIGURE 34.19 Histology section (A) and an optoacoustic image (B) of carcinoma *in situ* of a hamster cheek pouch. Embedding in parafin resulted in some mismatch of H&E image relative to COAT image.

with gradual cancer development could be characterized as a transformation of a tissue-layered structure into a heterogeneous structure. The nature of the optoacoustic contrast in mucosa and carcinoma must be established to enhance further the imaging sensitivity. We speculate that one factor contributing to the differentiation of cancer is the tumor angiogenesis network of microscopic blood vessels. The results from the *in vivo* study suggest that COAT may have applications for imaging, monitoring, and guiding biopsy.

34.9 Summary and Conclusions

About a decade ago our group began basic research and development of laser optoacoustic imaging systems for cancer detection in various organs. Presently, LOIS is being evaluated in patients with breast cancer, and COAT is being tested in an animal model of oral cancer. Future advancements of LOIS are envisioned in the direction of developing diagnostic utility and improved imaging parameters (sensitivity and resolution), accommodating the needs of continuous monitoring for ambulatory subjects, including those with implants, and in producing displays that intelligently combine structural, chemical, and functional information. Emphasis continues to be on maximizing accuracy of quantitative information, minimizing image-acquisition and processing time and costs, eliminating patient discomfort, and improving ease of image interpretation. The estimated manufacturing cost of the laser optoacoustic imaging system will not exceed the cost of an ultrasound imaging machine. The affordable price of LOIS and its portability will permit utilization of optoacoustic technology in diagnostic clinics. The application of low-level nonionizing NIR radiation will allow for continuous, safe, and frequent screening. The noninvasive diagnostics is painless and much less expensive than biopsy. In addition, LOIS can be used for image-guided biopsy and image-guided therapy, especially for monitoring the effect of chemotherapy with antiangiogenesis drugs. This hybrid technology employs the most useful features of optical spectroscopy and ultrasonic imaging: nonionizing NIR radiation (to achieve maximum tissue contrast) and low-noise piezoelectric transducers for ultrawide-band ultrasonic detection (to visualize both masses of abnormal tissue and fine details of tumor microcirculation). The diagnostic capability of LOIS to noninvasively differentiate breast carcinoma, fibroadenoma, and cyst will soon be tested in a statistically

significant number of patients. LOIS promises to become the first real-time, high-resolution imaging system that uses tissue contrast based on tumor angiogenesis. Two-color OAT, being less expensive than existing methods of invasive biopsy, may provide noninvasive diagnosis. Recent breakthroughs in all-solid-state laser technology and miniaturization and integration of multifunction electronic components allow for a portable and compact design of future commercial laser optoacoustic imaging systems.

Acknowledgments

The authors would like to express their deep gratitude to Dr. Valeriy Andreev, Dr. Sergey Solomatin, Dr. Vladimir Solomatin, Ms. Elena Savateeva, and other researchers at the Optoacoustic Imaging and Spectroscopy Laboratory; Dr. Massoud Motamedi and Dr. Rinat Esenaliev from the Center for Biomedical Engineering at the University of Texas Medical Branch at Galveston; and Dr. Declan Fleming, Dr. Zoran Gatalica, Dr. Tuenchit Khamapirad, and other UTMB clinicians who contributed to the development of OAT. The authors acknowledge support from the Texas Advanced Technology Program, the National Cancer Institute, the U.S. Army Medical Research and Materiel Command, and LaserSonix Technologies, Inc., Houston, Texas.

35.1 Introduction

Medical imaging technology has experienced many major advances over the last 20 years. A number of powerful tools are now available to clinically investigate large structures in the human body. The most widespread techniques are x-ray radiography, magnetic-resonance imaging, computed tomography, and echography.

In recent years, light as a possible technique for biological tissue imaging has received much attention. In histological observations, abnormal tissues can be easily distinguished from normal ones because of differences in optical properties (optical absorption or reflection, scattering, texture). Optical imaging could therefore reveal these optical contrasts, providing additional information for medical diagnosis. In addition, light has the advantages over x-rays of being noninvasive and nonionizing. Moreover, the cost of optical-imaging techniques would likely be less than that of the most common techniques currently in use.

Biological tissues are relatively transparent in the near infrared (NIR). However, they are highly scattering media; thus, conventional optical methods are unable to provide good-quality images. To overcome this difficulty a number of techniques have been proposed: time-resolved optical imaging,^{1,2} frequency-domain optical imaging,³ and optical coherence tomography.^{4–8} These techniques have proved successful for the determination of scattering and optical-absorption distributions in biological tissues. Nevertheless, resolution is no higher than 1 cm through samples several centimeters thick. Besides these purely optical methods, hybrid techniques that combine light and ultrasounds have been proposed. They include photoacoustic imaging^{9–11} and ultrasonically modulated optical tomography.^{12–26} The basic idea is to use ultrasonic waves, which scatter much less than light waves, to provide better localization

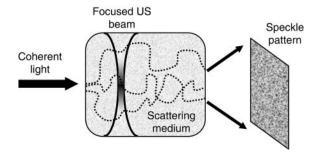

FIGURE 35.1 Schematic of AO imaging principle.

information for imaging than purely optical techniques. In ultrasonically modulated optical imaging, part of the light is modulated by an ultrasonic beam focused inside the biological tissue. Such tagged photons can be discriminated from background-unmodulated photons, and their origin can be directly derived from the position of the focused ultrasonic beam. Three-dimensional (3D) images can be built up by moving the focused ultrasonic beam. Several systems, using a single detector, have been developed.

Our laboratory has recently proposed a scheme for parallel detection using a charge-coupled device (CCD) camera as a detector array, leading to a dramatic increase in the signal-to-noise ratio (SNR). ^{17,19,21} We present here recent improvements of our ultrasonically modulated optical imaging setup. The principle of the technique is detailed and the performances are reported. In addition, 3D acousto-optic (AO) images of real biological tissues are shown. Finally, future possible developments and improvements are discussed.

35.2 The Principle of Acousto-Optic Imaging

The principle of AO imaging is schematically represented in Figure 35.1. A biological sample is illuminated by coherent laser light. Due to the highly scattering nature of the sample, a speckle field is generated everywhere around it. An ultrasound (US) beam focused on the sample induces periodic displacements of the scatterers (amplitude of a few nanometers), ^{14,15} and a modulation of the refractive index, ²⁶ mainly in the focal zone. As a result, the optical paths of light passing through the US focal zone are also modulated. Finally, the intensity of the speckle pattern is modulated at the US frequency (a few megahertz). The amplitude of the speckle modulation is directly related to the optical properties of the medium inside the US focal zone. In particular, if the optical absorption in the US focal zone is high, the probability that light will escape from this zone is low; consequently, the modulation of the speckle is low. Local differences in the optical absorption of the sample can thus be revealed. The influence of other optical properties, such as the light-scattering coefficient, is currently being studied.

A simple picture to help understand the principle of AO imaging is that of the "virtual modulated source." The tissue region where both light and ultrasound are present becomes a "virtual source," i.e., a source of modulated light that can be scanned through the sample. When it is scanned over an absorbing region, its intensity decreases. The distribution of light in the medium is roughly uniform; thus, the virtual source coincides with the US beam. The spatial resolution of this imaging technique is given by the size of the US focal zone (typically a few millimeters in diameter and several centimeters in length).

35.3 Setup

The experimental setup is shown in Figure 35.2. The sample is placed in a water tank $(20 \times 25 \times 25 \text{ cm})$ to ensure good acoustic impedance matching with the transducer. Two empty tubes closed at one end by a glass window hold the sample. In this configuration, the sample, slightly pressed between the two glass windows, presents a uniform thickness over the entire observed region, and the light paths avoid

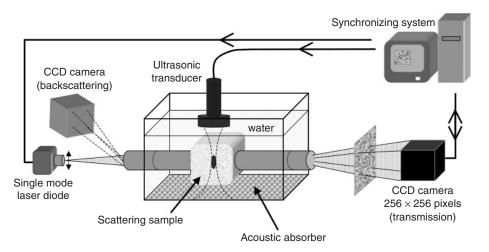

FIGURE 35.2 Experimental setup.

the water. Indeed, an experiment performed with light traveling in water had revealed that the speckle decorrelated very quickly due to water turbulence, inducing a very poor SNR. The sample is illuminated with a NIR (840-nm) single-mode laser diode (100 mW). This source was chosen for its high coherence length (several meters) and its ability to be modulated at high frequency, which is essential for our detection system (see Section 35.4 below). A diverging lens expands the light beam so that its diameter is ~2.5 cm upon entering the sample. The speckle pattern formed by the emerging scattered light is recorded on a CCD camera array of 256×256 pixels. The camera can be placed either opposite to the laser diode (transmission configuration) or close to it on the same side (backscattering configuration). The results in both configurations are compared in Section 35.5. The average diameter of a speckle grain on the CCD is $\phi_s \approx \lambda \, d/r$, where λ is the laser wavelength (840 nm), d is the distance between the exit face of the sample and the camera, and r is the effective radius of the aperture through which light exits the sample (1.4 cm). We match the speckle grain size to the pixel size (16 μ m × 16 μ m) to exploit the modulation of each speckle grain separately by adjusting the distance between the camera and the sample (d = 30 cm; we varied this distance to experimentally check the computed optimum value). However, with very thick samples we reduce the sample-to-camera spacing to collect light more efficiently.

The focused ultrasonic beam is emitted perpendicular to the incident-light beam. We have used two different acoustic transducers. The first one is a simple transducer of fixed focal length (69 mm) driven by a sinusoidal signal. The second one consists of eight independent concentric rings, each driven by its own electronics board. The operating frequency is 3 MHz. The focal length is varied electronically by suitable phase shifts of the otherwise identical driving waveforms. This transducer is mounted on a motorized angular rotation. This more sophisticated transducer can emit in both continuous wave (CW) and pulsed modes. The CW mode enables us to make AO images (as with the first transducer). In pulsed mode, the repetition rate is ~1 kHz. Each pulse typically contains two US periods (duration ~0.7 μ usec at 3 MHz). The transducer also acts as a receiver for the echoes of the pulse. When its angular motor is at rest, the transducer records the echoes of the pulse along the focused US beam. By scanning the emitter angularly step by step and repeating the same process at each step, we can reconstruct a 2D image of the acoustic properties of the medium. In this mode (the "B mode" of echography), where the amplitude of the echo is converted into brightness of the spot on a gray scale, we obtain an echographic 2D section of the medium ($\approx 4 \times 4$ cm) in about 0.1 sec. Suitable software allows discrete scanning of the US focus over an array of preselected locations as well as the acquisition of CCD camera frames at each of these locations.

By scanning a calibrated hydrophone in front of the second transducer, we mapped the pressure field emitted in water (Figure 35.3). The full width at half maximum (FWHM) of the focal zone is measured to be 1.4 mm transversely and 12.5 mm along the axis. Moreover, the US beam outside the focal zone

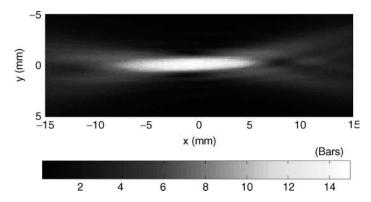

FIGURE 35.3 Map of pressure field emitted by ultrasonic transducer (right).

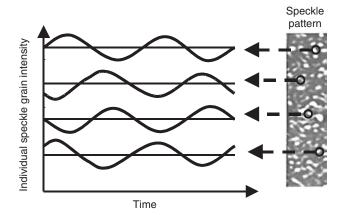

FIGURE 35.4 Evolution in the intensity of individual speckle grains.

also contributes somewhat to the speckle modulation. Consequently, while the resolution is very sharp in any direction transverse to the US beam, it is somewhat lower in the axial direction.

35.4 Parallel Multichannel Lock-In Detection

As explained above in Section 35.2, our aim is to detect the AO modulation of the speckle by ultrasound. As mentioned years ago by other authors, 15 "perhaps the most striking feature of AO imaging is the fact that the signal essentially resides in a single coherence area." Consequently, detecting simultaneously yet independently the modulations in a large number N of coherence areas (or "speckle grains") improves the SNR by a factor \sqrt{N} . We have chosen the 256×256 pixels of a CCD array camera as the N independent detectors. We set the sample-to-camera spacing to match the coherence area of the speckle to the size of a pixel. On each pixel we detect the amplitude of the modulation at the US frequency. We define our signal as the sum of N amplitudes. (Note: Since the relative phases of their modulations are random, if several coherence areas were matched to one single pixel, the sum would cancel out on the average [see Figure 35.4]).

In experiments where a single grain of speckle is detected by a single detector, the signal is usually analyzed with a lock-in amplifier. This extraction of the amplitude (and eventually of the phase*) of the modulated part of the signal can also be achieved by sampling and applying the discrete Fourier transform. Because we are dealing with 256×256 individual detectors, we will, of course, use the second approach.

^{*}The phase of each pixel is of little interest here. It is, however, convenient for testing the system.

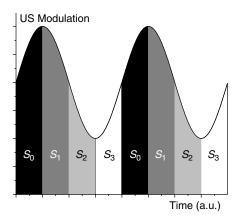

FIGURE 35.5 Principle of light chopping.

Using a CCD camera as a parallel detector raises two points of concern. First, it is an integrating detector; second, it has a limited frame rate (thus a low sampling frequency). Integration by the camera can be treated as a filtering process, and the computation of the amplitude from the integrated samples is readily carried out.

Dealing with the low frame rate requires careful mixing of the acoustic modulation and the optical-detection signals. The idea is to perform homodyne detection by modulating the laser source at the same frequency f as the acoustic transducer. Our signal is proportional to the product of the acoustic displacement by the laser intensity, and the signal detected by the CCD camera is thus the product of the two waveforms: the sum of a direct current (DC) component and a harmonic component at frequency 2f.

Comparing this method with conventional lock-in amplifier detection, our reference is the driving voltage of the ultrasonic emitter, our mixing is performed by the AO effect,* and the CCD camera is both the (multichannel) detector and the output filtering stage. The last component we need to emulate is the phase shifter. In our system, the phase shifter is implemented in the electronic chopping of the laser beam. This slightly tricky chopping is illustrated in Figure 35.5.

The electronic system (which may be called a sequencer) relies on a master clock that actually oscillates at frequency 4f. The idea is to switch the laser on during one period of this master clock (one quarter period of the signal) and off during the three remaining quarters. This goes on for a preselected number K of signal periods. The frame is then read, yielding the sum of the signals integrated over quarter periods, denoted by S_1 in Figure 35.5. For the next K periods the laser is on during the next quarter S_2 , then a frame is read again. We proceed similarly for the third and then fourth quarter, S_3 and S_4 , respectively.

Let S_1 , S_2 , S_3 , and S_4 denote the signals acquired on a given pixel during these four consecutive sequences of K periods each. It is not difficult to show that the amplitude A of the modulation seen by the considered pixel is (except for some unimportant constant factor) given by:

$$A \propto \sqrt{\left(S_1 - S_3\right)^2 + \left(S_2 - S_4\right)^2}$$
 (35.1)

A final point of concern in our implementation of this technique is the limited dynamic range of the CCD camera. The 8-bit resolution of the analog-to-digital converter is insufficient because the rounding-off noise (1 over 255 for 8 bits) is unacceptably high. However, it is well known that, provided some other noise of the order of the rounding-off noise is present, accumulating *K* periods in one frame reduces

^{*}Consequently, in this method the mixing is performed not by an electronic instrument but by the studied physical system. In addition, there is only one "mixer," and the multichannel character appears only at the level of the "output-filtering and detection" stage, i.e., the 64K pixels of the CCD camera.

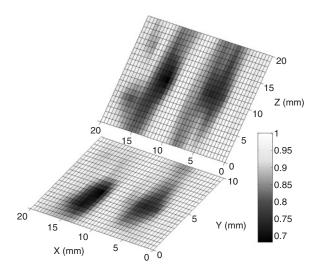

FIGURE 35.6 AO 2D images of two absorbing spheres embedded in a turkey breast sample. The upper section was recorded along the direction of US propagation. The lower section was recorded in a plane perpendicular to the US beam. Note that the axes are different.

the rounding-off noise by a factor \sqrt{K} . In other words, summing over K periods increases the effective dynamic range by a factor of \sqrt{K} .

At first glance, it seems that *K* should be as large as possible, but in practice, there is a trade-off between this effective dynamic range and other limitations. First, in our sequencer scheme, the sum over *K* periods is performed by the CCD camera itself through the integration of the signal. The number of periods is thus limited by the saturation of the camera. Second, the total measurement time (4*K* times the frame-acquisition time) must remain short enough to limit drifts in the signal.

35.5 Results

35.5.1 Samples

We worked mainly with two kinds of samples: turkey breast tissue and artificial phantoms ranging in thickness from 1 to 4.5 cm. The latter consist of a gelatin, in which agar grains are embedded to create small ultrasonic reflectors, and a latex, i.e., a suspension of polystyrene microspheres (diameter 220 nm), to scatter light. By varying the concentration of the latex we can change the scattering coefficient of the medium and adjust the acoustic properties of the medium by changing the gelatin and the agar concentrations. The advantages of these artificial phantoms are their homogeneity and their well-controlled properties. However, we believe that biological tissues should also be studied to tackle the concrete problems they will raise. This is why most of our experiments were performed on turkey breast samples, whose optical properties have already been studied.²⁸ Despite the absence of blood circulation in such samples, we believe they provide more realistic conditions than artificial phantoms.

35.5.2 Validation of the Principle on Simple Structures

Our first experiments were performed on turkey breast tissues in which we embedded artificial absorbing objects (dark ink or soft modeling clay). Figure 35.6 shows two 2D AO sections of a 35-mm-thick turkey breast sample in which were embedded two small absorbing spheres of soft modeling clay (3-mm diameter). One section was recorded scanning the US transducer along the direction of the US beam, and the second one perpendicular to it. The two absorbing spheres are clearly revealed on both images. However, the spatial resolution is very different. This is due to the shape of the US beam, which is much longer than it is wide, as discussed in Section 35.3.

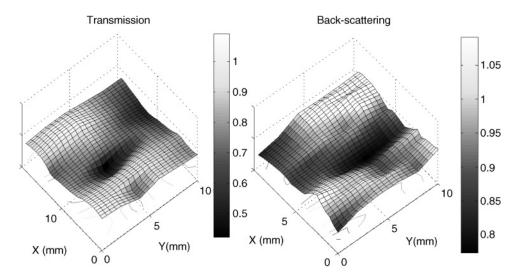

FIGURE 35.7 AO 2D images of an absorbing sphere embedded in a turkey breast sample recorded in transmission (left) and backscattering (right) configurations.

35.5.3 Validation of the Backscattering Configuration

In its current state, our setup is obviously not appropriate for making a real medical apparatus. In particular, the transmission configuration might be difficult to implement on thick organs. That is why we wanted to validate the backscattering configuration, where the light source and the detector were on the same side of the sample. 22,24 Figure 35.7 compares results recorded in transmission (left) and backscattering (right) configurations. The studied object was an absorbing sphere (\emptyset 3 mm) buried 10 mm deep inside a 35-mm-thick turkey breast sample. On both images the buried structure is clearly revealed at its actual position. However, the reconstruction of the image is more difficult in the backscattering configuration because we must take into account the decrease of the modulated light with increasing depth. Moreover, in the backscattering configuration, the sphere appears larger in the depth direction than its actual size. We believe this is a shadow effect: the photons have a low probability of reaching the region just behind the sphere and traveling back to the detector without being absorbed.

35.5.4 Intrinsic Structures in Biological Tissues

We also performed some experiments on *ex vivo* animal or human tissues presenting intrinsic contrasts. We revealed an unexpected naturally present white structure (probably a ligament) in a 2-cm-thick turkey breast sample. Figure 35.8A shows a picture of the sample after dissection, and Figure 35.8B shows the AO 2D image. The size of the imaged ligament agrees with its actual size measured after dissection (~3 mm).

We studied an *ex vivo* human womb presenting tumorous tissues. Figure 35.9 shows the image of the organ and an AO section taken along the black line. On the picture, the normal tissues appear darker than the abnormal ones. On the AO image, the normal, darker tissues yield a lower AO signal because they are more absorbent.

35.5.5 Comparison of the Acoustic and Acousto-Optic Contrasts

The second, more sophisticated, transducer (see Section 35.3) enabled us to study the origin of the AO contrast on various samples. In fact, AO contrast can originate in optical contrast (as explained in Section 35.2) or in mere acoustic contrast. If an US-absorbing structure is present in front of the acoustic beam, this will decrease the AO signal and can be misinterpreted as a light-absorbing structure. Our transducer

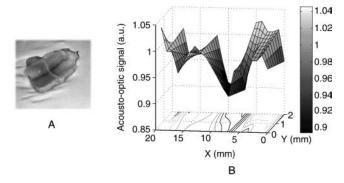

FIGURE 35.8 Detection of a white filament in a turkey breast sample. (A) Sample after dissection. (B) AO image of the sample before dissection, where the ligament is clearly revealed.

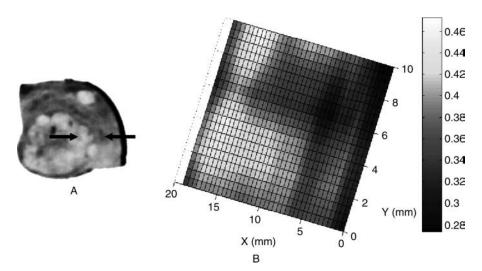

FIGURE 35.9 AO contrast of tumorous tissues on a human female womb. (A) Picture of the organ where the abnormal tissues appear darker than the normal ones. (B) The AO image shown was recorded in a plane perpendicular to (A) between the two arrays.

enables us to distinguish between these two possibilities by looking at the echographic, i.e., purely acoustic, image of the studied samples.

We performed a simple experiment on turkey breast samples in which we embedded a small cylinder (Ø 7 mm, length 30 mm) absorbing either light or US. The light-absorbent structure consisted in a turkey core that was colored with black ink and inserted back inside the sample. The US-absorbent cylinder was made of tough modeling clay. Figure 35.10 presents the comparison between the echographic 2D images and the AO profiles taken along the dotted lines for both objects. In the first case (modeling clay cylinder), the structure is clearly revealed by the echography. There the AO contrast is either a purely acoustic contrast or a combination of acoustic and optical contrast. In the second case (blackened turkey cylinder), the echographic image does not reveal any contrast. On the contrary, the cylinder is revealed by the AO scan. Here we can be sure that the AO contrast is purely optical. However, the contrast in the second case is poor.

35.5.6 Visualization of the "Virtual Modulated Source"

We can directly visualize the "virtual modulated source" (defined in Section 35.2) using a slight variant of the setup described above. We simply insert an objective in front of the CCD camera to image the exit

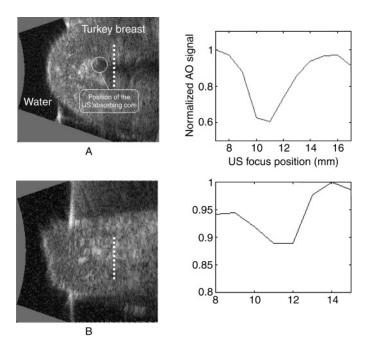

FIGURE 35.10 Comparison of echographic 2D sections (left) and AO profiles (right), for a US-absorbent cylinder (A) and a light-absorbent cylinder (B) embedded in a turkey breast sample. The AO profiles were recorded by scanning the US beam along the dotted white line.

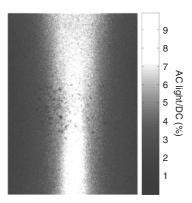

FIGURE 35.11 Distribution of the modulated light on the exit face of a scattering sample, normalized by the distribution of the DC light. This representation shows the "virtual modulated source" brought close to the exit face.

face of the sample on the CCD array. Moreover, now we look at the spatial distribution of this modulation on the exit face. We typically divide the CCD array into 40×40 squares of 6×6 pixels each, and we extract the modulation amplitude in each square separately (i.e., for each square, we sum the amplitudes of the 36 pixels). We thus obtain a map of the modulated light emerging from the sample. If we bring the US beam close to the exit face, the light coming from the modulation zone barely scatters before exiting the sample; thus, we obtain directly an image of the modulation zone. Figure 35.11 shows the distribution of the modulated light normalized by the distribution of the unmodulated light (the normalization avoids effects due to the nonuniform distribution of light in the medium). A shape very similar to that of the acoustic pressure field is apparent.

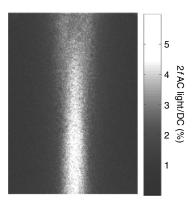

FIGURE 35.12 Visualization of the virtual modulated source at frequency 2f = 6 MHz. Comparison with Figure 35.11 shows that the size of the virtual source is noticeably reduced.

35.6 Prospects and Conclusions

Due to the shape of the US beam, the spatial resolution in the axial direction is lower than in the transverse direction. Furthermore, the contrast of structures that are small with respect to the US volume is low, as can be seen in Figure 35.10. To improve these two aspects, the ideal solution would be to use pulsed ultrasounds whose length (usually about two US wavelengths) determines the axial resolution. To our knowledge, this approach has not yet been used for thick light-scattering media or biological tissues. One alternative method, developed by Wang et al., 18,23 is to use a frequency-swept ultrasonic wave. Nevertheless, the contrast and the SNR must be improved to make this approach suitable for thick samples.

We have begun to explore another approach using the nonlinear response of the system. ²⁹ We expect AO nonlinear signal generation to be restricted to a region of sufficiently high acoustic pressure, i.e., to a region smaller than that of the linear signal. A second harmonic AO signal (f = 6 MHz) varying as the square of the ultrasonic amplitude has been found. The virtual source at this second harmonic frequency is smaller than that at the fundamental frequency, as shown in Figure 35.12.

The next step we foresee is to use two crossed beams and detect the AO signal at the beat frequency. When that happens, we expect the AO signal to come mainly from the small crossed zone.

To conclude, an AO imaging technique has been used to detect artificial and intrinsic optical contrasts through biological tissues several centimeters thick with a millimetric resolution. The first results of experiments on human *ex vivo* tumorous organs are very encouraging with regard to medical applications. Moreover, the preliminary experiments using the AO second harmonic signal open the door to a new way of improving both the contrast and the resolution of this technique.

Acknowledgments

The authors thank the personnel of Laboratory of Waves and Acoustic, ESPCI, for their collaboration, especially in characterizing the pressure field. They also thank D.A. Boas from Massachusetts General Hospital for fruitful discussions on the concept of the virtual source. They are grateful to PRL Corélec³⁰ for the design of a specific transducer. Financial support from the French Ministry of National Education, Research and Technology (grants 99 B 0510/0512/0513) is gratefully acknowledged.

36.1 Introduction

Photodynamic therapy (PDT) exploits the biological consequences of localized oxidative damage inflicted by photodynamic processes. A schematic outline of the major steps that lead to tumor destruction by PDT is given in Figure 36.1. Three critical elements are required for the initial photodynamic processes to occur: a drug that can be activated by light (a photosensitizer), light, and oxygen.¹ Interaction of light at the appropriate wavelength with a photosensitizer produces an excited triplet-state photosensitizer that can interact with ground-state oxygen via two different pathways, designated as Type I and Type II. The individual steps of these pathways are shown in Figure 36.2. The Type II reaction that gives rise to singlet oxygen (¹O₂) is believed to be the dominant pathway because elimination of oxygen or scavenging of ¹O₂ from the system essentially eliminates the cytocidal effects of PDT.².³ Type I reactions, however, may become important under hypoxic conditions or where photosensitizers are highly concentrated.⁴ The highly reactive ¹O₂ has a short lifetime (<0.04 msec) in the biological milieu and therefore a short radius of action (<0.02 μm).⁵ Consequently, ¹O₂-mediated oxidative damage will occur in the immediate vicinity of the subcellular site of photosensitizer localization. Depending on photosensitizer pharmacokinetics,

Photodynamic Effects $|P+| \text{light} \rightarrow {}^{3}P + {}^{3}O_{2} \rightarrow |O_{2} + S \rightarrow S(O)$ Tumor Immune Effects Necrosis Apoptosis Macrophages Neutrophils Immature Dendritic Cells Vascular Effects Vascular Effects Clotting and Hemorrhage

FIGURE 36.1 Illustration of the three major tissue targets affected by the photodynamic effect. Tumor cells can be damaged or killed directly by the effects of singlet oxygen generated within them, succumb to oxygen and nutrient deprivation due to vascular damage inflicted by PDT, or be attacked by the inflammatory/immune system activated by PDT.

these sites can be varied and numerous, resulting in a large and complex array of cellular effects. Similarly, on a tissue level, tumor cells as well as various normal cells can take up the photosensitizer, which upon activation by light can lead to effects on such targets as the tumor cells proper, the tumor and normal microvasculature, and the inflammatory and immune host system. PDT effects on all these targets may influence each other, producing a plethora of responses; the relative importance of each has yet to be fully defined. It seems clear, however, that the combination of all these components is required for long-term tumor control.

36.2 Subcellular Targets for Photosensitization

The potential cellular targets of PDT are shown schematically in Figure 36.3. They depend on the specific pharmacokinetic characteristics, such as lipophilicity, amphiphilicity, aggregation, and serum protein interactions (see Reference 1 for a review) and, therefore, the localization, of the photosensitizer but appear to be largely independent of cell type (Table 36.1). Localization studies have generally been carried out in *in vitro* cell systems where exposure conditions to the photosensitizer can be easily controlled or varied. Such studies have revealed that cellular photosensitizer distribution can be a dynamic process, influenced by such parameters as length of exposure and drug concentration.^{6–8} Photosensitizers may even relocalize after photodamage to an initial site of accumulation such as from lysosomes to other, possibly more sensitive, cellular locations, where they will then be available for activation.^{9,10} That subcellular localization of a photosensitizer, and consequently the target of PDT, may influence *in vivo* treatment outcome was demonstrated in a series of studies that related structure and activity of a

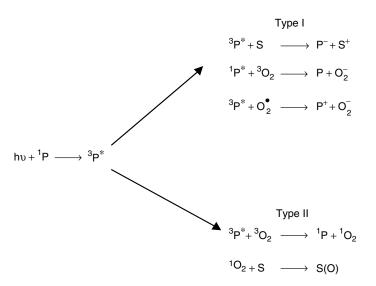

FIGURE 36.2 Photoreaction pathways emanating from the interaction of a photosensitizer with light where ${}^{1}P$ is a photosensitizer in a singlet ground state, ${}^{3}P^{*}$ is a photosensitizer in a triplet excited state, S is a substrate molecule, ${}^{9}P^{-}$ is a reduced photosensitizer molecule, ${}^{9}P^{+}$ is an oxidized substrate molecule, ${}^{3}O_{2}$ is molecular oxygen (triplet ground state), ${}^{9}P^{-}$ is the superoxide anion, ${}^{9}P^{+}$ is the superoxide radical, ${}^{9}P^{+}$ is the oxidized photosensitizer, ${}^{1}P^{-}$ is oxygen in a singlet excited state, and S(O) is an oxygen adduct of a substrate. FIGURE 36.4 Relationship of the log median time of tumor regrowth to 400-mm³ tumor volume to log P for a series of congeneric pyropheophorbide photosensitizers and to their subcellular distribution. Optimal compounds accumulate in mitochondria, suboptimal compounds in lysosomes. (From Henderson, B.W. et al., *Cancer Res.*, 57, 4000, 1997. With permission.)

Comparison of the subcellular localization of the most and least active compounds in the series revealed mitochondrial localization for the former and lysosomal localization for the latter. Nevertheless, such less active compounds can be very effective photosensitizers because the lack of sensitivity can be compensated with higher dosing, provided that treatment selectivity can be maintained.

36.2.1 Mitochondria

Although the first-generation photosensitizer Photofrin® and its forerunners are chemically heterogeneous and therefore exhibit heterogeneous subcellular distributions,⁷ the major target also appears to be the mitochondria.^{12–15} The development of chemically pure and well-defined photosensitizers and

the use of 5-aminolevulinic acid (ALA) for the intramitochondrial generation of photosensitizing protoporphyrin IX (PpIX)^{16,17} have allowed the targeting of specific subcellular sites and the analysis of the relative sensitivity to photodamage of these sites^{18–21} (also see Table 36.1). Again, the mitochondria have emerged as especially sensitive targets. Recent interest has focused on the mitochondrial permeability transition pore, a protein complex consisting of hexokinase, the peripheral benzodiazepine receptor (PBR), the voltage-dependent anion channel (VDAC), creatinin kinase, the adenine nucleotide translocator (ANT), and cyclophyllin D. Several of its components have been implicated as PDT targets.^{22–29}

36.2.2 Lysosomes

Hydrophilic or highly aggregated sensitizers may be taken up by pinocytosis or endocytosis and therefore accumulate in cytoplasmic vesicles.^{8,9,18,30} While PDT-induced rupture of lysosomes and release of damaging hydrolytic enzymes into the cytoplasm have been described,^{30,31} it appears now that lysosomes per se are not very effective targets for PDT.^{8,18} In a recent study, selective lysosomal photodamage that was associated with release of cathepsin B was followed by a gradual loss of mitochondrial membrane potential, release of cytochrome *c* into the cytosol, caspase 3 activation, and a limited apoptotic response.³² Thus, lysosomal damage may secondarily mediate mitochondrial damage. It has also been suggested that lysosomes might serve as reservoirs from which photosensitizers may be released after vesicle rupture and migrate to more sensitive sites.⁹ All these studies assume that initial sensitizer accumulation is restricted to the lysosomes, but it is still possible that high lysosomal concentration may mask small but highly effective sensitizer accumulations at other sites.⁸

36.2.3 Nucleus

Photosensitizers used in PDT generally do not accumulate in the cell nucleus, and therefore frank DNA damage, such as strand breaks, sister-chromatid exchanges, and chromatid aberrations, are much less frequently observed in PDT than in ionizing or UV irradiation.^{33–35} Consistent with these findings, the mutation potential of PDT was found to be significantly less than that of ionizing radiation or UV.³⁶

36.2.4 Plasma Membrane

The plasma membrane may become a target of PDT, especially if the sensitizer is highly lipophilic and the incubation time of cells *in vitro* is brief. Membrane damage manifests itself rapidly through blebbing^{20,37} as well as leakage of cytosolic enzymes^{38,39} and chromium.⁴⁰ Leakage of lactate dehydrogenase (LDH) showed the same kinetics as generation of prostaglandin E₂ from tumor cells *in vitro*, directly relating membrane disruption to production of eicosanoids.³⁹ The biosynthesis of eicosanoids, which play an important role in mediating the PDT tissue response (discussed below), is set in motion when phospholipases catalyze the liberation of free fatty acids from membrane phospholipids. Unsaturated phospholipids and cholesterol are important membrane targets of photodamage, and lipid peroxidation by PDT has been extensively studied and linked with cell lethality.^{41,42} Oxidation of intrinsic membrane proteins⁴³ and protein crosslinking⁴⁴ have also been observed. PDT can inhibit the plasma-membrane enzymes Na⁺K⁺-adenosine triphosphate (ATPase) and Mg²⁺-ATPase.⁴⁵ Ca²⁺ flux may be affected, and the plasma membrane may become depolarized.⁴⁶ Certain membrane-localized photosensitizers, such as mesotetraphenylporphines (TPPSs), can destroy microtubules in interphase cells and lead to arrest of cells in mitosis.^{31,47}

36.3 Mode of Cell Death

PDT can induce cell death via either the apoptotic or necrotic pathways.⁴⁸ Necrosis is metabolism-independent and a result of a massive insult. In contrast, the apoptotic pathway is an intrinsic physiological process that is dependent on active cellular metabolism and characterized by chromatin condensation, DNA

fragmentation, and the formation of apoptotic bodies.⁴⁹ The dominant mode of cell death depends on the photosensitizer used, the localization of the photosensitizer, and the treatment protocol.¹ Dellinger⁵⁰ demonstrated that increasing the drug incubation time prior to administration of light altered the mode of cell death induced by Photofrin-PDT; longer incubation times (1 d) resulted in apoptosis, while shorter incubation times (1 h) induced necrosis. The cellular localization of Photofrin changes with incubation time, moving from the cell membrane to the nucleus as the incubation time increases.⁸ Similar results have recently been published for zinc II phthalocyanine (Pc).⁵¹ Studies by Kessel and Luo¹⁹ demonstrated that photosensitizers that localize to the mitochondria (porphycenes PcM and PcD) resulted in apoptotic cell death, while those that localize to the lysosome (chlorin LCP) or cell membrane (cationic porphyrin, MCP) did not. Kessel et al.⁵² also demonstrated that photodamage of the cell membrane may inhibit the induction of apoptosis by photodamage to the mitochondria. These results were confirmed by Luo and Kessel,⁵³ and this study also demonstrated that the mode of cell death shifts in response to the photodynamic dose such that high doses result in a necrotic cell death, while lower doses result in an apoptotic mode of death.

The kinetics and extent of PDT-induced apoptosis also vary with photosensitizer and cell type treated.^{52–57} Photodynamic treatment of L5178Y murine lymphoma cells with ClAlPc resulted in apoptosis within 30 min of treatment.⁵⁷ Treatment of the lymphoma line P388 with ClAlPc or tin etiopurpurin (SnEt₂), which localize to the lysosome and the mitochondria, induced apoptotic nuclei within 1 h.^{52,53} However, treatment of the same cell line with tin octaethylpurpurin amidine, which localizes to the mitochondria, the lysosome, and the cell membranes, did not result in apoptotic nuclei until 24 h after treatment.

The rapid induction of apoptosis suggests that PDT triggers late-stage apoptotic processes directly. Release of cytochrome c from the mitochondria triggers caspase 3 activation and results in initiation of apoptosis at a late stage in the pathway. Solution control of release is associated with a loss of mitochondrial potential. PDT results in the loss of mitochondrial potential and the rapid release of cytochrome c. Several studies have demonstrated that PDT also induces rapid activation of caspases 3, 6, 7, and 8 and cleavage of poly(ADP-ribose) polymerase (PARP). Solution Solution Solution for the late shown that PDT-induced release of cytochrome c is sufficient to directly initiate a caspase-dependent apoptotic cell death. However, a recent study by Xue et al. Indicates that while caspase 3 is required for the late stages of apoptosis, it is not the critical lethal event in PDT-induced apoptosis.

Bcl-2 has been shown to block the release of cytochrome *c* from the mitochondria and thus prevent apoptosis. ⁵⁸ Several groups have altered the expression of bcl-2, through overexpression or antisense technology, and demonstrated that increasing the levels of bcl-2 enhances cellular resistance to PDT-induced apoptotic cell death. ^{67–70} Xue et al. ⁷¹ have demonstrated that Pc 4-PDT results in photochemical destruction of bcl-2. Similar results have been reported for AlPc-PDT. ⁷² Interestingly, a study by Kim et al. ⁷² reported that overexpression of bcl-2 enhanced the apoptotic response. In these studies, overexpression of bcl-2 was accompanied by an increase in bax, a proapoptotic member of the bcl-2 family. PDT resulted in the selective destruction of bcl-2 but had no effect on bax. The greater apoptotic response in the cells overexpressing bcl-2 was attributed to a higher bax:bcl-2 ratio after PDT. A PDT-induced shift in the bax:bcl-2 ratio toward apoptosis has also been reported by others. ^{67,73}

PDT also affects other proteins implicated in apoptosis. Phospholipases C and A₂, which are involved in the transient increases in intracellular calcium levels and DNA fragmentation, are activated by Photofrin-PDT.⁷⁴ The apoptotic-associated protooncogenes c-jun and c-fos are also activated by PII-PDT.⁷⁵ Ceramide, which has been linked to apoptosis in several malignant cell lines, accumulates following PDT and has been associated with PDT-induced apoptosis and cytotoxicity.⁷⁶ Gupta et al.⁷⁷ have demonstrated that Pc 4-PDT induces expression of nitric oxide and suggested that it may be involved in PDT-induced apoptosis. Finally, the tumor-suppressor gene p53, which can force damaged cells into the apoptotic pathway, is associated with Photofrin-PDT resistance,^{78,79} although there have been dichotomous reports on the role of p53 in PDT sensitivity.⁸⁰

36.4 Molecular Mechanisms

Alterations in gene expression are generally due to changes in the molecular mediators present in the cell. PDT has been shown to alter the expression of several molecular mediators including the redox-regulated transcription factor, AP-1.81,82 AP-1 is induced by changes in the redox potential83-85 and hypoxia.86 It is composed of homodimers of the products of the c-jun gene family or heterodimeric combinations of c-jun and c-fos family members. PDT induces prolonged expression of both c-fos and c-jun as a result of oxidative stress.75,87 Therefore, modulation of AP-1 activity by PDT might be mediated by changes in oxidative potential as a result of the generation of singlet oxygen or PDT-induced hypoxia.

NF-κB plays a critical role in the expression of immunomodulatory and proinflammatory genes. Rectivated NF-κB is a heterodimeric protein most commonly comprised of the p50 and p65 (Rel A) species. It is also activated in response to cellular oxidative stress. PNF-κB is sequestered in the cytoplasm by IκB proteins; phosphorylation of IκB results in its proteosomal degradation and release of NF-κB. P0,91 NF-κB binding activity was found to be induced by PDT P2-94 and has been proposed to play a role in determining the cellular response to PDT. For Granville et al. P2 demonstrated that cellular levels of IκB were transiently depressed following Verteporfrin PDT. Pyropheophorbide-a methyl ester-PDT also leads to IκB degradation. In contrast to these studies, other groups have failed to demonstrate NF-κB activation following Photofrin-PDT. Thus, NF-κB activation may be photosensitizer specific. It has also been suggested that activation is related to PDT dose because higher doses do not result in decreases in IκB. P2

In addition to AP-1 and NF-κB activation, PDT has been shown to stimulate stress-kinase-signaling pathways (SAPK/JNK, p38/HOG1)^{96,97} and HS1 phosphorylation,⁹⁸ as well as stress-response transcriptional activators. HIF-1 (hypoxia inducible factor-1) is a key regulator of the cellular response to hypoxia and induced in response to PDT.^{99,100} PDT also enhances the expression of the HIF-1 target gene, vascular endothelial growth factor (VEGF),¹⁰⁰ and it has been proposed that HIF-1 expression may act as a predictor of PDT responsiveness.⁹⁹ Finally, PDT also activates the heat-shock-protein (HSP) family promoters¹⁰¹ and induces the expression of HSPs and the related glucose-regulated proteins^{102–106} as well as heme oxygenase (HSP 32).¹⁰⁷

36.5 Tissue Targets of Photosensitization

36.5.1 Tumor Cells

The ability of PDT to eliminate tumor cells through direct photodamage has been most effectively studied by in vivo-in vitro tumor-explant methodology.¹⁰⁸ Such in-depth analysis has revealed that the full potential of direct photodynamic tumor-cell kill, provided by the gross tumor-photosensitizer concentration and absorbed-light dose, is generally not realized by in vivo PDT treatment.¹⁰⁹ Clonogenic assays carried out with a number of different photosensitizers and tumor systems immediately after potentially curative PDT exposures in vivo have revealed that at most 1 to 2 logs of direct tumor-cell kill have been achieved, 110-115 far less than the 7 to 8 logs required for tumor cure. Clearly, limitations to direct tumorcell kill exist *in vivo*, the most important of which may be (1) inhomogeneous photosensitizer distribution within the tumor including a gradual decrease of photosensitizer concentration with distance from blood vessels, 116 (2) insufficient light penetration through the tissue (light is attenuated exponentially with depth of tissue penetration^{117,118}), and (3) insufficient oxygen availability (discussed below under separate heading). That intrinsic tumor-cell sensitivity contributes to the overall PDT response was suggested by studies using tumor cells selected to be resistant to PDT.119 Tumors of resistant phenotype were less responsive to PDT than sensitive tumors while exhibiting equal vascular responses. The studies did not exclude the possibility, however, that tumor immunogenicity might have differed in the two tumor lines, thereby affecting the response. On the other hand, tumors expressing a multidrug-resistance phenotype that prevented the uptake of a cationic photosensitizer were nevertheless found responsive to PDT carried out with that agent, the antitumor effect being attributed to vascular disruption.¹²⁰ Studies like these illustrate PDT's ability to exert its antitumor action through several different tissue targets.

Initial studies trying to establish a pattern of selectivity of photosensitizer uptake in malignant vs. normal cells *in vitro* were largely unsuccessful.¹²¹ *In vivo*, moderately favorable tumor-to-normal-tissue ratios can be found for almost all photosensitizers, with establishment of these ratios depending on the specific pharmacokinetics of the compound as well as the pathophysiology of the tumor (for detailed reviews see References 1, 122, and 123). Mechanisms invoked for this "selectivity" range from leaky vasculature and impaired lymphatic drainage in tumors to low tumor pH and an increase in low-density lipoprotein and other membrane receptors on tumor cells. ^{124,125} Carrier systems, such as antibody conjugates, have been designed to direct the photosensitizer directly to the tumor cells. Such immunoconjugates have been directed against epitopes on ovarian¹²⁶ and colon-cancer cells¹²⁷ as well as against the epidermal growth factor receptor (EGFR) that is overexpressed in oral precancer.¹²⁸

36.5.2 Microvasculature

The microvasculature was one of the earliest tissue targets identified because vascular PDT effects are rapid and dramatic, especially with the use of the sensitizer Photofrin and its forerunners. Reduction or cessation of tumor microcirculation following *in vivo* PDT exposure employing a variety of photosensitizers has been demonstrated in preclinical models through numerous different techniques, summarized in Table 36.2. Since the kinetics of vascular shutdown and tumor-cell death have been found to coincide^{111,129} and inhibition of shutdown retards tumor response,¹³⁰ it has been argued that disruption of the tumor microcirculation is a major factor contributing to tumor control by PDT. Differences in response between tumor and normal microvasculature are subtle and difficult to discern.¹³¹ Careful doseranging studies have revealed that the tumor vasculature is slightly more susceptible to shutdown than its normal counterpart.^{132,133} It has also been demonstrated that Photofrin-PDT at high fluence rate can protect the normal skin microvasculature, but the same treatment fails to protect tumor vessels.^{134,135} Occlusion of the tumor-surrounding vasculature can contribute to tumor control, at least in preclinical models, presumably by adding to the nutrient deprivation and retardation of vascular resupply of the tumor.^{132,136} Another approach to retardation of vessel regrowth after PDT is the use of antiangiogenic agents in combination with PDT, which has been shown to enhance long-term tumor control.^{100,137}

The acute manifestations of PDT-induced vascular damage greatly depend on the type and dose of photosensitizer used. On the microscopic level, vascular changes in a rat cremaster muscle preparation after Photofrin-PDT included vessel constriction, occlusive platelet thrombi in arteries, arterioles, veins

TABLE 36.3 Vascular Response Mediators Generated or Affected by PDT

and venules, edema, and neutrophil margination and migration.^{138,139} Ultrastructural features included damage to numerous endothelial-cell organelles as well as perivascular changes such as degranulation of perivascular mast cells and damage to myocytes.¹³⁸ Npe6 (mono-L-aspartyl chlorin e6)-PDT in a rat chondrosarcoma model resulted in obstructive platelet thrombi but no vasoconstriction.¹⁴⁰ PDT with variously substituted zinc Pcs, tested in the same tumor model, showed a range of effects, including vessel constriction and leakage, with one compound (disulfonated zinc Pc) exhibiting no apparent effects.¹⁴¹

Numerous vascular-response mediators seem to be involved in these processes, summarized in Table 36.3. Most studied and prominent among them are the eicosanoids. They are products of the release from the cell membrane of arachidonic acid that is subsequently metabolized by cyclooxygenase to generate prostaglandins and thromboxanes and by lipoxygenase to form leukotrienes and hydroxy acids. The generation of a wide spectrum of arachidonic-acid metabolites by PDT has been described in mast cells, macrophages, endothelial cells, platelets, and tumor cells, as well as in animals. Interestingly, in vitro PDT exposure of platelets blocks their capacity to aggregate, 142,143 and in vitro exposure of endothelial cells is dominated by the release of prostacyclin (PGI₂), which inhibits platelet aggregation. ¹⁴³ These in vitro findings contradict the well-established proaggregating mechanisms observed in vivo and demonstrate the difficulty of translating in vitro data to the in vivo situation. The latter represents a much more complex interplay of mechanistic components that likely involves platelets, endothelial cells, leukocytes, macrophages, and other stromal cells. Thromboxane appears to play a major role in mediating the observed vascular effects, at least in rat models. 144 Antiinflammatory drugs, such as indomethacine or aspirin, can block the release of eicosanoids in vitro^{39,143} and in vivo.^{141,144-146} Rats that are made thrombocytopenic, and thus deprived of a source for thromboxane generation, also show a diminished vascular response. 147 Eicosanoids, in addition to serotonin, also appear to be involved in changes of tumor interstitial pressure observed after Photofrin-PDT, a consequence of fluid leakage from the vasculature and possibly contributing to occlusion of the tumor microvasculature. 148

36.6 Tumor Oxygenation and PDT

Any restriction of tissue oxygen supply *during* PDT light delivery will reduce ${}^{1}O_{2}$ production and therefore have negative consequences for treatment outcome. Such restrictions can arise from numerous sources including preexisting tumor hypoxia, acute vascular damage, and photochemical oxygen depletion. All of these can interact, and the dynamics of these interactions may determine treatment success.

36.6.1 Preexisting Tumor Hypoxia

Preexisting tumor hypoxia, a therapeutic problem still grappled with by radiation oncologists because of the oxygen dependence of sparsely ionizing radiation treatment, may limit the oxygen supply for PDT as well. Solid tumors are prone to develop hypoxic tumor regions due to deteriorating diffusion geometry, structural abnormalities of tumor microvessels, and disturbed microcirculation. 149 Hypoxic,

but viable, tumor cells located in these areas may be protected from PDT-induced photodamage. In a preclinical study, Fingar et al.¹⁵⁰ manipulated tumors pharmacologically and physically to induce a wide range of hypoxic tumor fractions (~2% to ~40%) and followed this with aggressive Photofrin-PDT. It was found that hypoxic fractions below 5% did not adversely affect tumor control, those of ~10% slightly diminished tumor control, and fractions of ~40% totally blocked tumor control. Vascular shutdown and nutrient deprivation following PDT were believed to be responsible for the elimination of small numbers of initially surviving hypoxic tumor cells. Early preclinical attempts to raise tumor oxygenation prior to PDT through the administration of a perfluorochemical emulsion and carbogen breathing were highly successful in increasing tumor oxygen levels (~tenfold) up to 1 h after PDT. The intervention did not alter long-term tumor control,¹⁵¹ probably because the vascular damage induced by the aggressive PDT regime overwhelmed any subtle improvement in treatment outcome that might have been attributed to increased tumor oxygenation. More recent studies, both preclinical and clinical, have demonstrated significantly improved PDT efficiency with adjuvant administration of hyperbaric oxygen or carbogen.^{69,152,153}

However, the factor that probably influences preexisting tumor hypoxia most profoundly is one that accompanies most PDT treatments, namely, changes in tumor temperature. Temperature increases due to PDT light delivery have been analyzed by Svaasand et al.¹⁵⁴ and have been recorded in preclinical models¹⁵⁵ and in patients' tumors.¹⁵⁶ Measurements of baseline intratumoral temperature and pO₂ in nodular basal-cell carcinomas have demonstrated a linear relationship between increasing tumor pO₂ and lesion temperature in ranges between 0 and 20 mm Hg and 30 to 35°C.¹⁵⁶ Upon laser illumination during Photofrin-PDT, the temperature in these lesions increased further in a fluence-rate-dependent manner. Surprisingly, even low-fluence-rate light produced significant temperature rises (150 mW/cm²: median temperature change +1.9°C [range 1.0 to 6.2], 30 mW/cm²: median temperature change +1.5°C [range 1.3 to 3.6]), and these correlated with increased tumor pO₂. Whether these relationships hold true for tumors other than skin tumors remains to be seen.

36.6.2 Oxygen Limitation through Vascular Damage

With photosensitizers that can acutely constrict and occlude vessels, blood-flow obstruction can be marked, very rapidly limiting the oxygen supply to the tumor. Photofrin-PDT in mouse models, for example, rendered up to 10% of tumor cells hypoxic within a very moderate light exposure (45 J/cm,² 10 min). This hypoxia was persistent and progressive with time, 50% of tumor cells being hypoxic within 1 h of such light exposure. Similar observations were reported for a rabbit-skin-tumor model, where a series of brief light exposures resulted in induction of irreversible tumor hypoxia that was cumulative with the number of exposures, i.e., fluence. Hypoxia induction by PDT depends greatly on the vascular supply of a given tumor and even on the site of tumor implantation in rodent models. Transient reoxygenation may occur depending on PDT dose. With certain second-generation sensitizers, many of which exert less severe acute effects on the vasculature than Photofrin, and a tendency toward the use of lower drug doses, such acute vascular effects are less likely to occur. As discussed above, the extent and timing of vascular damage, and therefore induction of tumor hypoxia, are very important for treatment outcome. Occurrence of vascular occlusion can be detrimental *during* treatment but beneficial *after* completion of the PDT tumor treatment.

36.6.3 Oxygen Limitation through Photochemical Oxygen Depletion

Photochemical oxygen depletion is roughly characterized by instantaneous or near-instantaneous development of tumor hypoxia upon light exposure of a photosensitized tumor/tissue and equally rapid reoxygenation upon cessation of light. The theoretical basis for this phenomenon has been provided through mathematical modeling of the dynamic changes to be expected in tissue when oxygen is consumed in the process of ${}^{1}O_{2}$ generation. ^{159,160} Photochemical oxygen depletion will occur in tissue if the rate of photodynamic-oxygen consumption is faster than the rate of oxygen resupply from the

vasculature. The major parameters that determine whether or not photochemical oxygen depletion will occur are (1) the absorption coefficient of the photosensitizer, (2) the tissue concentration of the photosensitizer, (3) the fluence rate of light, and (4) the vascular supply of the tissue. ^{159,161,162} If the first three parameters are high, $^{1}O_{2}$ production will be rapid and oxygen depletion favored; if the vascular supply of the tissue is poor, oxygen depletion will also be favored. The mathematical predictions have been validated in tightly defined *in vitro* systems, ^{163,164} in tumor models, ^{134,157,165,166} and in humans. ¹⁵⁶ Light fluence rate is the most easily controlled parameter, one that can be readily modulated during light delivery. Therefore, much attention has been paid to the effects of fluence rate on PDT oxygen consumption. It is clear that lowering of the fluence rate can diminish or eliminate photochemical oxygen consumption through lowering the $^{1}O_{2}$ -generation rate. However, the optimal fluence rate will depend on the other parameters listed above and therefore vary from situation to situation. In human tumors, the variability is great, both among patients and among lesions in the same patient. ¹⁵⁶

36.6.4 The Role of Photobleaching in Photochemical Oxygen Depletion

Photobleaching is the destruction of the photosensitizer by light-mediated processes. ^{167–170} Since photosensitizer concentration is one of the major determinants for photochemical oxygen depletion, it stands to reason that the destruction of photosensitizer through photobleaching during PDT will reduce the likelihood that oxygen depletion will occur. The most detailed studies of photobleaching have been carried out in an *in vitro* multicell tumor spheroid model. ¹⁷¹ Sustained illumination of Photofrin-photosensitized spheroids was shown to lead to a progressive decrease of photochemical oxygen depletion, implying reduction of photosensitizer levels and consistent with a theoretical model in which bleaching occurs via a self-sensitized singlet-oxygen reaction with the photosensitizer ground state. Similarly, PpIX was degraded by ¹O₂-mediated mechanisms, while another photosensitizer (Nile blue selenium) was degraded by ¹O₂-independent mechanisms. ¹⁷² Oxygen measurements in rodent tumor models and human basal-cell carcinomas also implicated photobleaching in influencing photochemical oxygen depletion. ^{134,156} In these studies, significant oxygen depletion was observed during the early time periods of illumination at high fluence rates of Photofrin-photosensitized lesions, but less or no oxygen depletion was detected toward the end of illumination, implying that the Photofrin concentration had been reduced through photobleaching below the threshold needed for oxygen depletion.

36.6.5 Enhancement of PDT Efficiency through Modified Light-Delivery Schemes

It is evident that any means by which the well-oxygenated tumor volume can be increased during light exposure should have beneficial effects on treatment outcome. Downward adjustment of treatment fluence rate is one such means; fractionation of light delivery is another. $^{134,173-176}$ While the former allows for continuous maintenance of oxygen levels sufficient for $^{1}O_{2}$ production, the latter facilitates reoxygenation of the tissue between light exposures. Significant enhancements of tumor response have been observed with either of these alternatives for PDT with Photofrin, ALA/PpIX, and mTHPC. In part, this may be due to a significant but moderate increase in direct photodamage to tumor cells. Direct tumor-cell death increased with low fluence rate PDT by $\sim 1/2-1$ log in the RIF mouse model. 115 However, the microvasculature, especially the normal tumor-surrounding microvasculature, can also be affected by modification of fluence rate. 135 One practical drawback of low-fluence-rate as compared with high-fluence-rate treatment is the increase in exposure time required to deliver a given fluence. Due to the higher treatment efficiency this can be somewhat, but not entirely, compensated for by a reduction of the total fluence delivered. In fact, a reduction of the total fluence may be necessary with low-fluence-rate treatment because the PDT efficiency for causing vascular and normal tissue effects will also increase, thereby decreasing treatment selectivity. 135,176

Enhanced responses to light-dose fractionation in ALA-PDT of murine tumors and normal rat colon may involve relocalization or resupply of PpIX during dark periods in addition to reoxygenation. 177,178

36.7.1 Immune Suppression

The effect of PDT on the host immune system is dichotomous, resulting in either immune suppression or immune activation. Although the mechanism leading to either immune activation or suppression is unclear, recent studies have indicated that the nature and extent of the tissue treated and the dose play a major role. 179,180 Cutaneous PDT suppresses allograft rejection 181-183 and contact hypersensitivity (CHS) reactions. 179,184-187 PDT suppression of CHS in murine models has been demonstrated with a number of different photosensitizers^{184–186,188–191} and is antigen-specific.^{184,185} The kinetics of CHS suppression is photosensitizer-dependent;¹⁸⁵ TPPS₄ and HpD-PDT induce immediate CHS suppression, while m-THPC and Photofrin-PDT suppression requires 72 h to develop. Kinetic differences have been linked to photosensitizer localization. 185 The mechanism of PDT-induced suppression appears to be associated with the induction of immunosuppressive cytokines. PDT induces tumor necrosis factor (TNF)-α, ^{187,192} which is involved in some aspects of UV-mediated immunosuppression.¹⁹³ However, it is not responsible for PDT-induced CHS suppression.¹⁸⁷ PDT also induces interleukin (IL)-10,^{179,189,194} which has been shown to inhibit cell-mediated immune responses including CHS. 189,195,196 Gollnick et al. 179 have shown that in vitro PDT induces IL-10 expression from keratinocytes as a result of activation of the IL-10 gene promoter by enhanced expression of AP-1 and prolonged IL-10 mRNA half-life. IL-10 is thought to mediate its suppressive activity through inhibition of the ability of antigen-presenting cells (APCs) to stimulate CD4+ T helper (Th1) cells. 195 Th1 cells, which secrete IL-2 and interferon (IFN)-γ, are necessary for induction of cell-mediated immune responses. The duration and strength of CHS reactions are increased in the presence of Th1 cells. 189 Th1 cells depend on the presence of IL-12, secreted from APCs such as macrophages and dendritic cells, for their development. 197,198 Cytotoxic T (Tc1) cells are the major effector cells in the CHS response¹⁹⁶ and also depend on IL-12 for their development. IL-12 secretion from APCs is inhibited by IL-10.195,196 Interestingly, Lynch et al.186 demonstrated that adoptive transfer of macrophages from mice treated with peritoneal Photofrin-PDT, which involves treatment of the entire peritoneal cavity, suppressed the CHS response to di-nitrofluorobenzene (DNFB) in the adoptively transferred animals, suggesting that this PDT regime altered the ability of the macrophages to induce Th1 and Tc1 cells.

Direct mechanistic studies into the role of IL-10 in PDT-induced suppression of CHS have yielded contradictory results that can be explained, at least in part, by the treatment regime and dose of PDT. Treatment with cutaneous PDT, using Photofrin and blue light centered at 430 nm, results in irradiation that is mostly limited to the skin. In contrast, transdermal PDT, with BPD-MA and illumination with 690-nm light, involves whole-body irradiation. Also, due to the greater depth of light penetration of this wavelength some irradiation of internal sites may occur. Both transdermal and cutaneous PDT result in CHS suppression and induce IL-10 expression in the skin. 179,189,194 Simkin et al. 189 implicated IL-10 as the active mediator in transdermal PDT-induced suppression of CHS by demonstrating that IL-10 knockout (KO) mice did not undergo transdermal PDT-induced CHS suppression. In contrast, cutaneous PDT treatment of IL-10 KO mice did induce CHS suppression.¹⁷⁹ The lack of involvement of IL-10 in the suppression of CHS by cutaneous PDT was further confirmed when studies using neutralizing anti-IL-10 antibodies failed to inhibit cutaneous PDT-induced CHS suppression. 179,191 Thus, it appears that the mechanism of PDT-induced suppression of CHS depends on the treatment regime. Regimes that result in large treatment fields and internal exposure, i.e., transdermal and potentially peritoneal PDT, mediate CHS suppression via IL-10. PDT regimes that employ lower doses and superficial cutaneous exposure suppress CHS reactions via an IL-10-independent mechanism.

Interestingly, CHS suppression by both transdermal and cutaneous PDT was reversed by administration of exogenous IL-12,^{179,189} suggesting that these processes share a common regulatory point, perhaps in the development of Th1 or Tc1 cells. A second potential suppressor of Th1 and Tc1 development, and thus of CHS, is IL-4. IL-4 has been shown to directly inhibit Th1-cell proliferation¹⁹⁹ and to induce anergy in Tc1 cells.²⁰⁰ Th2 cells, which are critical for the development of humoral immunity¹⁹⁹ and secrete IL-4, have been shown to negatively regulate CHS responses.⁷⁹ Induction of systemic IL-4 by cutaneous PDT

may result in direct inhibition of Th1/Tc1 cells and suppression of CHS responses. Preliminary data from our group suggest that cutaneous PDT results in the induction of systemic IL-4, and a recent study demonstrated that cutaneous PDT suppression could be transferred by a CD4⁺ T-cell population. ¹⁸⁰

In addition to the effects of cytokines on PDT-induced suppression of immune responses, the effect of PDT on the expression of immune molecules critical to immune-system activation should be considered. Transdermal PDT has been shown to inhibit the ability of Langerhans cells (LC) to stimulate alloreactive T cells, ¹⁸¹ and LC treated *ex vivo* expressed lower levels of major histocompatibility (MHC) antigens and CD80 and CD86 costimulatory molecules, which are needed for T-cell activation. Additionally, *in vitro* PDT-treated murine dendritic cells (DC) had a reduced ability to stimulate alloreactive T cells and exhibited lower levels of MHC molecules, costimulatory molecules, and adhesion molecules.²⁰¹ Thus, in addition to altering the function of APCs, PDT has the ability to disrupt the APC–T-cell cognate, which is needed for T-cell activation.

36.7.2 Immune Potentiation

In contrast to the immunosuppressive effects of transdermal or cutaneous PDT, tumor-directed PDT has been shown by a number of preclinical studies to trigger an inflammatory response and enhance a specific antitumor response. 123,202 PDT is characterized by the onset of an inflammatory reaction that is dominated by an influx of neutrophils. 194,203 The strength of the inflammatory response varies with photosensitizer; Photofrin-PDT induces a strong inflammatory response and a rapid influx of neutrophils, which appear to be critical to long-term tumor control. 204-207 HPPH-PDT induces a mild inflammatory response that is associated with reduced neutrophil infiltration,²⁰⁸ which is not critical to long-term tumor control following HPPH-PDT.²⁰⁸ The influx of neutrophils into the treatment site is preceded by an induction of chemokines and adhesion molecules critical to neutrophil migrations.²⁰⁸ Neutrophil infiltration is followed by an influx of mast cells and macrophages. 194,203 PDT enhances macrophage tumoricidal activity²⁰⁹⁻²¹¹ and stimulates macrophage release of TNF-α and tumor-cell recognition.⁷⁵ It has been suggested that nonspecific killing of tumor cells by inflammatory cells, potentially through the release of reactive oxygen species, contributes to the overall tumor kill by PDT.²⁰⁶ This hypothesis is supported by studies showing that if the PDT-induced inflammatory response is further stimulated by the addition of adjuvants or macrophage-activating factors, the overall tumor response to PDT is greater.^{212–214} The role of the innate immune response in overall tumor kill by PDT was also shown to involve NK (natural killer) cells. Depletion of NK cells reduced the long-term tumor control by PDT,²⁰² and augmentation of NK activity enhanced PDT tumor control.215

PDT has also been shown to enhance the adaptive or specific host antitumor response. 123,206 Tumordraining lymph-node cells isolated from PDT-treated mice are able to suppress subsequent tumor challenges when transferred to a naïve host.216,217 Canti et al.217 have shown that PDT-treated mice that remain tumor free for 100 d post-PDT are resistant to subsequent tumor challenges, suggesting the presence of immune memory cells. The establishment of immune memory by PDT was recently confirmed by studies of Korbelik and Dougherty²¹⁰ showing that immune cells isolated at protracted times post-PDT could transfer tumor immunity. The importance of the immune response in PDT was definitively shown by a series of experiments in scid (severe combined immunodeficient) and nude mice.^{204,210} PDT treatment, at a dose that was curative in immunocompetent BALB/c mice, provided only short-term cures of EMT6 tumors in scid and nude mice. The ability to provide long-term cures was restored when immunodeficient animals were reconstituted with bone-marrow cells from BALB/c mice. Depletion studies showed that the critical cells involved in the PDT-induced immune response were CD8+ cells, although CD4+ cells played a supportive role.²¹⁰ Interestingly, a recent clinical study has demonstrated an infiltration of CD8+ cells into PDT-treated tumor tissue. 218 These studies suggest that a functional immune system is necessary for long-term tumor control by PDT; however, the mechanism behind the potentiation of the immune response by PDT is unknown.

Several factors have been postulated to contribute to the ability of PDT to enhance the host antitumor immune response, including release of tumor antigens and stimulation of various proinflammatory cytokines

and other immunologically important genes, via activation of stress-response factors like AP-1 and NF- κB . ^{194,210} PDT has been shown to enhance the expression of a number of cytokines including IL-6, TNF- α , IL-1β, IL-2, and granulocyte-macrophage colony-stimulating factor (GM-CSF). 187,192,194,219,220 PDT modulation of IL-6 is the result of increased AP-1 activity.81 Preliminary mechanistic studies have suggested that IL-6 plays a critical role in long-term tumor control by PDT;208 however, its role in induction of the antitumor immune response is unknown. The release of tumor antigens by PDT is also likely to play a role in the initiation of the antitumor immune response. The mechanism by which tumor cells are killed and the environment into which tumor antigens are released have been shown to dictate the ensuing immune response.^{221,222} Release of tumor antigens into an inflammatory milieu is thought to promote an effective antitumor immune response,²²¹ and the presence of apoptotic and necrotic tissue acts to stimulate DCs,²²² which are necessary for initiation of the immune response.²²³ Thus PDT, by stimulating inflammation and generating apoptotic and necrotic tissue, provides an ideal environment for initiation of an antitumor immune response. Evidence from our laboratory demonstrating that PDT-generated tumor-cell lysates are able to activate DC in the absence of cofactors²²⁴ supports this hypothesis. An understanding of the mechanisms leading to PDT enhancement of the host antitumor immune response may allow for amplification of the response, thereby amplifying the effectiveness of PDT and potentially providing for protection against metastases outside the treatment field.

36.8 Conclusion

The scientific effort that supports this new cancer therapy has led to numerous significant advances. The development of new photosensitizers is essentially eliminating the problem of prolonged cutaneous photosensitivity and is extending treatment depth, an issue dealt with in detail elsewhere in this volume. The complex dynamics of tumor oxygenation in response to PDT are now largely understood. The oxidative stress effects of PDT on redox-sensitive transcription factors and the genes they control are being uncovered. The complex interplay of biological mechanisms governing the PDT tumor response has been realized. Given these accomplishments, it remains for them to be translated into actual patient benefit. Noninvasive probes need to be perfected that will allow the monitoring of photosensitzer levels, oxygen status, or, ideally, directly of singlet oxygen, the cytotoxic agent. New light-delivery regimes need to be devised for clinical use that will minimize oxygen limitations. The ways in which such regimes might influence redox-sensitive gene regulation and how these genes might affect treatment outcome need to be explored. Finally, our expanding understanding of the complex effects of PDT on host immunity needs to be exploited to modulate the PDT response.

37.1 Introduction

Photodynamic therapy (PDT) is a promising cancer treatment that involves the combination of visible light and a photosensitizer. Each factor is harmless by itself, but when combined with oxygen they can produce lethal cytotoxic agents, initially singlet oxygen, that inactivate the tumor cells. This enables greater selectivity toward diseased tissue, as only those cells that are simultaneously exposed to the photosensitizer, light, and oxygen are exposed to the cytotoxic effect. The dual selectivity of PDT is produced by both a preferential uptake of the photosensitizer by the diseased tissue and the ability to confine activation of the photosensitizer to this diseased tissue by restricting the illumination to the specific site.

FIGURE 37.1 Porphyrins and related tetrapyrrolic systems.

The porphyrins and related tetrapyrrolic systems are among the most widely studied compounds for use as photosensitizers in PDT.³ Porphyrins are 18π -electron aromatic macrocycles that exhibit characteristic optical spectra with a strong π – π * transition around 400 nm (Soret band) and usually four Q bands in the visible region. As shown in Figure 37.1, two of the peripheral double bonds in opposite pyrrolic rings are cross-conjugated and are not required to maintain aromaticity. Thus, reduction of one or both of these cross-conjugated double bonds (to give chlorins and bacteriochlorins, respectively) maintains much of the aromaticity, but the change in symmetry results in bathochromically shifted Q bands with high extinction coefficients.⁴ Nature uses these optical properties of the reduced porphyrins to harvest solar energy for photosynthesis with chlorophylls and bacteriochlorophylls as both antenna and reaction-center pigments.⁵ The long-wavelength absorption of these natural chromophores led to explorations of their use as photosensitizers in PDT.

As indicated above, PDT is based on the interaction of a photosensitizer retained in tumors with photons of visible light, resulting in the formation of singlet oxygen ($^{1}O_{2}$), the putative lethal agent. To achieve an effective destruction of tumor cells, a high quantum yield of singlet oxygen is required. Even in the absence of heavy-atom substitutions and coordination of transition-metal ions, porphyrin systems generally satisfy these criteria, which is why most sensitizers currently under clinical evaluation for PDT are porphyrins or porphyrin-based molecules.

At present, Photofrin®, a hematoporphyrin derivative, 7-11 is the only photosensitizer approved worldwide for the treatment of various types of cancer by PDT. It fits some of the criteria for ideal photosensitizers, but it also has several drawbacks. First, it is a complex mixture of various monomeric, dimeric, and oligomeric forms. 7-11 Second, its long-wavelength absorption falls at 630 nm, which lies well below the wavelength necessary for maximum tissue penetration. Finally, it induces prolonged cutaneous phototoxicity, a major adverse effect associated with most of the porphyrin-based photosensitizers.

It is well established that both absorption and scattering of light by tissue increases as the wavelength decreases and that most efficient sensitizers are those that have strong absorption bands from 700 to 800 nm.¹² Light transmission by tissues drops rapidly below 550 nm; however, it doubles from 550 to 630 nm and doubles again from 630 to 700 nm. This is followed by an additional 10% increase in tissue penetration as the wavelength increases toward 800 nm.³ Another reason to set the ideal wavelength for

PDT at 700 to 800 nm is due to the availability of easy-to-use diode lasers. Although diode lasers are now available at 630 nm (where clinically approved Photofrin absorbs), photosensitizers with absorptions between 700 and 800 nm in conjunction with diode lasers are still desirable for treating deeply seated tumors. Therefore, in recent years a variety of photosensitizers related to chlorins, bacteriochlorins, porphycenes, phthalocyanines, naphthalocyanines, and expanded porphyrins have been synthesized and evaluated for PDT efficacy. However, for designing improved photosensitizers for PDT it becomes necessary to consider several other factors, such as overall lipophilicity (i.e., a proper balance between hydrophobicity and hydrophilicity), pH, lymphatic drainage, and lipoprotein binding, that could influence the biodistribution and localization of sensitizers in tissue and tumors.¹³

The main focus of this chapter is to summarize the various synthetic strategies used by several research groups in designing long-wavelength-absorbing photosensitizers related to chlorins, bacteriochlorins, expanded porphyrins, and Pcs. An ongoing interest in developing target-specific photosensitizers will also be briefly reviewed. The majority of chlorins and bacteriochlorins have been generated through three different approaches. The first approach involves the modification of a preformed porphyrin. The second approach utilizes the use of chlorophyll *a* as the starting material for the synthesis of other chlorins and bacteriochlorins. The third approach utilizes the unstable bacteriochlorophyll *a* as a substrate for the synthesis of stable bacteriochlorins. Each procedure has been used successfully for the preparation of sensitizers that show promise in PDT, and each is discussed in terms of synthetic methodology and biological significance.

37.2 Chlorins and Bacteriochlorins from Porphyrins

37.2.1 Chlorins and Bacteriochlorins by Diimide Reduction

Almost 30 years ago, Whitlock et al. ¹⁴ developed an efficient diimide-reduction method for the synthesis of bacteriochlorins and isobacteriochlorins from porphyrins. Diimide reduction of metal-free tetraphenyl chlorin afforded tetraphenyl bacteriochlorin, while reduction of the corresponding zinc analog produced the related tetraphenylisobacteriochlorin. It is now accepted that the reduced double bond in chlorins induces a pathway for the delocalized π electrons that "isolates" the diagonal crossing-conjugated pyrrolic double bond such that reduction of this double bond is favored due to minimal loss of π energy over the double bond present in the adjacent ring. The presence of a metal changes the delocalization of the π electrons, which makes the adjacent pyrrolic ring more reactive, and diimide reduction produces mainly the corresponding isobacteriochlorin. To avoid the formation of an isomeric mixture this approach is useful only for the reduction of symmetrical porphyrins. This diimide-reduction approach was later employed by Bonnett et al. ¹⁵ for preparing the *meso*-tetra (m-hydroxyphenyl)-chlorin (m-THPC) 7 (650 nm) and the bacteriochlorin (m-THPBC) 8. The formation of these components was found to depend on the amount of the reductant used.

SCHEME 37.1

Although the formation of a bacteriochlorin resulted in further red shift in the electronic absorption spectrum with long-wavelength absorption near 750 nm, these molecules were generally found to be airsensitive. Among various chlorin analogs, *m*-THPC (Foscan®) 7 (Scheme 37.1) appears to be quite effective and is currently in phase III human clinical trials (see Chapter 38).

37.2.2 Chlorins and Bacteriochlorins by Diels-Alder Reaction

Cycloaddition reactions are among the most powerful reactions available to the organic chemists.¹⁶ The ability to simultaneously form and break several bonds, with a wide variety of atomic substitution patterns, and often with a high degree of stereocontrol, has made cycloaddition reactions the subject of intense study. In porphyrin chemistry, the [4 + 2] Diels–Alder reactions have been used by various investigators for converting porphyrins into chlorin systems. Callot et al. were the first to show that protoporphyrin IX (PpIX) dimethyl ester 9 could undergo cycloaddition reactions with various dienophiles¹⁷ (Scheme 37.2). A few years later Dolphin and co-workers discovered the utility of one such

SCHEME 37.2

analog named as benzoporphyrin derivative monocarboxylic acid (BPDMA) **12a** and **12b** for treating age-related macular degeneration (AMD) when activated with light at 690 nm.¹⁸ This treatment has already received approval worldwide. BPDMA has also been used for the treatment of cancer by PDT (see Chapter 38). However, due to its rapid clearance, it was found to be effective only if the tumors were treated with light at 3 h post injection of the drug. Pandey et al.¹⁵ developed another approach for preparing these analogs by using 8-acetyl-3-vinyl deuteroporphyrin IX dimethyl ester as a starting material (Scheme 37.3). The vinyl group was then replaced with various alkyl ether functionalities. Among

$$Me \xrightarrow{3} A \xrightarrow{NH} N \xrightarrow{B} Me$$

$$Me \xrightarrow{Q_2C} Me \xrightarrow{A_1H} N \xrightarrow{B_1H} Me$$

$$Me \xrightarrow{D_1H} Me$$

$$Me \xrightarrow{D_1H}$$

SCHEME 37.3

these analogs the related 8-(1-hexyloxy ethyl)-derivative **14** was found to be more effective than BPDMA in eradicating tumors in mice bearing SMT-F tumors. ^{19–21} This methodology was further extended independently by Pandey et al. ²² and You-Hin et al. ²³ for the synthesis of novel bacteriochlorins that involved a double Diels—Alder reaction on divinylporphyrins **15** and **17** (Scheme 37.4). These bacteriochlorins **16** and **18** exhibit long-wavelength-absorption maxima near 800 nm PDT efficacy.

SCHEME 37.4

Morgan et al.²⁴ have shown that bacteriochlorin-like macrocycles can also be generated by cyclization of either 5,10- or 5,15-*bis*[(ethoxycarbonyl)vinyl]-porphyrins. However, the resulting products rapidly decompose upon exposure to air, thus precluding their use as photosensitizers for PDT. For developing a general synthesis of stable bacteriochlorins, the same authors (A.R. Morgan, unpublished results) followed the pinacol-pinacolone approach in preparing ketochlorins **22** and **23**. In brief, dehydration of **19** produced a mixture of **20** and **21**, which on reaction with dimethylacetylenedicarboxylate (DMAD) produced the corresponding bacteriochlorins **22** and **23** as an isomeric mixture. This isomeric mixture showed some photodynamic activity in a mouse tumor model; 75% of the mice treated at a dose of 1 mg/kg were found to be free from palpable tumor 12 d after the light treatment. However, in this class of compounds, the spectroscopic properties of **22** and **23** resemble those of porphyrinones (longwavelength absorption near 700 nm) rather than bacteriochlorins (Scheme 37.5).

SCHEME 37.5

37.2.3 Benzochlorins and Benzobacteriochlorins

Benzochlorin consists of a benzene ring fused between the *meso*- and the adjacent β -position of the pyrrole ring. In a sequence of reactions, this class of compounds was first reported by Arnold et al. from octaethylporphyrin.²⁵ Morgan et al.^{26,27} were the first to demonstrate the photosensitizing efficacy of these analogs (e.g., **28**). One of the major problems associated with this preparation is the difficulty in metalation at the final step of the synthesis, and it is also difficult to chemically modify these benzochlorins. Therefore, this procedure has limited application in preparing a series of analogs with variable lipophilicity. This problem can be avoided by following the method recently reported by Li et al.^{28,29} (Scheme 37.6). In their approach, Ni(II)meso-(2-formylvinyl)octaethylporphyrin **26** was reacted with a

SCHEME 37.6

Grignard's reagent of various fluorinated or nonfluorinated alkyl halides or Ruppert's reagent. The corresponding intermediates via intramolecular cyclization under acidic conditions afforded the related free-base benzochlorins **34**. In this series of compounds, compared to the free-base analogs, the related Zn(II) complexes (671 to 677 nm) were found to be more effective both *in vitro* and *in vivo*. In preliminary screening, the fluorinated analogs showed better efficacy than the corresponding nonfluorinated derivatives (G. Li et al., unpublished results).

This methodology was later extended by Vicente and Smith³⁰ for the preparation of octaethylporphyrin-based benzochlorin **30** by intramolecular cyclization, of Ni(II)5,10 *bis*-(2-formylvinyl) porphyrin **21**

(Scheme 37.7). Unfortunately, attempts to remove the Ni(II) metal were unsuccessful. When Ni(II)5-(2-formyl-vinyl)-10-(2-ethoxycarbonyl-vinyl)octaethyl porphyrin was used as a substrate, the formation of

SCHEME 37.7

the reaction product was found to depend on the strength of the acid used.³¹ For example, reaction of **35** with sulfuric acid produced a chlorin containing both six- and five-member rings fused at the same pyrrole unit **36**. Replacing sulfuric acid with trifluoroactic acid (TFA) produced **37**, the Ni (II) complex of bacteriochlorin containing an ethylidine group at the peripheral position (λ_{max} 895 nm). Attempts to prepare the desired free-base analogs for investigating their application as photosensitizers were unsuccessful.

37.2.4 Purpurins (Tin Etiopurpurin Dichloride)

Purpurins have been known for quite some time as degradation products of chlorophyll. The first synthesis of this class of compounds was reported by Woodward³² during the synthesis of chlorophyll a by intramolecular cyclization of a *meso*-acrylate functionality to a β -pyrrolic position. This methodology was later followed by Morgan et al.³³ and others^{34,35} to synthesize a series of octaetylporphyrin, etioporphyrin, 5,10-diphenyl- and 5,10-dipyridylporphyrin-based purpurin analogs. Among all the purpurins evaluated for PDT efficacy, the Sn etiopurpurin (SnEt₂) **40** (Scheme 37.8) is considered the most effective *in vivo*.³³ Its long-wavelength absorption falls at 650 nm and produces a high singlet-oxygen quantum

SCHEME 37.8

yield. This product is currently in phase III clinical trials for the treatment of age-related macular degeneration (AMD), a major cause of blindness among people over 50 years of age.

37.3 Chlorins and Bacteriochlorins from Chlorophyll

Chlorophyll *a*, the green photosynthetic pigment, is one of the prototypes of the chlorin class of natural product. Because of its ready availability, a large amount of work has been done by several investigators to modify and synthesize other chlorin-like chromophores. The photosensitizers derived from chlorophyll *a* can be divided into three categories in which either the five-member isocyclic ring was cleaved or kept

intact or was replaced with other ring systems. Some of the photosensitizers in these series have attracted enormous attention; a description of them follows.

37.3.1 Aspartic Acid Derivative of Chlorin e_6 (Np e_6)

Chlorophyllin, a water-soluble degradation product of chlorophyll a, can be obtained by the cleavage of the isocyclic ring of chlorophyll.³⁶ Removal of magnesium resulted in chlorin e_6 with limited *in vivo* photosensitizing efficacy. It has been shown that replacing the vinyl group with alkyl ether groups of variable carbon units generally enhances the photosensitizing efficacy.³⁰ However, in this series, better results were obtained with the monoaspartyl derivative known as Npe₆.³¹ This photosensitizer appears to clear rapidly from skin, and good tumor response was obtained only after irradiation within 3 to 4 h of sensitizer administration. Npe₆ is in human clinical trials in Japan for treatment of endobronchial lung cancer. The recent extensive NMR studies of Npe₆ confirmed that in Npe₆, the aspartic-acid functionality is linked with an amide bond at position-15 (41) of chlorin e_6 ,³⁹ instead of at position-17 (42) as reported in several publications^{40,41} (Scheme 37.9).

SCHEME 37.9

37.3.2 Alkyl Ether Derivatives of Pyropheophorbide a

To understand the effect of various substituents on photosensitizing efficacy, the Roswell Park group synthesized and evaluated a series of pyropheophorbide *a* analogs with variable lipophilicity. In their effort to establish a structure-activity relationship (QSAR), a congeneric series of the primary and secondary alkyl ether derivatives of pyropheophorbide *a* were synthesized (the isocyclic ring was kept intact). For the preparation of these analogs, methylpheophorbide *a* obtained from *Spirulina pacifica* was converted into more stable pyropheophorbide *a* 43, which on reacting with HBr/AcOH and then the appropriate alcohol produced the corresponding ether analogs in excellent yield⁴² (Figure 37.10). At the

final step, the methyl ester functionality was hydrolyzed into the corresponding carboxylic acid **44** (HPPH: R = n-hexyl). These analogs exhibit long-wavelength absorption near 665 nm ($in \ vivo$) and showed excellent singlet-oxygen-producing efficiency (45%). The results obtained from the $in \ vivo$ studies in mice demonstrated that the photodynamic efficacy of these photosensitizers increased by when the length of the carbon chain was increased, reaching a maximum in compounds with n-hexyl and n-heptyl chains at position-3. Interestingly, the PDT efficacy decreased when the length of alkylether carbon-units was further increased. When compensated for differences in tumor photosensitizer concentration, the n-hexyl derivative (HPPH) [optimal lipophilicity] was fivefold more potent than the n-dodecyl derivative (more lipophilic) and threefold more potent than the n-pentyl analog (less lipophilic). Interestingly, the introduction of the hexyl ether side chain at other positions of the macrocycle (position-8 or position-20) significantly reduced the $in \ vivo$ efficacy. These data suggest that, besides the lipophilicity, the presence and position of the substituent may play an important role in drug efficacy. HPPH is currently at phase I/II human clinical trials for the treatment of a variety of cancers. Among the patients treated so far no long-term skin phototoxicity has been observed.

37.3.3 Alkyl Ether Analogs of Purpurinimides

Having developed a QSAR for the alkyl ether analogs of the pyropheophorbide series, the Roswell Park group extended its approach to photosensitizers with longer-wavelength absorption. For this study, the purpurin-18 methyl ester obtained from methylpheophorbide a^{45} was converted into purpurin-18-N-alkyl imides **46**. The vinyl group at position-3 was then replaced with a variety of alkyl ether analogs **47** (Figure 37.11) with variable carbon units with log P values ranging from 5.32 to 16.44 and exhibiting long-wavelength absorption near 700 nm. The same properties of the pyropheophorbide series, the Roswell Park group exhibition of the pyropheophorbide series, the Roswell Park group exhibition of the pyropheophorbide series, the Roswell Park group exhibition of the pyropheophorbide series, the Roswell Park group exhibition of the pyropheophorbide series, the Roswell Park group exhibition of the purpurin-18 methyl ester obtained from methylpheophorbide a^{45} was converted into purpurin-18-N-alkyl imides a^{45} or a^{4

SCHEME 37.11

In animal studies, this class of compounds was found to be quite effective *in vivo*. The results obtained from a set of photosensitizers with similar lipophilicity ($\log P = 10.68$ to 10.88) indicate that, like the pyropheophorbide series, in addition to the overall lipophilicity, the presence and position of the alkyl groups (O-alkyl vs. N-alkyl) in a molecule also play an important role in tumor uptake, tumor selectivity, and *in vivo* PDT efficacy.⁴⁷⁻⁴⁹

37.3.4 Benzoporphyrin Derivatives Derived from Pyropheophorbide *a* and Purpurinimides

One of the main synthetic problems associated with PpIX-based benzoporphyrin derivatives is to isolate the most effective analog (ring-A reduced, monocarboxylic acid) from the complex reaction mixture. To solve this problem the Roswell Park and Vancouver groups^{50,51} have reported the preparation of various BPD analogs (e.g.. **49**) from phylloerythrin and methyl 9-deoxypyropheophorbide (Scheme 37.12). Among these compounds, the benzoporphyrin derivative (*cis*- isomer) obtained from rhodoporphyrin XV di-*tert*-butyl aspartate was found to have PDT efficacy similar to BPDMA. This methodology was

Me

Me

SCHEME 37.12

also extended in the purpurinimde series, and the lipophilicity was altered by introducing N-alkyl groups with variable carbon units at the imide ring system $50.^{52}$ In preliminary *in vivo* testing, the corresponding N-hexyl and N-dodecyl analogs were found to be quite effective at a dose of $0.5~\mu M/kg$ when treated with light (135 J/cm, 2 75 mW/cm 2) at 728 nm and 24 h post injection. Under similar treatment conditions (treated with light at 690 nm) the BPDMA obtained from PpIX dimethyl ester did not produce any photosensitizing efficacy. 33 Thus, the Diels–Alder approach in the purpurinimide system provides a simple approach to generating effective photosensitizers with variable lipophilicity.

37.3.5 vic-Dihydroxy- and Ketobacteriochlorins

Me

Osmium tetroxide has very frequently been used for the conversion of porphyrins to the corresponding *vic*-dihydroxy chlorins and tetrahydroxy bacteriochlorins as a mixture of isomers.⁴⁵ The overall lipophilicity of these analogs can be altered by subjecting them to pinacolpinacolone recation conditions. The formation of the corresponding keto- analog is not straightforward and depends not only on the intrinsic

SCHEME 37.13

nature of the migratory group but also on the electronic and steric factors elsewhere on the porphyrin nucleus.⁵⁵ Therefore the concept of designing chlorin and bacteriochlorin analogs from porphyrins by following this approach was unsuccessful. A few years ago Chang et al.⁵⁶ showed that chlorins under

certain conditions could be converted into vic-dihydroxybacteriochlorins upon reaction with osmium tetroxide. The Roswell Park group extended this methodology to the pheophorbide chlorin e_6 , and a series of vic-hydroxy- and ketobacteriochlorins was synthesized. The stable ketobacteriochlorins had strong absorptions in the 710- to 760-nm region but showed no significant photosensitizing activity in mice (DBA/2) transplanted with SMT-F tumors. However, the ketobacteriochlorins obtained from 9-deoxypyropheophorbide a 51 and the related meso-formyl derivative with long-wavelength absorption showed long-wavelength absorptions at 734 and 758 nm, respectively (Scheme 37.13). Among these bacteriochlorins the triplet states were quenched by ground-state molecular oxygen in a relatively similar manner, yielding comparative singlet-oxygen quantum yields. In preliminary in vivo screening, the ketochlorins 53 (R = CHO) were found to be more photodynamically active than the related vic-dihydroxy analogs. Replacement of the methyl ester functionalities with di-tert-butylaspartic acids enhanced the in vivo efficacy. It appears to be cleared rapidly from skin, and good tumor responses can be obtained only after irradiation within 3 to 4 h of the sensitizer administration.

37.3.6 Bacteriochlorins Derived from 8-Vinyl Chlorins

The Roswell Park group combined the use of osmium tetroxide and the Diels–Alder approach for the construction of stable bacteriochlorins. In this approach, mesopurpurin-18 methyl ester **54** obtained from methylpheophorbide *a* was reacted with osmium tetroxide. The resulting *vic*-dihydroxy bacteriochlorin on reacting with *p*-toluenesulfonic acid in refluxing benzene produced the 8-vinyl derivative **55**, which on reacting with dimethylacetylene dicarboxylate (DMAD) under Diels–Alder reaction conditions produced bacteriochlorin **56** with long-wavelength absorption near 800 nm.⁵⁵ Unfortunately, the utility of this compound for use in PDT was diminished due to the unstable nature of the six-member anhydride ring system (Scheme 37.14). In a recent approach, the anhydride ring was replaced with an *N*-hexylimide ring system, and these compounds were found to be quite stable *in vivo* (G. Li et al., unpublished results). The preliminary *in vitro* photosensitizing results obtained from this compound are quite promising. This system also presents a unique opportunity to prepare a series of *N*-alkyl ether derivatives with variable carbon units and to establish the structure/activity relationship in a particular series of compounds.

 O_2Me O_2C O_2

SCHEME 37.14

37.3.7 Bacteriochlorins from Bacteriochlorophyll

Most of the naturally occurring bacteriochlorins have absorptions between 760 and 780 nm and have been studied by various investigators for their use as photosensitizers for PDT.⁶⁰ They were found to be extremely sensitive to oxidation, resulting in a rapid transformation into the chlorin state, which generally has an absorption maxima at or below 660 nm.⁶¹ Furthermore, if a laser is used to excite the bacteriochlorin *in vivo*, oxidation may result in the formation of a new chromophore absorbing outside the laser window, reducing the photodynamic efficacy. Due to the desirable photophysical properties and promising *in vitro/in vivo* photosensitizing efficacy of bacteriochlorins, there has been increasing interest in the synthesis of stable bacteriochlorins either from bacteriochlorophyll *a* or from the other related tetrapyrrolic systems.

In general, for designing improved photosensitizers, overall lipophilicity has proven to be one of the important factors. For example, among porphyrin-based photosensitizers, the hydrophobic porphyrins are preferentially accumulated and partitioned into corresponding hydrophobic loci *in vivo*. Moan et al.⁶² have shown that among diether derivatives of hematoporphyrin, retention in cells increases with decreasing polarity. The Roswell Park group has studied the uptake of a series of alkyl ether derivatives of pyropheophorbide *a* and found that a strong correlation existed between uptake and hydrophobicity, although each correlation cannot be extended to the *in vivo* PDT efficacy. On the other hand, photosensitizers with high partition-coefficient values (increased hydrophobicity) induced sensitizer insolubility, thereby preventing drugs from entering circulation. Therefore, a proper balance between hydrophobicity and hydrophilicity is probably the most important factor influencing tumor localization of sensitizers.

SCHEME 37.15

A simple approach used by the Roswell Park group was to vary the overall lipophilicity of various types of photosensitizers such as pyropheophorbide *a*, benzoporphyrin derivatives, benzochlorins, and purpurinimides by altering the length of carbon units in alkyl ether substituents; this approach has been quite successful. It was demonstrated that replacing an anhydride ring system in purpurin-18 (a chlorophyll *a* analog) with a six-member imide ring substantially enhanced its *in vivo* stability and retained effective *in vivo* photodynamic activity.⁶³ Therefore, to investigate the effect of such substitutions in the bacteriochlorin series, bacteriochlorophyll *a*, present in *Rb. sphaeroides*, was first converted (*in situ*) into bacteriopurpurin-18 (57),⁶⁴ which in a sequence of reactions was transformed into a series of related *N*-alkyl derivatives 58⁶⁵ (Scheme 37.15). To determine the effect of the presence of these alkyl substituents with variable carbon units, the acetyl- group was first reduced with sodium borohydride, which on reacting with HBr gas and an appropriate alcohol produced the corresponding alkyl ether derivatives of bacteriochlorin 59 in high yield. These compounds are stable both *in vitro and in vivo*, exhibit long-wavelength absorption near 790 nm, and show high tumor uptake. In preliminary *in vitro* and *in vivo* studies, some of these compounds have been found to be quite effective at low injected doses (Y. Chen et al., unpublished results).⁵⁸

37.4 Expanded Porphyrins

37.4.1 Texaphyrin

The texaphyrins are aromatic tripyrrolic, penta-aza, Schiff-base macrocycles that bear a strong but "expanded" resemblance to the porphyrins and other naturally occurring tetrapyrrolic prosthetic groups. 66 Like porphyrins, the texaphyrins are fully aromatic and colored compounds (Scheme 37.16). However they are 22π -electron electron systems rather than 18π -electron ones. This class of compounds exhibits long-wavelength absorption at >700 nm depending on the nature of substituents present at the peripheral position. Also, unlike porphyrins, the texaphyrins are monoanionic ligands that contain five, rather than four, coordinating nitrogen atoms within the central core, which is roughly 20% larger than that of the porphyrins. High-yield production of long-lived triplet states and their remarkable singlet-oxygen-producing efficiency are important

63. M = Lu (motexafin lutetium)

SCHEME 37.16

features of this class of photosensitizers. Currently, two different water-solubilized lanthanide(III)texaphyrin complexes — i.e., the gadolinium(III) (62)67 and lutetium(III) (63)68 derivatives (Gd-Tex and Lu-Tex, respectively) — are being tested clinically. The first of these, XCYTRIN™, is in a pivotal phase III clinical trial as a potential enhancer of radiation therapy for patients with metastatic cancers of the brain receiving wholebrain radiation therapy. The second, in various formulations, is being tested as a photosensitizer for use in the treatment of recurrent breast cancer (LUTRIN); is in phase II clinical trials for treatment of photoangioplastic reduction of atherosclerosis involving peripheral arteries (ANTRIN); and is in phase I clinical trials for light-based treatment of AMD (OPRTIN).65

37.5 Phthalocyanines and Naphthalocyanines

Phthalocyanines (Pcs) and naphthalocyanines (Ncs) can be regarded as azaporphyrins containing four isoindoles linked by nitrogen atoms⁶⁹ (Scheme 37.17). Compared to porphyrins, Pcs and Ncs offer high molarextinction coefficients and red-shift maximums at 680 nm for Pcs and 780 nm for Ncs resulting from the benzene or naphthalene rings condensed at the periphery of the porphyrin-like macrocycle. They possess high singlet-oxygen-producing efficiency, and interestingly chelation of the metal ions such as zinc or aluminum increases the singlet-oxygen yield to nearly 100%. Therefore, metal complexes of Pcs and Ncs have attracted attention for their use as photosensitizers in PDT. In recent years, a large number of metalated or nonmetalated Pc-based photosensitizers have been synthesized by introducing a variety of substituents at the peripheral positions. If the valency of the central metal is higher than two, it binds various axial ligands. All of these chemical changes in the Pc and Nc skeleton alter their PDT efficacy. Aggregated Pc and Nc are inactive photochemically because of a greately enhanced rate of excited singlet-state deactivation by internal conversion of the ground state. In the Pc series, Olenick et al. in collaboration with Kenney⁷⁰ synthesized and evaluated four silicon analogs with variable lipophilicity to learn more about the structural features that

SCHEME 37.17

silicon Pc must have to be a good PDT photosensitizer. All these analogs produced similar photophysical properties; however, the photosensitizer denoted as Pc4, bearing a long-chain amino axial ligand **65**, has shown promising results both *in vitro* and *in vivo* and is presently entering clinical trials.⁷¹ Further, it was concluded that the structural features leading to improvement in the association between the photosensitizers and important cellular targets were more useful than those leading to improvements in their already acceptable photophysical and photochemical characteristics. A series of benzyl-substituted phthalonitriles, substituted at the 3,4- and 4,5-positions, was converted into a series of Zn(II) hydroxyphthalocyanines (Pc phenol analogs). Their efficacy as sensitizers for PDT was evaluated on the EMT-B mammary tumor cell line. *In vitro*, the 2-hydroxy Zn Pc was the most active, followed by 2,3- and 2,9-dihydroxy ZnPc, with the 2,9,16-trihydroxy ZnPc exhibiting the least activity. *In vivo*, the monohydroxy derivative and the 2,3-dihydroxy analog were both efficient in inducing tumor necrosis, but complete tumor regression was poor even at high doses. In contrast, the 2,9-dihydroxy isomer at 2 μM/Kg induced tumor necrosis in all animals treated, with 75% complete regression. These results underline the importance of the position of the substituents on the Pc macrocycle to optimize tumor response and confirm the PDT potential of the unsymmetrical Pcs bearing functional groups on adjacent benzene rings.⁷²

Rodgers et al. in collaboration with Kenney and collaborators⁷³ developed a new route to siliconsubstituted Pcs and Pc-like compounds that are robust and flexible. One of the siloxysilicon compounds with the ligand 5,9,12,16,23,28,32-octabutoxy-33H, 35H[b,g]dinaphtho[2,3–1:2',3'-q]porphyrazine **69** has a q band at a wavelength of 804 nm and an extinction coefficient of $1.9 \times 10^5 \,\mathrm{M}^{-1} \,\mathrm{cm}^{-1}$ (Scheme 37.18).

SCHEME 37.18

These compounds showed promising *in vitro* photosensitizing efficacy *in vitro*; however, in animal studies, compared to Pc (Pc 4), they were found to be less effective. A first photophysical study of a member of the family of subnaphthalocyanines (SubNcs) has been described.⁷⁴ The cone-shaped unsubstituted SubNcs, synthesized in 35% yield, showed distinctive photophysical properties that are better than those of the related planar Pcs and Ncs. SubNc absorbs in the red part of the spectrum and has substantial fluorescense. Tripletand singlet-oxygen quantum yield are substantially higher than those of the related Pcs and Ncs. These results, together with their synthetic availability, high solubility, and low tendency to aggregate, make this class of sensitizers worthy of further study with a view to investigating their PDT applications.

37.6 Target-Specific Photosensitizers

Since the introduction of the first PDT drug Photofrin there has not been much success in improving the photosensitizer's tumor selectivity and specificity because tumor cells in general have nonspecific affinity to porphyrins. Although the mechanism of porphyrin retention by tumors is not well understood, the balance between lipophilicity and hydrophilicity is recognized as an important factor. Some attempts have been made to direct photosensitizers to known cellular targets by creating a photosensitizer conjugate, where the other molecule is a ligand specific to the target. For example, to improve localization

to cell-membrane cholesterol⁷⁸ and antibody-conjugates have also been prepared to direct photosensitizers to specific tumor antigens.^{79–81} Certain chemotherapeutic agents have also been attached to porphyrin chromophores to increase the lethality of the PDT treatment.⁸² Certain protein and microsphere conjugates were made to improve the pharmacology of the compounds.⁸³ These strategies seldom work well because the pharmacological properties of both compounds are drastically altered.⁸⁴

Recently, the bovine serum albumin conjugate of a sulfonated Pc (BSA-AlPcS₄) prepared by Brasseur et al. has been shown to target the scavenger receptor of macrophages.⁸⁵ Relative photocytotoxicities were reported using a receptor-positive and a receptor-negative cell line, where their lethal effects correlated with its receptor affinity. Also, ceratin adenoviral proteins have been employed to target lung cancer cells rich in the appropriate class integrin receptor.⁸⁶ Using the EMT-6 murine model, *in vivo* results were encouraging with Pc–adenoviral protein conjugates. Further, both AlPc and CoPc have been covalently labeled with epidermal growth factor (EGF), and this conjugate produced a fivefold increase in photocytotoxicity as compared with nonconjugated Pc.⁸⁷

Since oligosaccharides play essential roles in molecular recognition, 88 porphyrins with sugar moieties should have both good aqueous solubility and possible specific membrane interaction. In addition to providing the molecule with polar hydroxy groups, the sugar moiety may lead the conjugate to a cell-surface target through specific binding to its receptor. Oligosaccharides play essential roles in various cellular activities as antigens, growth signals, targets of bacterial and viral infection, and glues in cell adhesion and metastasis, where the saccharide–receptor interactions are usually specific and multivalent. 89 This specificity suggests a potential utility of synthetic-saccharide derivatives as carriers in directed drug delivery. Therefore, in recent years, a number of carbohydrate derivatives of various photosensitizers have been synthesized. Hombrecher et al. 90 reported the preparation of a galactopyranosyl-cholesteryloxy-substituted porphyrin by following

SCHEME 37.19

the McDonald approach. Several tetra- and octaglycoconjugated tetraphenylporphyrins were also reported by Yano et al.,⁹¹ Cornia et al.,⁹² Momenteau et al.,⁹³ and Ono et al.,⁹⁴ A glycosylated peptide porphyrin synthesized by Krausz et al.,^{95,96} showed promising *in vitro* PDT efficacy. Maillard et al.,⁹⁷ reported the synthesis of a glycoconjugated *meso*-monoarylbenzochlorin (related to 71 and 73; see Scheme 37.19). This compound displayed good *in vitro* PDT efficacy in tumor cell lines. A few years ago, Bonnett et al.,⁹⁸ showed that, compared to β-hydroxy-octaethylchlorin 75, the related glycosylated analog was more effective as a photosensitizing agent *in vitro* as well as *in vivo*. Montforts et al.,⁹⁹ further explored this approach by attaching hydrophilic carbohydrate structural units to certain chlorins. Such conjugation increased the water solubility of the parent chlorins by introducing an estradiol with a diethyl spacer. The chlorin–estrogen conjugate was then prepared in the hope that it would bind to an estrogen receptor that could induce destruction of a mammalian carcinoma. In a recent report, Aoyama et al., 100 reported the synthesis of certain tetraphenylporphyrin-based saccharide-functionalized porphyrins and demonstrated the importance of hydrophobicity masking for the saccharide-directed cell recognition. Since the saccharide–receptor interactions are ubiquitous, well-defined/well-designed synthetic saccharide clusters may serve as a new tool in glycoscience and glycotechnology.

It is known that galectins are involved in the modulation of cell adhesion, cell growth, immune response, and angiogenesis; therefore, it is likely that their expression plays a critical role in tumor progression. 101 Gal-1 mRNA levels increase 20-fold in low tumorigenic and up to 100-fold in highly tumorigenic cells. 102 The Roswell Park group has recently reported the synthesis and biological significance of certain β -galactose-conjugated purpurinimides (a class of chlorins containing a six-member fused imide ring system) **76** to **80** (Scheme 37.20) as a Gal-1-recognized photosensitizer via enyne metathesis. 103 Molecular-modeling analysis using model photosensitizers and the available crystal structures of galectin–carbohydrate moiety indicated that when the β -galactose moiety is placed at the appropriate position the photosensitizer does not interfere with the galectin–carbohydrate recognition. Intracellular studies with known cell-surface counterstains confirmed the cell-surface recognition of the conjugates. Under similar drug and light doses, compared to the free purpurinimide analog, the galactose-and lactose-conjugated analog showed a considerable increase both *in vitro* and *in vivo* photosensitizing efficacy. These results, therefore, indicate the possibility for developing a new class of tumor-specific photosensitizers for PDT based on recognition of a cellular receptor. 103

37.7 Summary

This chapter has focused largely on the chemical rather than the biological aspects of various porphyrin-based photosensitizers for use in PDT. It is important to note that porphyrin-based compounds, in addition to their use in cancer, have also shown potential for application in other areas: treatment of AMD, tumor imaging by MRI (magnetic resonance imaging), psoriasis, bone-marrow purging, and purification of blood infected with various viruses including HIV. Since the discovery of Photofrin, enormous progress has been made in the development of various porphyrin-based compounds with improved photophysical characteristics. In recent years, a number of pharmaceutical companies — such as QLT Pharmaceuticals, Vancouver, B.C., Canada; Miravant, Santa Barbara, CA; Scotia Pharmaceuticals, Stirling, U.K.; Ciba Vision, Atlanta, GA; Pharmacia, Stockholm, Sweden; DUSA, Wilmington, MA; Pharmacyclics, Palo Alto, CA; and Light Sciences Corp., Seattle, WA — have shown major interest in PDT. However, given the possible implications for the use of porphyrin-based compounds (porphyrins, chlorins, bacteriochlorins, expanded porphyrins, Pcs) for the treatment of cancer by PDT, future design strategies for new agents should be directed toward tumor-specific drug molecules. Such compounds might show greater tumor selectivity with reduced skin phototoxicity, a major problem associated with most of the porphyrin-based compounds.

38.1 Introduction

Photodynamic therapy (PDT) refers to photodynamic action *in vivo* to destroy or modify tissue. Originally developed for treatment of various solid cancers, its applications have been expanded to include treatment of precancerous conditions, e.g., actinic keratoses, high-grade dysplasia in Barrett's esophagus, and noncancerous conditions, e.g., various eye diseases and age-related macular degeneration (AMD). PDT currently is approved for commercialization worldwide both for various cancers (lung, esophagus) and for AMD

PDT requires a drug (photosensitizer), light corresponding to an absorption band of the photosensitizer, and endogenous oxygen. The absence of any of these agents precludes the photodynamic effect.

The putative cytotoxic agent is singlet oxygen,¹ an electronically excited state of ground-state triplet oxygen formed according to the Type II photochemical process, as follows:

```
P + hv \rightarrow P^* (S) Absorption

P^* (S) \rightarrow P^* (T) Intersystem crossing

P^* (T) + O_2 \rightarrow {}^1O^*_2 + P Energy transfer
```

where P = photosensitizer, $P^*(S)$ = excited singlet state, $P^*(T)$ = excited triplet state, and ${}^1O^*_2$ = singlet excited state of oxygen.

38.2 The Photosensitizer

Only photosensitizers that undergo efficient intersystem crossing to the excited triplet state and whose triplet state is relatively long lived (to allow time for collision with oxygen) and have few other competing pathways will produce high yields of singlet oxygen. Most photosensitizers in clinical use have tripletquantum yields in the range of 40 to 60%, with the singlet oxygen yield being slightly lower. Competing processes include loss of energy by deactivation to ground state by fluorescence or internal conversion (loss of energy to the environment). However, while a high yield of singlet oxygen is desirable, it is by no means sufficient for a photosensitizer to be clinically useful. Pharmacokinetics, pharmacodynamics, stability in vivo, and acceptable toxicity play critical roles as well. For example, it is desirable to have relatively selective uptake in the tumor or other tissue being treated relative to the normal tissue that necessarily will be exposed to the exciting light as well. Pharmacodynamic issues, such as the subcellular localization of the photosensitizer, may be important as certain organelles appear to be more sensitive to PDT damage than others (e.g., the mitochondria). Toxicity can become an issue if high doses of photosensitizer are necessary to obtain a complete response to treatment. For example, although PDT is rarely carried out on the liver, dark toxicity to the liver is often the main limiting toxicity seen in animal toxicity studies. Along the same lines, lack of in vivo stability would be a further issue relating to toxicity, as the toxicity profile of the breakdown products may need to be evaluated as well. In spite of all these impediments, there is a large number of photosensitizers potentially useful in PDT, several of which are currently in various stages of clinical trials for U.S. Food and Drug Administration (FDA) approval. Additional information on photosensitizers and mechanisms involved in PDT are provided in Chapter 36 of this handbook.

38.2.1 Light

A limiting factor in PDT is the penetration of the activating light into tissue. Visible light in the red region of the spectrum (the most penetrating) has a general penetration depth (l/ϵ) in the range of 2 to 6 mm, depending on the wavelength and the tissue. However, the depth of the biological effect of PDT (necrosis, apoptosis, vascular collapse) is generally found to occur at approximately twice this depth, i.e., 4 to 12 mm, meaning that approximately 10% of the incident light, i.e., the intensity drop-off at two penetration depths, is sufficient to elicit the photodynamic effect in tissue. As would be expected, the liver is one of the most opaque of tissues (due to pigmentation) and the muscle one of the most transparent. Most solid cancers originate in epithelial tissue (carcinomas) and have optical penetration depths of 3 to 5 mm (at ~600 nm) to approximately 6 to 10 mm (at 800 nm, where an optical window exists between absorption by blood and that of water).

Light sources generally are gas-vapor lasers, e.g., argon-pumped, wavelength-tunable dye lasers or solid-state lasers such as frequency-doubled neodymium:yttrium-aluminum-garnet (Nd:YAG) pumped-dye lasers or diode lasers, which are currently being used more frequently. However, appropriate lamps can be used as well, as was the case in the early days of PDT and is currently the case for treatment of actinic keratoses. Light from the laser is generally coupled into quartz fibers of various configurations. For lesions involving the skin and in certain other instances, a lens fiber with a microlens on the tip is

used to produce a homogeneous spot; for treatment of esophageal and lung tumors as well as for interstitial placement a fiber with a diffuser on the end is used, allowing for scattering of the light laterally from the fiber over a distance of 1 to 5 cm generally; for bladder treatment a bulb-type tip is used to produce isotropic distribution over the entire bladder wall. Details of the light dosimetry for particular types of treatments will be described below.

38.3 Methodology of Clinical Photodynamic Therapy

The following discussion refers to the photosensitizer Photofrin® as used in PDT where the most information is available, but with some differences the basic discussion applies to the use of most photosensitizers.

38.3.1 Photosensitizer Injection

Patients receive an intravenous bolus injection of Photofrin in doses ranging from 1 to 2 mg/kg body weight. With Photofrin, as well as certain other photosensitizers that are taken up by the skin, this immediately renders the patient susceptible to severe burns from bright light exposure (sunlight being the most likely source), a condition that generally lasts 4 to 6 weeks but may be longer. Therefore, the patient, family, and others are educated prior to injection to take appropriate precautions, e.g., by wearing clothing to cover the body completely, a broad-brimmed hat, etc. However, patients should not remain in darkened rooms during the day as photobleaching by low-level light enhances clearance of the drug from the skin. Patients are asked to expose a small area on the back of their hand to bright sunlight for 10 min beginning about 4 weeks after injection before slowly beginning to go into the sun. Should a reaction occur, patients are advised to wait an additional week and retest their sun sensitivity. While cutaneous photosensitivity is a bothersome side effect of certain photosensitizers, it is our experience that patients rarely refuse PDT treatment for this reason.

38.3.2 Injection-Light Treatment Time Interval

The amount of time between injection and light exposure varies considerably between photosensitizers, ranging from 1 to 2 d for Photofrin to 15 min for AMD treatment. In general, for solid tumor treatment it is best (but not always necessary) to allow for photosensitizer clearance from normal tissue that may also be exposed to the activating light during treatment to minimize damage as much as possible. However, some photosensitizers demonstrate little retention in tumors and therefore are generally activated shortly after injection. While this risks the normal tissue, in some cases the dosimetry can be adjusted to minimize the damage to normal tissue. Selectivity can also be increased by using a minimum amount of photosensitizer and increasing the light dose to compensate because photobleaching of the lower amount of photosensitizer generally found in the normal tissue can lead to protection. Interstitial placement of the fibers into the tumor also tends to protect surrounding normal tissue but is not always feasible or desirable, e.g., attempts to insert fibers into obstructing esophageal tumors can result in perforations; in this case, they are generally placed within the lumen adjacent to the tumor, while in the case of endobronchial tumors insertion into the tumor can often be done without risking perforation.

38.3.3 Light Dosimetry

Light dosimetry is probably the most difficult variable to define in PDT because the optimum light dose in one organ may be ineffective or toxic in another. Time-consuming light-dose ranging protocols must be carried out to define this parameter for each indication. (Recently it has been recognized that the light-dose rate may also be important; see Chapter 36 of this handbook.) Table 38.1 summarizes the general range of PDT variables used for various photosensitizers, showing the large range of time interval, drug doses, and light fluence. However, even for a single photosensitizer like Photofrin, light doses range from 15 J/cm² in bladder to over 200 J/cm² for skin lesions.

TABLE 38.1 Photosensitizers in Clinical Trials

Photosensitizer ^a	Photosensitizer Dose (mg/kg)	Interval (h)	Energy Dose ^b J/cm ² or J/cm	Wavelength (nm)	Indications
Photofrin	1–2	24–48	15–215 (1) 100–300 (2)	630	Esophageal, lung, skin, bladder, head and neck, brain, and certain other sites
ALA (Levulan)	Topical ALA	14-18	10(1)	Blue	Actinic keratosis
	(20% in vehicle)			(peak at 417 nm)	
mTHPc (Foscan)	0.15	72-96	10-20(1)	650	Oral (approved in Europe)
SnET ₂ (Purlytin)	1.2	4	200 (1)	660	Breast metastases
Lutetium Texaphyrin	1.5–3	3	100-150	732	Prostate, photoangioplasty, AMD
BPD-MA (Visudyne)	6 mg/m ² (~0.15 mg/kg)	0.25	50 (1)	699	AMD (also in Phase III trial for skin cancer)
HPPH (Photochlor)	3–6 mg/m ²	24-48	50-150 (1)	665	Skin, lung, esophagus
,	(~0.08–0.15 mg/kg)		150 (2)		
PC4	_	_		_	Cutaneous cancers (no further information available)

Note: Photofrin = polyhematoporphyrin ethers; ALA = aminolevulinic acid; mTHPc = meta-tetetrahydroxyphenylchlorin; SnET2 = tin etiopurpurin; Lutetium Texaphyrin = a pentadentate aromatic metalloporphyrin; BPD-MA = benzoporphyrin derivative mono acid; HPPH = 2-[1-hexyloxyethyl]-devinylpyropheophorbide-a; PC4 = a silicon phthalocyanine; AMD = age-related macular degeneration.

38.3.4 Photodynamic Therapy with Photofrin

Photofrin (polyhematoporphyrin ethers), the first and, thus far, only photosensitizer approved by health agencies worldwide for treatment of cancer, remains the most widely used in routine clinical practice for treatment of esophageal and lung cancers (approved), as well as in a host of off-label indications (e.g., skin cancer, bladder cancer, brain tumors, head and neck cancer, etc.).

The method of treatment and outcomes for the various indications beginning with those approved by various health agencies worldwide are described in the following sections.

38.4 Health Agency–Approved Indications for Photofrin-Photodynamic Therapy

38.4.1 Obstructive Esophageal Cancer

This indication is for palliation of partially or totally obstructing tumors in the esophagus. Photofrin, obtained as lyophilized powder, is dissolved in 5% dextrose for injection shortly before a single bolus injection of 2 mg/kg body weight. Because this photosensitizer is accumulated and retained in the skin (as well as in most other tissues and tumor), patients are immediately rendered photosensitive and must take precautions against exposure to bright lights (e.g., in a dental office) and especially sunlight. While the supplier of Photofrin suggests precautions continue for 90 d, it is our experience that clearance occurs within 30 to 60 d, although there have been some reported cases of up to 90 d. We ask our patients to expose a small patch of skin on the hand to bright sunlight for 10 min at 30 d post injection and, if redness and swelling occur, to continue taking precautions for another week and then until reaction no longer occurs, at which time they can slowly increase exposure. Patients should not remain in the dark, as low-level light aids clearance by photobleaching the drug. In addition, since Photofrin is activated by visible light, sunscreens and window glass are not protective. As a further precaution, we supply sunglasses

^a Chemical structures can be found in Chapter 37.

^b J = Joules; J/cm² refers to surface dose; J/cm refers to Joules delivered per cm from a diffusing fiber.

TABLE 38.2 Objective Tumor Response — PDT vs. Nd:YAG Laser in Partially Obstructing Esophageal Cancer

	W	Week 1		nth 1
	PDT	Nd:YAG	PDT	Nd:YAG
Complete + partial response	45	40	32 a	20
Stable disease	24	22	15	14
Progressive disease	3	1	11	14

^a Statistically different, p < 0.05; 118 patients in each arm.

to wear when outside. This cutaneous photosensitivity is an annoyance, but we have rarely had a patient refuse treatment because of it.

Approximately 48 h post injection the photosensitizer localized to the tumor is activated by light at 630 nm (generally derived from a laser) that is directed via a single-quartz fiber optic and delivered to the tumor through the biopsy channel of an endoscope. The distal end of the fiber is fitted with a diffusing surface, generally 2.5 to 5.0 cm in length, which allows the light to scatter laterally to the tumor on the wall of the esophagus. In some instances, the fiber may be inserted directly into the tumor, although care must be taken to avoid perforation of the esophageal wall. This can be problematical because obstructing tumors may cause distortion of the esophagus, making insertion of the fiber somewhat blind. In most instances, the fiber is placed in the remaining lumen adjacent to the tumor. Some physicians place patients under general anesthesia, but this is generally unnecessary, and conscious sedation is used most often. The light dose is 300 J/cm of diffuser length with a power density of 400 mW/cm diffuser length, requiring 12.5 min to deliver the prescribed dose. Patients will often experience mild to severe chest pain (due to treatment-induced edema) controlled with analgesics. Other adverse reactions include fever, abdominal pain, constipation, and substernal pain. Patients are examined endoscopically 2 d following treatment to judge initial response, to obtain biopsies, and to remove necrotic debris (not generally necessary). Also, if necessary, a second light treatment can be administered at this time (an advantage of long tumor retention of Photofrin). The treated tumor becomes blanched, and noninvolved areas in the light field generally are found to be edematous and erythemic. Table 38.2 summarizes the outcome of the randomized clinical trial of PDT vs. Nd:YAG laser thermal ablation carried out for the U.S. FDA and other health agency approvals.2

Only at 1 month was the advantage of PDT evident; this outcome is similar to that seen for PDT treatment of obstructive endobronchial tumors vs. Nd:YAG ablation (see the following section). This may reflect the ability of the light to reach more of the tumor than is possible with the Nd:YAG laser, which must be aimed at the tumor; care must be taken to avoid perforation. (In the clinical trial noted above there were seven perforations in the Nd:YAG group vs. one in the PDT group.)

38.4.2 Obstructing Endobronchial Tumors (Nonsmall Cell Lung Cancer)

Also approved by the U.S. FDA and other health agencies is the palliative treatment of obstructive endobronchial tumors. The treatment approach is similar to that for the obstructing esophageal tumors (2.0 mg/kg body weight Photofrin, 630 nm light treatment approximately 48 h later) with certain notable differences. The light dose is 200 J/cm diffuser (8.3 min), generally delivered interstitially when feasible with 1.0- or 2.5-cm diffuser fibers. Also, 2 d following treatment patients are re-endoscoped, and all necrotic tumor debris and exudate must be removed because they can further obstruct the airway. This step is especially critical when the treatment is near the carina and debris and exudate can extend into both mainstem bronchi, presenting a potentially life-threatening outcome.³

As in the esophageal study, patients in this multicenter phase III trial were randomized to PDT or thermal ablation with the Nd:YAG laser. Also, as was seen in the esophageal trial, there was no statistical difference in outcome until after 1 week (see Table 38.3).⁴

TABLE 38.3 Objective Tumor Response of PDT vs. Nd:YAG Laser for Obstructing Endobronchial Cancer (211 patients)

	Week 1		Month 1	
	PDT	Nd:YAG	PDT	Nd:YAG
Complete and partial response	59	58	60	41

 TABLE 38.4 Outcome of Patients with Microinvasive Lung Cancer

	11 Patients	62 Patients
CR (3 months) (biopsy proven)	3/11	31/62
Recurrence	1	11
Median time to recurrence		>2.7 years
Median survival		2.9 years
Median disease-specific survival		4.1 years

For example, at 1 month 40% of PDT-treated patients demonstrated improvement in symptoms (dyspnea, cough, hemoptysis) vs. 27% of Nd:YAG patients. Adverse reactions included photosensitivity reaction (20% in PDT arm only), hemoptysis, cough, dyspnea, chest pain, and fever, which occurred with similar frequency in both arms.

38.4.3 Early Stage Endobronchial Tumors

Treatment of microinvasive, nonsmall cell endobronchial tumors using Photofrin-PDT is the only indication thus far approved by the U.S. FDA and other health agencies where the intent is not palliation but cure. Also, unlike the palliative approval previously described, this study was approved based on several studies not specifically designed and carried out by the sponsoring company but, rather, independently in three noncomparative studies. Patients in this study included those with CIS (carcinoma *in situ*) or microinvasive tumors. Also included were patients not considered candidates for surgery (or radiation therapy in some cases).

Patients received 2 mg/kg Photofrin and 2 d later were treated endoscopically using a diffuser fiber (usually 1 to 2.5 cm) delivering 200 J/cm of diffuser length at 630 nm. Because these lesions are very thin, the fiber was held in the lumen adjacent to the lesion. Patients were rescoped 2 d following treatment, and the treated area was debrided.

Results with 102 patients indicated biopsy-proven complete response in 79% of patients (initial followup), with more than half continuing to be complete responders often more than 2 years post treatment. The median survival was 3.5 years and disease-specific survival 5.7 years. In a smaller segment of this trial population with microinvasive lung cancer (the actual approved indication), 62 inoperable patients were treated, 11 of whom were considered not to be candidates for surgery or radiation therapy. Table 38.4 indicates the outcome in this group.^{5,6}

38.4.4 Early Stage Esophageal Cancer

Although not yet approved by the U.S. FDA, a Phase III randomized, controlled, multicenter trial of Photofrin-PDT in patients with high-grade dysplasia (HGD) in Barrett's esophagus was recently completed for filing with the U.S. FDA. This study randomized patients to receive an acid suppressor, Omeprazole (Prilosec), or PDT plus Omeprazole. Endoscopic PDT was applied using a specially designed balloon light applicator with windows of 3, 5, or 7 cm in length produced from diffuser fibers of 5, 7, or 9 cm in length. The last centimeter on each end is blocked off because the power at the ends of the diffuser is less than that emitted in the center of these fibers. The balloon was inserted deflated and then inflated in place to an appropriate pressure to allow "unfolding" of the esophageal wall without shutting

down the blood flow. The Photofrin dose was 2.0 mg/kg injected approximately 2 d prior to light delivery of 130 J/cm of diffuser length. A preliminary report⁷ at 6-month follow-up indicated that HGD was eliminated in 72% of patients in the PDT group but only in 31% of patients in the control group (Omeprazole alone). Moreover, at 2 years 70% of responders in the PDT group continued to be complete responders, while none of the patients in the Omeprazole-alone group were without HGD. Significantly, only 10% of patients in the PDT group progressed from HGD to esophageal cancer vs. 19% of patients receiving only Omeprazole.

Overholt et al. have reported on 100 patients treated for this indication with Photofrin and the balloon light emitter. Of 73 patients with HGD, 56 were complete responders, and 32 had complete elimination of the Barrett's. The current practice is to subject patients with HGD to an esophagectomy, a surgical procedure associated with high mortality (5 to 10%) and morbidity.

Barrett's esophagus is also eliminated by PDT treatment by 70 to 100% in most patients, being replaced with normal squamous mucosa. While not a specific endpoint in the trial, PDT appears to be one of the few methods currently available to remove this acid reflux–induced inflammatory process, a risk factor for developing esophageal cancer (from 0.5 to 1.9% of patients with Barrett's esophagus will progress to HGD, and up to 50% of patients with HGD will go on to esophageal cancer over a 3-year period⁹).

38.5 Other Indications for Photofrin-Photodynamic Therapy

In addition to the approved or soon-to-be-approved indications of PDT using Photofrin, numerous other types of cancers have been treated including those of the head and neck, especially early stage, ¹⁰ skin, ^{11,12} brain, ^{13,14} bladder, ¹⁵ intrathoracic cavity (especially as an adjunct to surgery for mesothelioma), ^{16,17} and intraperitoneal tumors, such as ovarian studding ¹⁸ and cholangiocarcinoma. ¹⁹ Several of these are discussed in the following sections.

38.5.1 Cholangiocarcinoma

A potentially very useful application of PDT is in the treatment of cholangiocarcinoma cancer. These tumors are generally diagnosed late when surgery is rarely curative. In nonresectable cases, drainage or biliary bypass is used for palliation. Radiation therapy and chemotherapy appear to be of little benefit. In a series of 21 patients reported by Ortner et al., ¹⁹ nonresectable patients were treated with Photofrin (2 mg/kg) 2 d prior to endoscopic fiber placement in the lumen (630 nm, diffuser fibers, 2.5 or 4.0 cm of diffuser length delivering 180 J/cm at a constant total power output of 800 mW). There was a dramatic drop in bilirubin in the PDT group (69 μmol/l) vs. stenting alone (20 μmol/L), and the Karnofsky score improved from 49 to 73 in the PDT arm. Eight patients were alive at 82 to 739 d post treatment, and median survival was about 1 year. A small randomized trial has been reported²⁰ with 35 patients, 20 to PDT + endoprostheses insertion (EP), and 15 to EP alone. An additional 34 patients who refused randomization received compassionate PDT + EP and were analyzed separately. The PDT treatment was as above. The median survival for the PDT + ES was 493 d vs. EP-alone group of 98 d. The compassionate PDT + EP group had median survival of 406 d. All patients in the control arm (EP alone) are dead; six are alive in the PDT + EP compassionate group and two in the PDT + EP group. Significant improvement in bilirubin levels was seen in both groups receiving PDT + ED, but none was seen in the EP-alone group. Karnofsky scale improved only in the PDT + EP compassionate group. It was concluded that addition of PDT to EP was a valuable improvement in palliation treatment because of significantly increased survival and improvement in quality of life. As a result of this outcome the randomized trial was stopped for ethical considerations.

38.5.2 Head and Neck Cancers

Application of PDT to treatment of head and neck cancer was initially limited to treatment of patients with advanced disease who had failed or recurred on standard therapy. These patients rarely benefited

from PDT. However, more recently, Biel¹⁰ has shown a high success rate in PDT treatment of early stage disease of the oral cavity and larynx. Twenty-five patients who had failed radiation therapy for early laryngeal cancers (CIS or T1) received Photofrin (2 mg/kg) followed 2 days later by 630 nm light at an energy dose of 80 J/cm². All patients received a complete response and remain free of disease with a mean follow-up of 27 months. An additional 23 patients with early carcinomas (CIS T1, T2) of the oral cavity, nasal cavity, and nasopharynx were treated similarly, and all were initially complete responders, with a mean follow-up of 26 months. One patient with recurrent leukoplakia of the tongue recurred at 12 months, one with recurrent cancer of the tongue and floor of the mouth recurred at 8 months, one patient developed regional metastases at 2 months, and another patient with nasal cancer recurred at 3 months post-PDT.

38.6 Photodynamic Therapy as Adjuvant Treatment

38.6.1 Head and Neck Cancers

PDT has been used frequently as an adjuvant to surgery in an attempt to "clean up" the remaining cancer cells in the operative bed. Biel has reported on five patients with recurrent infiltrating squamous cell carcinoma all of whom had failed previous surgery, radiation therapy, and chemotherapy. Patients received 2 mg/kg Photofrin followed 2 d later by surgery and PDT at 50 J/cm². He reported no postoperative complications. With a follow-up of 18 to 30 months only one patient had recurred in an area outside the surgical and PDT field.

38.6.2 Brain Tumors

Muller has treated over 100 patients with surgery and PDT.¹³ Most had glioblastoma or astrocytoma, newly diagnosed or recurrent. These tumors are rarely curable by surgery, radiation therapy, or chemotherapy. The adjuvant studies were undertaken to determine the safety and feasibility of adding PDT to the surgical resection. Photofrin (2 mg/kg) was injected 12 to 36 h prior to light treatment using a specially designed expandable balloon applicator that fit within the surgical cavity and was filled with a light-scattering material (1:1000 dilution of lipid). The delivered light at 630 nm was measured using a "pick-up" fiber placed adjacent to the balloon. Total energy doses ranged from 440 to 4500 J, with an energy density of 8 to 110 J/cm². The mortality rate was 3%, with a combined serious mortality and morbidity rate of 8%. Eight patients with recurrent gliomas who received more than 60 J/cm² had a median survival of 58 weeks, while 24 who received less than 60 J/cm² had a median survival of 29 weeks.

Twenty patients with all types of brain tumors who received PDT at first operation had median survival of 44 weeks, with a 1-year survival of 40% and 2-year survival of 15%. Again, a light-dose effect was found, with those patients who received less than a total light dose of 1200 J having a median survival of 39 weeks and those with light doses greater than 1200 J having a median survival of 52 weeks. Patient characteristics in the two groups were similar. Patients with high Karnofsky score (>70) and who received light doses over 1260 J had a median survival of 92 weeks, with 1- and 2-year survival of 83% and 33%, respectively. The authors conclude that PDT with Photofrin is safe and appears to increase survival, especially at the higher light doses. A multicenter, randomized (high or low light dose) trial is currently ongoing to verify this conclusion.

38.6.3 Mesothelioma

This asbestos-induced disease of the mesothelium can be very advanced before becoming symptomatic and, like the brain tumors discussed above, is rarely curable by surgery, radiation therapy, or chemotherapy. Moskal et al. have reported on a series of 40 patients treated by a combination of surgery and PDT.¹⁷ Patients received 2 mg/kg Photofrin, and 2 d later as much tumor was removed as possible or debulked to 5 mm or less. PDT was then carried out by delivering 630 nm light to the entire thoracic cavity via

four to six diffuser-type delivery fibers (2.5 to 5.0 cm in diffuser length) placed so as to deliver 20 to 30 J/cm² as evenly as possible. This was done in two placements of the fibers, posteriorly and anteriorly. Because of the large area to be treated (estimated from the CT scans) total light-treatment time can range up to 4 h at a power density of approximately 10 J/cm². Postoperative staging indicated 12 patients with Stage I disease, 10 being completely resected; 11 patients with Stage II disease with complete resection; 25 patients were Stage III, only 5 of whom could be completely resected (3 died); and 2 patients with Stage IV disease. Morbidity and mortality rates for patients with Stage I or II were 38% and 0%, and for Stage III or IV, 48% and 11%, respectively. Patients requiring extrapleural pneumonectomy did not benefit from the combined treatment, as 43% of these patients had a bronchopleural fistula, much higher than the 1 to 4% reported in the literature. However, Stage I and II patients not requiring pneumonectomy appear to have increased survival (41% at 2 years) compared to those receiving surgery alone.

38.7 Other Photosensitizers

Because of prolonged cutaneous photosensitivity induced by Photofrin (30 to 60 d) and less-thanoptimum absorption in the red region of the spectrum, a host of newer photosensitizers are undergoing clinical trials. (See Table 38.1 and Chapter 41 of this handbook.)

38.7.1 ALA

δ-Aminolevulinic acid (ALA) is involved in the heme pathway in which the final metal-insertion step can be obviated with a large excess of ALA, thereby causing the build-up of protoporphyrin IX (PpIX), a porphyrin photosensitizer. Injectable PpIX is not a useful photosensitizer because it is not well retained by tumors or other tissues and clears the system very rapidly. However, the intracellular accumulation of PpIX through excess ALA can be effective. In fact, topically applied ALA is approved by the U.S. FDA for the treatment of actinic keratosis, a precancerous lesion that can lead to squamous cell carcinoma. The sponsor has also developed a special blue-light source that can be fitted on the patient's head to allow treatment of the entire face for patients with numerous lesions. In the Phase III trials, patients were treated topically with 20% ALA in a proprietary vehicle (Levulan*) and the next day received the blue-light treatment (approximately 15-min exposure). In one study of 117 patients, 80% of lesions had a complete response that increased to 94% with a second treatment, while in the placebo group (placebo + light) only 32% of lesions responded completely after two treatments. Adverse reactions included a stinging, burning sensation, which was well tolerated.

Topical ALA has also been applied to the treatment of superficial skin cancers — with excellent results. It is less effective for nodular lesions. ¹² In this treatment, the ALA (10 to 40%) was applied topically in leucerin cream for various periods (usually 4 or 24 h) and then activated at 635 nm derived from a dye laser delivering light doses up to 200 J/cm². In this treatment, the pain is sufficient to require local injection of an anesthetic prior to treatment. Most patients tolerate this well.

ALA is currently being investigated as a fluorescent localizing agent in bladder cancer (see Section 38.8) and for treatment of low-grade dysplasia in Barrett's esophagus.²²

38.7.2 mTHPc (Foscan)

This chlorin-type photosensitizer has been approved in Europe for treatment of oral cancers. Fan et al. have reported preliminary clinical results.²³ Nineteen patients with various stages of disease (8 with field change disease) were injected with mTHPc (0.15 mg/kg) and 72 to 96 h later treated with varying light doses at 652 nm. Three patients with single T3 lesions received a complete response, as did three of six T4 tumors. Field change disease responded less well, with 9 of 14 T1 and T2 lesions responding completely. Adverse reactions included one patient with tongue tethering and necrosis of normal tissue in another. However, while mTHPc is approved in Europe for this indication, the U.S. FDA chose not to approve it in the United States, although as of this writing this decision is under review.

38.7.3 SnET2 (Purlytin, Tin Etiopurpurin)

While trials have been completed with this photosensitizer in cutaneous breast cancer metastasis, the sponsoring company chose not to file for approval for the indication. However, they have completed two placebo-controlled clinical trials with 933 patients in 59 centers for AMD.²⁴ These trials concluded in December 2001 (a 2-year follow-up period is required).

38.7.4 Lutetium Texaphrin (Lu-Tex)

This is an example of a so-called expanded metalloporphyrin system resulting in a strong shift in the red absorption band from around 620 to 732 nm, where nearly optimum tissue penetration occurs. Current clinical trials are in locally recurrent prostate cancer and noncancerous indications, AMD and photoangioplasty.²⁵ Details are not available. Moderate to severe pain during treatment has hampered studies of treatment of various cutaneous malignancies.

38.7.5 HPPH (Photochlor)

Three Phase I/II clinical trials of PDT with this new chlorin-type photosensitizer are under way at Roswell Park Cancer Institute: partially obstructing esophageal cancer, early stage lung cancer, and basal cell carcinoma.

In obstructing esophageal cancer eight patients have been treated at 6 mg/m² (0.15 to 0.19 mg/kg body weight) and 150 J/cm of 665-nm light delivered at approximately 48 h post infusion of HPPH. All patients have achieved partial or complete opening of the esophageal obstruction, and most have had improvement in dysphagia. In these trials, patients are tested daily for cutaneous photosensitivity for 3 to 4 d using a solar simulator (1-cm spot on the underside of the wrist) at doses up to 133 J/cm². Only two patients have had a mild erythemic reaction. Although the in-house solar simulator indicates very little cutaneous photosensitivity, the patients still are advised to test their reactions to sunlight by exposing a small area on the back of their hands for 10 to 30 min daily until no HPPH-induced reaction is found before ceasing precautions.

38.7.6 PC4

This silicon phthalocyanine, with two axial ligands on silicon, a hydroxy group, and a dimethylamino-propyl siloxy group, has just recently entered Phase I dose-escalation clinical studies with cutaneous lesions. No information is available as of this writing.

38.7.7 BPD-MA (Verteporfin®)

38.7.7.1 AMD

The macula constitutes a small, highly specialized region of the human retina. The central part is rich in photoreceptor cells and is the area responsible for high visual acuity in humans. The end result of macular degeneration is the ultimate destruction of photoreceptor cells in the macula as well as the underlying cells of the retinal pigmented epithelium (RPE). Macular degeneration is the leading cause of blindness in the developed world and is most prevalent in people over the age of 60. There are two principal forms of AMD: dry or nonexudative AMD and wet or exudative AMD. While wet AMD constitutes only about 10% of all cases of AMD, it is responsible for most of the vision loss associated with the disease. Approximately 500,000 new cases of wet AMD are reported every year worldwide. Because this is a disease predominantly of caucasians, the main areas of disease incidence are North America and Europe. Wet AMD occurs when rapidly growing abnormal blood vessels develop under the macula in a process described as subretinal neovascularization. The newly formed vessels do not mature properly and leak into the subretinal space, effecting detachment of the RPE and the ultimate degeneration and destruction of the photoreceptor cells in the region of the lesion.

The underlying causes of wet or dry AMD are not well understood, but there is evidence for genetic tendencies since there are familial as well as racial propensities in disease occurrence. While there is strong circumstantial evidence for a genetic base for the disease, the genes relating to susceptibility are clearly complex and are not well understood at this time. Familial studies on patients with Stargardt's disease have clearly identified a specific gene mutation associated with this severe macular disorder. The gene identified is a photoreceptor-cell-specific ATP-binding cassette transporter gene (ABCA4), and patients with Stargardt's disease, as well as a number of other disorders associated with the retina, express mutations in this gene, which is polymorphic.²⁶ A recent study has shown that patients who express particular mutations in at least one allele of this same gene are at either a three- or fivefold greater risk of developing wet AMD.²⁷ These studies support the genetic basis for susceptibility to AMD but also demonstrate that the genetic basis is complex and no doubt involves additional gene loci. It has been suggested that the ABCA4 gene plays a functional role in the eye. Most ABC transporters act as "flippases," i.e., as transporters of the protonated complex of all-trans retinal and phosphatidylethanolamine (Nretinylidene-PE). In knockout mice lacking the ABCA4 gene, phosphatidylethanolamine accumulates with resulting deposition of a major lipofuscin fluorophore (A2-E or a pyridinium bis-retinoid, which is derived from two molecules of vitamin A aldehyde and one molecule of ethanolamine) in the retina. Accumulation of lipofuscin in the macular region of aging eyes is characteristic of AMD.²⁸

The exudative or wet form of AMD is diagnosed using standard fluorescein angiography. Serial fluorescent photography of the macular area can readily identify where vessel leakage is occurring because fluorescein will pool in the area of neovasculature. Exudative AMD is subdivided into two categories based on the speed of visible leakage on angiographs. The "classic" form of AMD is considered the most aggressive form of the disease, and leakage occurs rapidly during the angiography. This form of AMD is characterized by rapid progression and concurrent vision loss. Lesions that leak slowly and show up on angiograms late are defined as "occult" wet AMD. These lesions lead to vision loss at a slower rate than the classic form.

Although the overwhelming majority of research and clinical testing with PDT has addressed the application of this technology in the treatment of solid tumors, during the past decade and a half possible applications in other disease areas have been investigated. Because many photosensitizers accumulate or are retained somewhat selectively in both rapidly dividing cells as well as neovascular endothelial cells, the PDT effect, at least on solid tumors, has been elegantly demonstrated using Photofrin to effect both the tumor cells themselves and the neovascular bed underlying rapidly growing tumors.^{29,30}

Ocular conditions involving either neoplasias or hypervascularity lend themselves to PDT because of the accessibility to light of all parts of the eye. Early investigator-sponsored studies using Photofrin for the treatment of ocular tumors demonstrated the effectiveness of this therapy in destroying local tumors as well as the neovascular bed surrounding them. The Verteporfin molecule (also termed BPD-MA or Visudyne) is a hydrophobic photosensitizer with pharmacokinetic properties that make it a desirable drug to use in indications such as AMD. It is formulated as a liposome in order to render it soluble in water. However, once in association with plasma the drug demonstrates an affinity for lipoproteins much greater than its affinity for the liposomal constituents. Consequently, it is almost instantaneously released from the liposome and transferred to LDL and HDL in blood. This somewhat unusual characteristic results in very rapid uptake of the drug by neovascular endothelia and a treatment window for selective accumulation at between 15 and 30 min following intravenous administration. Therefore, unlike most photosensitizers, which rely on selective retention by target cells, Verteporfin achieves selectivity by differential uptake by target tissue.³¹ Verteporfin has the additional advantage of having a very short half-life (4 to 5 h in humans). Thus, treatment at an early time interval permits use of relatively low drug doses, and with the rapid half-life patients are photosensitive for only 24 h.

Research was undertaken in 1992 to investigate the feasibility of using Verteporfin for the treatment of AMD. Initially two models in the rabbit were used — induced corneal neovasculature and implanted ocular tumors. Results from these studies were encouraging and showed in both instances that the expected thrombotic closure of neovasculature was seen in PDT-treated eyes. These studies also suggested a window of selectivity in which normal vasculature might be preserved.³² Final proof-of-concept work

involved the primate model for AMD in which thermal laser damage to the retina induces a neovascular lesion on the choroid. Although self-limiting, this model is considered the most reliable one for testing treatments for AMD. Results from these studies were encouraging and continued to demonstrate effective closure of neovascular vessels at time intervals from 10 to 60 min following intravenous administration.³³

Phase I/II clinical work with Verteporfin was initiated in 1996 in which patients with AMD received a single treatment with Verteporfin and were followed for 12 weeks by angiographic examination and visual-acuity evaluation. A variety of regimens were tested involving two different drug doses, five different light doses, and two different times of treatment. These studies revealed that at 7 d post-PDT all lesions treated showed complete closure of neovasculature with no accompanying vision loss or closure of normal retinal blood vessels, with the exception of two patients who received the highest light dose (150 J/cm² at 690 nm and 600 mW/cm). In these patients, closure of normal retinal vessels was observed, thereby demonstrating the level at which selectivity was lost. Interestingly, while patients on average did not lose significant visual acuity at either 4 weeks or 12 weeks following treatment, a majority of them did show the presence of vascular leakage at the 12-week time point, indicating that repeat treatment would likely be necessary if a sustained benefit of PDT were to be maintained.³⁴

These preliminary clinical trials, in which approximately 150 patients had participated, led to development of a protocol for two pivotal Phase III trials for treatment of patients with AMD with lesions that contained a classic component. The study design involved randomization of patients in a 2:1 ratio of Verteporfin treatment vs. placebo. A total of 609 patients were accrued in the two trials; approximately 400 received treatment, while 200 received placebo. Patients were tested for baseline visual acuity and lesion assessment by angiography. They received either Verteporfin intravenously at a dose of 6 mg/m² or placebo. Fifteen minutes after drug administration, light treatment of 50 J/cm² at 600 mW/cm was administered to the lesion using a diode laser emitting at 690 nm. Patients returned every 3 months, at which time they were tested by angiography for evidence of vessel leakage. If leakage was present, they received another treatment. Visual acuity was tested at each visit. The primary endpoint was designated as showing a significant difference between treatment vs. placebo in a loss of three lines of vision (approximately 15 letters on a standard eye chart) at 12 months. Secondary endpoints included serious vision loss (six lines), lesion size and progression, contrast sensitivity (a measure of reading ability), and actual visual acuity. Although this was a 2-year study, agreement with regulatory bodies permitted filing for approval if the 12-month primary endpoint was achieved. All primary endpoints achieved significance at the 12-month time point.³⁵ These patients have now been followed for nearly 4 years. After 2 years all patients, including placebo patients, have been receiving treatment if needed. Visual acuity in treated patients stabilized within the first year, and no loss of vision has been observed in years two and three.³⁶

Visudyne (Verteporfin) therapy has now been approved for wet predominantly classic AMD in more than 50 countries, and over 50,000 patients have been treated.

Further clinical trials have been carried out to test the ability of PDT to arrest progression of the occult form of AMD. A placebo-controlled study of similar design to that used for the classic form containing lesions was carried out with similar endpoints. In this study, the significance of the primary endpoint was not reached at 12 months, but patients on treatment did stabilize during the second year, and all endpoints were significant at 2 years. Because occult disease is slower progressing than the classic form, it is not surprising that the difference between placebo and treatment arms took longer to show a significant difference.³⁷

In addition to AMD, other ocular conditions have been treated with Visudyne therapy. These diseases include conditions that cause choroidal neovasculature similar to that seen in AMD. Among these are pathologic myopia, a complication of extreme nearsightedness, and acular histoplasmosis syndrome, a complication of a parasitic infection. Regulatory approval for these conditions has also been granted in both North America and Europe.³⁸

These studies have established PDT as first-line therapy for AMD and other conditions. The safety of repeated treatments has been established, with very few side effects noted. In the occult trial, about 4% of patients experienced severe vision loss within the first week after treatment. A majority of these patients recovered from this event but are not recommended for further treatment.

Two other photosensitizers have been tested clinically for their effect on choroidal neovasculature. These are tin ethyl etiopurpurin (Purlytin) and texaphrin. Phase I/II studies with Purlytin showed vessel closure similar to that seen with Visudyne.³⁹ A Phase III placebo-controlled trial has almost completed 2 years of follow-up, and results should be made available early in 2003. Since this also is a hydrophobic photosensitizer, one would assume that vessel closure similar to that seen with Visudyne should be achieved. Texaphrin has been tested in Phase I/II clinical trials in approximately 70 patients. These results, reported at various ophthalmology meetings, suggested that vessel closure was difficult to achieve, even at high drug doses. It is possible that the relative water solubility of this drug vs. Visudyne and Purlytin to some extent does not lend itself to rapid cell uptake.

PDT is now established as part of the ophthalmologist's armamentarium for the treatment of abnormal vascular conditions in the eye. The therapy has proven itself to be both safe and efficacious. In addition to the diseases mentioned above, there are a number of other ocular conditions in which PDT could play a role including diabetic macular edema, diabetic retinopathy, corneal neovasculature, and ocular tumors. While alternative therapies for these conditions exist, unlike AMD, for which there was no treatment, it is possible that PDT may offer some advantages over existing therapies.

38.8 Photodetection

Photosensitizer fluorescence as a marker of early stage cancers has been studied in several indications. PpIX fluorescence derived *in situ* from ALA has proven capable of detecting lesions in the bladder not detectable by ordinary cystoscopy. Ale Riedl et al. have recently demonstrated the clinical significance of this increased detection rate. In a prospective, randomized study of 102 bladder cancer patients with tumors ranging from TaG1 to T1G3, 51 received transurethral resection under white-light cystoscopy and 51 received ALA-induced fluorescence guided transurethral resection. Fluorescence detection was carried out by instilling into the bladder 1.5 g ALA in 50 cc sodium bicarbonate (to achieve a pH of 6.5) and left in place 1 to 4 h (the time did not appear to affect the outcome). A white-light source coupled with a band-pass filter to produce blue light was used to excite the red fluorescence of PpIX. Six weeks later all patients underwent ALA-assisted transurethral resection. Tumor was detected in 39% (20 of 51) of patients who initially received the standard method, and 16% (8 of 51) of the ALA group experienced a reduction in tumor recurrence of 59% (p = 0.005). The authors conclude that ALA-assisted transurethral resection is an inexpensive and effective method for significantly increased tumor detection in the bladder.

38.8.1 Detection of Early Stage Lung Cancer

As is well known, early stage lung cancer is difficult to detect, and earlier screening studies of high-risk patients using chest x-ray and sputum cytology have shown no survival benefit. Recently, however, spiral CT and fluorescence bronchoscopy have been investigated for detection of early lung lesions — the former to detect peripheral lesions and the latter mainly for centrally located lesions. At this institution we have initiated a screening program of high-risk patients (previous history of lung cancer or head and neck cancer or exposure to asbestos) using an FDA-approved fluorescence-endoscopic method called LIFE (Light Induced Fluorescence Excitation) from Xillix Corporation for examination of the central airways. This system has been shown to be nearly three times as likely to detect an early lesion when used with white-light bronchoscopy as white-light bronchoscopy alone. It is based on the principle that even very early dysplasia or CIS tends to accumulate endogenous chromophores (e.g., porphyrins), thereby presenting a reddish-brown fluorescence compared to normal bronchial mucosa, which is seen as greenish in color. 42 The suspicious areas are confirmed by biopsy. In addition, each patient is screened using spiral CT for detection of peripheral lesions. Appropriate patients are treated by PDT. While this is a relatively modest trial of 500 patients, the intention is not only to investigate these techniques for efficacy in detection of early lesions but also to determine effect on survival after appropriate treatment (and not, incidentally, to assist in convincing third-party payers to reimburse for screening).

38.9 Future Directions for Photodynamic Therapy

While PDT has been mainly a cancer therapy, it is clear that its applications are extending to many noncancerous conditions, as is evident from the previous discussion. Other areas currently being investigated are prevention of restenosis after balloon angioplasty for cardiac artery disease, treatment of rheumatoid arthritis (inflammatory cells are particularly prone to photosensitizer uptake), and certain early-detection indications.

39.1 Introduction

The joining of tissue by the application of heat through the use of hot-loop forceps was first described in the 1960s. In 1964, a neodymium laser was used to join small blood vessels — the first reported use of a laser for thermal welding of tissue. Since then, numerous experimental studies have been conducted using a variety of lasers for welding of soft tissues including blood vessels, the genitourinary tract, the gastrointestinal tract, liver, spleen, nerves, dura mater, skin, sclera, trachea, and cartilage. As we enter the 21st century, laser tissue welding has reached the threshold at which it is moving from the laboratory bench to clinical application, making this an exciting time for all involved. This chapter reviews the principles, theory, and application of laser tissue welding. An insight is also provided into several important developments that have been made involving the use of light-activated surgical adhesives to

assist in the welding procedure, infrared (IR) temperature feedback control of the laser device, and computer modeling of the welding process. In addition, this chapter provides a comprehensive review of current and future clinical applications of laser tissue welding including developments in the fields of endoscopic and laparoscopic surgeries.

39.2 Background Principles and Theory

Lasers have been demonstrated to be extremely useful in many medical and surgical applications as both diagnostic and therapeutic tools. The use of laser energy to induce thermal changes in connective-tissue proteins is of particular interest for the joining of severed tissue, where proteins within the target tissue are coagulated to form a bond between the two adjoining edges. As the degree of success of all new surgical techniques must ultimately be judged in comparison with existing techniques, the following sections review the most common closure methods currently in use.

39.2.1 Conventional Closure Methods

The conventional methods for tissue repair use sutures, staples, or clips.¹ Sutures are favored because they are cost-effective, reliable, and, more importantly, suitable for almost any type of tissue. However, due to their mechanical intrusion, the use of any of these conventional fasteners causes tissue injury. By their very nature they result in a foreign body being left in the tissue. Tissue injury and foreign-body reaction can give rise to inflammation (nonspecific immune response of tissue to injury resulting in redness and swelling), granuloma formation (development of a grain-like tissue lesion), scarring (permanent marking of tissue), and stenosis (abnormal narrowing or constriction of tissue lumens). Sutures become difficult or tedious to execute in microsurgical or minimally invasive endoscopic applications, where staples or clips are better suited. Staples and clips are not easily adapted to different tissue dimensions, however, and maintaining precision of alignment of the tissue is difficult because of the relatively large force required to deploy them. Finally, none of these fasteners produces a watertight seal over the repair.

39.2.2 Other Closure Methods

Besides sutures, staples, and clips, other closure techniques, including both biological and nonbiological adhesives as well as various coupling devices, have been tested. Fibrin glue has long been used as a biological surgical adhesive.²⁻⁴ Fibrin glue imitates the final step of blood coagulation and thus has been used effectively for hemostasis. However, repairs formed with fibrin glue alone are typically weak in comparison with suture repairs.⁵ Consequently, the glue is almost always used in conjunction with stay sutures.⁴ Among the various synthetic adhesives available, cyanoacrylates are the most popular.⁶⁻⁸ However, they are toxic to the tissues, not absorbed in the normal wound healing process, and cause foreign-body granulomas and allergic reactions. Two examples of anastomotic coupling devices are the UNILINK (3M, St. Paul, MN) anastomotic system^{9,10} and the 3M Precise Microanastomotic System (3M).^{11,12} While these devices and several others like them have produced superior repairs with regard to anastomotic time and patency rate when compared to suture, they suffer from size inflexibility and often involve the sacrifice of some length of the structure being anastomosed.

39.3 The Recognition and Development of Laser Tissue Welding

The feasibility of laser tissue welding was first shown by Yahr and Strully in 1964, when they used a neodymium laser to join small blood vessels.¹³ In 1979, Jain and Gorisch reported the first reproducible experimental use of laser tissue welding.¹⁴ In that report, a neodymium:yttrium-aluminum-garnet (Nd:YAG) laser was used for microvascular anastomosis of rat carotid and femoral arteries. The work was followed up with a report on a small series of clinical studies.¹⁵ Since then a wide range of lasers

have been used for laser tissue welding. Infrared sources include carbon dioxide (CO₂), thulium-hol-mium-chromium, holmium, thulium, and neodymium rare-earth doped garnets (THC:YAG, Ho:YAG, Tm:YAG, and Nd:YAG, respectively), and gallium aluminum arsenide diode (GaAlAs) lasers. Visible sources include potassium-titanyl-phosphate (KTP) frequency-doubled Nd:YAG, and argon lasers. The laser energy is absorbed by water at the infrared wavelengths and by hemoglobin and melanin at the visible wavelengths, thereby heating proteins within the target tissue. As temperatures rise and heating times are prolonged, cellular and tissue structural proteins undergo denaturation and conformational changes, a process defined as coagulation. Table 39.1 lists the absorption coefficients, reduced scattering coefficients, and optical penetration depths, in water and tissue, of commonly available medical lasers.

39.3.1 Benefits of Laser Tissue Welding

While laser tissue welding is unlikely to replace sutures in all applications, it has been shown to achieve functionality comparable to that of conventional suturing techniques, ^{17–19} with the added advantage of moderately reduced operation times, ^{20,21} reduced skill requirements, ^{22,23} reduced suture and needle trauma, ²⁴ reduced foreign-body reaction, ^{25,26} and reduced bleeding. ²⁷ Repairs formed using laser tissue welding tend to heal faster, ^{24,28,29} have the ability to grow, ³⁰ and exhibit better cosmetic appearances. ^{29,31} Welding also has the potential to form complete closures, enabling an immediate watertight anastomosis intraoperatively in the case of vascular, ³² genitourinary-tract, ³³ and gastrointestinal repairs. ³⁴ A watertight closure is also advantageous for neural repairs as it discourages the exit of regenerating axons and the entry of fibroblasts. ^{35,36}

39.3.2 Limitations of Laser Tissue Welding

Although some success has been achieved in experimental applications, two disadvantages of the laser-assisted procedure are foreseen for the clinical application of the technique: the first is the low strength of the resulting anastomosis, especially in the acute-healing phase up to 5 d postoperative; the second is

thermal damage of tissue by direct laser heating and heat transfer. Technical difficulties with the ambiguity of the endpoint for the procedure, ^{32,37} tissue apposition, ³⁸ and poor reproducibility ^{39,40} are also concerns.

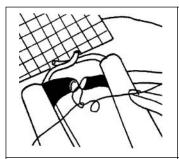

Low-strength anastomoses can lead to an anastomotic aneurysm (swelling) or even rupture of the repair. Dehiscence rates of 8 to 90% have been reported for laser repair of tissue in comparison to 0 to 12% for suture-repaired tissue. 41–44 Most researchers have used one to four temporary or permanent stay sutures to improve the success rate of their laser anastomoses. 23,45,46 This complicates the operative procedure and does not eliminate the sutures or their consequent problems. Another approach has been to apply an extra layer of tissue, such as venous grafts in vascular repair 47,48 or the epineurium in nerve repair,43 to the anastomotic site. This approach also avoids foreign-body reactions, but suitable tissue must be prepared, and the operation is technically challenging.

Thermal damage to tissue is a particular concern in medical laser applications.^{49–52} Tissue welding is achieved by laser-induced heating of tissue to levels that can cause immediate irreversible damage of the structural proteins of the tissue (refer to Section 39.5 for a discussion on the mechanisms of laser tissue welding). The resulting denaturation of protein is not specific to the target tissue, and all irradiated tissues are heated. The general objective of laser tissue-repair techniques is to obtain coagulation of a desired volume of tissue with minimal effects in the surrounding healthy tissue. The CO₂ laser has been favored for laser repair of thin tissues due to its short penetration depth (17 μm) in tissue. 19,36,46,53 However, in thick tissues, it does not permit complete sealing of the anastomotic site. In such tissues, welding is achieved by using either high irradiances or long exposure times. 41,54-57 High irradiances present the risk of tissue charring, which may cause secondary disruption of the repair or aneurysm formation. Long exposure times result in the conduction of heat from the initial absorption zone. This is a particular problem when heat is conducted in a horizontal direction from the anastomotic site to the surrounding healthy tissue. The argon laser has a much deeper penetration depth in tissue (500 to 714 µm) and is thus better suited to thicker tissues.⁵⁸ However, difficulty has been experienced in accurately determining the dosimetry of the laser energy due to variations in the concentration of hemoglobin and melanin present in the tissue, local tissue thickness, and state of hydration. 42,59,60 A narrow margin exists between a successful and an unsuccessful weld. Too low an irradiance results in a weak bond, whereas excessive laser irradiances result in excessive thermal damage to the tissue with drying and shrinkage of the tissue proteins, thereby reducing the flexibility and strength of the weld.

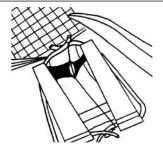

Surgeons generally look for visible signs of the tissue being heated, such as tissue coaptation, discoloration, drying, and contraction, as markers of the endpoint for tissue fusion.^{61–65} These rather subjective indicators are not always reliable. For example, disparities in tissue properties can cause differences in the absorption characteristics. In addition, the irradiance at the tissue surface can vary significantly for identical procedures if the laser-spot size or energy-delivery rate is varied. These differences will cause the tissue temperature to fluctuate during the laser procedure. Since the thermal damage to the irradiated tissue strongly depends on the tissue temperature achieved during the laser procedure,^{49–52} the resulting surgical outcome can be highly variable.

The use of cryogen spray to cool the anastomotic site has been investigated as a means of reducing thermal damage and hence increasing weld strength, and it has met with good results.⁶⁶ The possibility of irradiating the tissue through water or saline has also been investigated.^{56,67} As the thermal conductivity of water is approximately twice that of air, the tissue cools more efficiently by releasing heat into the water. However, due to the short penetration depth in water of many of the infrared laser wavelengths commonly used for laser tissue welding (Table 39.1), insufficient energy may reach the tissue and prevent the desired coagulation effect from being achieved.

Good apposition of the tissue edges is also essential for tissue welding, where even the smallest gaps can act as a lead point for failure of the entire repair. To solve this problem suture devices (Figure 39.1) and various mechanical apposition devices have been developed to hold the tissue edges together during the laser-welding procedure. ^{23,68,69} Building on this concept, the resulting tensile strength of welded tissue has been shown to increase significantly with apposition pressure. ⁶⁹ Another concern associated with laser anastomosis of blood vessels, the genitourinary tract, and the gastrointestinal tract includes the

Blood flow is temporarily interrupted during the anastomosis procedure by means of a clamp. Two sutures are inserted on the vessel to be anastomosed.

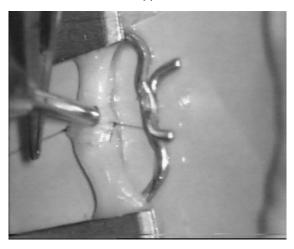

By tensing the sutures, the edges are straightened and juxtaposed. The sutures are tensed on the edges of the vascular clamb.

The anastomosis is completed by continuous spot welding with a diode laser on both faces of the vessel successively exposed. The sutures and clamp are removed upon completion of the anastomosis.

possibility of stenosis at the irradiated sites.⁷⁰ Dissolvable stents have been used to successfully separate the anterior and posterior walls of such tissues, allowing for an easier and faster welding procedure.^{19,71,72}

39.3.3 Photochemical Welding

Photochemical welding of tissue has been investigated as an alternative method for tissue repair without the use of heat and its associated tissue damage.^{73–78} The technique utilizes chemical cross-linking agents that, when light-activated, produce covalent cross-links between the collagen fibers contained within the tissue.⁷⁴ In theory, this technique should produce stronger bonds than the noncovalent bonds produced by photothermal welding. Agents used for photochemical welding include 1,8-naphthalimide,^{75,76} rose bengal (RB),⁷⁸ riboflavin-5-phosphate (R-5-P),^{77,78} fluorescein (Fl),⁷⁸ methylene blue (MB),⁷⁸ and *N*-hydroxypyridine-2-(1H)-thione (N-HPT).⁷⁸ Table 39.2 lists the absorption maxima and absorption coefficients at typical laser-excitation wavelengths for each of these photosensitizers. Of particular interest is the fact that photoactive

tissue welding does not rely on the healing properties of blood vessels. The ability of the technique to repair avascular tissue could prove to be quite advantageous to many orthopedic applications.⁷⁵ Further studies to determine optimal treatment parameters in terms of cross-linking ability, strength, and long-term healing response are necessary before clinical acceptance of this procedure will be gained.

39.4 The Recognition and Development of Laser Tissue Soldering

Two advances have been useful in addressing the issues of low repair strength and thermal damage associated with laser tissue welding: (1) the addition of endogenous and exogenous materials to be used as solders and (2) the application of laser-wavelength-specific chromophores.

The addition of endogenous and exogenous materials helps to maintain edge alignment and to strengthen the wound, particularly during the acute postoperative healing phase, while shielding the underlying tissue from excessive thermal damage caused by direct absorption of the laser light. Useful materials include blood,^{79–81} cryoprecipitate (typically plasma),^{82–84} fibrinogen,^{62,85,86} and albumin.^{87–91}

The application of wavelength-specific chromophores provides for differential absorption between the dyed region and the surrounding tissue. An advantage of this technique is that the area may be bathed by the laser radiation while energy is absorbed selectively only by the target. Hence the requirement for precise focusing and aiming of the laser beam may be removed. Furthermore, due to the increased absorption characteristics of the dyed tissue or solder, lower laser irradiances may be used to achieve the required effect, increasing the safety of the technique. Examples of dyes that have been used to assist laser tissue-welding procedures include carbon black and Fen 6 for use with Nd:YAG lasers, 92-94 indocyanine green (ICG) for use with ~800-nm diode lasers, 61,88-91,95 iron oxide and fluorescein for use with KTP frequency-doubled Nd:YAG lasers, 96,97 and basic fuchsin, methyl violet, crystal violet, chlorin(e6), and fluorescein isothiocyanate for use with argon lasers. 60,92,98,99

The combination of serum albumin and ICG dye with an ~800-nm diode laser, first described by Poppas et al., has gained the most widespread popularity (Figure 39.2). 100 The light-sensitive ingredient in the protein solder is the ICG dye, which has a maximum absorption coefficient at 805 nm of 2 × 10^5 M $^{-1}$ cm $^{-1}$. 101 The dye is water soluble and preferentially binds to serum protein, thereby ensuring that the absorbed heat is efficiently transferred to the protein solder. Since direct tissue absorption at this laser wavelength is low, the dye-containing solder absorbs most of the incident-light energy. Consequently, the amount of thermal damage to the surrounding tissue caused by direct laser-light absorption is minimized. The increased temperature at the repair site during laser treatment denatures the albumin solder, enabling it to bond with the tissue. The resulting solder coagulum is nonimmunogenic 102 and is

FIGURE 39.2 Intraoperative photograph showing the tibial nerve of a rat repaired using four solid-protein solder strips (60% BSA, 2.5 mg/ml ICG, and deionized water) in conjunction with a diode laser ($\lambda = 805$ nm, spot diameter = 1 mm, $E_0 = 12.7$ W/cm,² t = 40 sec). (Image courtesy of Karen McNally and Judith Dawes, Macquarie University, Sydney, Australia.)

gradually absorbed in the normal wound-healing process. ¹⁰³ Moreover, the presence of the solder coagulum increases the initial laser repair strength. ³²

The efficacy of diode-laser tissue soldering using ICG-doped albumin-protein solders has been demonstrated, with good results, in a wide range of tissues including blood vessels, ^{104–108} the genitourinary tract, ^{91,109–112} the gastrointestinal tract, ³⁴ liver, ¹¹³ nerves, ^{114,115} dura mater, ¹¹⁶ skin, ^{117–119} trachea, ^{120,121} and cartilage. ¹²² In addition to these successes, much has been learned about the optimal solder specifications.

Initial studies with protein solders employed liquid formulations containing low protein concentrations (e.g., 25% serum albumin). Application of these fluid solders to the repair site is often difficult due to problems associated with "runaway" of the low-viscosity material, which leads to large variations in the surface area and thickness of the applied solder. This variation makes determination of the optimal laser dosage difficult. As a result, the strength of repairs formed using liquid-protein solders is often inferior to that of sutured repairs. Lauto et al. 103 and Lauto 124 have shown that the strength of solder—tissue bonds depends on protein concentration. Bovine serum albumin (BSA) concentrations of 25, 50, and 66% (2.5 mg/ml ICG) formed bonds having acute tensile strengths of 10.4, 37.5, and 69.2%, respectively, of that of sutured nerves. 103 An attempt to improve on liquid solders was made by further concentrating the albumin solder to produce solid-protein solder strips. 89,115,125 Repairs formed using the solid-protein solder have been found to be comparable in strength to native tissue. 89 In addition, solid-protein solder strips are easier to handle and apply to the tissue surface than their liquid counterparts, and slight rehydration of the solid solder surface during application improves adhesion so as to hold the tissue edges in close approximation during the repair procedure. Finally, the uniform dimensions of the solid-protein solder strips allow preselection of optimal irradiation parameters, reducing any ambiguity regarding the endpoint for the procedure.

Chan et al. investigated the effects of hydration on tissue repairs formed with liquid-protein solder using scanning electron microscopy analysis. The solder was observed to detach from the tissue substrate once the specimens were submerged in a hydrated environment of phosphate-buffered aqueous saline. This was traced to inadequate heat transmission through the solder, which produced unstable protein globules, rather than a homogeneous solder coagulum. Subsequent studies showed that the tensile strength of repairs could be improved by an order of magnitude (257 N/cm² vs. 5.2 N/cm², 32 31 N/cm², 127 and 2.8 N/cm² — see Reference 102) if a series of small (0.2-µl) droplets of solder (25% BSA and 2.5 mg/ml ICG) were applied to the tissue and each droplet were coagulated individually. 128,129

The laser solder-repair technique has been reported to be much faster to perform than conventional suture techniques while providing an immediate leak-free closure with improved histological behavior, improved cosmetic appearance (Figure 39.3), and fewer intraoperative complications including disruptions.

More recent advancements in light-activated surgical adhesives for tissue soldering are discussed in Section 39.6.

39.5 Mechanisms of Laser Tissue Welding and Laser Tissue Soldering

The precise mechanism of laser tissue welding and soldering is still unknown. An understanding of both the tissue and the solder proteins involved in the welding and soldering processes as well as the heat-induced interactions that occur within them is fundamental to the establishment of their physical bonding mechanisms.

Proteins are composed of many amino acids polymerized by condensation between their amino and carboxyl groups. The amino-acid sequence of the protein's polypeptide chain is its primary structure. The important distinguishing features of proteins are found in their secondary structure comprising α -helices and β -sheets. These are discussed below in relation to the structural properties of both collagen and the most common solder protein, serum albumin.

39.5.1 Structural Properties of Collagen

Collagen proteins are a major constituent of all tissue extracellular matrices. They are involved in both structural maintenance and tissue growth and are thought to be the principal agents involved in thermal repair procedures.³² There are more than 20 types of collagen present in the body. Although the basic structure of all types is the same, there are variations from type to type, depending on the function of the collagen. Collagen constitutes about 20% of the dry weight of the large elastic arteries such as the aorta (up to 50% in smaller vessels), about 80% of that of skin,¹³¹ and about 50% of that of peripheral nerves. Table 39.3 lists the types of collagen found in the various layers of blood vessels, skin, and peripheral nerves.

TABLE 39.3 Types of Collagen Found in Blood Vessels, Skin, and Nerves

Tissue	Collagen Type
Blood Vessel ^a	
Tunica adventitia	I
Tunica media	I, III

Epineurium	I
Perineurium	I, III
Endoneurium	III

^aCollagen types IV, V, and VI appear in small amounts in the wall of blood vessels.

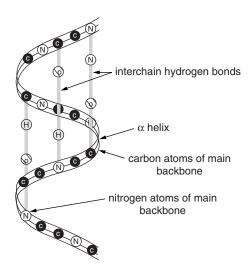

FIGURE 39.4 Schematic showing hydrogen bonds occurring between the adjacent α -helix turns in protein secondary structures. (Adapted from Yudkin, M. and Offord, R., *Comprehensive Biochemistry*, Longman, London, 1973.)

The α -chains of collagen consist of a fiber (called the D fiber) that, along with the amino acids, cause the primary left-handed helical conformation of the α -chain and the superhelical conformation of the overall molecule. Each α -chain coils into a left-handed helix and intertwines with two other such helices to form a triple-stranded superhelix known as a tropocollagen. A tropocollagen molecule is a rod-like particle of about 3000 Å in length and 15 Å in thickness. It he long molecules typically run parallel in a fibril and overlap each other by about one quarter of their length. This causes cross striations in the fibril bands at intervals of 640 Å. It has three helical chains forming the tropocollagen are then wrapped around one another in a higher-order rope-like fashion to produce the tight, triple-helical structure of the molecule. It

The stability of the collagen superhelix is due to many factors. Interchain hydrogen bonds strengthen the helix, as shown in Figure 39.4. The hydrogen donors are the peptide NH groups, while the hydrogen acceptors are the peptide CO groups on the other chains. The hydrogen bonds are directed perpendicular to the long axis α -chains, giving the protein elasticity. Weaker van der Waals bonds between residues on different strands further strengthen the helix. Steric repulsion between pyrolidine rings in the proline

residues also help to stabilize the helix.¹³⁵ Some types of collagen, including types I and III collagen, are stabilized even further by intermolecular and intramolecular covalent cross-links. The degree of each type of cross-linking depends on the age and function of the tissue.¹³¹

39.5.2 Mechanism of Laser Tissue Welding

39.5.2.1 Photothermal Welding

Many mechanisms of laser tissue welding have been proposed including collagen-to-collagen fusion, ^{38,136,137} the covalent cross-linking of tissue proteins, ^{38,56,59,138} denaturation of structural tissue proteins, ^{139,140} acceleration of natural fibrinogen polymerization, ¹⁴¹ formation of noncovalent bonding between collagen molecules, ¹⁴² and interdigitation and rope-like twisting of collagen fibers (Figure 39.5). ^{143–148} Menovsky et al. proposed that the mechanism of bonding achieved with the CO₂ laser is collagen-to-collagen bonding. ¹³⁷ After laser irradiation, collagen fibrils of both dura mater (the connective tissue that covers the spinal cord and brain) and peripheral nerves appeared to be swollen, densely packed, and fused together when viewed with scanning electron microscopy. White et al. investigated the mechanism of tissue fusion in argon laser-welded vein and arterial anastomoses using electron-microscopy examination and measuring the formation of [3H] hydroxyproline as an index of collagen synthesis. ³⁸ Follow-up studies concluded that tissue fusion is governed by a biochemical mechanism involving covalent cross-linking between collagen bundles in the extracellular matrix. ^{56,59,138} Based on scanning electron microscopy analysis of carotid arteries, the mechanism of Nd:YAG-induced laser welding has

been suggested to be the interdigitation of collagen fibers, which appear to be increased in caliber and swollen and to lose their periodicity immediately after irradiation.^{143,145} Two theories incorporating these observations and others found in the literature have been postulated to describe the mechanism of laser tissue welding.

The first theory is based on triple-helix reformation within the collagen fibers. An increase in the local temperature of collagen fibers modifies the triple-helix structure of tropocollagen, inducing alterations of viscosity and periodicity. Heat-denatured collagen unwinds its helix to expose sites for intermolecular interactions, especially in transversely cut fibers. As the collagen superhelix is mostly stabilized by cooperative interactions from a large number of weak, reinforcing bonds, it has been hypothesized that when one bond is lost, adjacent bonds are quickly broken, resulting in a domino effect. When cooled over a few minutes, the α -strands then conform themselves into their lowest energy states. He glycine residue from each α -chain is folded into the helix center for extensive hydrogen bonding, and hydroxyproline molecules further stabilize the whole structure. Using this theory, strong welds are created by transincisional fiber fusion but not side-on-side fiber fusion.

The second theory is based on the random noncovalent bonding of opposed collagen layers caused by heat denaturation and, consequently, coagulation. Lemole et al. observed transected rat tail tendons to bind together when heated in a constant temperature water bath at 62°C for 4 min. ¹⁴⁴ Rapid quenching of the tendon repairs in a cooler bath immediately after treatment produced stronger bonds than slow cooling. Based on these observations the authors suggested that some form of hydrogen, ionic, or van der Waals bonding between the transected collagen fibers occurred during heat treatment of tissue. Covalent bonding was disputed by Bass et al. based on identical gel electrophoretic mobility patterns and circular dichroism measurements obtained for both laser-treated and control rat-tail tendons. ^{142,150} In these studies, an 808-nm diode laser and ICG were used to weld rat-tail tendon and blood vessels. Laser treatment was shown to induce strong noncovalent interactions among the collagen strands that sealed the vessel edges together, with the denatured collagen exhibiting random triple-helix-coil transitions and aggregations of randomly oriented fibrils.

The results of Tang et al. support the theory of noncovalent bonding. ¹⁴⁷ Collagen fibers in rat aortas were observed to lose a proportion of their birefringence after diode laser welding at 830 nm, suggesting that the protein helices had been disrupted. Under electron-microscopic examination, collagen fibers were visualized as being either fused, "roped," swollen or dissolved, and surrounded by normal collagen fibers situated in the same zone. This was thought to be due to the presence of several types of collagen in the vessel wall, where each type of collagen has a different stability to temperature resulting from differences in chemical composition. Tang et al. suggested that the main type of adhesion in laser fusion was the "roping" of two parallel collagen fibers. Cross-linking was observed to occur at the cut ends of the collagen fibers and between their parallel faces.

The view shared by both of these theories is that laser irradiation induces thermal restructuring within the extracellular matrix. In particular, the thermal restructuring is thought to take place within the tissue collagen, where new bonds and interactions with adjacent proteins are formed and then stabilized upon cooling.

39.5.2.1.1 Temperatures Required for Laser Tissue Welding

While it appears that the thermal effect is fundamental to the mechanisms behind laser tissue welding, the optimum temperature range for tissue welding remains undetermined. Temperatures at which laser welding has been reported to be successful range from 45 to 140°C, depending on the laser source.

Using a CO₂ laser for microvascular anastomosis, tissue fusion has been observed to begin at approximately 70°C with coagulation of denatured collagen in the media and adventitia and fibrin polymerization. 56,151 Histological examination of the repairs showed the optimum temperature for CO₂-induced welding to be around 80 to 100°C, as inferred from thermographic images. In contrast, weld-strength analysis and silver-halide fiber-optic radiometry have been correlated to show the optimal temperature for CO₂ laser-assisted welding to be 55 \pm 5°C in the urinary bladder, 52,152 skin, 153 and corneal 154 models.

Successful welds with the argon laser have been achieved at reported temperatures of 45 to 50°C for arterial vein anastomoses under concomitant saline irrigation using thermography and acute histological examination. So Contrary to these results, Martinot et al. 155 and Klioze et al. 49 demonstrated that the temperature range suitable for argon laser fusion was really 60 to 77°C, also using thermography and histological examination. Cilesiz et al. have reported even higher optimal temperatures for tissue welding using an argon laser. 156 Based on bursting-strength analysis, optimal welds of canine intestine were achieved between 90 and 95°C using the argon laser and controlled-temperature feedback with an infrared radiometer.

The optimum temperature for welding of porcine skin using an Nd:YAG laser was found to be 65 to 75°C using infrared thermometry when tensile-strength measurements were made.³⁷ Much higher temperatures of 90 to 140°C, measured by 3-mm-diameter thermistors, were determined to be optimum when welding human plaque–arterial-wall separations *in vitro* based on shear-strength analysis.¹⁵⁷ Finally, the optimum temperature for welding of vascular repairs using a 1.9-µm diode laser was found to be 80°C in a rat model.¹⁵⁸

In summary, the effective welding temperature depends on wavelength, solder and tissue type, irradiation parameters, and boundary conditions such as the presence of convective cooling by air or water and blood perfusion. It appears that required temperatures for laser tissue welding, with collagen as the major bonding component, are in the range of 60 to 80°C.³² The determination of more definitive temperatures is more difficult because thermal coagulation of proteins is a rate process driven by energy and not by temperature thresholds.^{16,159} The temperatures outside this range observed in some investigations may relate to differences in the initial tissue conditions (e.g., tissue temperature and level of hydration), distribution and duration of heating, accuracy of the thermal sensor used, and the portion of the tissue that is monitored. Of particular note are the differences observed between measurements made on *in vitro* and *in vivo* tissue. Temperatures measured from *in vitro* tissue specimens are typically higher than those measured for *in vivo* tissue due primarily to conductive heat loss secondary to perfusion.¹⁶⁰ However, variations in tissue hydration and in tissue optical and thermal properties also contribute to this discrepancy. In addition, discrepancies will be observed when different criteria, such as tensile strength and histological examination, are used to judge the "success" of the resultant repairs.

39.5.2.2 Photochemical Welding

The feasibility of photochemical tissue welding was first demonstrated by Judy et al. in a study performed using a newly designed and synthesized class of photochemical dyes to weld dura mater.⁷³ In this study, photochemical investigation strongly suggested that the dye functioned as a photoalkylation agent following activation to an intermediate state by visible light. The activated species was found to react readily with nucleophilic amino-acid residues such as tryptophan, tyrosine, cysteine, and methionine. The production of covalent cross-links in type I collagen was determined to be the underlying mechanism involved in photochemical tissue welding using brominated 1,8-naphthalimide dyes activated by 420-nm light. This finding was consistent with previous studies where light and photosensitizers were reported to produce intermolecular covalent cross-links in proteins.^{74,161–166} More recent studies utilizing 1,8-naphthalimide for photochemical welding of meniscus and articular cartilage¹⁶⁷ and rose bengal for welding of corneal tissue⁷⁸ support these findings.

39.5.3 Structural Properties of Serum Albumin

Serum albumin is commonly used as a constituent of solder for laser tissue-repair procedures (refer to Section 39.4). Albumin has a molecular mass of about $66,400 \text{ Da}^{168}$ and is highly soluble in water. It is a globular protein composed of three triple-helical domains shaped as an ellipsoid with a diameter of 38 Å and a length of 150 Å. The triple-helical domains consist of both α -chains and β -strands. The β -strands are aligned adjacent to each other such that hydrogen bonds can form between both the NH-groups and the CO-groups of the adjacent β -strands. The β -sheets formed from these β -strands are pleated with carbon atoms, as shown in Figure 39.6. A series of cysteine disulfide bridges, which constitute

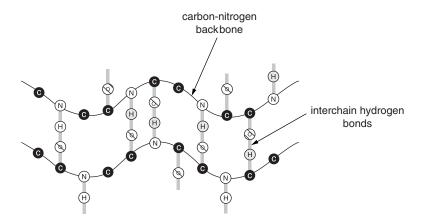

FIGURE 39.6 Schematic showing the β pleated sheet in protein secondary structures. (Adapted from Yudkin, M. and Offord, R., *Comprehensive Biochemistry*, Longman, London, 1973.)

covalent bonds, stabilizes the albumin structure. Due to the strong covalent bonds in the β -sheet, albumin has much less elasticity than collagen.

39.5.4 Mechanism of Laser Tissue Soldering

Several studies investigating the thermal denaturation process of albumin have been conducted. $^{169-172}$ With increased temperature, intramolecular motion has been shown to increase and irreversible structural alterations to occur. 172 Loss of α -helix and gain of β -form have been shown to occur between 62 and 75°C, according to infrared laser and Raman studies. 171 The denaturation point of human serum albumin has been found to be 63°C using differential scanning calorimetry. 173 In another study using differential scanning calorimetry, the peak denaturation temperatures for bovine, porcine, canine, and human serum albumin containing fatty acid were found to be 65.31 \pm 0.50°C, 65.32 \pm 0.20°C, 66.97 \pm 0.69°C, and 67.77 \pm 0.88°C, respectively. 174 Fatty-acid-free albumins were found to denature at significantly lower temperatures. Nuclear magnetic resonance studies suggest comparable results with denaturation occurring at 72°C. 172

Marx showed that the much smaller albumin monomers (80 to 150 Å) were able to diffuse among the collagen fibers (500-nm diameter) as they underwent thermally driven conformational transitions due to laser irradiation.¹⁷⁵ The albumin monomers then polymerized by hydrophobic effects to form an interdigitated matrix among the collagen fibers. Using scanning electron microscopy to investigate laser tissue repair of dura mater and peripheral nerves, Menovsky et al. reported that coagulated albumin forms a solid bridge between the tissue edges, which is melted on and between the collagen fibrils.¹³⁷ This finding was supported in a later study by Park and Min using albumin solder in conjunction with a CO₂ laser for ossicular reconstruction. ¹⁷⁶ Using a fluid protein solder, Kirsch et al. showed that a scaffoldlike internal lattice was formed when the water content of the solder vaporized, causing the albumin component to bubble and desiccate.¹⁷⁷ This scaffolding was incorporated into the healing tissue layers. After 5 to 7 d, cellular ingrowth into the solder was observed with the deposition of collagen extracellular matrix proteins. These results were similar to those of Tang et al., where a large number of new collagen fibers were observed to have proliferated in the vessel walls by the tenth day of regeneration after treatment with an 830-nm diode laser. 147,148 Finally, in a study by McNally et al., scanning electron microscopy suggested albumin intertwining within the tissue collagen matrix and subsequent fusion with the collagen as the mechanism for laser tissue soldering. 178

39.5.4.1 Temperatures Required for Laser Tissue Soldering

If thermal restructuring is the main mechanism of laser tissue soldering, then the strength of the solder-tissue bond depends on appropriate temperatures being reached for a suitable duration (set by the choice of laser and solder parameters) to obtain protein restructuring and on the contact area between

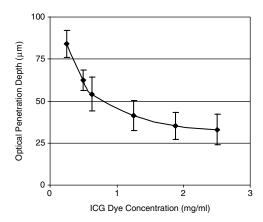

FIGURE 39.7 Optical penetration depth of 805-nm light in solid-protein solder (60% BSA) at a range of ICG dye concentrations.

the solder and the tissue, which determines the number of available bond sites. The proteins at the solder–tissue interface must denature simultaneously to allow the solder proteins (albumin) to bind to the adjacent tissue proteins (collagen). The energy applied to the solder and the tissue must be high enough to initiate molecular transformation, i.e., hydrogen-bond breaking, to permit polypeptide rearrangement. This energy represents the activation energy required for rotation around the C–N bond that links the amino acids.¹⁷⁹ Subsequent to hydrogen-bond breaking, polypeptide uncoiling in the tissue collagen would require additional energy.¹⁸⁰ An activation energy of 480 J/g (energy content of hydrogen bond in tissue with two hydrogen bonds per peptide) with an additional energy requirement in excess of 800 J/g was suggested in a study by Kung et al.¹⁸⁰

39.6 Recent Advances in Light-Activated Surgical Adhesives

The results of the various studies discussed above are indeed promising for the future of laser tissue repair; however, several problems associated with the technique still must be overcome. In particular, four disadvantages of laser tissue soldering have been identified. (1) Solid-protein solders are initially malleable, but they quickly dry and become very brittle and inflexible. As such they are not easily adapted to different tissue geometries. Liquid solders, on the other hand, tend to "run away" from the application site before they can be denatured with the laser. (2) Protein solders are soluble in physiological solutions prior to denaturation, which can be problematic during application. In addition, as these solders are often subjected to blood dilution during operation, the solder may undergo mechanical alteration that can weaken the solder—tissue bond. [8] (3) Whether water or an absorbing dye is used as the chromophore, more energy is generally absorbed near the upper portion of the solder, closer to the laser source. Irradiation of the solder produces a temperature gradient over the depth of the solder. The gradient is a function of the irradiance and the absorption coefficient, μ_a , of the solder/dye combination. The 1/e penetration depth of the laser light is defined as $1/\mu_a$, neglecting scattering of the naturally clear solder. Figure 39.7 shows a plot of the optical penetration depth of laser light at 805 nm in albumin-protein solders containing different concentrations of ICG dye. The optical penetration depth is observed to decrease with increased ICG-dye concentration. Depending on the temperature gradient and the laser exposure, the upper portion of the solder can become overcoagulated while the most critical region the solder-tissue interface — remains uncoagulated. Nonuniform denaturation across the solder thickness can result in the formation of unstable solder-tissue bonds.^{89,126} (4) The achievement of good apposition between tissue edges during tubal anastomoses is particularly difficult. In addition, there is a high risk of fusing the anterior and posterior walls together during the laser-welding or laser-soldering procedure, which can result in stenosis at the irradiated site.⁷⁰ Stay sutures can be used to combat this problem; however, they only tend to complicate the operative procedure and introduce the additional risk that a foreign-body reaction will occur.

Researchers continue to search for a new range of light-activated surgical adhesives that can combat the four identified problems associated with current laser tissue-soldering techniques. Recent advancements have included the development of (1) semi-solid solders and polymer-reinforced solders as a means of improving the flexibility of the adhesive, (2) predenaturation of the solders as a means of enhancing the stability of the adhesive in physiological fluids prior to laser denaturation, (3) layered solders containing different chromophore concentrations as a means to improve control of the heat-source gradient through the adhesive during laser irradiation, and (4) stents as a means to provide good tissue apposition during the laser procedure.

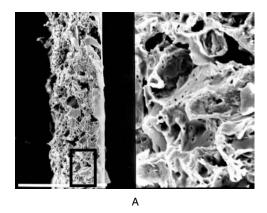

39.6.1 Semi-Solid and Polymer-Reinforced Solders

Improvements on liquid- and solid-protein solders have been made with the introduction of semi-solid solder made of hydroxypropylmethylcellulose (HPMC), albumin, and water.¹⁷⁴ HPMC is a synthetic water-soluble, nonstarch polysaccharide that has been safely used in humans and animals to lower cholesterol.^{182,183} Bleustein et al. have shown that repairs formed using semi-solid solder in conjunction with an Nd:YAG laser in canine small-bowel and porcine-skin models are much stronger than both 50% liquid solder and 60% solid solder and that they remain stronger than liquid solder repairs at 7 d.¹⁷⁴ The semi-solid solder is observed to have better handling characteristics.

Another improvement on traditional liquid- and solid-protein solders involves the use of synthetic polymers, which when doped with serum albumin provide better flexibility along with improved repair strength over previous published results using albumin-protein solders alone. 184 Poly(lactic-co-glycolic acid) (PLGA) is one of several types of poly(alpha ester)s, a class of synthetic biodegradable polymers and copolymers, under investigation. PLGA, a copolymer of glycolic acid and lactic acid, is degraded in vivo by hydrolysis of the ester bonds. The products are eliminated through normal metabolic pathways. 185 In addition to current usage in biodegradable sutures, these materials have been researched as drugdelivery systems. Thin membranes of PLGA of various thickness are easily fabricated in the laboratory using a solvent-casting technique. 186,187 By adding salt to the polymer mixture during the casting stage, and later leaching it out, one can produce membranes of a desired level of porosity (Figure 39.8). The resulting porous membranes quickly absorb the traditional protein-solder mix of serum albumin and an absorbing chromophore. A range of dopants, including hemostatic and thrombogenic agents, antibiotics, anesthetics, and various growth factors, can be added to the solder-doped polymer membranes to enhance the rate and quality of wound healing.³² Finally, the in vivo degradation rate, and consequently the drugdelivery rate, can be tailored by altering the composition of the polymer. 185,188 McNally et al. have shown that the bursting pressure of repairs performed on both heparinized and unheparinized blood vessels using the reinforced solder (Figure 39.9) is comparable to that measured in native vessels. ^{108,189} In addition, repairs formed with the adhesive technique were achieved more rapidly than suturing, and acute leakage was observed less frequently. Reinforcement of traditional liquid-solder coagulums with thin strips of PLGA membranes has also been investigated with good success rates. 190,191

39.6.2 Predenatured Solder

Prior to laser denaturation, protein solders tend to dissolve within a few minutes of application in a hydrated environment.¹⁹² This can be quite problematic for most surgical procedures using the protein solder, where ultimately there must be some time lag between placement of the solder and laser treatment. Predenaturation of albumin-protein solders using hot-water baths set at temperatures between 65 and 80°C or low concentrations of tissue fixatives are currently under investigation as a means for reducing the solubility of the materials in physiological solutions prior to laser irradiation.^{90,184} McNally et al. have shown predenaturation of solid protein solder at 75°C to be a feasible option for reducing the solubility of the solder and ensuring that minimal mechanical alteration occurs during the surgical procedure that

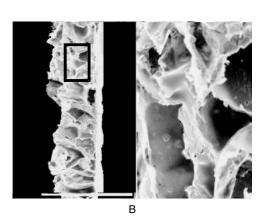

FIGURE 39.8 Scanning electron micrographs of PLGA scaffolds prior to doping with protein solder. By using salt particles of different sizes, membranes were prepared with the same porosity but with different pore diameters. (A) Scaffold cast using salt particle sizes $\leq 106 \, \mu m$ in diameter. (B) Scaffold cast using salt particle sizes of 106 to 150 μm in diameter. The right half of each micrograph shows a higher magnification view (526 times) of the section of the micrograph highlighted by a rectangular frame on the left half of the micrograph (88 times). The scaffolds exhibit a uniform pore morphology, which is interconnected, thus yielding an open-cell polymer. (From McNally, K.M. et al., Lasers Surg. Med., 27(2), 147, 2000. With permission.)

could weaken the solder-tissue bond.¹⁸⁴ Predenaturation of the solid-protein solder improves the flexibility of the solder, a feature that has proven beneficial for the formation of flexible stents (Figure 39.10) now being used for sutureless end-to-end ureteral anastomoses.^{90,105} Tanning with glutaraldehyde had previously been applied to human umbilical vein grafts,¹⁹³ collagen grafts prepared from bovine carotid arteries,¹⁹⁴ and albumin-coated knitted polyester grafts¹⁹⁵ to improve the tensile strength of the grafts. The strength of repairs formed using solder predenatured with 0.5 to 1.0% glutaraldehyde, however, were not as strong as their heat-denatured counterparts.¹⁸⁴ This was attributed to the fact that glutaraldehyde is a known fixative, and some degree of fixation would have occurred in the albumin-protein solder.

39.6.3 Chromophore Concentration Gradient

Wavelength-specific chromophores such as ICG are typically added to protein solders to provide for selective absorption of the laser light as a means of minimizing the degree of collateral thermal damage caused to the surrounding tissue during the laser procedure (see Section 39.4). The optical penetration depth of 805-nm light in solid-albumin-protein solders containing 2.5 mg/ml ICG, the most common ICG dye concentration used by researchers, is approximately 35 μ m. Thus, approximately 63% of the laser light is absorbed in the anterior surface of the solder, and thermal conduction is relied upon to transfer the heat to the posterior

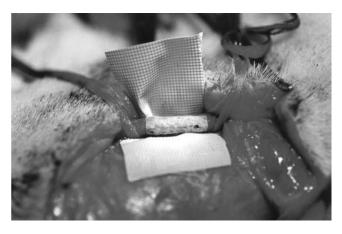

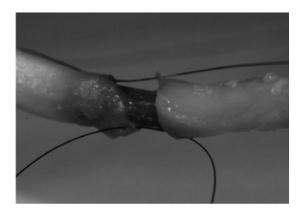

FIGURE 39.9 (Color figure follows p. 28-30.) Intraoperative photograph showing the right carotid artery of a canine repaired using a solder-doped polymer membrane in conjunction with a diode laser ($\lambda = 805$ nm, spot diameter = 2 mm, $E_0 = 15.9$ W/cm², t = 100 sec). The polymer membrane was fabricated using PLGA with an 85:15 copolymer ratio and 70% NaCl with particle sizes of 106 to 150 μ m and doped with protein solder composed of 50% BSA, 0.5 mg/ml ICG, and deionized water. (From McNally-Heintzelman, K.M. et al., *J. Biomed. Opt.*, 6(1), 68, 2001. With permission.)

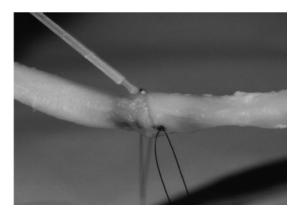

FIGURE 39.10 Use of an albumin stent (50% albumin, 10 m*M* ICG) for laser-assisted (λ = 810 nm, spot diameter = 1 to 2 mm, P = 1 W, pulse width = 0.1 sec, repetition rate = 5 Hz) uretal anastomosis. The addition of dye to the stent maximizes heat conduction at the solder/tissue interface. (Image courtesy of Hua Xie, Oregon Medical Laser Center, Portland, Oregon.)

surface of the solder, where it is needed to provide adequate solder-tissue fusion. As solders often range in thickness between 100 and 250 µm, this assumption is not always valid. In a study by McNally et. al., two 75-m-thick solid-protein solder strips containing different ICG dye concentrations were pressed together using a vice to form a single solid solder strip 150 µm thick.¹⁹⁶ The solder strips were pressed together immediately after preparation, prior to drying, so as to create a chromophore-concentration gradient across the thickness of the solder, rather than two separate layers. Repairs made with solders containing a chromophore-concentration gradient formed by placing a protein solder strip containing 0.25 mg/ml ICG on top of a strip containing 2.5 mg/ml ICG were found to be approximately 58% stronger than those formed using solder containing 2.5 mg/ml ICG and approximately 33% stronger than those formed using solder containing 0.25 mg/ml ICG. The improved strength of repairs formed using solders containing this concentration gradient was attributed to more even heating across the thickness of the protein solder, eliminating the problems of "overcooking" the anterior portion of the solder while having insufficient coagulation at the vital solder–tissue interface. Lauto et al. applied a similar principle when designing their two-layered solders. 197 In this study, the top layer of solder contained no chromophore, and the bottom layer of solder contained $0.39 \pm 0.08\%$ carbon black. Each layer was approximately 55 to 75 μm thick. Heat diffusion from the black midplane of the two-layered solder was found to decrease the difference in temperature recorded on the solder surface and at the solder-tissue interface.

39.6.4 Biocompatible Stents

Biocompatible stents have been used for several years to assist surgical procedures during conventional microsuturing of blood vessels. ¹⁹⁸ The function of the stent is to separate the anterior and posterior walls of the vessel, allowing for an easier and faster repair procedure with minimal tissue injury. He et al. ¹⁹ and He and Tang¹⁹⁹ have extended this idea to obtain a hybrid technique that they refer to as the "stented welding" technique. Stents fabricated using a mixture of glyceride, diglyceride, and triglyceride — elements found naturally in the blood circulatory system — and a melting temperature of 39°C have been used for small-vessel (0.4 to 0.6 mm) anastomosis by CO₂ laser welding in a rat model. ¹⁹ This melting temperature was selected to match the blood temperature of rats, ensuring that the stent would become completely molten once blood flow was restored after surgery. All repaired arteries remained patent at 1 h post surgery, with no detectable stenosis or dilation at the repaired sites. The stent was dispersed in the bloodstream with no evidence of adverse effects. When compared with conventional microsuturing techniques, the stented welding procedure offers the benefits of having a high patency rate, being less time-consuming and involving less hand manipulation. ¹⁹⁹ As such this new technique holds great promise for extension to laser-soldering techniques as well.

More recently, researchers at New York Hospital—Cornell University Medical Center have designed a biocompatible stent with a self-expandable mechanism to facilitate laser-assisted tubal anastomoses. Thin films, prepared from deacetylated chitosan dissolved in acetic-acid solution, are pulled and wound around a cylindrical rod in a helical fashion to manufacture the stents (Figure 39.11). The elastic nature of the chitosan-combined with the helical shape, makes the stent self-expand when inserted in small ducts. Upon stent insertion, tubal anastomoses can be achieved using standard laser-welding and soldering techniques. Lauto et al. have used these new stents to perform laser-soldered vasal anastomoses in wistar rats, where 12 of 13 anastomoses were observed to have remained open inside the vas deferens at 8 weeks postoperative despite a high incidence of sperm granuloma formation.²⁰⁰

39.7 Beyond the Laser

39.7.1 Automated Dosimetry

Although several successful experimental studies have been conducted using laser tissue welding and soldering techniques, they have not yet gained widespread clinical acceptance because reliable results have been difficult to obtain. As discussed in Section 39.2.2 above, a major limitation of this approach

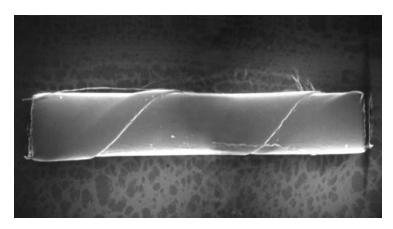

FIGURE 39.11 Chitosan stent prepared from deacetylated chitosan film pulled and wound around a cylindrical rod in a helical fashion. (Image courtesy of Antonio Lauto, New York Hospital–Cornell University Medical Center, New York.)

seems to be the lack of a satisfactory objective criterion for the optimal laser exposure required to produce a strong and durable repair. Several studies have been conducted to develop a system that could monitor the condition of the tissue undergoing the welding/soldering process and regulate the laser exposure accordingly. The successful implementation of such a system could remove much of the uncertainty from laser tissue welding and soldering techniques, rendering them both simpler and more effective.

Protein denaturation is a rate process governed by the local temperature–time response.^{201,202} It can be approximated by a simple Arrhenius model:^{156,158,159}

$$\Omega(z,t) = -\ln\left[\frac{C(t)}{C(t_0)}\right] = \int_0^t A \exp\left(-\frac{E_a}{RT}\right) dt$$
 (39.1)

where Ω is the damage integral [no units], $C(t_0)$ represents the amount of native (undamaged) tissue originally present at time t_0 [M], C(t) is the amount of native tissue at time t [M], A is the frequency factor or preexponential factor [sec⁻¹], E_a is the activation energy [J/mol], R represents the universal gas constant [8.314 J/mol K], and T is the absolute temperature [K].

This equation is used to describe kinetic processes in which a population of reactants, $C(t_0)$, is converted to reaction products, C(t), at a rate that depends on temperature. Coagulation (observable damage) is defined as $\Omega = 1.0$, which corresponds to a reduction in reactant concentration by $1/e^{.203}$ The total damage, Ω , is the summation of all damage increments over time.

The values of A and Ea depend on the tissue or solder irradiated and are determined by plotting experimental data in the form of $\ln(t_0)$ vs. 1/T, with $\Omega = 1.0$. Agah et al. determined values of A and E_a for human aorta to be 5.6×10^{63} sec⁻¹ and 4.30×10^5 J/mol, respectively.²⁰⁴ The rate of damage formation

$$\frac{d\Omega(z,t)}{dt} = A \exp\left(-\frac{E_a}{RT}\right) \tag{39.2}$$

for these coefficients is illustrated in Figure 39.12. The figure graphically illustrates the importance of the temperature–time relationship in the occurrence of thermal damage. Rate coefficients for various tissues have been published by Pearce and Thomsen.¹⁶

The extent of protein denaturation is linearly proportional to time and an exponential function of temperature. As a result of this exponential dependence, temperature is the dominant parameter for governing the extent of the reaction. Thus, an obvious variable to monitor is the tissue temperature.²⁰⁵ Several research groups have attempted temperature-controlled tissue bonding for laser tissue welding^{50,52,158,206} and laser tissue soldering^{37,65,207,208} techniques.

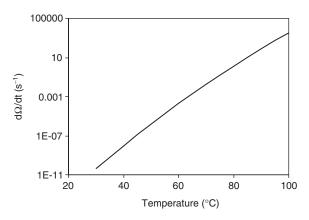

FIGURE 39.12 Rates of accumulation of damage in human aorta. Rate coefficients $(A = 5.6 \times 10^{63} \text{ sec}^{-1} \text{ and } E_a = 4.30 \times 10^5 \text{ J/mol})$. (From Agah, R. et al., *Lasers Surg. Med.*, 15(2), 176, 1994. With permission.)

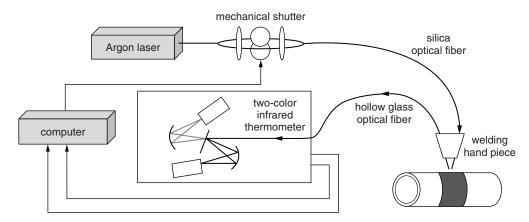

FIGURE 39.13 Schematic of the LLNL temperature feedback system. A two-color infrared temperature sensor is used to control the laser used to heat the weld site.

The difficulty of radiometric temperature measurement is control of the distance between the detector and the surface of the tissue. To measure temperature with a hand-held device IR-remitted power must be measured at two wavelengths. The ratio of these measurements provides a unique measurement of temperature, based on Planck's radiation law, which is independent of the distance between the detector and tissue.²⁰⁹ Systems that incorporate two-wavelength detection for tissue welding have been developed at Tel Aviv University and Lawrence Livermore National Laboratories (LLNL) (Livermore, CA).

Researchers at Tel Aviv University have used the concept of infrared radiometry to develop a noncontact technique to measure the surface temperature of biological materials during laser tissue welding/soldering. Their system is based on a CO_2 laser and on infrared-transmitting AgClBr fibers.^{52,152,205} The laser beam is focused on the tissue–solder surface, and a remote infrared thermometer is used to monitor the black-body radiation emitted from the tissue–solder surface during the laser heating procedure. A feedback loop is then used to control the surface temperature during the laser procedure. Using this system, temperature control to \pm 0.1°C has been achieved with a response time of 0.1 to 0.2 sec.⁵² This fiberoptic system could be adapted for endoscopic laser welding.

A schematic of the sensor developed at LLNL is shown in Figure 39.13. The sensor has a single 700- μ m core and a hollow-glass optical fiber mounted on one prong of a two-pronged welding handpiece. The other prong is the silica optical fiber that transmits the laser beam that welds the tissue. While the

laser beam is heating the tissue surface, the sensor's hollow fiber collects and transmits the infrared radiation to the detectors. Using a single optical fiber for both wavelength bands guarantees that the radiation transmitted in each path originates from the same geometric region on the target, providing true values for the temperature and emissivity. The hollow fiber optic has a small numerical aperture that can accurately monitor the surface temperature of a 0.8-mm spot at a distance of 1 cm. The variable working distance means that the surgeon can more easily maneuver around the surgical site while still obtaining accurate temperature measurements.

Another technique for monitoring the temperature of laser-irradiated tissue has involved the use of temperature-sensitive liposome-encapsulated dyes.²¹⁰ Heating of the liposomes by means of a laser causes the lysis of the liposomal membrane.^{211,212} The fluorescence emission is then measured with a fluorescent imaging system. The amount of the drug release has been shown to increase linearly with increasing temperature, allowing measurement of the temperature of the laser-irradiated tissue.²¹⁰ While the response time of this technique depends on the release latency time of the liposomes, using different liposome formulations for different temperature ranges, e.g., di-stearoyl-phosphatidyl-choline (DSPC) for temperatures between 53 and 62°C and di-stearoyl-phosphatidyl-ethanolamine (DSPE) for temperatures between 65 and 75°C, can reduce this limitation.

Finally, Tang et al. have used native fluorescence spectroscopy to monitor molecular changes in laser-treated tissue and thus evaluate laser-induced thermal tissue damage. 147,148,213,214 Examples of natural-tissue fluorophores include collagen and elastin. Most recently, they have shown that fluorescence emission from collagen at 380 nm with 340-nm excitation and from elastin at 450 nm with 380-nm excitation decreases with thermal damage in a predictable fashion following laser skin welding. 213,214

39.7.2 Optical-Thermal Models of Laser Tissue Repair

Computational modeling of the laser-tissue-interaction process can be used to explore and reduce the experimental parameter space including laser irradiance, exposure time, protein concentration, and chromophore concentration. The use of numerical models, such as the radiative transport equation,²¹⁵ the diffusion approximation,^{216–218} Beer's law,²¹⁹ or the Monte Carlo technique²²⁰ for optical modeling and the finite difference or finite element techniques²²¹ for thermal modeling, have helped in the understanding of the basic optical and thermal mechanisms of laser–tissue interactions that are pertinent to laser tissue welding and soldering. Using the bioheat-transfer equation

$$\frac{1}{\alpha} \frac{dT}{dt} = \nabla^2 T + \frac{Q}{k} + \rho c_p \omega (T_f - T)$$
(39.3)

where T is temperature [K], t is time $[\sec]$, α is thermal diffusivity $[m^2/\sec]$ ($\alpha = k/\rho c$, where ρ $[kg/m^3]$ is the tissue density, and c_p [J/kg/K] is the tissue heat capacity), k is the thermal conductivity of the tissue [W/m/K], Q is the heat-source term $[W/m^3]$, ω is tissue perfusion [kg of perfusate/kg of tissue/kg, and kg is the fluid temperature [K], as well as the Arrhenius rate process relation (Equation 39.2), thermal destruction of tissue has also been simulated by a rate process that is a linear function of time and an exponential function of temperature. These optical and thermal models are now being combined together to account for local irreversible changes in the optical and thermal coefficients of the tissue due to thermal damage. (223-226)

Researchers at LLNL have developed a two-dimensional (2D) model, LATIS (LAser-TISsue interaction), which uses coupled Monte Carlo, thermal-transport, and mass-transport models to simulate tissue welding of multilayered tissue. ^{225,227–230} In this model, light transport is calculated with the Monte Carlo technique. The absorbed energy serves as the source term to a modified version of the heat-conduction equation, which takes account of the tissue hydrodynamic response including evaporation and water diffusion. The dynamic optical properties of each layer are modeled as a kinetic function of tissue temperature rise and thermal damage as governed by the Arrhenius relation. Thus, full coupling of the optical and thermal response of the tissue is achieved. In an *in vitro* study of laser tissue welding mediated

with a dye-enhanced protein solder for repair of arteriotomies approximately 4 mm in length, temperature histories of the surface of the weld site were obtained using a fiberoptic-based infrared thermometer.²³⁰ Comparison of the experimental and simulated thermal results showed that the inclusion of water transport and evaporative losses in the model, a concept first reported by Torres et al.,²³¹ was necessary to determine the thermal distributions and hydration state of the tissue. Such volumetric information, used in conjunction with weld strength assessment, provides an interesting tool for investigating the mechanisms of laser–tissue fusion.

McNally et al. have developed a transient 2D optical-thermal model that accounts for dynamic changes in optical and thermal properties with temperature to investigate the mechanisms leading to thermal damage during laser tissue soldering. The model was implemented using the electrical circuit simulator SPICE (Simulation Program with Integrated Circuit Emphasis). Electrical analogies for the optical and thermal behavior of the solder and tissue were established. With these analogies, light was propagated using a flux representation of the light, and the electrical simulator was used to calculate heat transfer with an algorithm based on the finite-difference technique. Thermal damage was calculated using the Arrhenius rate process relation. Temperature-dependent absorption and scattering coefficients, thermal conductivity, and thermal diffusivity²²⁶ were incorporated in the SPice Optical-Thermal Simulation (SPOTS), as well as the time-domain behavior of a scanning laser source.

Experimental results from an *in vitro* study performed using an 808-nm diode laser in conjunction with ICG-doped albumin-protein solders to repair bovine aorta specimens compared favorably with numerical results obtained from SPOTS using dynamic optical and thermal properties. ¹⁹⁶ In these studies, infrared radiometry and histological analyses were used to determine the solder surface temperature and the extent of thermal damage in the tissue substrate, respectively, as a result of varying laser and solder parameters. The maximum surface temperature was overestimated by almost 10% when dynamic properties were not taken into account. This difference corresponds to over two orders of magnitude difference in terms of the Arrhenius tissue-damage integral. Thus, the incorporation of dynamic changes in optical and thermal properties of tissue during laser-induced heating does appear to represent a significant advance in computer modeling of laser-tissue interactions.

39.8 Clinical Applications

39.8.1 Cardiothoracic and Vascular Surgery

In cardiothoracic and vascular surgery, it is often necessary to perform anastomoses on vessels with diameters in the range of 0.5 to 5 mm. Suture repair of such vessels can be technically challenging.²⁷ This fact has prompted several researchers to commence the search for an alternative technique that can produce strong, reliable, and reproducible repairs. Laser welding for achieving vascular anastomoses was first proposed in the early 1960s.¹³ Since then, extensive effort has been expended in performing vascular anastomoses using a wide range of lasers including CO₂, ^{19,53,83,233,234} THC:YAG, ⁷¹ 1.9-µm diode, ^{21,23,107,180} Nd:YAG, ^{21,107,235} ~800-nm diode, ^{104,108} and argon ^{27,58,236,237} lasers.

Laser welding has been shown to produce excellent patency with faster anastomotic times and reduced problems of foreign-body reaction in comparison with suturing. 30,58,236,238 In addition, histological studies have shown that laser welding can lead to improved healing, with an increased ability for expansion and growth at the anastomotic site⁵⁸ and reduced neointimal hyperplasia compared with suture repairs. 27,41,58 One major complication associated with the laser welding is the risk of thermal injury to the vessel wall, which can result in thrombogenesis. 180,234 If thermal injury is limited to the superficial layers, thrombogenesis may be prevented. 53,56,60

The first clinical application of laser tissue welding was performed in 1985 on a 44-year-old female patient with chronic renal failure for whom an arteriovenous fistula was created using a low power CO₂ laser and a few stay sutures.^{233,239} Based on the excellent results of this study, laser-assisted arteriovenous and arterio-arterial anastomoses of the peripheral vessels in 35 patients were subsequently attempted. Pressure-tolerance tests, tensile-strength tests, and microscopic examinations at the sites of the laser

anastomoses were compared with the conventional suture method. No significant differences between laser and suture methods were observed.²³³

In 1990, White et al. investigated the feasibility of forming vascular anastomoses using an argon laser and four evenly spaced biodegradable stay sutures. In initial animal studies, femoral arteriovenous fistulas were created bilaterally in each of ten dogs and studied histologically over a period of 2 to 24 weeks. ²³⁶ All anastomoses remained patent without hematomas, aneurysms, or luminal narrowing during this evaluation period. Control suture specimens at the same intervals exhibited an organized fibrous-tissue response to the suture material. Clinical adaptability of the laser-welding technique was subsequently evaluated in five patients at 10 to 27 months by physical examination and duplex scanning. No evidence of abnormal healing was observed.

One significant advance in the area of plastic and reconstructive surgery has been the microsurgical transfer of free flaps. During these procedures, microsurgical-vessel anastomoses are necessary to restore blood circulation. These anastomoses are performed on vessels whose diameters are less than 5 mm. Conventional anastomoses use very fine sutures, typically around 22 µm in diameter, and as such patency of these anastomoses is highly dependent on the surgeon's skill. ²⁴⁰ Laser tissue welding and soldering offer a potential solution to this problem. ^{18,23,71} In 1999, Maitz et al. demonstrated the use of a fully biodegradable, diodelaser-activated protein tube for sutureless microvascular anastomoses. ¹⁰⁵ The protein tube is used to achieve good apposition of the tissue edges during end-to-end anastomoses while separating the anterior and posterior walls of the vessel to prevent vascular occlusion. The combination of these biodegradable protein tubes with a diode laser provides a quick and reliable technique to successfully anastomose small-diameter arteries, avoiding vessel-wall fibrosis by eliminating any permanent implanted devices.

Diagnostic catheterization and interventional cardiac procedures including coronary angioplasty require hemostasis at the puncture site immediately following the procedure. Several techniques have been investigated as a means for achieving rapid hemostasis including manual compression as well as the application of either collagen vascular hemostatic devices or suture-mediated devices.^{241–243} While these conventional techniques are effective in achieving adequate hemostasis in most patients, they are not without complications. Manual compression is uncomfortable and often painful for the patient. Risks associated with the collagen vascular hemostasis devices include arterial occlusive complications, local infection,²⁴⁴ and allergies to the collagen.²⁴⁵ Although suture-mediated devices can achieve closure of the site just as well as open surgical methods, they are limited by the complexity of the devices and a steep learning curve associated with the procedures.^{244,246} One possible alternative to the conventional techniques for achieving rapid hemostasis at the puncture site is laser tissue soldering. In a 2000 study, McNally et al. demonstrated the feasibility for using protein-solder-doped polymer membranes in conjunction with a diode laser for achieving rapid vascular hemostasis following cardiac procedures in both canine and porcine models.^{108,189} In the porcine study, the patency rate of both unheparinized and heparinized vessels was 100% at 3 d postoperative with evidence of intraluminal thrombosis seen in only 1 of the 24 repaired vessels.¹⁰⁸ In addition, repairs formed with the adhesive technique were achieved more rapidly than suturing, and acute leakage was observed less frequently.

Sealing of prosthetic vascular grafts to native vessels has also been attempted.^{247–251} Limited success has been achieved using tissue-welding techniques; however, laser soldering, used in conjunction with a few stay sutures to provide good apposition between the tissue edges and the graft material, has been particularly useful in providing a watertight seal over the repair.^{248,251}

Lastly, laser tissue welding and soldering techniques have been used to repair air leaks after lung biopsy or wedge resection²⁵² and bronchial stump leaks.¹⁰⁴ In these studies, laser soldering was found to be superior to both conventional suturing and fibrin-glue techniques. Attempts have also been made to weld an expanded polytetrafluoroethylene (e-PTFE) patch to the trachea to promote healing.²⁵³

39.8.2 Dermatology

Laser welding and soldering techniques offer many potential advantages over standard suture and staple closure of cutaneous tissue including minimal tissue handling, quicker closure times, minimal foreign-body

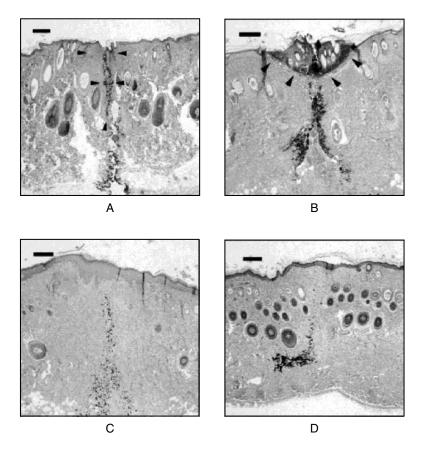

FIGURE 39.14 Photomicrographs showing wounds closed by Nd:YAG laser ($\lambda = 1.06 \, \mu m$, spot diameter = 4 mm, P = 10 W, pulse width ~80 msec, pulse interval = 8 sec): (A) day 0, (B) day 6, (C) day 14, and (D) day 28. Arrows indicate border of the thermal damage zone. The chromophore (India ink) is visible along the borders of the incision. At day 0 a "funnel-shaped" thermal denaturation zone with an average width of 200 μm near the epidermis and 50 μm in the mid-dermis is seen. At day 6, the epidermis had hypertrophied to 300 μm, and a complete epithelial bridge had formed under the necrotic tissue contained within the thermal damage zone. Wound healing progressed between days 14 and 28, with granulation tissue appearing in the papillary dermis, thus filling the gap created after sloughing of thermally damaged tissue (around day 10) from the wound site. Scale bars = 200 μm. (From Fried, N.M. et al., Lasers Surg. Med., 27(1), 55, 2000. With permission.)

and inflammatory response, maximal tissue alignment, early reepithelialization, watertight closure, and, most important, improved cosmesis.²⁵⁴ Laser welding has been explored as an alternative method of skin closure by many researchers using a variety of sources including CO₂,^{55,254,255} Nd:YAG, ^{254,256,257} diode,³¹ and argon²⁵⁴ lasers.

As mentioned above, a superior cosmetic result is claimed as the principal advantage of laser skin closure. The principal disadvantage is dehiscence. It is nearly impossible to obtain full-thickness welds while limiting thermal denaturation lateral to the weld site in the epidermis and papillary dermis. While thermal denaturation of tissue is necessary to produce a strong weld, excessive thermal damage may result in initially high-weld strengths, which then decrease because of sloughing of the necrotic tissue during wound remodeling, eventually leading to unnecessary scarring and dehiscence. 66,94 Dye enhancement of the laser-welding procedure has been investigated to minimize unwanted collateral thermal injury by ensuring selective energy deposition, thereby allowing the use of low-power lasers (Figure 39.14). Combinations include ICG with a diode laser 95,258 and India ink with an Nd:YAG laser. 66,94,259 In 2000, Fried and Walsh used India ink as an absorber to create welds with immediate tensile strengths higher

than sutured wounds. ⁹⁴ Application of a variety of soldering agents has also been shown to greatly improve the strength of cutaneous repairs. ^{29,51,118,119,177}

More recent studies have focused on optimizing the welding technique to minimize the effects of collateral thermal damage. In a 2000 study, Fried and Walsh showed that the typical thermal-denaturation profile demonstrated significant denaturation near the tissue surface. The extent of denaturation then decreased with depth as both absorption and scattering attenuated the incident radiation. Surface cooling with either a water or cryogen spray can effectively invert the denaturation gradient to minimize the problem of scar formation in the epidermis and papillary dermis that can affect cosmesis. Additionally, weld strength may be improved when denaturation is confined to the mid- and deep dermis resulting in a larger cross-sectional area for collagen bonding across the weld site. In the study by Fried and Walsh, dynamic cryogen cooling of the epidermis and papillary dermis was proven effective in reducing the amount of collateral thermal tissue damage.

39.8.3 General Surgery

Laser tissue welding has been investigated as an alternative technique for repair of most tissue types in the gastrointestinal tract, where, compared with suture closure, it has been found to be a much easier technique with greater speed, a better healing response, and no stone formation. The first published study about laser bowel welding was reported in 1986 by Sauer et al.²⁶¹ A CO₂ laser was used to repair longitudinal transmural incisions in otherwise intact rabbit ileum, producing strong hermetic closures. Visual observation of a slight desiccation and shrinkage of the tissue indicated the endpoint of the procedure. In 1989, Sauer et al. proposed the use of an Nd:YAG laser to create end-to-end small bowel anastomoses in a rabbit model. India ink, applied to the tissue edges prior to laser irradiation, was used as an absorbing chromophore. The anastomoses were performed using a biocompatible, water-soluble, intraluminal stent that held both intestinal edges in contact without any sutures or staples.²⁶² In 1989, Oz et al. investigated the feasibility of using a pulsed THC:YAG (2.15 µm) and a CW argon laser (488 to 514 nm) for welding of biliary tissue.⁶¹ Visual indicators similar to those used by Sauer et al. for the endpoint of the welding procedure were used. In this study, bowel anastomoses formed by argon-laser welding withstood the highest pressures prior to breaking. The tissue surfaces of bowel anastomoses formed with the THC:YAG were frequently charred, possibly explaining the lower breaking pressures. In 1994, Rabau et al. described the healing process of CO₂ laser intestinal welding in a rat model.²⁶³ Laser intestinal anastomoses were found to be more prone to dehiscence than their suture alternatives during the first 4 d postoperative to only improve with time, becoming at least as effective as sutured repairs by 7 to 10 d postoperative. In 1997, Cilesiz et al. investigated the use of argon⁵⁰ and Ho:YAG²⁶⁴ lasers for temperature-controlled laser intestinal welding with good results. The healing response of repairs formed with the argon and Ho:YAG lasers compared well with control sutured anastomoses, although wound abscesses were more prevalent in the Ho:YAG group, leading to delay in mucosal healing.

In a 2001 study, Wadia et al. evaluated laser soldering using ICG-doped liquid-albumin solders in conjunction with a diode laser for repair of liver injuries. Hajor liver trauma has a high mortality rate because of immediate exsanguination and a delayed morbidity from septicemia, peritonitis, biliary fistulae, and delayed secondary hemorrhage. Common surgical techniques for repair of liver lacerations include mass ligation with absorbable sutures, packing with reexploration, for mesh hepatorrhaphy, he fibrin sealant. These techniques are notoriously difficult to apply — a particular concern in such a surgical situation where time is of the essence. Thus, an alternative technique for achieving rapid hemostasis following liver injuries would be greatly beneficial. The laser-soldering technique was shown to effectively seal the liver surface and join lacerations with minimal thermal injury while working independently of the patient's coagulation status.

39.8.4 Gynecology and Obstetrics

Laser welding techniques hold great potential for many surgical procedures on the fallopian tube and ovaries, where reconstruction is required to preserve fertility.²⁶⁸ Laser welding was first proposed by von

Klilizing et al. in 1978 for fallopian-tube reconstructive surgery.²⁶⁹ In this study, a CO₂ laser was used to perform end-to-end-anastomoses of cornua uteri with a 70% pregnancy success rate. Since then, experimental studies on tubal sterilization-reversal surgeries using lasers have had mixed results. With zero success in the rate of pregnancy, Fayez et al. presented less-than-satisfactory results for CO₂ laser reanastomosis of rabbit uterine horns in a 1983 study.²⁷⁰ In a 1984 study by Choe et al., CO₂ laser microsurgery was shown to significantly reduce postoperative adhesions in microsurgical uterine-tube reanastomosis compared with conventional microsurgery using a scalpel; however, they were unable to weld with the CO₂ laser.²⁷¹ In these studies, the main problem with laser repairs appeared to be nonuniform heating of the tissue. More successful results were seen in a 1991 study by Vilos et al., where a CO₂ laser was used to perform a series of intraluminal-isthmic fallopian-tube anastomoses with a patency rate of 100%.²⁷²

The use of a low-power diode laser in conjunction with protein solder could avoid some of the earlier problems associated with uneven heating of the tissue. In 1995, Kao and Giles compared laser-welding and soldering techniques with conventional suture techniques for tubal reconstruction in a rabbit model.²⁷³ Operative time was significantly reduced for both laser techniques compared with the suture technique, and all techniques resulted in excellent healing. With the protection of serum albumin, the laser-assisted anastomoses did not cause any thermal damage, and the anastomotic sites could tolerate the distension pressure of pregnancy and parturition without problems. Laser welding without protection of serum albumin, however, showed potential for thermal damage and dehiscence. Finally, the implantation and pregnancy rates were comparable for all three types of procedures.²⁷³

Laparoscopic tubal procedures using conventional suture techniques have been extremely tedious and time-consuming.²⁷⁴ With further improvement in laser welding and soldering techniques, expeditious laparoscopic reanastomosis of fallopian tubes may be possible. In addition, the use of absorbable stents should make tubal welding and soldering techniques more feasible (see Section 39.6.4).

39.8.5 Laparoscopic and Endoscopic Surgery

Laparoscopic and endoscopic surgeries provide an ideal environment for laser-tissue-welding and soldering techniques, where conventional suture techniques remain time-consuming and tedious, and stapling devices are not usable in all applications. ^{275,276} Although laser welding and soldering techniques have not yet eliminated the need for suturing laparoscopically, particularly for tubal anastomoses, their potential in achieving this end is promising. ^{3,96,277–280} In a 1993 study, Poppas et al. used a 532-nm KTP laser with fluorescein as a chromophore for laser anastomosis of ureters in a canine model. ⁹⁶ Fluorescein emits a visible fluorescence when exposed to laser energy, thereby allowing the laparoscopic surgeon to see when the laser light is hitting the target. This helps reduce the incident of collateral thermal damage as a result of a wandering laser beam. This system was subsequently tested laparoscopically in a porcine model, and the results compared favorably with those of conventional suturing. ³ Closures formed with the laser-welding technique were achieved more rapidly than suturing techniques with superior histological results, and acute leakage was observed less frequently. Laparoscopic surgery should become more appealing to clinicians as soon as an approximation technique is discovered that is easy to use, safe, and able to reliably hold tissue together in the laparoscopic environment. ²⁸⁰

39.8.6 Neurosurgery

Techniques for nerve closure using sutures are well established. In a human patient, suture repair of a severed nerve may involve the individual joining of 40 fascicles, with three or four microsutures per fascicle. Since meticulous care is required, such an operation tends to be prolonged.⁴³ In addition, problems involving poor coaptation of the nerve fascicles, with loss of regenerating axons and scar formation, and mechanical damage to nerve tissue and intraneural circulation are also concerns.³² Early attempts at laser welding of nerves demonstrated the technique to be significantly faster than conventional microsuture techniques; however, the hoped-for superiority of nerve regeneration after laser repair was not seen, with dehiscence rates of 12 to 60%.^{43,281,282} Experimental studies by Maragh et al. suggest that

these high dehiscence rates stem from the fact that the high power densities required to coapt the nerve edges induce thermal damage in the epineurium, while low power densities do not result in sufficient tensile strength.²⁰

More recent studies with CO_2 lasers 36,81,283,284 and diode lasers combined with a dye-enhanced protein solder $^{81,114,115,123,284-286}$ hold greater promise for neurosurgical application of laser repair techniques. In 2000, Hajek et al. used a CO_2 laser for nerve coaptation in rat sciatic nerves. A larger degree of scarring and constriction was observed in nerves anastomosed by classical microsuture than that of the laser technique, with no significant difference in the quality of the action potentials of both groups. 283 Likewise, in a similar study by Happak et al. published in 2000, better results were obtained during functional evaluation of the sciatic-function index and the toe-spread index from the laser nerve coaptations than conventional suture coaptations. 36 In addition, the morphologic evaluations of the fiber density and area fraction were better in the laser group.

Laser tissue soldering reduces the effects of thermal damage while reinforcing wound strength, providing a promising technique for many neurosurgical applications. 81,114,285 In a 1995 study by Trickett et al., laser repair was noted to be a significantly faster procedure, inducing no inflammation and no foreign-body reaction. 123 Promising results in terms of axonal regeneration and functional results have also been reported. 103,115,123,284

Laser-soldering techniques were also shown to possess several advantages over microsuture techniques for repair of the inferior alveolar nerve in two 1998 studies by Curtis et al.^{287,288} In these studies, histochemical analysis showed comparable mean neuron counts and mean tracer uptake by neurons for the microsuture and laser-weld groups. Giant cell reactions were identified in two of the primary suture cases and axon deflection in three cases, demonstrating possible advantages of the laser-weld technique that showed no adverse reactions by axons or epineurium to the coagulative repair with the solder.

Finally, in a 1996 study by Foyt et al., laser soldering was shown to significantly decrease the incidence of cerebrospinal-fluid leak after dural closure, with the additional benefit of making dural closure possible where space constraints make traditional suture closure difficult.¹¹⁶

39.8.7 Ophthalmology

Conventional ophthalmic incision closure using corneal sutures is very demanding and time-consuming, even in the hands of a skilled surgeon.²⁸⁹ Postoperative complications include wound leakage, foreign-body reaction to stitches, corneal astigmatism as a result of tight sutures, sutures loosening as a result of wound contraction providing a portal of entry for microorganisms or epithelial ingrowth, and irritation of the cornea and conjunctiva with giant papillary conjunctivitis from exposed knots.²⁹⁰ Sutureless closure would overcome these problems.

The first attempts to weld corneal tissue with a CO_2 laser were unsuccessful because the heat created by the absorbed laser light induced corneal contraction, which widened rather than closed the incisions. ^{291,292} Corneal-tissue closure with a 1.9- μ m diode laser, on the other hand, has been used to achieve leak-proof, full-thickness closure of corneal incisions. ²⁹³ In a 1995 study by Williams et al., laser welding at 1.9 μ m was shown to stimulate homogenous wound healing by activating leukocytic and fibroblastic infiltration uniformly across the wound, thereby reducing the risk of postoperative astigmatism. ²⁹³ Success with a hydrogen fluoride laser (λ = 2.3 to 2.6 μ m), which has a penetration depth similar to that of the 1.9- μ m diode laser, suggests that treatment depth is important when selecting a laser for welding of corneas. ^{294,295} Despite these relative successes, the CO_2 , diode, and HF wavelengths are all strongly absorbed in tissue, and as such there is a relatively high risk of thermal damage associated with the laser-welding procedure, which could result in irreversible damage to the transparent structures of the eye. ^{294,296,297}

The ideal welding technique for opthalmic applications would utilize low temperatures to minimize thermal damage, thereby reducing the resulting contraction of the ocular tissue, which tends to result in tissue separation rather than fusion. Two attempts have been made to reduce the risk of thermal damage associated with ophthalmic laser-welding techniques: (1) the use of temperature-controlled welding

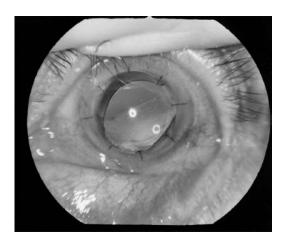

FIGURE 39.15 (Color figure follows p. 28-30.) Aspect of a human cornea at 3 months after diode-laser-assisted penetrating keratoplasty (transplantation of the cornea), where laser welding ($\lambda = 805$ nm, $P \sim 70$ mW, $t \sim 200$ sec, chromophore: saturated ICG solution in saline) was used despite the conventional continuous suture (eight interrupted stitches had been applied during the surgery, as in the conventional PK procedure, to hold the corneal button). (Image courtesy of Roberto Pini, Istituto di Elettronica Quantistica—C.N.R., Florence, Italy.)

systems^{154,208} and (2) the application of a chromophore to the weld site to make the welding technique more selective and localized.^{298,299} In a 2001 study by Pini et al., the first application of laser welding to clinical transplantation of the cornea, the welding effect was observed to be localized in the incision with no thermal side effects or inflammatory response when low-power irradiation was used.²⁹⁹ In addition, the healing process appeared to occur earlier and be more effective using the laser welding technique than suture techniques (Figure 39.15). Laser-solder closure has also been investigated as a means of improving the initial strength of the repairs.^{208,300}

39.8.8 Orthopedic Surgery

One potential use of laser welding in orthopedics is repair of tendons. Currently, microsurgical suture techniques are used to treat ruptured or lacerated tendons. Suture material produces a foreign-body reaction, which may inhibit natural healing and promote adhesions. The laser welding technique avoids this problem, and it could prove to be a useful tool in many orthopedic reconstructive procedures. The feasibility of laser welding of tendinous tissue was investigated in a 1996 study by Kilkelly et al. using CO₂ and Nd:YAG lasers in conjunction with a 25% human-albumin solder, and an argon laser in conjunction with a fluorescein-dye-doped albumin solder. Morphologic analysis showed greater tissue injury and inflammatory response in laser-treated tendons than in those treated with suture. In addition, they were unable to produce a weld sufficient to withstand the significant tensile loads to which tendons are subjected immediately after repair. After 14 d, however, there was no significant difference between the strength of the laser and suture repairs.

Laser welding of meniscus tears were reported in a 1995 study by Forman et al. using an argon laser in conjunction with a fibrinogen solder.³⁰⁴ Meniscal laser repairs also suffered from low initial strength; however, the solder was observed to provide a biological scaffold that was compatible with reparative cell migration and proliferation, resulting in cartilage formation with the biomechanical properties of native meniscus. The fibrocartilage produced after conventional repair is typically not as compatible.

Photothermal welding techniques are less successful in the avascular tissue often encountered in orthopedic applications because they rely on the presence of blood vessels to mediate a healing response in the form of scar tissue. Tendons, for example, are quite unique in their structure, as they are almost exclusively (>90%) composed of densely packed, highly organized type I collagen bundles. For this reason, photochemical-welding techniques, which utilize light-activated chemical cross-linking agents to produce

covalent cross-links between collagen fibers, might be better suited for orthopedic applications as they do not rely on the healing properties of blood vessels (see Section 39.2.2.3).

39.8.9 Otolaryngology

One possible application of laser tissue welding in the field of otolaryngology is the formation of tracheobronchial anastomoses. ^{120,305,306} A major and often fatal complication of lung and combined heart–lung transplantation is dehiscence of the tracheobronchial anastomosis. ³⁰⁷ Conventional suture techniques suffer from suture-line leaks, microabscesses, and perianastomotic infection, eventually leading to granulation formation, stenosis, or dehiscence. In 1990, Auteri et al. investigated the possibility of performing laser-welded tracheobronchial anastomoses using an 808-nm diode laser and ICG-dyeenhance fibrinogen and a single suture. ¹²⁰ Laser-welded and sutured anastomoses exhibited similar bursting pressures and histology immediately following the repairs; however, at 21 and 28 d postoperative, the laser-welded anastomoses exhibited less peritracheal inflammatory reach and showed visibly smoother luminal surfaces.

Other possible applications of laser welding and soldering in the field of otolaryngology include the fixation of flaps to vocal cords or other mucosal flaps,¹²¹ the repair of fascial grafts in tympanoplasty,³⁰⁸ and the sealing of pharyngocutaneous fistulas.³⁰⁹ In addition, the vascular and neural techniques discussed in Sections 39.2.7.1 and 39.2.7.5, respectively, would be applicable.

39.8.10 Urology

Laser tissue welding has been tested on almost every organ and tissue in the genitourinary tract.^{33,310} Urologic applications demand watertight, nonlithogenic closures due to the continuous flow of urine. Urine lacks the clotting ability of blood and thus requires a tighter anastomotic closure than is required in vascular surgical applications. Consequently, suture techniques in the urinary tract tend to be relatively technically demanding and time-consuming. In addition, the suture material itself can act as a nidus for stone formation. Laser welding can provide an immediate watertight, nonlithogenic anastomosis with tensile strength that is superior to that of traditional closure techniques.³¹⁰ Applications of laser tissue welding to open urologic surgery include vasovasostomy,^{110,311–313} urethral reconstruction (hypospadias repair),^{91,117,314,315} ureterotomy repair,^{3,97} and pyeloplasty.⁵

The majority of clinical successes using laser tissue-welding and soldering techniques have been made in the field of urology. In 1988, Rosemberg reported the results of 14 patients who had a vasovasostomy by CO₂ laser.³¹¹ He demonstrated postoperative sperm counts of more than 20 million/ml in 86% of his patients in comparison with 43% for those patients receiving standard microsurgical repair. A significant reduction in total operative time was also noted. In a 1989 study, Gilbert and Beckert also performed vasovasostomies on four males using an Nd:YAG laser and achieved normal sperm counts in two of these patients.³¹² Of the remaining two patients, one was reported to have cryptospermia and the other oligoasthenospermia. In 1996, Kirsch et al. examined the use of laser tissue soldering using ICG-doped albumin solder in conjunction with an 808-nm diode laser for hypospadias repair in 30 children.³¹⁵ The laser solder-repair technique performed faster than conventional suture techniques, providing an immediate leak-free closure (intraoperative leak pressures for laser solder anastomoses were 94.2 \pm 24.2 mm Hg as opposed to 20.0 ± 2.9 mm Hg for suture controls). In addition, no intraoperative complications were noted, and the laser-soldering technique had an overall complication rate of 19 vs. 24% of those with suture repair. In a 2001 study, Kirsch et al. compared the results of laser tissue soldering with ICGdoped albumin-protein solder (n = 54) and conventional suturing (n = 84) for hypospadias repair on 138 boys between the ages of 4 months and 8 years (mean age 15 months).91 While stay sutures were used for tissue alignment in the laser solder-repair group, the total number of sutures was reduced by a factor of three compared to the controls. In addition, the mean operative time was reduced by a factor of five compared to the controls. The complication rate was 4.7% in the laser solder-repair group and 10.7% in the control group, with fistula in 2 of the 54 laser-solder cases and fistula and meatal stenosis in 7 and 2 of the 84 control cases, respectively. The ease of the laser technique and the lower complication rate in the laser group indicate that laser tissue soldering is an acceptable means of tissue closure in hypospadias repair. In addition to these clinical results, a tremendous amount of laboratory work has shown that laser tissue welding and soldering techniques can be applied to closure of genitourinary tissue using several different wavelengths.^{3,5,97,100,110}

39.9 Summary

Laser tissue welding is a technological advance for tissue closure that offers many beneficial features over conventional closure techniques including reduced suture and needle trauma, reduced foreign-body reaction, better cosmetic appearance, reduced bleeding, the potential to form an immediate watertight anastomosis intraoperatively, and shorter operating times. Major advances have addressed the problems that have prevented the widespread clinical use of laser welding. The incorporation of polymer-membrane scaffolds has reduced the runoff associated with liquid solder alone. The development of biodegradable stents has improved tissue approximation. The incorporation of temperature-monitoring systems for feedback control has provided the basis for objectifying the endpoint of laser irradiation, thus eliminating reduced weld strength secondary to under- or overheating. Future advancements in the use of light-activated surgical adhesives and the development of laser-delivery systems will certainly open up more applications for this growth.

40.1 Historical Overview

In 1960, long after Einstein proposed the theoretical concept of stimulated photon emission, Maiman built the first laser. Leon Goldman then pioneered the use of lasers in dermatology. Treatment of basal cell carcinoma with ruby and neodymium lasers and tattoo removal with Q-switched ruby laser were reported in 1964 and 1965, respectively. Buby and other pulsed lasers were essentially abandoned when

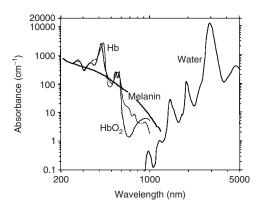

FIGURE 40.1 Absorption spectra of major skin chromophores.

argon-ion and carbon dioxide (CO₂) lasers were used for coagulation and cutting during the 1970s. A new era began in the early 1980s when Anderson and Parrish proposed a theory for target-selective injury with pulsed lasers called selective photothermolysis.⁶ A 450-μsec yellow-dye laser was initially developed for treating port-wine lesions, the first laser-cavity design intrinsically motivated by a medical need.⁷ At present, selective photothermolysis is the basis for low-risk treatment of microvascular lesions, tattoos, and benign pigmented lesions.

40.2 Skin Optics

Optical penetration into skin is determined by a combination of absorption and scattering. The principal chromophores (absorbing molecules) for optical radiation in skin are water, melanin, and hemoglobin. When absorption occurs, photon energy is transferred to the chromophore. The excited chromophore can dissipate this energy in various ways including by photochemical reaction, heat, or re-emission of light. Absorption spectra of the major chromophores in skin throughout the ultraviolet (UV), visible, and infrared regions are shown in Figure 40.1. The absorption coefficient (μ_a) is the probability per unit path length that a photon at a particular wavelength will be absorbed. Absorption depends on the concentration of chromophores present. Scattering occurs when the photon changes its direction of propagation. About 4 to 7% of light is reflected upon striking the skin surface because of the sudden change in refractive index between air and stratum corneum. The remaining light penetrates into the skin and can be either absorbed or scattered by molecules, particles, and structures in the tissue.

Absorption is the primary process limiting penetration of UV and visible light through the epidermis. Proteins, melanin, urocanic acid, and DNA absorb UV wavelengths shorter than about 320 nm. For wavelengths from 320 to 1200 nm, especially at the shorter wavelengths, melanin is the primary absorber of light in the epidermis. Water is the dominant skin chromophore for mid- and far-infrared wavelengths. In the dermis, scattering by collagen fibers is very important for determining optical penetration of light.

In general, scattering is an inverse function of wavelength, which accounts in part for a large increase in optical penetration into the dermis, with increasing wavelength from UV through visible and near-infrared (NIR) wavelengths. The absorption coefficient of the dermis is low throughout the visible and NIR spectrum, except in blood vessels. Blood has strong absorption in the blue, green, and yellow wavelengths and a weak but significant absorption band in the 800- to 1000-nm range. An optical "window" exists between 600 and 1300 nm, which are the most penetrating wavelengths. The least-penetrating wavelengths are in the far-UV and far-infrared due to protein and water absorption, respectively. For visible and NIR wavelengths, the exposure spot size also affects the effective penetration depth of a laser beam into skin due to scattering.9

40.3 Laser-Skin Interactions

The Grotthus-Draper law states that no effect of light occurs without absorption. In other words, laser light can impose a tissue effect only when it is absorbed by chromophores. There are three basic effects: photothermal, photochemical, and photomechanical effects. In practice, these modes of laser interaction frequently coexist, but one or two usually dominate. Photothermal effects are the mainstay of current clinical laser use. The majority of current laser applications in dermatology use photothermal effects.

40.4 Photothermal Interactions

Unlike photochemistry, which requires a given photon quantum energy, heating can occur after absorption at any wavelength. Thermal effects on tissue are both time- and temperature-dependent. The Arrhenius model states that the rate of thermal denaturation of a given molecule is exponentially related to temperature. Therefore, the accumulation of denatured material rises exponentially with temperature and proportionally to time. Temperature is an expression of average molecular kinetic motion. At high temperatures, the specially configured macromolecules necessary for life are shaken open, resulting in loss of function. Most proteins are denatured above 60°C and DNA above 70°C. Type I collagen, the major protein in dermis, has a sharp melting transition for the fibrillar form near 70°C, causing irreversible coagulation and shrinkage of the connective-tissue matrix. Above 100°C, tissue water is vaporized. If desiccated tissue is heated further, carbonization occurs.

One popular use of lasers in dermatology is for precise tissue ablation, called laser resurfacing. Two main factors influence laser vaporization or ablation of tissue. The first is the penetration depth for the laser radiation, which depends on wavelength. The second is the rate of tissue vaporization, which depends on the amount and rate of laser energy absorption; this is discussed in the next section.

40.5 Selective Photothermolysis

The term "selective photothermolysis" was coined to describe site-specific, thermally mediated injury of pigmented tissue targets by pulses of radiation. This technique relies on selective absorption of a brief optical pulse to generate and confine heat at certain pigmented targets. Selective photothermolysis has three basic requirements. First, the wavelength used must be preferentially absorbed by the targeted structure. This can be achieved by choosing a wavelength within absorption bands for a chromophore associated with the target, e.g., melanin in a pigmented hair follicle or hemoglobins in a blood vessel. Second, a sufficient fluence (fluence = energy/area) is required to achieve a damaging temperature in the targets. Third, the pulse duration or exposure time must be about equal to or less than the time needed for the targets to cool. As soon as heat is created in the chromophores, it begins to dissipate by conduction. Thus, competition between active heating and passive cooling determines how hot the targets become. One useful concept is that of the "thermal relaxation time," defined as the time needed for substantial cooling of a target structure. When the laser exposure is less than the thermal relaxation time for a given light-absorbing target, maximal thermal confinement occurs. Thermal relaxation time is proportional to the square of the target's size and to shape. Thus, small objects cool much faster than large ones. For a given diameter, spheres cool faster than cylinders, which cool faster than planes. For most tissue targets the simple rule of thumb is that the thermal relaxation time in seconds is about equal to the square of the target dimension in millimeters.

Many of the cutaneous target structures treated by selective photothermolysis are heterogeneous such that the light-absorbing chromophore is not identical to the actual target. For example, blood-vessel walls, rather than the light-absorbing blood contained within these vessels, are the actual targets when treating a vascular birthmark. Because heat must flow from blood to the surrounding vessel wall, ideally one should use a pulse duration approximately equal to the thermal relaxation time of the entire vessel structure. A similar example is laser hair removal, in which heat generated by light absorption in the pigmented hair shaft must flow into surrounding structures of the hair follicle.

40.6 Photomechanical Interactions

Photomechanical interactions, sometimes called photoacoustic interactions, are characterized by light-induced stress and strain, leading to mechanical disruption of tissue structures, organelles, membranes, and cells. Rapid thermal expansion, high-pressure stress waves, low-pressure tensile waves, cavitation, and local vaporization can occur when laser pulses are absorbed by tissue. Rapid heating with thermal expansion and vaporization is often involved. For example, hemorrhage occurred when a 1-µsec 577-nm pulsed dye laser (PDL) was tested for the treatment of vascular lesions, prior to the present generation of longer PDLs. ¹⁰ In contrast, mechanical effects may be the primary therapeutic mechanism for the treatment of pigmented lesions and tattoo removal with Q-switched lasers.

40.7 Photochemical Interactions

Classic photobiology of skin is based on photochemical reactions. The major application for laser-induced photochemistry at present is photodynamic therapy (PDT). PDT involves the therapeutic use of photochemical reactions mediated through the interaction of photosensitizing agents, light, and oxygen for the treatment of malignant or benign diseases. PDT is a two-step procedure. In the first step, the photosensitizer is administered to the patient and is allowed to be absorbed by the target tissues. The second step involves activation of the photosensitizer, in the presence of oxygen, with a specific wavelength and fluence of light delivered to the target tissue. In general, PDT drugs transfer the excitation energy to oxygen, creating a reactive intermediate, singlet oxygen. Selectivity for tissue damage depends on the distributions of the three factors necessary for PDT effect: drug, light, and oxygen.

40.8 Laser Safety

The potential hazards from laser use are injury to the skin and eyes, aerosolization of hazardous biologic materials, ignition of fires, and electrocution. Eye injuries result from absorption of laser light by the structures in the eye including the retina, lens, sclera, and cornea. Lasers operating between 400 and 1400 nm are particularly dangerous to the retina. Wavelengths between 295 and 320 nm and between 1 and 2 μ m may injure the lens. Injury to the cornea is possible from the wavelengths in the UV and most of the infrared at wavelengths beyond 1400 nm.¹¹ Appropriate safety goggles that filter specific wavelengths of laser light must be worn at all times while the laser is in operation. Each pair of goggles should be marked with the appropriate wavelength of protection and optical density (OD) for the specific lasers in use. Prescription glasses or clear plastic wrap-around goggles made of polycarbonate are generally satisfactory when using far-infrared sources such as CO_2 and erbium:yttrium-aluminum-garnet (Er:YAG) lasers.

Skin burns can be caused directly by laser-beam exposures, or by laser-ignited fires. Despite the shallow depth of photon penetration, surgical $\rm CO_2$ laser-beam burns can occur rapidly and deeply. NIR wavelengths penetrate deeply into skin; continuous or pulsed 1064-nm neodymium:yttrium-aluminum-garnet (Nd:YAG) lasers can cause deep, severe burns. Continuous or quasicontinuous visible-light lasers such as potassium-titanyl-phosphate (KTP) (532 nm) or argon lasers tend to produce an intermediate burn depth. Surgical instruments used in the operating room should have black anodized or sandblasted, roughened surfaces to reduce the potential eye or skin hazard from the reflected laser beam.

The smoke plume generated by laser vaporization of tissue may contain bacteria, viral DNA, or viable cells that may have infective potential. Intact DNA from papilloma virus has been documented in CO₂ laser plume. ¹² Although the p24 HIV gag antigen has been detected in CO₂ laser–vaporized plume, infectivity is low. ¹³ Apart from infectious risk, the vaporized material can be an irritant to respiratory mucosa. ¹⁴ The Q-switched and dye lasers used for tattoo and pigmented lesions can eject large tissue fragments from the skin due to subsurface vaporization. Protective cylinders and shields that attach to

the end of the laser handpiece should be used to contain fumes, vaporized particles, and splattered tissue. The surgeon and laser-room staff must also wear specifically designed laser-filter facemasks during the procedure, and a good local exhaust ventilation must be used.

Fires ignited by laser exposure are a major hazard, especially in the presence of oxygen and flammable items such as drapes, gauze, clothing, and flammable solvents like alcohol. The use of plastic endotracheal tubes with greater than 40% oxygen is particularly hazardous when CO₂ lasers are used near the tube. Endotrachial tube combustion is rapid and releases toxic fumes that can permanently destroy the patient's airway. Drapes should be wet with sterile water or saline solution and be moistened repeatedly throughout the surgery. Ignition of dry hair is a common hazard, with or without oxygen in the surgical field. Hair should be wetted.

Lasers can pose an electrical hazard if accidental discharge occurs. Electrical risks can persist within the laser itself even after power has been disconnected when the energy-storage capacitor may still hold a substantial charge. A high-energy xenon flashlamp is also a potential source of electrical hazard. Appropriate grounding and other electrical safety procedures are essential.

40.9 Lasers for Vascular Skin Lesions

40.9.1 Mechanisms of Action

Laser wavelengths absorbed by hemoglobin are used to treat cutaneous vascular lesions such as portwine stains (PWSs), hemangioma, spider angioma, cherry angioma, venous lake, and telangiectasia of face and legs. The basic objective in treating vascular lesions is to irreversibly damage abnormal blood vessels but spare normal skin tissue. Argon and other continuous and quasicontinuous visible-light lasers were first used to treat PWSs. The risk of scarring in the pink PWS of children was high.¹⁵ The PDL was then developed based on the concept of selective photothermolysis. In the first theoretical formulation of selective photothermolysis, 7 a 1-msec, 577-nm pulse of at least 2 J/cm² was predicted as theoretically ideal for most pediatric PWSs. Initially, however, such long pulses were not available at this wavelength. A 1-usec PDL was tested at 577 nm in normal human and animal skin and was noted to cause histologically selective injury with extensive hemorrhage to dermal vessels. 10,16 In an attempt to minimize vaporization injury and maximize thermal coagulation of vessels, the pulse duration was lengthened. A 400µsec, 577-nm PDL was constructed, tested clinically on PWSs, and noted to work well with a low risk of scarring, even in children.¹⁷ Subsequently, a longer wavelength (585 nm), approximately twice as penetrating, was shown to offer similar vascular selectivity with greater depth of effect. ¹⁸ A flashlamp-pumped, tunable dye laser near 585 nm (0.5-msec pulse duration) is now a standard method for treating PWS because of the very low risk of scarring when used in single pulses at 6 to 8 J/cm² fluence. With its short pulse duration, this laser produces transient purpura because of hemorrhage and a delayed vasculitis. Dierickx et al. demonstrated experimentally that the thermal relaxation time for vessels roughly 60 um in diameter was between 1 and 10 msec.¹⁹ PDLs with a pulsewidth of 1.5 msec have subsequently shown better clearing of PWSs. Pulses longer than about 10 msec tend to produce less immediate purpura (hemorrhage).

Purpura occurring immediately after laser treatment is generally due to blood vaporization, vessel ruptures, and hemorrhages. When the pulse duration exceeds about 20 msec, immediate purpura can generally be avoided. Recently, a number of tunable pulse-width sources, including pulsed dye (585 nm), frequency-doubled Nd:YAG (532 nm), alexandrite (755 nm), Nd:YAG (1064 nm), diode (800 nm), and flashlamps (500 to 1200 nm), have become available. Another potential advantage of long pulses is that skin cooling can more effectively protect the epidermis than can shorter pulses. In general, good results can be achieved with pulse durations that nearly match the thermal relaxation time of the target vessels, using sufficient fluence in combination with active skin-cooling methods, which are described below.

Wavelength affects the depth of vascular-lesion treatment and uniformity of heating luminal blood. Generally, the longer the laser wavelength up to 1200 nm the deeper the penetration depth^{6,17,20} due to

lower scattering and absorption. At wavelengths weakly absorbed by hemoglobins, such as 700 to 1100 nm, high treatment fluences are needed. Spot size also plays a significant role in determining the depth of effective treatment. The intensity of a narrow beam (small spot size) tends to suffer greater loss with depth, as light is scattered outside the beam diameter. Larger exposure spots are therefore desirable when target vessels are deep in skin.²¹ Increasing the spot size has been shown to increase clearing with the 585-nm PDL in PWSs and hemangiomas.^{22,23} Another significant issue is the number of pulses delivered to a single skin site. The Arrhenius model suggests that thermal injury is cumulative over time; therefore, in theory, multiple lower-fluence pulses that do not cause hemorrhage might be used to accumulate selective, gentler, and more complete damage to microvessels. This has been reported in animal and human studies.^{24,25}

Fast events occurring during exposures of blood vessels to 532-nm and 1064-nm laser pulses (1- to 50-msec pulse duration) have recently been observed using fast imaging microscopy. In order of increasing fluence, the fast events were blood coagulation, vasoconstriction, thread-like appearance of the treated vascular segment, vessel disappearance, intravascular cavitation, extravascular cavitation, vessel-wall rupture and hemorrhage, and shrinkage of perivascular collagen. The apparent mechanism for vessel disappearance, a desired endpoint for treating vascular lesions, is contraction of intravascular blood and perivascular-collagen shrinkage after thermal denaturation. This occurs most reliably when the pulse duration is approximately equal to the thermal relaxation time of the exposed blood vessels.

40.10 Laser Devices

In addition to pulsed lasers, continuous and quasicontinuous visible-light lasers have been used to treat vascular lesions. These include argon (488 to 514 nm), krypton (520 to 530, 568 nm), argon-pumped tunable dye (488 to 638 nm), and copper-vapor and copper-bromide (578 nm) lasers. A variety of new lasers have been developed over the past decade. These include standard and long-pulsed PDL, 532-nm pulsed lasers with pulse duration of 1 msec to 100 msec, pulsed alexandrite laser at 755 nm with pulse duration up to 20 msec, pulsed 800-nm diode lasers with pulse durations from 5 to 1000 msec, pulsed 1064-nm Nd:YAG laser with pulse duration up to 100 msec, and a filtered broad-spectrum flash-lamp intense pulsed light source (IPLS).

PDLs contain a rhodamine dye, which is excited by a xenon flashlamp to produce yellow light. The traditional PDL emits 585-nm-wavelength light and 450-µsec pulse duration that penetrates the dermis to a depth of 1.2 mm. ^{17,18} Newer versions emit tunable 585- to 600-nm wavelengths at a pulse duration of 1.5 msec, or tunable pulse durations from 0.4 to 20 msec in a stuttered-pulse mode. One manufacturer offers an integrated cryogen-spray skin-cooling apparatus, which is less painful and in pigmented skin allows treatment at somewhat higher fluences without epidermal damage. Copper-vapor and copper-bromide lasers emit light at 511 nm and 578 nm in a "pseudocontinuous" emission consisting of 20-nsec pulses at a frequency of 15,000 Hz. The KTP laser emits 532-nm light that has a similar hemoglobin-absorption coefficient as 585-nm light. Melanin absorption is somewhat higher at 532 nm, however. These devices produce millisecond-domain pulses, either as a true millisecond pulse or as a millisecond "macropulse" of rapid delivery of shorter "micropulses." In practice, the experience and skill of the laser operator is a large variable affecting clinical outcome, regardless of the type of laser used.

40.11 Port-Wine Stain

The PWS is a congenital malformation of dermal microvasculature present in 0.3 to 0.5% of newborns and persists throughout life. Histologically, PWSs reveal an increased number of venules in the papillary and upper reticular dermis.²⁶ PWSs darken progressively with age, from pink to red to deep violet, and are frequently associated with progressive hypertrophy, a raised and nodular surface.²⁷ The darkening correlates with vessel dilation, not an increase in the number of vessels.

Treatments of PWSs have included skin grafting, ionizing radiation, cryosurgery, tattooing, dermabrasion, and laser treatments. At present, lasers clearly offer the treatment of choice. The current standard treatment of PWSs is with PDL at a wavelength ranging from 585 to 600 nm, 0.4 to 1.5 msec pulsewidth, and fluence of 3 to 10 J/cm² with 3- to 10-mm exposure spots delivered with minimal overlap. The somewhat shorter pulses are ideal for pediatric PWS in which the vessel diameters are relatively small, while long-pulsed PDLs may be more suitable for resistant or adult PWS.^{28,29} Approximately 50 to 75% lightening of PWSs is achieved within two to three treatments with PDL therapy. Complete resolution of the lesions can be achieved with repetitive laser treatments in about half of patients.³⁰ Immediate purpura in the treated areas is the treatment endpoint and takes 10 or more days to subside.

Several prognostic criteria have been used in predicting the outcome of PWS treatments. These include age of patient, site, size, color, and microvascular pattern of the lesion. In one study, it was shown that the major determinants of treatment response in order of decreasing importance were PWS location and size and patient's age.³¹ The site of a PWS clearly has prognostic significance. PWSs on the face and neck tend to respond better than elsewhere on the body, and the worst results are seen on the distal limb.^{32–34} For PWS of the head and neck, centrofacial lesions (medial aspect of the cheek, upper cutaneous lip, and nose) and lesions involving dermatome V2 respond less favorably than lesions located elsewhere on the head and neck (periorbital, forehead/temple, lateral aspect of the cheek, neck, and chin).³⁵ Central forehead PWSs respond most favorably.³¹ Another prognostic factor for the response of PWS to laser treatment is the initial size of the lesion being treated. Small PWSs have shown a greater response to laser treatment than larger lesions.^{31,36}

There are contradictory reports concerning the influence of patient age and color of PWSs on the outcome of laser treatment. Although young children are generally considered to respond better to PDL treatment, 17,28,32 some authors found no age dependence. 37-39 However, there are strong arguments in favor of treating PWS during infancy. These include rapid expansion of the PWS area as the child grows, ease of treatment under topical anesthesia only, completion of therapy prior to the child's formation of physical self-image, and avoidance of the psychological trauma associated with disfigurement during socialization and early school years. With regard to color of lesions, some authors report best results in pink lesion,³² while others report better results in red lesions.⁴⁰ In one study, color of PWSs was found to be of no prognostic value.³³ Fiskerstrand et al. demonstrated the correlation of the treatment outcome and the size and color of PWSs. 41,42 The vessels of the good responders were located significantly more superficially than the vessels of the moderate and poor responders. The poor responders had significantly smaller vessels than the moderate and good responders. The moderate responders had deeper but larger vessels than the poor responders. The vessel diameter was correlated to the color, with pink lesions having the smallest diameter vessels and purple lesions the largest. Vessel depth was partly reflected in the lesional color, as the pink and purple lesions had significantly deeper vessels than the red ones. These results indicate that pink lesions predict poor blanching due to deeply located small vessels, while red lesions predict a good therapeutic result because of more superficially located vessels.

The two major microvascular patterns examined by a videomicroscope are ectasia localized to the capillary loops (type 1) and dilated ectatic vessels in the superficial horizontal plexus in a ring pattern (type 2). It has been shown that type 1 lesions are more likely to respond to laser therapy than are type 2 or mixed lesions.⁴³ Eubanks et al. subsequently demonstrated that PWSs in areas that typically respond well to laser treatment (V3, neck, and trunk) are more likely to have a type 1 pattern, whereas PWSs in areas that have a poorer response to therapy (V2, distal extremities) are more likely to have a deeper type 2 pattern.⁴⁴ The videomicroscope study of PWSs may in the future provide a better prognostic guide for treating PWS.

Although PDLs at present have been established as the treatment of choice for PWS, the results are variable and unpredictable.³³ Treatment is somewhat more effective using higher fluences, e.g., PDL with cryogen spray cooling^{45–49} or long-pulsed KTP laser.⁵⁰ A controversy is the apparent "recurrence" of PWS after treatment with lasers. The natural course of a PWS is to darken and dilate over years, and residual

PWS vessels follow this course. One study reported that almost 50% of PWSs darken 3 to 4 years following discontinuation of treatment.³⁹ Michel et al. reported 16.3% recurrence rate in 147 PWS patients treated with PDL at least 1 year after the last treatment. Since children under 10 years of age did not show any PWS recurrence, the authors pointed out that age at the beginning of treatment may have an influence on the recurrence rate.⁵¹ In theory, a high-energy pulsed 1064-nm Nd:YAG laser could offer a combination of vascular selectivity and deep penetration that may be superior to PDL treatment. However, controlled studies of appropriate pulsed Nd:YAG lasers for PWS treatment have not yet been reported.

Topical anesthesia is usually satisfactory for the treatment of PWS lesions in adults, but local or regional anesthesia may be required. General anesthesia should be considered in children under 12 years of age to minimize the risk of eye injury and pain associated with the multiple treatments.⁵²

Side effects from PDL treatment of PWSs occur infrequently. In a study of 701 PWS patients with 3877 PDL treatments, hyperpigmentation was the most frequent side effect observed (9.1%) followed by blistering, atrophic scar (4.3%), hypopigmentation, crusting, and hypertrophic scar (0.7%).⁵³

40.12 Hemangioma

Hemangiomas are common "benign" proliferations of blood vessels occurring in up to 10% of all children by the age of 1 year. They typically undergo a rapid growth phase during the first year of life followed by complete or partial involution by age 12 years.⁵⁴ Histologically, there are dense collections of thinwalled vessels interspersed with sheets of vascular endothelial cells. Because of the natural course with spontaneous involution of hemangioma, conservative management has been advocated for the majority of these lesions. Indications for early interventions include alarming hemangiomas, hemangiomas with associated complications such as recurrent bleeding, infection, and ulceration, hemangiomas in certain locations (such as the nose, lip, and ear) that are more likely to result in permanent anatomic distortion and scarring, and extreme familial or patient distress.⁵⁵⁻⁵⁷ The alarming hemangiomas are those lesions that cause, or threaten to cause, ocular compromise, respiratory distress, congestive heart failure, gastrointestinal bleeding, and extensive skin ulceration.55 Hemangiomas have been treated with varying success using compression therapy, ionizing radiation, intralesional or systemic corticosteroids, interferon α , cryosurgery, embolization, and various laser therapies. The treatment methods used depend on the age of patient, site and size of lesions, and stage of the disease. Early surgery is an option in some cases of pedunculated hemangiomas. Superficial hemangiomas are generally treated with local corticosteroids (potent topical or intralesional), PDL, or both. Larger lesions with a deeper component and alarming hemangiomas usually require the administration of systemic corticosteroids.⁵⁷

Laser treatment of infantile hemangiomas is very controversial. One report evaluating 617 cases of hemangiomas treated with PDL noted that laser treatment halted progression or induced regression in the majority of patients. Total regression was achieved in nearly half of the small superficial hemangiomas; however, a tightly controlled study of these self-regressing lesions is still lacking.⁵⁸ In clinical practice, treatment with PDL appears to be effective and may be the treatment of choice for small, superficial cutaneous hemangiomas (Figure 40.2). Hemangiomas with a deep component do not benefit from PDL treatment due to the limitation of the laser-penetration depth. Early therapeutic intervention with PDL may or may not prevent proliferative growth of the deeper or subcutaneous component of the hemangioma. 59-61 Even in carefully selected patients with relatively superficial lesions, PDL treatment is variably effective, presumably because of continued growth of a deeper component not reached by the laser. 62,63 In large disfiguring hemangiomas, PDL has been used as an adjunct to glucocorticosteroid or interferonα treatments. 64 Systemic interferon treatment in infants is associated with development of spastic diplegia, a major complication limiting this form of therapy. Laser treatment is generally accepted for control of ulcerated hemangiomas, leading to a decrease in pain, promotion of healing, and acceleration of involution.65-67 One to three laser treatments have been reported to heal most ulcerated lesions.65,66 However, laser treatment has also been reported to induce ulceration.⁶⁸ The continuous 1064-nm Nd:YAG laser is sometimes used to debulk and photocoagulate hemangiomas, often by interstitial fiber-optic delivery. In

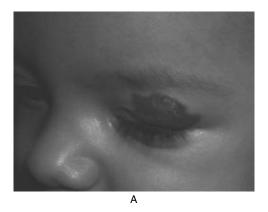

FIGURE 40.2 (Color figure follows p. 28-30.) (A) A hemangioma of the left upper eyelid prior to treatment. (B) After a series of eight treatments with the 595-nm pulsed-dye laser at 10 to 15 J/cm² and 7-mm spot size, the hemangioma cleared significantly.

a study of 25 children with bulky lesions, 72% of cases showed good to excellent response to Nd:YAG laser photocoagulation.⁶⁹

40.13 Telangiectases and Dilated Leg Veins

Telangiectases are common dilated, superficial blood vessels associated with aging, chronic sun damage, scars, malformations, acne rosacea, and other conditions. Dilated veins are also common in both sexes due to poor venous return from incompetent vein valves, pregnancy, prolonged standing or sitting, aging, and heredity. Sclerotherapy, which consists of local injection of substances that kill endothelial cells lining blood vessels, remains the gold standard of treatment for telangiectasias of the lower extremities. Facial telangiectases are less responsive to sclerotherapy than those located on the leg and more prone to complications.⁷⁰ Therefore, laser treatment in general has a greater role for treating facial telangiectases.

Red linear and arborizing telangiectases frequently occur on the face, particularly on the nose, cheeks, and chin. They measure 0.1 to 1.0 mm in diameter and represent a dilated venule, capillary, or arteriole. With a 532-nm KTP laser and pulse duration in the millisecond range, good to excellent results can be obtained on facial telangiectasia with minimal side effects. Immediately after appropriate laser treatment with green, yellow, or infrared laser pulses between about 10 and 50 msec, the abnormal vessels appear subtly darker and coagulated or simply disappear from view. In a study comparing the copper-vapor laser and PDL in the treatment of facial telangiectases, both lasers provided satisfactory and comparable

results at 2 and 6 weeks, but PDL induced more post-treatment purpura (bruising) and other side effects. Postoperative swelling, healing time, and incidence of postinflammatory hyperpigmentation were greater with the PDL compared to the copper-vapor laser.⁷³ The results of KTP laser and PDL in the treatment of facial telangiectasia are also comparable. A comparison of long-pulsed dye (590 nm) and KTP lasers for facial telangiectasia showed a somewhat better result with long-pulsed dye laser according to blinded grading of response.⁷⁴ However, patients strongly preferred the KTP laser due to its lower incidence of post-treatment purpura and other side effects. This stimulated development of so-called "stuttered-pulse" dye lasers (SPDLs), which emit a train of several 0.4-msec pulses during about 20 msec. The SPDL produces less purpura than conventional PDLs but still more than a simple KTP-laser pulse of similar duration.

Laser treatment of leg telangiectasia has improved greatly over the past 5 years, to the point that it is almost comparable in efficacy to sclerotherapy. Before this, argon, argon-dye, copper-vapor, KTP:YAG, pulsed-dye, and krypton lasers were used with disappointing results. Traditional PDLs (585 nm, 0.4 msec, 6 to 8.5 J/cm,² 5-mm spot size) are ineffective for vessels greater than 0.2 mm in diameter.⁷⁵ Based on theoretical considerations, longer wavelengths and longer pulse durations would be more appropriate for treatment of most leg veins. Longer wavelengths are needed to penetrate deeper into skin. Longer pulse width produces less mechanical injury, with more uniform thermal damage of large vessels, and no purpura. Attempts to modify yellow PDLs for leg-vein therapy have met with limited success. At a wavelength of 595 nm or 600 nm and a pulse duration of 1.5 msec, with 2 × 7 mm elliptical spot at fluences of 15 and 20 J/cm², there was only 50 to 75% clearance of leg veins less than 1.5 mm in diameter after one to three treatment sessions. ^{76–78} A comparison of 595-nm PDLs at 1.5- and 4-msec pulse duration found neither to be effective for vessels greater than 1 mm in diameter.⁷⁹

Vessel size and depth largely determine the appropriate choice of laser for treatment. Recent studies suggest that NIR, millisecond-domain alexandrite, diode, and Nd:YAG lasers are considerably superior to visible lasers for treating vessels larger than about 1 mm in diameter but less effective for small vessels. One study evaluated 28 patients with leg telangiectasia treated with a 755-nm long-pulsed alexandrite laser. Each patient received three laser treatments given at 4-week intervals with a fluence of 20 J/cm², 5-msec pulse duration, 10-mm spot size, and single or double pulse at 1 Hz. The greatest response was seen in medium-diameter (0.4- to 1.0-mm) leg vessels. Reduced response was seen in large-diameter (1.0- to 3.0-mm) vessels, while small-diameter (less than 0.4-mm) vessels did not respond at all.80 In another study, each of the 20 leg telangiectatic patients was treated once using one to three passes of a 755-nm, 3-msec alexandrite laser at fluences of 60 to 80 J/cm². By 12 weeks, 65% of 51 treatment sites showed greater than 75% clearance, and an additional 22% showed greater than 50% clearance.81 One study evaluated an 800-nm diode-array laser on leg veins using fluences of 15 to 40 J/cm² with 5- to 30msec double or triple pulses. Three treatment sessions were given every 4 weeks. By 2 months after the last treatment, complete clearing occurred in 22%, 75% clearing in 42%, and 50% clearing in 32% of area treated.82 A diode laser with scanner was also evaluated for leg-vein treatment. After 2 treatment sessions, 2 to 4 weeks apart, 18% had 75 to 90% clearance, 21% had 50 to 75% clearance, 18% had 25 to 50% clearance, and 36% had less than 25% clearance.83

The NIR, 1064-nm laser provides good absorption by hemoglobin and deeply penetrates into the skin to the depth of a few millimeters. This allows selective and deep vascular injury of larger leg veins. Recent studies confirm the effectiveness of millisecond-domain 1064-nm Nd:YAG laser treatment of venulectasia and reticular veins up to 4 mm in diameter^{84–86} (Figures 40.3 and 40.4). In one study, 25 women were treated up to three times with a 1064-nm Nd:YAG laser at 6-week intervals. A double pulse of 7 msec at 120 J/cm² was used for vessels 0.2 to 2 mm in diameter, and a single pulse of 14 msec, fluence 130 J/cm², with 6-mm spot size was used for vessels 2 to 4 mm diameter. A total 64% of patients achieved 75% or greater clearing of vessels after a maximum of three treatment sessions. The results of leg-vein treatment with the IPLS are variable. Although some studies showed encouraging results, ^{87–89} contradictory results have been reported, and the treatment technique requires significant experience to achieve good results. ⁹¹

В

FIGURE 40.3 (A) Leg veins in the thigh of a 54-year-old woman before treatment. (B) 6 months after one treatment with long-pulsed Nd:YAG laser (at 350 J/cm², 50 msec, and 3-mm spot size).

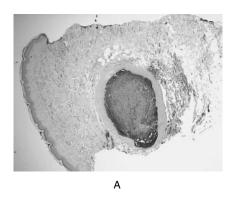

40.14 Other Vascular Lesions

Other cutaneous vascular lesions that have been reported to respond to laser treatment include venous lakes, angiofibromas, angiokeratomas, poikiloderma of Civatte, cherry angiomas, spider angioma, acne rosacea, adenoma sebaceum, angiolymphoid hyperplasia with eosinophilia, pyogenic granulomas, and granuloma faciale.92-94

40.15 Other Applications

40.15.1 Warts

PDL-treated warts had reported clearance rates of 45 to 99%. 95-99 Kauvar et al. treated 142 patients with 703 recalcitrant and 25 previously untreated warts with PDL at fluences of 7.25 to 9.5 J/cm². The overall response rates for warts on all sites were 74% after one treatment and 93% after an average of 2.5 treatments. 6 Subsequent studies were performed to analyze the treatment technique using an infrared thermal camera to compare differences in heat accumulation at sites treated with single- vs. multiplelaser pulsing with varying pulse-repetition rate. The results suggest that multiple pulses at a fast repetition rate (at least 1 Hz) contribute to wart response by accumulating heat within the lesions. 100 Another study prospectively evaluated the efficacy of PDL therapy (9.0 to 9.5 J/cm², 5-mm spot size) vs. conventional liquid-nitrogen cryotherapy or cantharidin in the treatment of warts. A total of 194 warts were evaluated by the conclusion of the study. Complete response was noted in an average of 70% of the warts treated with conventional therapy and in 66% of those in the PDL group.⁹⁹ Thus, laser therapy is one among many alternative treatments for warts. KTP lasers have also been reported to improve recalcitrant warts in 80% of patients. 101 The combination of laser with other therapy has not been well studied.

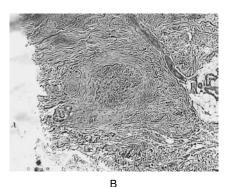

FIGURE 40.4 Histology of leg veins. (A) 1 day after treatment with long-pulsed Nd:YAG laser. Thrombosis and necrosis of the whole vascular wall are demonstrated. (B) 1 month after treatment. Fibrosis of the entire vascular structure is shown.

40.15.2 Hypertrophic Scars, Keloids, and Striae

Many studies address PDL treatment of hypertrophic scars, keloids, and striae distesae ("stretch marks"), but these indications remain controversial. ^{102–107} Striae may respond better to lower fluences (3.0 J/cm²) in one or two treatments. ¹⁰⁶ A recent prospective, single-blind, randomized, controlled study assessed the efficacy of PDL and silicone-gel sheeting in hypertrophic scar treatment. There was no significant difference between either PDL or gel sheeting and the untreated control areas. ¹⁰⁸

40.15.3 Psoriasis

Several studies indicate that PDL offers an effective treatment for stable plaque-type psoriasis, and the device has been cleared by the U.S. Food and Drug Administration (FDA) for this purpose. ^{109–111} In one study, 0.4-msec and 1.5-msec PDLs were compared, and no significant effect by pulse duration was found. Patients responding to treatment with the PDL remained in remission for up to 13 months. ¹¹¹

40.15.4 Laser Treatment of Pigmented Lesions (Melanin)

Melanocytes at the base of the epidermis synthesize melanin in the form of 0.5-µm intracellular organelles called melanosomes. The thermal relaxation time of a melanosome is just under 1 µsec. Selective photothermolysis of melanosomes was first described in 1983⁶ using 351-nm, submicrosecond excimer laser pulses at less than 1 J/cm² fluence. Melanin absorbs across the UV, visible, and NIR spectrum, with decreasing absorption at longer wavelengths. Across this wide spectral range, any laser with sufficient power or pulse energy can cause thermal injury due to absorption by melanin. Shorter wavelengths

damage pigmented cells with relatively lower fluences, while longer wavelengths penetrate deeper into the skin but need more energy to induce melanosome disruption. In clinical terms, short wavelengths affect only superficial pigmented lesions, leaving deeper structures intact, while longer wavelengths can affect pigmented targets in dermis such as hair follicles.

Target specificity of laser pulses depends on wavelength and pulse width. The appropriate pulse width depends primarily on the size of the target and its thermal relaxation time. The calculated thermal relaxation time for melanosomes is about 250 to 1000 nsec. Submicrosecond or even femtosecond laser pulses cause individual pigmented cell death by violent cavitation, a microscopic steam bubble erupting around each melanosome after the laser pulse, but longer pulse widths, in the hundreds-of-microseconds domain, do not appear to cause specific melanosome damage. ¹¹² The immediate effect of submicrosecond near-UV, visible, or NIR laser pulses in pigmented skin is immediate whitening, which fades away after several minutes. Immediate skin whitening correlates well with melanosome rupture seen by electron microscopy¹¹³ and is presumably due to residual gas bubbles after cavitation of melanosomes. Nearly identical but deeper whitening occurs with Q-switched laser exposure of tattoos. This offers a clinically useful immediate endpoint. Larger pigmented targets, such as hair follicles and "nests" of congenital nevus cells, are more effectively treated with much longer pulses, e.g., in the millisecond domain.

The clinical importance of matching laser pulse width with the intended pigmented targets' thermal relaxation time is well illustrated by comparing skin responses to Q-switched (nsec) vs. long-pulsed (msec) ruby lasers, both at a wavelength of 694 nm. At typical fluences, the Q-switched ruby laser is excellent for treating nevus of Ota, in which individual pigmented cells are the target, but it is incapable of permanent hair removal. In contrast, the long-pulsed ruby laser is capable of permanent hair removal but has little effect on nevus of Ota.

40.15.5 Epidermal Pigmented Lesions

Epidermal pigmented lesions are typically responsive to many different treatments that damage the epidermis but spare the dermis including lasers, cryotherapy, and electrosurgery. These common lesions include freckles, benign lentigo, and café-au-lait macules (CALMs). Pigment-selective submicrosecond pulsed lasers include green-light lasers (510-nm pulsed-dye, 532-nm frequency-double Nd:YAG), redlight lasers (694-nm ruby and 755-nm alexandrite), and NIR (1064-nm Nd:YAG) lasers. Lasers with little or no selective absorption, such as CO2, erbium:YAG (Er:YAG), and some low-power continuous or quasicontinuous wave lasers, e.g., argon, krypton, or copper-vapor lasers, are also effective for treating pigmented epidermal lesions. Superficial pigmented lesions, such as ephelides (freckles), solar and labial lentigines, and seborrheic keratoses, can be effectively treated with any of the pigment-specific and nonspecific lasers.¹¹⁴⁻¹¹⁷ Successful treatment of freckles in Asian skin with Q-switched alexandrite laser has been reported. Substantial improvement was achieved with an average of 1.5 laser-treatment sessions at 7.0 J/cm² without long-term side effects.¹¹⁸ Todd et al. compared three lasers (Q-switched frequencydoubled Nd:YAG laser, krypton laser, 532-nm diode-pumped laser) with liquid nitrogen for treatment of solar lentigines. Of the 27 patients treated, 25 preferred laser therapy to cryotherapy, with the Qswitched frequency-doubled Nd:YAG laser being the most preferred 119 (Figure 40.5). Hyperpigmentation and hypopigmentation are common post-treatment side effects. In general, postinflammatory hyperpigmentation is most frequent in darker skin types and suntanned individuals. The risk of hypopigmentation may be somewhat higher after Q-switched ruby laser than after Q-switched alexandrite or Nd:YAG lasers.

Treatment of CALMs yields variable results, whether pigment-selective or nonselective lasers are used. 114,120,121 There is a controversial study reporting complete lightening of all 34 large CALMs treated with a 510-nm pigmented-dye laser with no evidence of recurrence at 1-year follow-up. Each lesion received an average of 8.4 laser treatments with energy densities ranging from 2.0 to 4.0 J/cm² at intervals of 6 to 8 weeks. 122 In another study, 16 CALM patients were treated with 511-nm copper-vapor laser and automated scanner. Patients received one to four treatment sessions using a mean fluence of 8.9 J/cm² (range 7 to 22 J/cm²). The responses were graded as good to excellent in 15 cases and poor in one case. Transient pigmentary changes have been observed in some cases. 123 A recent study reports a "Q-switched"

Α

FIGURE 40.5 (A) Senile lentigo at the right cheek of a 50-year-old woman prior to treatment. (B) 6 months after one single treatment with 532-nm Q-switched Nd:YAG laser, the lesion faded almost completely. (Images courtesy of Hirotaka Akita, M.D.)

laser-resistant" CALM being successfully removed with Er:YAG laser resurfacing. 124 In general, CALMs require repeated treatment over a period of months or even years to achieve maximal clearing.

The term "atypical" is used to describe pigmented lesions containing cellular dysplasia or precursor lesions for melanoma. Treatment of these lesions must be approached with extreme caution. For atypical melanocytic lesions, laser treatment may not be adequate for eradication of lesions. In one study, two patients with atypical-appearing solar lentigines were treated with Q-switched ruby laser. In both cases, the initial results were excellent, but they recurred several months later and biopsy showed lentigo maligna, a form of melanoma *in situ*. 125

40.15.6 Dermal and Mixed Epidermal/Dermal Pigmented Lesions

Laser treatment of melasma is difficult, the results are variable and unpredictable, and recurrence is the rule. Taylor and Anderson assessed the efficacy of Q-switched ruby-laser treatment of melasma and found that, regardless of fluence used, no permanent improvement was observed. Transient darkening was

В

FIGURE 40.6 (Color figure follows p. 28-30.) (A) A 4-month-old girl with nevus of Ota on her right face prior to treatment. (B) Almost complete clearing after five treatments with Q-switched alexandrite laser. (Images courtesy of Harue Suzuki, M.D.)

noted after laser treatment in some patients. No textural changes were seen after healing, except for a slight depression at high fluences on black patients. Page Recently, resurfacing lasers (pulsed/scanned carbon dioxide or Er:YAG) have been used in the treatment of refractory melasma, with satisfactory results. In one study, full face-skin resurfacing using an Er:YAG laser was performed using 5.1 to 7.6 J/cm² energy to ten refractory melasma patients. Marked improvement of melasma was noted immediately after laser surgery; however, all patients exhibited postinflammatory hyperpigmentation between 3 and 6 weeks postoperatively, requiring biweekly glycolic-acid peels. At the end of 6 months, significant improvement in the melasma was demonstrated using clinical scoring and melanin reflectance spectroscopy assessment. In another study, complete resolution of dermal-type melasma was achieved with a combination of pulsed CO₂-laser resurfacing followed by Q-switched alexandrite-laser treatment. Abnormal melanocytes are first destroyed with pulsed CO₂ laser, and then dermal melanins are selectively eliminated with the alexandrite laser.

Dermal melanocytosis includes nevus of Ota, nevus of Ito, and mongolian spot. The Q-switched ruby, Q-switched alexandrite, and Q-switched Nd:YAG lasers are all highly effective and are the treatment of choice for these pigmented lesions (Figure 40.6). Significant or complete clearing of lesions can be achieved after an average of four to six treatment sessions with fluences ranging from 5 to 12 J/cm². ^{129–132} Ueda et al. classified 151 Japanese patients with nevus of Ota according to lesion color; the patients were treated with Q-switched ruby laser at 5 J/cm² and 6.5-mm spot size. In general, the degree of lightening of lesion was directly proportional to the number of treatments performed. To achieve good to excellent results in brown, brown-violet, violet-blue, and blue-green nevi at least three, four, five, and six treatment sessions were required, respectively. ¹³³

In a clinicopathologic study of nevi of Ota treated with Q-switched alexandrite laser, lesions less than 1 mm deep achieved the best results.¹³⁴ Chan et al. retrospectively reviewed the complications following treatment of nevi of Ota with Q-switched alexandrite, Q-switched Nd:YAG, or a combination of both lasers. Hypopigmentation was the most common complication encountered in all three groups with the incidences of 38, 10.5, and 7.6% in the combined, Q-switched alexandrite, and Q-switched Nd:YAG laser-treated groups, respectively.¹³⁵ The same author also proposed a new classification of nevi of Ota and noted that periorbital underresponse (panda's sign) may be due to overly cautious treatment in that area.¹³⁶ Once the nevus of Ota has fully cleared after laser treatment, the results are usually permanent. However, repigmentation has been observed in one patient during pregnancy.¹³⁷

Acquired bilateral nevus-of-Ota-like macules (ABNLM), also called nevus fuscoceruleus zygomaticus or nevus of Hori, is a dermal melanocytic lesion characterized histopathologically by the presence of

elongated melanocytes in upper dermis similar to that found in nevus of Ota. Q-switched ruby and Q-switched Nd:YAG lasers have been shown to be effective treatments for these conditions. 138-140

Postinflammatory hyperpigmentation may result from any inflammatory insult causing dermal melanin deposition. Pigment-specific lasers are expected to improve these lesions, but the results so far have been disappointing. 126

Dark infraorbital circles result from dermal melanin deposition, postinflammatory pigmentation from atopic or contact allergic dermatitis, superficial plexus of blood vessels, and shadowing from lax skin and infraorbital swelling. Several pigment-specific laser systems, such as Q-switched ruby laser, Q-switched alexandrite laser, and Q-switched Nd:YAG laser, have been shown to improve infraorbital pigmentation related to dermal melanin deposition. When lax skin or infraorbital swelling is the cause of infraorbital darkening, significant lightening can be achieved following CO₂ laser resurfacing. 142

Nevus spilus presents as a circumscribed tan-colored macule (CALM component) containing smaller darkly pigmented macules or small papules (nevo-melanocytic nevus component). Dysplastic nevus and malignant melanoma arising within these lesions have been described; thus, caution should be exercised in treating nevus spilus with lasers. These pigmented lesions have a variable response to laser treatment. The CALM component may be more resistant to treatment, requires more treatment sessions, and tends to recur. In one study, two lesions of nevus spilus were treated with the Q-switched ruby laser. Complete clearances of lesions occurred after two to seven treatments, but the CALM component recurred within 6 months after the last treatment. However, in another study, six patients with nevus spilus were treated with the Q-switched ruby laser and the Q-switched Nd:YAG laser at 532 or 1064 nm. All lesions showed >80% or complete response to Q-switched ruby laser at 5.5 to 10 J/cm². The Q-switched ruby laser produced significantly better results than both Q-switched Nd:YAG lasers.

Becker's nevus is an acquired patch of hyperpigmentation plus hypertrichosis in pubescent boys. These lesions are typically located on the shoulder, chest, and proximal arm. Satisfactory results are not easily obtained with the Q-switched lasers. Although hyperpigmentation has been treated successfully, recurrence rates have been high, and the terminal hairs within the nevi may decrease temporarily. His, 148 With the new long-pulsed red or infrared lasers for hair removal more effective treatment results can be achieved. Nanni and Alster reported successful results treating a case of Becker's nevus with long-pulsed (3-msec) ruby laser. Ninety percent reduction of hair and pigmentation was achieved after three laser-treatment sessions at fluences of 18 to 22 J/cm², 10-mm spot size, and at 6- to 8-week intervals. The clinical reduction in hair and pigment continued to be evident 10 months after the final treatment without scarring or skin textural change. 149

40.15.7 Nevomelanocytic Nevus

Nevomelanocytic nevi are usually pigmented "moles" consisting of melanocyte-related cells present at the base of the epidermis (junctional nevi), within the dermis (dermal and congenital nevi), or both (compound nevi). The lesions may be acquired or congenital and exhibit cellular atypia ranging from benign to malignant (melanoma arising within a nevus). The use of pigment-specific lasers to remove congenital and acquired melanocytic nevi remains controversial. The standard method of nevus removal is surgical excision with complete histologic evaluation. For the time being, laser treatment should be considered only in selected cases in which surgical excision cannot be performed; otherwise, it may result in unsightly scars. Continuous-wave (CW) lasers, such as the argon and CO₂ lasers, have been used in the past to remove nevomelanocytic lesions, including congenital nevi, but they resulted in significant scarring. Recurrences were not uncommon, and occasional pseudomelanoma (melanoma-like lesions occurring in the context of wound healing) could be seen.

Despite controversy, the Q-switched ruby laser has been used for the treatment of small and medium congenital nevi, with some good clinical improvement after several sessions. ^{150–152} Vibhagool et al. reported that Q-switched ruby laser at 8 J/cm² and 5-mm spot size is moderately effective at treating small nevomelanocytic nevi. Two thirds of the lesions showed complete response, and one third showed partial response. In cases of partial response, residual nevomelanocytic nests were identified at depths of

0.1 to 0.4 mm from the surface.¹⁵² Grevelink et al. also reported that Q-switched ruby and Q-switched Nd:YAG lasers were capable of removing the superficial portions of congenital nevi to depths of 0.16 mm and 0.44 mm, respectively.¹⁵¹ Similar results were noted in other studies including a comparative study of benign melanocytic nevi treated with the Q-switched alexandrite and the Q-switched Nd:YAG lasers.¹⁵³ However, in these reports, congenital melanocytic nevi (CMN) were either incompletely removed or recurred within 1 year of laser treatment. Recently, Nelson and Kelly reported treating an infant with medium-sized congenital CMN with Q-switched ruby laser. Five years after only one treatment, the lesion remained clinically and histologically clear.¹⁵⁴

Pulse duration appears to be important for laser treatment of acquired and congenital nevi. In a study of ruby-laser pulse duration and fluence for treatment of extensive congenital nevi, complete clearing was reported after four treatments at 15 J/cm² at 1-msec pulse duration, but Q-switched ruby laser (nanosecond-domain pulses) was ineffective for clearing the lesions. Subsequent long-term histological study revealed the presence of residual nevus cells in the dermis at approximately 1 mm below the skin surface covered by a thin zone of fibroplasia that masked the residual nevomelanocytes. No clinical or histologic evidence of malignant degeneration was observed in the treated areas up to 8 years after laser treatment. In another study of benign acquired and dysplasic melanocytic nevi treated once with normal-mode vs. Q-switched ruby lasers, 52% of the nevi showed significant decrease in pigment, but no lesion had complete histologic response. The authors suggested that currently lasers should not be used in the treatment of atypical nevi. 157

The effects of pigment-specific laser pulses on melanocytes with the potential for malignant transformation are not well understood. Removal of the superficial portion of nevi might be beneficial by decreasing the number of melanocytic cells capable of malignant degeneration. ^{150,153} On the other hand, healing after laser treatment may stimulate or select for persistent nevus cells with neoplastic change. To date, there have been no reports of melanoma arising in benign pigmented lesions treated with lasers. However, patients who have had a nevomelanocytic lesion removed by laser must continue to be followed, and any signs of recurrence should be approached cautiously.

40.15.8 Tattoos

Tattoos consist of phagocytosed submicrometer ink particles trapped in the lysosomes of phagocytic dermal cells, mostly fibroblasts, macrophages, and mast cells. Most tattoos can effectively be removed or substantially lightened using Q-switched lasers, with a low risk of scarring. The mechanisms of tattooink removal involve fracture of ink granules followed by release from cells into the dermis. Some of the ink is eliminated by lymphatic and transepidermal elimination, but most of it is rephagocytosed by somatic dermal cells within a few days.¹⁵⁸ In general, different laser wavelengths are needed to remove different tattoo-ink colors. Black tattoo ink, which is typically carbon or black iron oxide, has a broad absorption spectrum and is well treated by either Q-switched ruby, Q-switched alexandrite, or Q-switched Nd:YAG lasers. Red and orange tattoo inks can be removed with green pulses (510-nm pulsed-dye or 532-nm Q-switched frequency-doubled Nd:YAG lasers). For green colors, Q-switched ruby and to some extent Q-switched alexandrite lasers can usually achieve successful clearing, but the Q-switched Nd:YAG laser is generally ineffective. 159-161 (Figure 40.7) Green and yellow ink are usually the most difficult to remove. Resistant tattoos can be ablated with CO₂ or Er:YAG lasers, but this produces scarring. In general, the responses of tattoos to laser treatment are fluence-dependent, and amateur tattoos require fewer treatments than professional ones. 162,163 Traumatic tattoos usually contain less pigment than others and require even fewer treatments. Q-switched Nd:YAG laser is preferred in darkly pigmented patients with black tattoos because of fewer epidermal side effects due to melanin absorption. Pulse duration also affects the treatment result. For example, picosecond laser pulses were more efficient than nanosecond laser pulses for tattoo removal.164

Cosmetic tattoos containing red iron oxide (Fe₂O₃) and titanium oxide (TiO₂) can turn black on exposure by Q-switched lasers. ¹⁶⁵ Ink darkening is probably a combination of chemical reduction and changes in particle size. A similar reaction has been reported as localized chrysiasis after Q-switched ruby

Α

В

С

FIGURE 40.7 (A) Multicolored tattoo prior to treatment. (B) Site "C" after three treatments with Q-switched ruby (694-nm) laser shows loss of green and black inks but not red. Other sites treated with Q-switched Nd:YAG (1064, 532-nm) laser show loss of red and black inks, but not green. (C) After six further treatments using both lasers on the entire tattoo, all ink colors have substantially faded.

laser treatment in patients receiving parenteral gold therapy. 166 Recently, Ross et al. reported a significant association between the presence of TiO_2 in tattoos and poor response to laser treatment. 167

40.16 Other Exogenous Pigments

Drug-induced pigmentations are typically due to a complex of drug and melanin deposits in dermal macrophages and hence are similar in some ways to tattoos. Exogenous ochronosis from hydroquinone treatment of melasma has been successfully treated with Q-switched ruby laser. Minocycline-induced cutaneous pigmentation has also been successfully treated with Q-switched alexandrite, Q-switched KTP, amiodarone-induced blue-gray hyperpigmentation can resolve with Q-switched ruby lasers. In and imipramine-induced hyperpigmentation was effectively treated with Q-switched alexandrite and Q-switched ruby lasers.

Dermal hemosiderin in Kaposi's sarcoma and dermal melanin pigments after antimalarial therapy have also been reported to be effectively treated with Q-switched ruby laser.¹⁷⁶ Circumscribed siderosis

after intramuscular or intravenous iron injection has been effectively treated with Q-switched ruby and Nd:YAG lasers after 3 to 16 treatment sessions. 177

40.16.1 Laser Hair Removal

There are many medical and surgical settings in which excessive hair growth is a crucial problem. Hirsutism often is associated with ovarian, adrenal, or pituitary disorders. Impressive hypertrichosis may be part of a congenital syndrome or drug-induced. Hair-removal methods include shaving, plucking, chemical depilatories, waxing, electrolysis (DC current), electrothermolysis (RF current), and laser hair removal. Only the last three methods are known to produce permanent hair loss.

There are two potentially important targets for permanent hair removal: the "bulb" and "bulge" areas of hair follicles. The bulb is the neurovascular papilla at the base of anagen (active growth phase) hair follicles, responsible for hair-shaft growth, and typically about 3 to 7 mm below the skin surface. The bulge or stem-cell area is a region near the insertion of arrector pili muscle, about 1.5 mm below the skin surface, and is the source of new matrix cells with each hair cycle. 179,180 These stem cells appear to be necessary for cycling of the hair follicles into the anagen phase. Perifollicular vessel damage may also play a role in the laser hair-removal process. 181

Various lasers and light sources have been developed for hair removal. These include ruby, alexandrite, diode, and Nd:YAG lasers and IPLSs. These devices target melanin, the endogenous pigment. Therefore, laser hair removal is more effective for darker hair colors.

Photomechanical destruction of hair has been attempted with low-fluence, Q-switched, 1064-nm Nd:YAG lasers in combination with a topically applied carbon suspension, which was supposed to act as an exogenous chromophore.¹⁸² This was the first approved laser hair-removal treatment; it did not produce permanent hair loss but was effective for temporary control of hair growth, with few side effects. In theory, the carbon was intended to penetrate into hair follicles and provide a target for Q-switched laser pulses to generate photomechanical injury. However, there is no evidence that the carbon particles actually penetrate the follicle or that they offer an advantage over the laser alone, and complete hair regrowth was reported within 6 months after treatment.¹⁸³ If greater uptake of carbon could be achieved and a longer, more energetic Nd:YAG laser pulse were used, the approach might be more effective. Alternatively, a dye other than carbon could be used that stains the viable follicular epithelium and absorbs red or NIR wavelengths.

Photochemical destruction of hair follicles by PDT has been reported by Grossman et al. A 20% solution of aminolevulinic acid (ALA) was applied topically under occlusion for 3 h, followed by 100 to 200 J/cm² fluences of 630-nm light delivered over about 30 min from an argon-pumped dye laser. Three months after treatment there was significant loss of hair in sites treated with high ALA and high fluence, without scarring. 184

Photothermal destruction of hair follicle relies on melanin in the hair shaft and the matrix to provide local absorption of a pulse of light, which is timed to produce heating and destruction of the follicles. The wavelength region capable of reaching follicular targets, with sufficiently strong and selective absorption by melanin, lies between about 600 and 1100 nm. Pulsed optical sources that operate in these wavelength regions include 694-nm ruby laser, 755-nm alexandrite laser, 800-nm diode laser, 1064-nm Nd:YAG laser, and xenon flashlamp, which is an incoherent source spectrally filtered to emit in this spectrum. These optical hair-removal devices have pulse durations in the millisecond domain. Laser hair removal requires destructive heating of hair follicles due to melanin absorption, without significant injury to the epidermis, which also contains melanin. For patients with fair skin and darkly pigmented hair there is a wide range of safe and effective laser fluences using any of these devices. For darkly pigmented or tanned skin, however, various combinations of longer wavelength, longer pulse duration, and active skin cooling are used to minimize the risk of unwanted epidermal injury. Dynamic (epidermal) and bulk (epidermal and dermal) cooling devices have been developed that are most useful with short and long pulses, respectively. Temporary hair removal for a few months is easily achieved even at low fluences and appears to be due to induction of the catagen and then the telogen (resting) phase. Transition to catagen

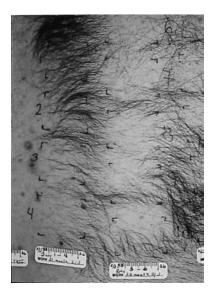

FIGURE 40.8 Hair removal more than 20 months after treatment with 800-nm diode laser (left) and 694-nm ruby laser (right), in test sites on the back.

and telogen is a common follicular response to injury, for example, from stress, drugs, hypoxia, surgery, and after laser treatment, from photothermal injury. Permanent hair reduction requires higher fluences, which are capable of necrosing follicular target regions, and has been defined as "a significant decrease in terminal hairs after a given treatment, which is sustained for a period of time longer than the complete growth cycle of hair follicles at the given body site" (Figure 40.8).

A ruby laser was first reported by Grossman et al. ¹⁸⁵ to remove hair from normal human skin. In a fluence-response study of fair-skinned volunteers with dark hair, test sites on the back or thigh were either wax-epilated or shaved before laser exposures with a range of 0 to 60 J/cm² at 694 nm, 0.3 msec, and 6-mm diameter in contiguous exposure spots delivered through an ice-cold sapphire window pressed against the skin. Significant temporary hair loss lasting 1 to 3 months was induced in all laser-treated sites in all subjects, while the hair loss at 6 months was fluence-dependent. Wax epilation protected hair follicles from laser-induced hair loss at 6 months, suggesting that absorption of light by the pigmented hair shaft is involved in the mechanisms for long-term hair removal. Subsequently, laser-induced hair loss up to 2 years after a single ruby-laser treatment with high fluence (>30 J/cm²) was reported in 4 of 13 subjects. ¹⁸⁶ No scarring occurred, and about one third of the subjects had transient pigmentary changes. Selective thermal injury of superficial and deep follicular epithelium was observed histologically. Ruby lasers were the first devices marketed for permanent laser hair removal and remain useful, especially in patients with light-colored hair and relatively fair skin.

Alexandrite lasers, with a slightly longer wavelength than ruby lasers, behave very similarly to ruby lasers for hair removal. Alexandrite lasers provide slightly greater depth of penetration but lower absorption by pheomelanin, the dominant form of melanin in "red" hair. Several studies have shown that alexandrite lasers are effective in removing unwanted hair. 187–189 In one study, 11 patients received five treatments at 3-week intervals in the groin area using alexandrite laser at 20 J/cm², 20 msec, and 10-mm spot size. At 1-year follow-up, an average of 78% clearance of hair was noted, with no evidence of scarring and pigmentary changes. 190 Another study compared alexandrite laser and electrolysis for hair removal. The right axilla was treated by four electrolysis sessions with an intensity of 4 to 8 mA at 3-week intervals, and the left axilla was treated three times at 4-week intervals with 3-msec alexandrite laser at 30 to 50 J/cm². The average clearance rate of the hairs was 74% by laser and 35% by electrolysis 6 months after the initial treatment. 191 Recently, equivalent clinical and histologic responses with a long-pulsed alexandrite (2-msec pulse, 10-mm spot) and a long-pulsed diode laser (12.5 msec or 25 msec, 9-mm spot) at either 25 J/cm² or 40 J/cm² for hair removal were reported. 192

A widely used and versatile laser for hair removal is a pulsed 800-nm diode laser, with variable pulse width of 5 to 30 msec, spot size of either 9×9 or 12×12 mm, delivered through a cold sapphire window. The 9×9 -mm version was used to remove hair from 38 subjects with average fluences of 33.4 J/cm², in one to four treatment sessions (mean, 2.7). More than 60% of the subjects showed more than 75% hair reduction after a mean interval of 8 months after the last treatment. 193 In another study, 50 volunteers with Fitzpatrick skin types II and III and dark brown or black hair were treated using the same laser system. After one treatment, hair regrowth ranged from 22 to 31% at 1 month, then remained stable at 65 to 75% at 3 months and thereafter for 20-month average follow-up. There were relatively longer growth delays after two treatments, with hair regrowth beginning at 6 months after treatment and ranging from 47 to 66% for the remainder of the follow-up evaluations. Side effects were limited to transient pigmentary changes.¹⁹⁴ Baugh et al. treated 36 subjects with varying shades of brown or black hair using an 800-nm diode laser guided by a scanner. Patients received one to four treatments during the course of the study. Significant fluence-dependent hair reduction was demonstrated between treatment and control groups. At 48 J/cm², the highest dose, a mean hair reduction of 43% was achieved 30 d after the final treatment, and 34% was achieved 90 d after the final treatment. Darker hairs were more effectively treated than lighter hairs, which is typically the case for all lasers and flashlamps used for hair removal. 195

Millisecond-domain, long-pulsed Nd:YAG (1064-nm) lasers also are capable of inducing long-term hair loss; however, higher fluence is needed to compensate for the lower melanin absorption. These lasers, when delivered in combination with skin cooling, are excellent for controlling hair growth in dark-skinned individuals, e.g., for pseudofolliculitis barbae in men of African descent. In one study, 15 patients were treated with a 30-msec pulsed Q-switched Nd:YAG laser at fluences between 125 and 150 J/cm². The average hair reduction was 36% at 7 d, 52% at 30 d, and 59% at 90 d. 196 In another study, 208 subjects were treated using a long-pulsed Nd:YAG laser with a fluence of 23 to 56 J/cm² at 1-month intervals until desirable results were obtained. Every session resulted in a 20 to 40% hair loss, depending on the color of hair. Complete epilation was obtained in four to six sessions. Only white hair did not respond, and no patients had blistering or hypo- or hyperpigmentation. 197 In another study, 20 dark-skinned women with skin phototypes IV through VI and dark brown to black terminal hair on the face, axillae, or legs were treated with a long-pulse (50-msec) 1064-nm Nd:YAG laser. A series of three treatments at fluences ranging from 40 to 50 J/cm² were delivered to the identified treatment areas on a monthly basis. Substantial hair reduction was seen after each of the three treatment sessions. Prolonged hair loss was observed 12 months after the final laser treatment (70 to 90% hair reduction). 198

Filtered xenon flashlamps, also called intense pulsed light (IPL), emit a wide-wavelength band of noncoherent light pulses. A variety of these sources have been shown to produce permanent hair removal. Gold et al. performed a study using IPL to remove hair in 37 subjects. Patients received a single treatment with energies of 34 to 55 J/cm². Approximately 60% hair removal was noted at 12-week follow-up.¹⁹⁹ In a multicenter study, 40 women with hirsutism on the upper lip and chin were treated with an IPL, with an average fluence of 38.7 J/cm² and a mean wavelength of 585 nm. Within six treatments, 76.7% of the hair was removed.²⁰⁰ In another study, 48 patients with Fitzpatrick skin types I through V randomly enrolled for two treatments 1 month apart with an IPL system. Parameters used were a 2.8- to 3.2-msec pulse duration typically for three pulses with thermal relaxation intervals of 20 to 30 msec with a total fluence of 40 to 42 J/cm². Hair reductions of 42 and 33% were noted at 8-week and 6-month follow-ups, respectively.²⁰¹ A prospective study compared long-term results of single vs. multiple treatments with IPL in 34 patients. Parameters used were a cut-on wavelength of 615 to 695 nm, pulse duration of 2.6 to 3.3 msec, fluence of 34 to 42 J/cm², and 10 × 45-mm exposure field. The mean hair-removal efficiency achieved was 76% after a mean of 3.7 treatments and a mean 21.1-month follow-up; more than 94% of the treated sites reached >50% hair loss.²⁰²

Before initiating laser hair-removal procedures, factors to consider include skin color, hair color, hair diameter, and density of hair. These factors affect laser parameters to be used and in turn affect the efficacy and side effects of treatment. For any given laser type, efficacy is laser-fluence-, hair-color-, and hair-diameter-dependent, but the side effects are laser-fluence-, skin-type-, and hair-density-dependent. Perifollicular erythema and edema are expected as an endpoint for laser hair removal. In general, laser

hair removal is effective and safe in the majority of patients with dark hair and relatively fair skin. With a combination of longer wavelength, longer pulse duration, and parallel cooling, dark skin can be safely and effectively treated.²⁰³

40.17 Lasers Targeting Water as Chromophore

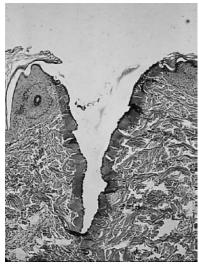

Laser skin resurfacing (LSR) uses water in tissue as a target chromophore to rapidly deposit energy in a thin layer of tissue, which vaporizes in a controlled way. Due to strong water absorption in the far infrared, either CO₂ lasers (10,600 nm) or Er:YAG lasers (2940 nm) are used. The epidermis and upper dermis are precisely ablated, with a predictable zone of residual thermal damage followed by reepithelialization from the residual hair follicles and remodeling of dermal collagen during wound healing. The depth of residual thermal injury must be limited, which is accomplished by vaporizing a thin layer at the surface in a time short enough to limit the amount of heat conducted into the dermis.

40.17.1 CO₂ Lasers

With pulsed CO₂ lasers at fluences of 4 to 19 J/cm² per pulse, precise tissue ablation of tissue (20 to 40 μ m thick) with less than 100- μ m residual thermal damage (RTD) can be produced.^{204,205} The minimum ablation depth per "pass" of laser exposure is consistent with the optical penetration depth, which is about 20 μ m for the CO₂ laser (and is equal to 1/ μ _a, where μ _a is the tissue absorption coefficient of about 500 cm⁻¹) at this laser wavelength.²⁰⁴ Selective tissue ablation with minimal RTD occurs when the laser energy is deposited faster than the thermal relaxation time of the heated tissue layer, which for CO₂ lasers is around 1 msec (Figure 40.9). To cleanly vaporize the superficial layer of skin with minimal RTD, a CO₂ laser delivering energy in less than 1 msec must produce a fluence greater than 5 J/cm² (the vaporization threshold).^{204–207}

For illustration, a popular pulsed laser and a scanned-CW laser will be compared, i.e., the UltraPulse 5000 laser (Coherent, Palo Alto, CA) and the SilkTouch laser (Sharplan, Allendale, NJ), respectively. The UltraPulse laser delivers up to 500 mJ in single pulses, with a duration of about 1 msec. This energy is delivered in a 3-mm collimated beam, generally guided by a computer-pattern generator (CPG) at an average power of up to about 80 W. Rapid precise placement of these high-energy pulses can be done manually, but the CPG provides very rapid and precise arrays. A typical mode uses a 2.25-mm exposure spot spacing, 300 mJ per pulse, and a power of 60 W, resulting in placement of pulses in one of six chosen patterns at a rate of 220 Hz. The amount of overlap between adjacent pulses is programmable via the CPG, from zero to 60% overlap. In contrast, the SilkTouch laser system uses a standard continuous CO₂ beam focused to a 100- to 200-μm-diameter spot that is manipulated by a pair of rotating mirrors in the delivery handpiece to scan various patterns at the tissue rapidly, resulting in a tissue dwell time of about 1 msec. Round or rectangular scanning patterns typically ranging from 4 to 9 mm may be chosen.

The CO₂ laser ablation threshold is about 5 J/cm² for submillisecond pulses and may be somewhat higher for rapidly scanned beams (around 15 J/cm²).^{208,209} In general, treatment is performed well above the ablation threshold, whether a pulsed or scanned-CW laser is being used. Thermal damage and dermal temperatures have also been shown to be about 15% to 20% higher for scanned-CW vs. pulsed lasers.²⁰⁹ Despite these differences, the clinical efficacy and side effects have been shown to be similar in side-by-side comparisons treating perioral and periorbital wrinkles.²¹⁰ In typical clinical use, two passes with the SilkTouch laser appear to be approximately equal to three passes with the UltraPulse laser in terms of the amount of tissue removed and the depth of residual thermal necrosis.^{211,212} It must be emphasized that clinical judgment and careful assessment of ablation depth at the time of treatment is absolutely necessary as a guide to laser resurfacing. Experienced physicians obtain essentially equivalent clinical results with any of the commercially available lasers for skin resurfacing. Treating patients in a cookbook fashion is, in general, hazardous. One very helpful sign of tissue depth during laser resurfacing is immediate shrinkage. This obvious reaction, due to thermal denaturation of type I collagen at about

Α

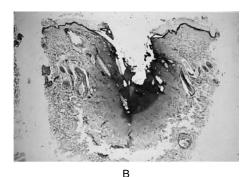

FIGURE 40.9 Photomicrograph of skin biopsy specimens comparing the amount of residual thermal damage (RTD) after CO₂ laser ablation. (A) After submillisecond CO₂ laser. (B) After continuous CO₂ laser exposure. Note minimal amount of RTD in submillisecond exposure.

70°C, occurs only when the dermis is initially subjected to a layer of residual thermal damage. Clinically, it is well established that some dermal injury is necessary for improvement of moderate wrinkles, regardless of the type of laser being used. In contrast, epidermal pigmented lesions, such as freckles, lentigines, and CALMs, can be removed without dermal injury. Typically, the first pass with pulsed lasers, either CO₂ or Er:YAG, causes little or no immediate shrinkage.

40.17.2 Er:YAG Lasers

The Er:YAG laser, operating at 2940 nm, is even more strongly absorbed by water than the CO₂ laser. The μ_a of pure water at this wavelength is approximately 13,000 cm⁻¹. In tissue, which is typically 70% water, the μ_a is approximately 9000 cm⁻¹, and the optical penetration depth, $1/\mu_a$, is approximately 1 μ m. However, thermally induced changes in μ_a during Er:YAG laser pulses tend to increase the optical penetration depth. The estimated thermal relaxation time of the layer in which the laser energy is absorbed is approximately 1 to 10 μ sec. The calculated threshold fluence for tissue ablation is 0.28 J/cm², which is close to that measured for submicrosecond Er:YAG laser pulses. However, longer (e.g., 100 to 1000 μ sec) Er:YAG laser pulses are used for LSR to provide better hemostasis. For the Er:YAG lasers used

for skin resurfacing, the tissue-ablation threshold is typically 1.5 J/cm². $^{2.13,215}$ With submicrosecond Er:YAG laser pulses, the RTD zone is only 5 to 10 μ m. 214 Short-pulse Er:YAG lasers are therefore capable of ablating only one or two cell layers at a time with minimal residual injury. This is excellent for extremely fine ablation but a poor choice when hemostasis is needed. 216,217 When operated to produce longer pulses, hemostasis can be achieved (and thermal injury increased intentionally) by allowing more thermal conduction to occur. Thus, Er:YAG lasers can be made to perform more like a CO_2 laser, and vice versa, by manipulating fluence and pulse duration. 218,219 When the same absorbed power density (W/cm³ deposited at the surface of the tissue) is used for both systems, one generally sees similar effects. Some Er:YAG-laser manufacturers have made this laser behave like the CO_2 laser (increasing RTD and improving hemostasis) by either adding a simultaneous CO_2 laser or manipulating the pulse duration and fluence of the Er:YAG pulses.

40.18 Mechanisms of Action

Tissue removal (ablation) was initially thought to be the most important mechanism in LSR, as if one were literally sculpting the skin. While sculpting may play some role, it is also well established that other, nonselective agents, such as dermabrasion, acids, and solvents (chemical "peels"), can achieve equivalent clinical results. Furthermore, when ablation-plus-RTD depth into the dermis is less than the wrinkle depths, marked cosmetic improvement is often observed. It appears that a combination of collagen shrinkage and dermal extracellular matrix remodeling during wound healing contributes to the final cosmetic improvement. When the CO₂ laser interacts with tissue, there are three distinct zones of tissue alteration correlating with the degree of tissue heating: (1) a zone of vaporization; (2) underlying this, a zone of irreversible thermal damage and denaturation, resulting in tissue necrosis; (3) and below this, a zone of reversible, sublethal thermal damage.

Immediate collagen shrinkage occurs in the zone of irreversible injury and, to some extent, the zone of reversible injury. This accounts for the visible tissue tightening observable as the CO₂ laser interacts with the dermis, but there is controversy about the role of immediate collagen shrinkage in achieving the final outcome. Using two to five passes with a pulsed CO₂ laser, shrinkage increases somewhat with the number of passes, while the zone of dermal collagen denaturation stays constant (~115 μm).²⁰⁹ In pigs, pulsed CO₂ laser resurfacing produces immediate tissue contraction (maximum of approximately 38%) and residual thermal damage that is saturable for multiple passes and high fluences.²²⁰ A subsequent study in pigs showed that CO₂ laser resurfacing produces short- and long-term wound contraction greater than that induced by purely ablative methods (mechanical or Er:YAG laser) for the same total depth of injury. Wound contraction over time was dependent on both the depth of RTD and depth of ablation. Wounds with more than 70 µm RTD layer healed with greater fibrosis (microscopic scarring), as evidenced by greater compaction and horizontal orientation of collagen fibers in the superficial dermis after healing. These data suggest that initial collagen contraction and thermal damage modulate wound healing,²²¹ Also supporting this concept is a greater and more sustained elevation in collagen content after CO₂ laser injury vs. 50% trichloroacetic acid "peel" in mouse skin.²²² New collagen deposition and remodeling in the dermis appear to be responsible for the long-term clinical improvement (up to 1 year) after LSR, although immediate tissue shrinkage is present for only a short period.212,223-225 Another study found increased elements other than collagen, e.g., factor 13, vimentin, and actin expression, after pulsed CO₂ laser injury in a pig.²²⁶ Contraction of these filaments may provide a scaffold for deposition and organization of collagen during wound healing, which may contribute to skin tightening and decreased surface irregularities seen after CO₂ laser resurfacing.

It is interesting to contrast mechanisms of LSR with those of a "face-lift," a common surgical procedure for wrinkles and skin laxity in which facial skin is stretched. Two nearby points on facial skin typically become closer together after laser resurfacing, whereas after a face-lift the same two points typically grow further apart. The combination of LSR and plastic surgery is often more effective than either modality alone.

FIGURE 40.10 Skin resurfacing. (A) Before treatment. (B) 6 months after three passes of pulsed CO_2 laser resurfacing (fluences 5 and 3.5 J/cm²).

40.19 Indications for Laser Skin Resurfacing

40.19.1 Acne Scars

LSR is moderately beneficial in treating atrophic partial-thickness nondistensible scars, ²²⁷ although results vary. ²²⁸ Kye reported 40% improvement of acne scar at 3-month follow-up after Er:YAG-laser treatment. ²²⁹ With acne scar treatment, a longer postoperative interval (12 to 18 months) prior to assessment for retreatment was advocated because continued clinical improvement was observed as long as 18 months after CO₂ laser resurfacing, with an 11% increase in improvement observed between 6 and 18 months postoperatively. ²³⁰ Kwon and Kye treated 12 patients with hypertrophic scars, 20 patients with depressed scars, and 4 patients with burn scars using Er:YAG laser, 2-mm handpiece, 500 to 1200 mJ/pulse at 3.5 to 9 W. In this series, 9 of 12 hypertrophic scars, 17 of 20 depressed scars, and 2 of 4 burn scars were substantially improved. ²³¹

40.19.2 Photoaging

Chronic photoaging, comprised of rhytides, dyschromias, solar lentigines, ephelides, and actinic keratoses, has been shown to respond very favorably to CO₂ LSR (Figure 40.10). Ross et al. showed that scanning laser with a short dwell time performed just as well as a pulsed laser in a side-by-side comparison trial. Fr:YAG lasers have also been used successfully in this context. Size-235 It is now apparent that clinical improvement following equivalent-depth dermal laser wounding with the Er:YAG laser is less than that observed following CO₂ LSR, although the time of re-epithelialization and postoperative erythema are shorter. Side-by-side comparison studies using CO₂ laser alone and combined CO₂/Er:YAG laser resurfacing have demonstrated that the overall healing times and erythema can be reduced without compromising clinical efficacy in the combined CO₂ and Er:YAG laser treatment group. Activation of residual thermal damage from 120 to 150 μm to 80 to 100 μm, reepithelialization times by an average of 3 d, and duration of erythema by approximately 1 month, in the combined laser treatment group, but there were no differences in the relative depths of granulation tissue, fibroplasia formation, and the degree of clinical improvement. It appears that excellent clinical outcomes probably require residual thermal damage zones in the 60- to 70-μm range or higher. The Er:YAG laser may prove safe and effective for photoaged skin of the neck, arms and hands, and chest.

In clinical practice, both lasers are useful for deep photodamage. The CO₂ laser is used to efficiently remove the epidermis in a single pass, followed by a second pass to produce collagen tightening. A third pass is used in selective areas of deeper photodamage. This may also be followed by one to two passes with the Er:YAG laser. For superficial therapy, when the patient desires rapid healing and is willing to accept improvement only in texture and pigmentation, a single pass of the CO₂ laser can be performed without wiping the epidermal debris away. For single-pass wounds, not wiping decreased the level of wounding. In contrast, not wiping in multiple-pass wounds significantly increased the depth and variability of residual thermal damage and necrosis, resulting in prolonged healing. Deeper wrinkles caused by facial expression, for example, the glabella and nasolabial folds, do not respond as well as finer wrinkles, especially perioral and periorbital rhytides. These are best managed with other techniques, e.g., injections of botulinum toxin.

40.20 Other Indications

Almost any skin lesion treatable with electrodesiccation or currettage or exhibiting irregular surface topography can be considered for LSR. Epidermal processes, such as actinic and seborrheic dermatoses, diffuse solar lentigines, actinic cheilitis, superficial basal cell carcinoma, and squamous cell carcinoma *in situ*, often respond nicely to resurfacing. Dermal processes, including nonmovement-associated rhytides and papular elastosis, xanthelasma, sebaceous hyperplasia, rhinophyma, and angiofibroma, may also be responsive to pulsed CO₂ or Er:YAG laser therapy.²⁴⁶ Laser-assisted hair transplantation²⁴⁷ and various unrelated conditions, including xanthelasmas, viral warts, Hailey-Hailey disease, and lymphangioma circumscriptum, have been reported to respond to CO₂ laser treatment.^{248,249} Recalcitrant psoriatic plaques have been reported to be effectively treated with Er:YAG laser resurfacing.²⁵⁰

40.21 Contraindications

Patients with a history of keloid generally should not undergo LSR. Any patient with severe systemic disease or diseases complicated by immunosuppression should not be treated, as these may alter wound healing. Isotretinoin has been reported to produce atypical scarring with resurfacing methods. It is recommended that patients discontinue isotretinoin for at least 1 year before laser treatment.²⁵¹ Any condition in which the adnexal structures are compromised (e.g., radiation therapy, collagen vascular disease or are nonabundant (the skin on the neck and extremities) may retard re-epithelialization.^{251,252}

40.22 Side Effects and Complications

The most common short-term side effects include postoperative erythema, edema, pain, pruritus, burning discomfort, a sensation of tightness, and textural changes. Postoperative erythema occurs in all patients, and its duration is mainly a reflection of the depth of thermal damage.²⁴⁶ The risk of complications is largely determined by the depth and extent of the resurfacing. Before re-epithelialization occurs, the major complications are bleeding, particularly following Er:YAG laser resurfacing, and infection. *Staphylococcus aureus* and *Pseudomonas aeruginosa* appear to be the most common infective agents, followed by *S. epidermidis* and *Candida albicans*.²⁵³ Antiherpetic prophylaxis should be used in patients having full facial or lower facial laser peels, irrespective of a history of HSV. The role of prophylactic antibiotics is controversial. A retrospective study of 130 patients undergoing laser resurfacing revealed a significantly higher rate of infection in patients receiving combination intraoperative and postoperative antibiotic prophylaxis.²⁵⁴ Late complications include acneiform folliculitis and milia formation, contact dermatitis, pigmentary change, scarring, and ectopion.²⁵⁵

Generally, pigmentary changes are related to the level of injury. Injury just to the papillary dermis is more likely to cause hyperpigmentation and is dependent on skin type. With deeper passes, hypopigmentation is possible or even common. Normally, hyperpigmentation is seen 2 to 4 weeks after injury, but hypopigmentation is typically more delayed, sometimes occurring several months after surgery. Two types of hypopigmentation can be recognized. One is a relative hypopigmentation compared to the mottled coloration of background photodamaged untreated skin that can be prevented by feathering the perimeter of the area or performing a full-face procedure. Another type is the true hypopigmentation, which usually occurs 6 to 12 months after LSR. This common delayed, and apparently permanent, side effect may be caused by loss of epidermal melanin or by underlying fibrosis.²⁵⁶ Permanent hypopigmentation is a significant concern limiting LSR in moderately pigmented skin.

40.23 Nonablative Laser "Rejuvenation"

LSR has excellent efficacy but also requires weeks of recovery and occasionally causes unwanted side effects and complications. A novel nonablative approach for treating wrinkles and scars was recently

introduced and is variously called nonablative laser resurfacing, nonablative rejuvenation, and subsurfacing. As discussed, clinical improvement following LSR is partly due to sculpting by ablation, partly due to remodeling during healing after controlled thermal injury, and perhaps partly due to shrinkage of dermal collagen, immediately tightening the dermis. Nonablative rejuvenation attempts to achieve all of these effects, except sculpting, by creating an "upside-down" thermal injury in which the epidermis is spared while the dermis is heated to temperatures that denature collagen or stimulate a healing response. This is easily accomplished by cooling the epidermis while propagating optical energy through it that is absorbed in the dermis. Apparently, the optical energy may be absorbed by any dermal structure or chromophore.

The first devices for nonablative rejuvenation used mid-infrared lasers, which are weakly or moderately absorbed by water, but it has also been observed that selective photothermolysis using visible light pulses absorbed by blood vessels produces beneficial effects on photoaged skin. The present popularity of this approach is such that many lasers and light sources are being used for this purpose including Q-switched 1064-nm Nd:YAG lasers, 585-nm pulsed-dye lasers (0.3 to 20 msec, at fluences below the threshold for immediate purpura), 980-nm diode laser, 1320-nm long-pulsed Nd:YAG and 1540-nm Er:glass lasers in combination with skin cooling devices, 1440-nm diode lasers, and IPL sources. All of these seem to offer real but subtle and minimal improvement in wrinkles compared with skin resurfacing. New dermal collagen formation and remodeling has been shown histologically.^{257–263} At present, only a 0.3-msec, 585-nm PDLs used at fluences less than about 3 J/cm² have been cleared by the U.S. FDA specifically for this indication. There was a significant (about 10% of cases) risk of scarring associated with the 1320-nm Nd:YAG laser system, which apparently has been successfully minimized by monitoring peak skin temperature as a technique for calibrating individual treatment fluence. Promising results have also been reported of photorejuvenation using IPL.^{264,265} Among 97 patients treated with IPL, "good" or "excellent" results were subjectively rated for improvement in pigmentation in 90% of the patients, in 83% for telangiectasia, and in 65% for skin texture, without major side effects. 265 However, there may be nothing unique about optical energy for stimulating an upside-down minor burn of the skin. Radiofrequency current, microwaves, and ultrasound are other radiant-energy sources capable of dermal heating.

40.24 Ultraviolet Laser Phototherapy

Excimer laser phototherapy has recently emerged in dermatology. Psoriasis is a genetic autoimmune disease affecting about 3% of the population worldwide and leads to annoying and occasionally lifethreatening skin lesions, or arthritis. Psoriasis has traditionally been treated with drugs and with UVlight therapy. Initially, sunlight or broadband UV sources were used, followed by artificial UV-B (290 to 320 nm) sources, and then by narrow-band UV-B lamps (maximum 311 nm). The action spectrum for clearing psoriasis shows a sharp maximum of efficiency between 300 and 310 nm.²⁶⁶ The 308-nm XeCl excimer laser has recently been shown to clear psoriasis faster than conventional phototherapy.^{267,268} The excimer laser beam is selectively directed toward lesional skin, thereby sparing the surrounding normal skin from unnecessary radiation exposure and allowing a higher fluence to be used on the skin lesions. Bonis et al. first demonstrated that the cumulative dose needed for clearing of lesions was much less (by a factor of more than six) with XeCl excimer laser than with narrow-band UV-B therapy.²⁶⁷ In animal models and human epidemiological studies, cumulative UV exposure is associated with increased risk of nonmelanoma skin cancer, which is one of the side effects of UV phototherapy for psoriasis and other skin diseases. Presumably, the excimer laser poses a much lower risk of UV-induced skin cancer compared with conventional phototherapy because of lower cumulative dose and treatment of a much smaller fraction of the total body surface area.

The commonly used lasers and light sources with their applications in dermatology are summarized in Table 40.1.

TABLE 40.1 Lasers and Light Sources Used in Dermatology

Laser	Wavelength (nm)	Mode	Pulse Duration (sec)	Typical Uses
Excimer	308	Pulsed	10-7	Psoriasis, vitiligo, lichen planus
Argon	488, 514	CW		Vascular
Copper vapor/bromide	512, 578	QCW	10^{-8}	Vascular, epidermal pigment
Pulsed dye (green)	510	Pulsed	3×10^{-4}	Epidermal pigment
KTP/df Q-switched Nd:YAG	532	QCW/Q-switched	10-8	Vascular/epidermal pigment
Pulsed dye (yellow)	585-600	Pulsed	4×10^{-4}	Vascular, warts, striae, hypertrophic scar, and keloid
Argon-dye	630	CW		PDT
Ruby-Q-switched	694	Pulsed/Q-switched	$10^{-3}/10^{-8}$	Hair removal/epidermal and dermal pigment, tatoo
Alexandrite/ Q-switched alexandrite	755	Pulsed/Q-switched	$10^{-3}/10^{-7}$	Hair removal, leg vein/epidermal and dermal pigment, tattoo
Diode	800	Pulsed	10^{-3}	Hair removal, vascular (telangiectases, leg vein)
Nd:YAG/Q-switched Nd:YAG	1064	Pulsed/Q-switched	$10^{-3}/10^{-8}$	Hair removal, vascular/epidermal and dermal pigment, tattoo
Nd:YAG	1320	Pulsed	10^{-3}	Nonablative dermal remodeling
Diode	1450	Pulsed	10^{-3}	Nonablative dermal remodeling
Erbium:glass	1540	Pulsed	10^{-3}	Nonablative dermal remodeling
Erbium:YAG	2940	Pulsed	10^{-3}	Skin resurfacing, ablation of epidermal lesions
CO ₂	10,600	CW/pulsed	10^{-4}	Skin resurfacing, ablation of epidermal lesions
Xenon flashlamp	500–1200	Pulsed	10-3	Hair removal, telangietases, epidermal pigment, and non-ablative dermal remodeling

Note: CW = continuous wave; QCW = quasi-continuous wave (rapid, low energy pulses); pulsed (high-energy pulses).

41.1 Introduction

The lung cancer epidemic has resulted in many patients with malignant obstruction of the central airways. Conventional therapy, including radiation therapy, chemotherapy, or dilation techniques with rigid bronchoscopy, has proven to be inadequate in relieving symptomatic airway obstruction. Thus, the application of laser technology for the treatment of various tracheobronchial obstructions, using standard rigid and flexible bronchoscopes, has proven to be a major advance in the treatment of these patients and was the original stimulus for the specialty of interventional pulmonology. The successes of laser bronchoscopy have stimulated interest in other endobronchial therapies such as cryotherapy, electrocautery, and brachytherapy.

Laser bronchoscopists must be experts in diagnostic bronchoscopy techniques, become knowledgeable in laser physics and laser–tissue interaction, and be comfortable dealing with patients with respiratory insufficiency, acute hypoxemia, and airway bleeding. This chapter reviews laser physics, laser–tissue interaction, and laser safety as it relates to bronchoscopic applications. Indications, contraindications, and techniques of laser bronchoscopy are also addressed.

41.2 Laser Light

A light amplification by stimulated emission of radiation (laser) beam is an intense form of electromagnetic energy channeled into parallel, synchronized rays of light of the same wavelength that are used in many industrial, research, and medical applications. Traditionally, the portion of the electromagnetic spectrum that has had the greatest diagnostic and therapeutic application in medicine ranges from 0.01 to 200,000 Å. Included in this range are gamma rays, x-rays, and ultraviolet (UV), visible, and infrared

light. The human eye perceives visible light as different colors, with the shorter wavelengths of 400 nm seen as violet blue and the longer wavelengths of 700 nm seen as red light.

All light is produced by the spontaneous or stimulated emission of energy by atoms, the smallest components of a molecule. The Rutherford-Bohr model of the atom, although not wholly accurate, provides a good model for understanding the structure of the atom where the nucleus contains positively charged particles called protons and neutral particles called neutrons. Orbiting the nucleus at a distance are negatively charged electrons that balance the positively charged protons. Each electron orbit corresponds to a particular quantized energy level where the energy of each orbital is directly proportional to its distance from the nucleus and increases in incremental or quantum steps.

In the spontaneous emission of light, an input of energy is required to "excite" electrons from a low-to a high-energy orbit. A photon, which is a discrete particle of electromagnetic energy, is released when excited electrons surrounding the nucleus spontaneously drop from their high-energy orbit back to a low-energy orbit, which is detected as "light." The energy of the photon released is equal to the energy input that was required to excite the electron and is calculated by multiplying the frequency of the photon (measured in hertz) by Planck's constant $(6.623 \times 10^{-34} \times 10^{-34})$ joule seconds). This implies the energy of an electromagnetic wave is directly proportional to its frequency and inversely proportional to its wavelength. As an example, a high-frequency, short-wavelength photon, such as a photon of blue light, is more energetic than a low-frequency, long-wavelength photon of red light.

Lasers differ in that photons that contribute to laser light are, in large part, released via induced or stimulated emission as opposed to spontaneous emission. In stimulated emission, an atom is already in an excited or high-energy state. A passing photon from an external source and with the correct energy is absorbed by the excited atom and induces the release of two photons that travel in the same direction and have the same energy and whose electromagnetic waves are perfectly in phase. The energy requirement of the passing photon (that is responsible for the initiation of the stimulated photon emission) must equal the energy difference between the high- and low-energy orbits of the excited atom. Although the excited atom would have released one photon via spontaneous emission, without the aid of the passing external photon, the transition from an excited state to ground state happens sooner after being induced by the passing, external photon.¹ This release is termed stimulated emission of radiation and is the basis for laser-light energy.

When the process of stimulated emission is amplified to an intense level by an external energy source, a specialized form of light energy is created, which we term laser light. Lasers create their form of light energy by using an optical cylinder containing a medium consisting of solids, gases, or dyes. The cylinder contains a fully reflective mirror at one end and a partially reflective mirror at the other end. Atoms of the laser medium become excited when an external source adds thermal, electrical, or optical energy to the system. A chain reaction of photon release is initiated by spontaneous emission of energetic photons as electrons switch from high- to low-energy orbits. A spontaneously emitted photon with the right energy can induce an excited atom to release two photons, each of which can induce an excited atom to release two more photons. This process continues, doubling the number of photons released at each step; all the photons are moving in the same direction and with the same energy, and their electromagnetic waves are perfectly in phase. This intense laser-light energy exits through the partially transmissive mirror at a rate directly proportional to the incoming external energy source. The energy is emitted as laser light and has special properties of stimulated light emission.^{2,3}

Three unique properties of laser light make lasers particularly useful.^{1,3} First, all waves of laser light are in phase with each other and have identical frequencies, wavelengths, and velocities as they travel through space. This property is known as coherence, and it results in a concentration of laser power at the target point. Second, the electromagnetic waves emitted by a laser are monochromatic, meaning that all waves have nearly the same frequency and thus the same wavelength, color, and energy. This characteristic permits all of the radiant energy to be centered in a narrow electromagnetic spectral band. Finally, all waves of laser light are essentially parallel and are thus considered collimated. This property permits lasers to travel great distances with minimal loss of intensity of light energy. Ordinary light energy (i.e., incandescent bulbs) will scatter in multiple directions at varied wavelengths, making it good for illumination

but inadequate for more precise medical applications. Laser light, on the other hand, is emitted in a narrow, parallel bundle with minimal scatter into space,^{3,4} making it particularly useful as a surgical tool. Compared with most other forms of light, lasers also have a high luminosity (brightness), which makes them useful for light therapy.

Two other important characteristics of laser light determine a laser's impact on a target. The transverse electromagnetic mode (TEM) is one measure of a laser's energy distribution per unit of cross-sectional area of the beam. Although lasers are collimated and coherent, the impact configuration on a target is not perfectly uniform, as illustrated in the ideal mode. Instead, the actual cross-sectional-impact configuration of most lasers is symmetric in a bell-shaped or Gaussian distribution, with more beam intensity being concentrated in the center of the target. This impact configuration is termed basic mode.

In addition to the TEM, its power density also determines a laser beam's intensity, which is the concentration of power (energy per unit time) per unit of cross-sectional area of the beam. Optical lenses focus the laser beam into a small focal spot, creating a high power density in that area. For each laser, the beam focus is fixed to prevent divergence and loss of power density. The power density is a function of the size of the focal spot. The smaller the focal spot, the higher the power density. The power density can also be intensified by increasing the incoming power of the beam, which is usually in the range of 20 to 100 W for most medical lasers. Therefore, power density is directly proportional to incoming power and inversely proportional to the area of the focal spot. This intensity of a concentrated beam makes it useful for cutting, coagulating, and vaporizing tissue.

A laser's TEM and power density are important determinants of the laser beam's effect on the target tissue. Because the TEM determines the profile of the beam's effective cross-sectional area, it also determines the pattern of tissue interaction. The tissue cavity created by laser destruction has the same configuration as the intensity profile (basic mode) of the laser beam. The extent of tissue destruction is a function of the amount of energy absorption, the length of exposure, and the power density of the laser beam. When laser light is applied to tissue, some of the energy penetrates into the tissue and is absorbed, producing heat; some energy is dissipated, and the rest of the energy is reflected back. Power density at the surface of the tissue will be higher than the power density farther inside because of the partial reflection of energy.

Absorption attenuates the original power density incrementally as it passes deeper into the tissues. The distance below the surface of the tissue at which the power density has decreased to a percentage of the original level (usually 1%) is termed the attenuation depth.³ It is differentiated from penetration depth, which is the distance at which the laser energy no longer has significant effects on the tissue. Laser beams can still have a considerable effect on tissues even after 99% attenuation if the exposure is prolonged or if the power density of the original beam is very high. For instance, if the laser beam has an original power density at the surface of 100 W/cm², only 1 W/cm² will be present at the 99% attenuation depth. However, if the original power density at the surface is 10,000 W/cm², 100 W/cm² will be present at the 99% attenuation depth. The attenuation depth is a function of the tissue type and the wavelength of the laser light, whereas the penetration depth depends on the tissue type, wavelength, and power density.

The amount of attenuation that occurs secondary to absorption is termed the attenuation coefficient.³ Each laser has a different scattering characteristic when the beam penetrates living tissues, but the amount of scattering within tissues generally depends on the tissue type and wavelength of the laser beam. Lasers that have high scatter coefficients function well as coagulators, whereas lasers that have high absorption coefficients are more useful for precision cutting. For instance, a carbon dioxide (CO₂) laser has a high absorption coefficient that produces rapid tissue vaporization and makes it an ideal cutting instrument. Its low scattering coefficient, however, limits its ability to photocoagulate bleeding tissues. In contrast, a neodymium:yttrium-aluminum-garnet (Nd:YAG) laser functions well as a coagulator because of its high scattering coefficient, but it is a relatively poor cutting instrument. Nevertheless, the Nd:YAG laser is capable of serving both functions because at higher power settings or within dark tissues more absorption and vaporization occur. The main determinant of a laser's effect on a particular tissue is the proportion of the scattering and absorption coefficients at the wavelength of the individual laser.

Lasers can interact with living tissues in different ways.² Light energy is converted into heat energy, enabling the thermal effects of laser radiation to be used for cutting, vaporization, and coagulation of tissues. Because of their high water content, living tissues readily absorb laser energy. This laser energy is rapidly converted into heat, which results in cell destruction. Lasers can also mechanically disrupt tissues either by pressure waves or by inducing vaporization of intracellular or extracellular water, resulting in separation of tissue layers. This interaction is useful in the removal of cataracts or intravascular atheromatous plaques. Laser-light energy can also stimulate various biochemical reactions by interacting with photosensitizing chemicals absorbed by abnormal tissues. This use of laser light is termed photodynamic therapy, which is used in the diagnosis and treatment of patients with tracheobronchial malignancies.^{5–8}

The substance used as the laser medium determines the performance characteristics of individual lasers. Each substance produces varying wavelengths of emitted light. The first laser used a synthetic ruby crystal as a laser medium; now, commonly used materials include argon, krypton, fluorescent organic dyes, gold vapor gas, helium-neon, potassium titanyl phosphate (KTP), CO₂, and a combination of erbium (Er) or Nd:YAG.

The argon gas laser has a wavelength of 514 nm in the visible blue–green spectrum and can be transmitted through optical fibers. Because of its blue color, however, much of its energy is absorbed in hemoglobin, which greatly limits its use in photoresection of endobronchial malignancies. The gold vapor and liquid-dye lasers are used to excite the photosensitizer dihematoporphyrin ether, which is selectively retained by tumor cells. By exposing the tissue to appropriate laser light, clusters of tumor cells can easily be identified and treated. The helium-neon gas laser has no therapeutic role in laser bronchoscopy, but it produces light in the visible spectrum, making it useful as an aiming guide for other lasers, such as the CO₂ and Nd:YAG laser. The KTP laser uses a solid medium similar to the Nd:YAG laser and has been used in photocoagulation and resection of tracheobronchial stenosis.

The CO₂ laser has commonly been used for lesions of the aero digestive tract.¹¹ The CO₂ laser has a long wavelength of 10,600 nm, resulting in prompt absorption by most living tissues. This invisible infrared electromagnetic energy is rapidly converted to thermal energy, resulting in vaporization of the water in the tissue. If the tissue has high water content, absorption is further enhanced, and tissue destruction is more precise. The CO₂ laser's high absorption and low scatter coefficients give it a predictable depth of penetration and make it ideal for precise surgical applications.^{3,12} Tonsillectomy, adenoidectomy, and uvulopalatopharyngoplasty (UPPP) have been performed with the use of the CO₂ laser.¹³ Although well accepted for the treatment of benign and malignant lesions of the head and neck,¹⁴ its use in tracheobronchial malignancies has been limited. The CO₂ laser can seal small vessels and lymphatics up to 0.5 mm in diameter,^{15,16} but it is an ineffective photocoagulator and cannot reliably control bleeding from larger vessels. Another important drawback of the CO₂ laser is its cumbersome articulated mirror delivery system, which requires a micromanipulator and surgical microscope for operation. Use of this system for lower airway tumors requires precise alignment of the laser beam down the entire length of a rigid bronchoscope. This complex setup makes resection difficult and often precludes the use of certain suction devices.

The Nd:YAG laser has been used extensively for the treatment of patients with tracheobronchial malignancies because the laser beam is delivered through a quartz optical fiber, which is easily adaptable for use with either the flexible or rigid bronchoscope.¹⁷ The Nd:YAG laser operates in the invisible near-infrared (NIR) range of the electromagnetic spectrum at a wavelength of 1064 nm. At this wavelength, scattering exceeds absorption for most lighter-colored tissues, which makes the Nd:YAG laser effective at coagulating large amounts of tissue. If the tissue is darker pigmented or if a higher power setting is used, absorption and vaporization can be increased. The wide power range (5 to 100 W) of the Nd:YAG laser contributes to its versatility by permitting photocoagulation at low settings and vaporization at higher settings. The Nd:YAG laser penetrates to about 6 mm and will coagulate vessels of up to 2 mm in diameter. A new type of Nd:YAG laser has been developed with a wavelength of 1320 nm, which may have advantages over the current system because of slightly less tissue scatter.⁹ The Nd:YAG laser fiber can be fitted with a sapphire tip to permit a contact operational mode, but because these tips limit viewing

contact probes are usually not used in tracheobronchial endoscopy.⁴ Because the noncontact Nd:YAG laser is the most commonly used laser for tracheobronchial disease, the rest of this chapter will concentrate on the use of this laser for bronchoscopic applications.

41.3 Indications

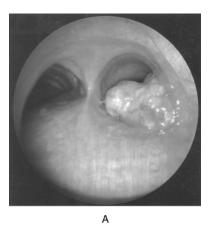

The Nd:YAG laser has been used to reestablish airway patency in patients with primary bronchogenic and metastatic malignancies, benign tumors, tracheal stenosis, and tumors of uncertain prognosis. Malignant tracheobronchial obstruction from primary bronchogenic carcinoma is the most common indication for Nd:YAG laser bronchoscopy and accounts for 49 to 75% of the cases (Table 41.1). Tracheobronchial obstruction as a result of endobronchial metastasis from renal, thyroid, colon, breast, and esophageal carcinomas account for between 6 and 18% of laser bronchoscopies and are the next most common indication for the procedure. Although they are responsible for less than 10% of the cases of tracheobronchial obstruction, benign tumors, such as hamartomas, fibromas, papillomas, lipomas, and amyloidomas, are an excellent indication for use of the Nd:YAG laser. Endobronchial amyloid and tracheopathia osteoplastica are usually not curable by laser resection, but these lesions are relatively slow growing and often do not require multiple treatments.

At many institutions, tracheal stenosis represents a relatively common indication for laser bronchoscopy, accounting for 10 to 27% of the cases. Tracheal stenosis usually occurs after translaryngeal intubation or tracheotomy, but it can occur without a known cause or in response to granulomatous or diphtheria infections. Personne et al.²¹ have identified three main types of iatrogenic stenosis. The diaphragm type of stenosis (type I) consists of a concentric fibrotic intraluminal stricture without involvement of the tracheal wall and is ideal for laser resection. The second type of stenosis (type II) involves extrinsic, "bottle-neck narrowing" of the trachea secondary to collapse of the tracheal wall. Because no intraluminal component is present, use of the Nd:YAG laser for this type of narrowing is contraindicated. The last type of stenosis (type III) is a combination of the first two types and may be acceptable for laser therapy of the intraluminal fibrotic ring in certain situations. If stenosis is suitable for endoscopic therapy, the laser is used to make radial incisions in the tracheal scar before gentle rigid bronchoscopic dilation of the tracheal or subglottic stenosis.^{25,26} Some patients with severe obstruction of the lower airway may require a permanent tracheotomy or implantation of a silicone stent or a Montgomery tracheal T tube to maintain patency of the airway.^{25–29}

A less common indication for endobronchial laser therapy is treatment of tumors of uncertain prognosis, which include carcinoid, adenoid cystic, spindle cell, mucoepidermoid, and other mixed cell types. These lesions should be resected surgically if possible, but in many instances, surgery is impossible because the lesions are widespread or the patient is a poor operative candidate. Other infrequent uses for the Nd:YAG laser include treatment of tracheobronchial granulomas,²² removal of suture threads, control of hemorrhage from biopsy sites or necrotic mucosa,¹⁸ and even vaporization of granulation tissue surrounding an aspirated foreign body.³⁰

TABLE 41.2 Characteristics of Lesions for Laser Bronchoscopy

Favorable Lesions for Laser Resection	Unfavorable Lesions for Laser Resection
Tracheal and main stem lesions Polypoid lesions Short lesion length Large endobronchial involvement Visible distal bronchial lumen Functional lung distal to the obstruction	Extrinsic lesions Diffuse lesions with extensive submucosal involvement Upper lobe and segmental lesions Long tapering lesions Total bronchial obstruction

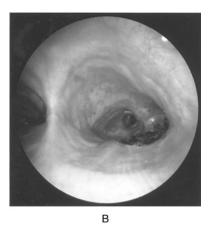

FIGURE 41.1 (Color figure follows p. 28-30.) Photographs illustrating the use of the Nd:YAG laser and mechanical resection to remove an endobronchial lesion from the lung. (A) Endobronchial lesion due to nonsmall-cell lung cancer seen in the right mainstem bronchius arising from the right upper lobe. (B) Endobronchial lesion has been removed using the Nd:YAG laser and mechanical resection.

Nd:YAG laser bronchoscopy is indicated for any centrally obstructing lesion within the airway lumen of the tracheobronchial tree, but some lesions are more favorable for treatment than others (Table 41.2). Although location of the lesion is a primary concern, the appearance of a lesion is also important. For instance, mechanical resection of short, polypoid lesions is technically easier than resection of lesions that involve a longer portion of the airway. Because much of laser bronchoscopy involves the use of the rigid bronchoscope to physically resect the tumor, long tapering lesions with extensive submucosal infiltration make the procedure technically more difficult and often reduce the chances for a successful outcome. Complete obstruction of the airway lumen also complicates the procedure because it makes it difficult to know the course of the bronchus beyond the area of obstruction. Most patients do not have complete airway obstruction, and a passage beyond the lesion can often be found by gently probing the area with a suction catheter or a flexible bronchoscope. If the course of the bronchus can be determined, mechanical and laser resection can proceed. Otherwise, complete obstruction of the airway lumen is a contraindication to laser bronchoscopy, and it represents the most common reason for not performing laser resection.³¹ Figure 41.1 illustrates the use of the Nd:YAG laser and mechanical resection to remove an endobronchial lesion from the lung.

41.4 Contraindications

Because the procedure is often used as palliative therapy for individuals with severe malignant tracheobronchial stenosis, there are actually few contraindications to laser bronchoscopy. The only absolute contraindication to laser bronchoscopy is lack of an intraluminal lesion. Because lesions extrinsic to the

airway are not amenable for treatment, it is important to confirm that the airway narrowing is not the result of compression from mediastinal tumors, lymphadenopathy, or lobar collapse or the result of type II tracheal stenosis. Failure to recognize extrinsic airway compression as a cause of airway narrowing can result in inadvertent perforation of the tracheobronchial wall. Except for extraluminal disease, there are few other reasons not to consider laser resection even in patients who are at a higher surgical risk. Personne et al.²¹ performed laser resection on 267 patients *in extremis* with severe hypoxia or coma and recorded only a 2.7% mortality rate. A low rate of fatal complications of 0.3 to 3% has been confirmed by three other large series.^{18,20,22} Although there are few absolute contraindications to laser bronchoscopy, a number of relative contraindications need to be considered (Table 41.3). A preoperative evaluation is often used to identify cardiovascular and respiratory problems that might place the patient at an unacceptably high risk for complications. The palliative benefits of laser bronchoscopy frequently outweigh the small risk of postprocedural complications. In many instances, respiratory insufficiency is both the primary indication for the procedure and the reason why the patient is a higher surgical risk. For some patients, bronchoscopic laser resection represents the only chance for rapid relief of dyspnea.

It is important to know whether there is functional lung distal to the obstruction. Lung parenchyma that is severely damaged by radiation treatments or recurrent postobstructive pneumonia is unable to participate in gas exchange even when the obstruction is removed.³² In addition, significant tumor involvement of the pulmonary artery can result in irreversible ventilation—perfusion inequalities, negating any effects of laser resection. Computed tomography of the chest can be helpful in evaluating lung parenchyma in the region of the obstruction.

The type and location of the lesion may be additional relative contraindications to laser bronchoscopy because they influence the likelihood of procedural complications. Tumors involving the posterior tracheal wall can extend into the esophagus, increasing the risk of perforation or fistula formation during laser applications. The risk of airway erosion and perforation is also increased by extensive preprocedure radiation therapy, which can distort and soften the tracheal wall. Particular caution should be taken with upper-lobe lesions because laser treatment can result in excessive bleeding owing to the proximity of major vessels. Coagulopathies, electrolyte abnormalities, hypotension, and sepsis represent other obvious contraindications to laser endoscopy and should be corrected before the procedure.

41.5 Anesthesia

The method of anesthesia delivery for Nd:YAG laser bronchoscopy depends on the type of bronchoscopic technique.³⁴ Some bronchoscopists prefer to operate through the open end of the rigid bronchoscope, and thus a different type of ventilation is required. Several authors prefer spontaneous assisted ventilation,³⁵ but others^{20,36,38,39} use a manual Venturi jet-ventilation technique. This method of ventilation enables the surgeon to operate through the open end of the rigid bronchoscope while ventilation is maintained by manually injecting an air—oxygen mixture at 20 to 60 breaths per minute.^{37,38,40} A high-frequency jet-ventilation technique has also been described wherein a machine delivers approximately 300 breaths per minute.⁴¹ The effectiveness of manual Venturi jet ventilation has been well validated,^{42,43} and the use of continuous CO₂ monitoring is not required. Standard O₂ pulse oximetry is recommended to avoid inadvertent desaturation events during the procedure. After rigid bronchoscopy, most patients are easily extubated in the operating room after clearance of the intravenous anesthesia.

41.6 Techniques for Laser Bronchoscopy

41.6.1 Rigid vs. Flexible Bronchoscopy

The Nd:YAG laser can be used with either a flexible or rigid bronchoscope, and which instrument is better has been discussed widely.^{44,45} Ironically, the original papers in the early 1980s by Toty⁴⁶ and Dumon⁴⁷ described the use of the Nd:YAG laser with both the flexible and rigid bronchoscopes. For the next few years, the flexible bronchoscope was used alone or in conjunction with an endotracheal tube or rigid scope in the majority of laser resections.^{23,31,48,49} Subsequently, reports of major complications, including deaths resulting from massive hemorrhage^{23,34,50} and airway fire,⁵¹ began to surface, and by the late 1980s many authors^{23,52} advocated using the rigid bronchoscope for most Nd:YAG laser resections.

41.6.2 Flexible Bronchoscopy

The major advantage of the flexible bronchoscope is its versatility and familiarity to the pulmonologist. In the *Bronchoscopy Survey* by the American College of Chest Physicians,⁵³ the flexible scope was used by more than 80% of responding physicians at some point in their practice. The popularity of the flexible scope for laser procedures may be partly related to the limited number of physicians who are trained in rigid bronchoscopy. In this survey, only 8.4% of the responders used the rigid scope in their practice. This trend away from the use of rigid bronchoscopy limits the choice of methods to apply the Nd:YAG laser, but in some instances, flexible bronchoscopy may actually be the preferred technique. The flexible scope is small and maneuverable, which permits easier access to distal airway lesions and improves visualization of the bronchial tree. Aiming the laser beam is also easier with the flexible scope because the operator has more control over the tip of the laser fiber.⁵⁴ The versatility and familiarity of the flexible scope make it well adapted for the safe and effective laser resection of specific lesions within the trache-obronchial tree.⁵⁴

Another theoretical advantage of the flexible bronchoscope is the potential to avoid the inherent risks of general anesthesia including myocardial infarction, arrhythmia, hemodynamic instability, CO₂ retention, barotrauma, and prolonged neuromuscular weakness.^{34,36,55} Unger⁴⁵ and Toty et al.⁴⁶ advocate the use of flexible bronchoscopy for most tracheobronchial laser procedures and reports no significant anesthesia-related hemodynamic or ventilatory complications in more than 290 procedures performed under topical anesthesia. Cardiovascular complications, such as myocardial infarction, however, can still result from flexible bronchoscopy,⁵⁴ especially if severe hemorrhage or airway compromise occurs. In fact, the only deaths in some studies using flexible bronchoscopy for laser procedures have not been the result of anesthetic complications but rather due to uncontrollable hemorrhage.^{23,34,54} Although complications related to general anesthesia for rigid bronchoscopy have been well documented,^{20–22,35} the overall rate of occurrence is exceedingly low. Cavaliere et al.¹⁹ reported respiratory failure in only 0.5%, cardiac arrest in 0.4%, and

myocardial infarction in 0.2% of 2253 cases in which more than 90% were performed under general anesthesia using a rigid bronchoscope. In a separate prospective study³⁵ of 124 interventional rigid bronchoscopies, no cardiac complications occurred, and transient reversible hypoxemia was seen in only 15% of cases.

41.6.3 Rigid Bronchoscopy

Although there may be advantages to flexible bronchoscopy for certain situations, the rigid bronchoscope is now generally preferred for most large obstructing tracheobronchial lesions.^{20–22,52} Rigid laser bronchoscopy has a number of important advantages over flexible bronchoscopy including efficiency, effectiveness, and, most important, safety. It is usually more efficient because larger pieces of tumor material can be removed through the rigid scope, significantly reducing the time of the procedure and the total number of procedures required.^{44,54} Other advantages of rigid bronchoscopy include the ability to perform stent implantation or removal at the time of the laser intervention. Both silicone stents and self-expandable metal stents can be placed through a rigid bronchoscope.

Although improved efficiency is desirable, the most important advantage of rigid bronchoscopy is safety. Three safety priorities for laser bronchoscopy^{56–59} are maintenance of ventilation, effective suction, and a clear visual field. Thus, the rigid bronchoscope is a safer instrument for laser application in patients at higher risk for procedural complications.

Bronchoscopists performing laser photoresection of tracheobronchial lesions should be proficient in both techniques to assess the risks and benefits of each technique as it applies to a particular patient.

41.7 Safety

Laser safety requires knowledge of the properties of individual lasers and the potential hazards that can arise with improper use. Each laser has a different capacity for producing injury, and the American National Standards Institute (ANSI) has classified lasers (I to IV) based on the degree of their potential hazard. This classification system uses an accessible emission limit (AEL) and a maximum permissible exposure (MPE) limit for various organs. The AEL is the amount of laser radiation that can be collected by a specific detector per unit of area. The MPE corresponds to the total energy absorbed by the tissue and is a function of the wavelength of the laser and the duration of exposure. A class I rating is given to lasers that do not emit hazardous levels of radiation and represent the lowest risk for injury. Class II lasers are also very safe if exposure duration is limited to less than 0.25 sec in the visible band of light because the natural aversion reflex of the eye is rapid enough to avoid injury by this type of laser. Their low power gives an AEL of below 1 mW, which is the arbitrary power level that separates class II lasers from the next laser class. Class III lasers have a wide power range between 1 and 500 mW and can be potentially dangerous even if viewed momentarily. Most surgical lasers are classified as class IV because they have a power output above 500 mW. The main safety risks for surgical lasers are thermal and ocular injuries related to accidental reflection of laser light.

Inadvertent injury to the patient and operating-room personnel is an important safety concern with the use of class IV surgical lasers. Misdirected laser-light energy can reflect off instruments and shiny surfaces located near the operating field, causing corneal, retinal, and thermal injury to exposed areas. Surgical instruments can be roughened or blackened to help diffuse and absorb these potentially dangerous reflections of laser light. Even if a laser beam is reflected, it retains much of its focus and intensity because of the collimation and coherence properties of laser light. The dangers of reflected laser light are often not readily apparent because Nd:YAG and CO₂ lasers have wavelengths in the invisible range of the electromagnetic spectrum. The bronchoscopist may actually be at the highest risk for injury because Nd:YAG laser light can scatter and reflect back along the endoscope. This is usually not a concern with the CO₂ laser as the optics of the system protects the operator from injury. To avoid inadvertent injury from reflected laser light, safety glasses or eye shields are mandatory for all operating room personnel as well as for the patient. In addition, the windows in the procedure room should be covered to protect anyone outside the room from becoming accidentally exposed. Signs indicating the use of laser light

should also be placed on the doors entering the room. Certain built-in precautions, such as foot pedals for laser activation and a standby mode, help to avoid accidental deployment of laser energy.

One of the most recognized hazards of class IV surgical lasers is retinal or corneal injury. Although the eye has a natural lid-aversion reflex that limits exposure to bright light, the power density of certain lasers is great enough to produce significant damage. Because of their various wavelengths, lasers affect the eye in different ways. Laser beams with short wavelengths in the UV region (100 to 400 nm) or long wavelengths in the far-infrared region (1400 to 10,000 nm) of the electromagnetic spectrum are absorbed by the cornea and lens of the eye. Lasers with wavelengths in the visible and NIR region (400 to 1400 nm), such as the Nd:YAG laser, are more dangerous to the retina. This area of the electromagnetic spectrum has been termed the retinal hazard region because laser light of this wavelength can be focused by the lens onto the retina with a magnitude of up to 100,000 times.⁶² If the beam becomes focused onto a small point on the retina, significant damage can occur from thermal effects. If the damage is in an area such as the fovea of the macula, irreversible loss of fine vision can occur. Unfortunately, the loss of vision is usually permanent because neural tissue has limited ability to regenerate itself. For this reason, all lasers in classes II to IV should be considered potentially dangerous to the eye if adequate precautions are not taken. The type of eye protection is important because safety glasses are designed for use with lasers of a specific wavelength. Eye protection manufactured for use with one type of laser may not be protective against lasers with a different wavelength. For instance, clear plastic safety glasses are adequate for brief exposures to CO₂ laser energy because of the limited penetration of CO₂ laser light, but an Nd:YAG laser can easily penetrate plastic or glass. For protection against the Nd:YAG laser, special eyewear with an optical density of 7.0 at 1064 nm is required.

Although ocular damage is the most feared safety risk, the skin and airway mucosa are also susceptible to injury from the laser. The likelihood of injury to the skin may actually be greater than to the eye because of the larger area of exposure. Lasers in the visible and NIR region (400 to 1400 nm), such as the Nd:YAG laser, can produce thermal injury severe enough to create third-degree burns.⁶² The CO₂ laser, however, has a longer wavelength (10,600 nm), which limits skin penetration and reduces the risk of a severe burn. Nevertheless, thermal injury can still occur if exposure is prolonged or if plastic, paper, or cloth items near the surgical field are accidentally ignited by the laser. The airway mucosa is also vulnerable to thermal injury because airway fires can occur if the flexible bronchoscope, endotracheal tube, or plastic suction catheter is accidentally ignited by the laser.⁵¹ A polyvinyl chloride (PVC) endotracheal tube should not be used with a CO₂ laser because it is flammable, and toxic gases can be released from the burned plastic. The use of a red rubber tube with aluminum wrapping can reduce the risk of airway fires caused by the CO₂ laser. 63 This special tube should not be used with an Nd:YAG lasers because the darker rubber tube may actually absorb more laser energy. The risk of airway fires can also be reduced by limiting the power of the Nd:YAG laser exposure time and the inspired oxygen FiO₂.⁶⁴ The use of a metallic rigid bronchoscope will also substantially reduce the risk of airway fires, although with proper precautions a flexible bronchoscope or endotracheal tube can be used safely during laser applications. Although airway fires and burns are rare events, they are important safety considerations when using most types of surgical lasers.

The composition of the smoke plume generated by the laser has also recently come under investigation. 65 In 1988, a questionnaire study by Lobraico et al. 66 demonstrated an association between $\rm CO_2$ laser treatment of papillomas and the subsequent development of these lesions in the treating physicians. Furthermore, Garden et al. 67 demonstrated the presence of intact human papilloma virus (HPV) DNA in the vapors of laser-treated verrucae and cautioned practitioners about the potential transmissibility of infection. Abramson et al., 68 however, were unable to demonstrate HPV DNA present in the smoke plume from vaporization of laryngeal papillomas unless direct suction contact was made with the tissue during surgery. The presence of human immunodeficiency virus (HIV) DNA in laser smoke has also been documented, but sustained growth of the cultured cells did not occur, possibly because of damage produced by the laser energy. The risk of clinical disease in surgical personnel from viral transmission has not yet been established, but special safety precautions are recommended until further studies can be performed.

Certain guidelines need to be followed for the safe operation of the Nd:YAG laser during bronchoscopy. For flexible bronchoscopy these recommendations concentrate on the prevention of hemorrhage and airway fires. To help avoid these complications and achieve successful results, the location of the tip of the laser fiber should be known at all times. When firing the laser, the tip of the fiber should be at least 4 cm from the distal end of an endotracheal tube and at least 4 mm from the end of the bronchoscope to prevent ignition of the plastic. The concentration of inspired oxygen should also be 40% or less to decrease the risk of airway fires. The tip of the laser fiber is best positioned 0.4 cm to 1 cm from the lesion and should be kept clean at all times. When appropriately positioned, the laser should also be fired parallel to the airway wall in pulses of 0.4 to 1 sec in duration with a setting of 20 to 40 W. The goal of the Nd:YAG laser application should not be to vaporize the tumor completely but rather to photocoagulate the lesion to produce hemostasis and necrosis. Residual tumor can be removed mechanically with biopsy forceps, a balloon catheter, or vigorous suctioning, eliminating the need for vaporization. Aggressive use of laser energy should also be avoided because penetration of the Nd:YAG laser is often deeper than is apparent on the surface, and the full extent of tissue necrosis is not complete until 24 to 48 h after the procedure. 45 Instead, repeat bronchoscopy is recommended in a few days to assess the extent of the remaining tumor and need for further treatment. For smaller lesions subsequent bronchoscopy may not be necessary, but for large obstructing lesions a multiple-stage procedure is often the safest approach. If these guidelines are followed, Nd:YAG laser bronchoscopy can safely and effectively be performed through the flexible bronchoscope with successful palliation in more than 80% of patients.⁵⁶

For rigid bronchoscopy, the same Nd:YAG laser fiber is passed down the barrel of the scope along with a suction catheter and telescope. The laser fiber is aimed at the lesion by manipulating the rigid scope itself. The laser power settings remain at 20 to 40 W, with a pulse duration of 0.4 to 1 sec; this results in the application of about 22 J laser energy per pulse to the lesion. The rigid metal bronchoscope is nonflammable, and thus the laser fiber does not have to extend beyond the end of the scope. It is important, however, to keep the flexible suction catheter out of the laser field to avoid any chance of fire. The laser fiber should be in close proximity (<1 cm) to the lesion because laser energy disperses as it exits the tip of the fiber, and the distance to the lesion determines the effective power density. As with flexible laser bronchoscopy, the initial goal should be photocoagulation of the tumor and not vaporization. Debridement of the remaining tissue can be accomplished by alligator forceps or a suction catheter. If needed, the beveled end of the rigid bronchoscope can also be used to shear off parts of the tumor once photocoagulation has devitalized the tissue. Care must be taken not to perforate the airway wall with the rigid scope. It is always important to know the path of the distal airway before aggressively advancing the scope beyond the tumor. The flexible scope can be helpful for blunt dissection of the tumor and in evaluating the airways distal to the main obstruction. After most of the tumor has been removed by these means, hemostasis can be achieved through further laser photocoagulation.

41.8 Outcome

Although the use of laser bronchoscopy has become more common for benign and malignant tracheobronchial obstruction, ^{18–21} no randomized controlled trials exist proving a survival benefit in treated patients. Numerous studies, however, have shown a significant palliative benefit with regard to relief of dyspnea, control of hemoptysis, and facilitation of weaning from mechanical ventilation. In 1419 patients with bronchogenic carcinoma, Cavaliere et al.¹⁹ achieved satisfactory immediate results corresponding to a normal airway lumen gauge or significant improvement in ventilation in 93% of patients. Brutinel et al.²³ found that airway caliber was improved in 79.7% of 182 sites and that even completely obstructed airways could be opened 57.7% of the time. In a previous study at the Lahey Clinic, ²⁰ subjective symptomatic relief was demonstrated after 313 of 400 procedures (78.3%) in patients with benign and malignant disease.

Although many of the larger studies relied on subjective measurements of improvement, other studies have documented objective benefits in pulmonary function tests, performance scores, and even ventilation-perfusion scans after laser bronchoscopy. Spirometry and flow-volume loops have shown immediate

functional improvement, with increases in peak expiratory flow rates ranging from 26 to 512%.^{70,71} Waller et al.⁷² showed a mean overall improvement in FEV₁ of 27% and symptomatic relief in 103 of 116 patients whose main complaint was dyspnea. Gelb and Epstein⁴⁹ reported significant improvement in Karnofsky performance scores, dyspnea index, in 23 of 27 patients with incomplete malignant obstruction of the tracheobronchial tree. Jam et al.⁷³ also used Karnofsky scores in patients treated by Nd:YAG laser photoresection and reported an improved performance status in 13 of 15 patients lasting between 2 and 13 months. Other performance scores, such as the simple 0 to 4 symptom score used by Clarke et al.,⁷⁴ confirmed good symptomatic relief in 73% of their first 200 patients consecutively treated with laser bronchoscopy.

Ventilation-perfusion relationships have also been studied in patients undergoing laser bronchoscopy. George et al.⁷⁵ found that both ventilation and perfusion improved after laser treatments in 23 of 28 patients (82%) and that spirometric values, 6-mm walking distance, Karnofsky performance index, and breathlessness scores also improved significantly. In addition, it appears that improvements are not simply transient. Although some patients with benign and malignant tracheobronchial lesions may require multiple procedures, Emslander et al.⁷⁶ reported complete or partial removal of tumor in 74% of 224 laser applications and showed that in 72% of the successful results, the stenoses were still open after 4 to 6 months.

Nd:YAG laser photocoagulation is also effective at controlling hemoptysis^{9,73,74} from malignant endobronchial lesions, with a response rate estimated to be 60%.⁹ Although photocoagulation for hemoptysis has shown initial success, long-term benefits were not as easily maintained as with treatment for relief of dyspnea. Clarke et al.⁷⁴ reported that patients who were treated principally for hemoptysis tended to have a recurrence of their symptoms within 30 d of treatment, whereas those who were treated for dyspnea or cough tended to experience recurrence much later.

Laser bronchoscopy has also been shown to be beneficial for patients with impending respiratory failure as well as for those who require mechanical ventilation. Radiation therapy can relieve cough, chest pain, and dyspnea in 60 to 80% of patients, but it only relieves atelectasis in 25% of patients, and improvement is usually delayed.⁷⁷ External-beam-radiation therapy is a common palliative intervention for patients with bronchogenic carcinoma, but only laser bronchoscopy provides the means for rapid resolution of symptoms. In one series,⁷⁰ laser bronchoscopy successfully relieved breathlessness and avoided mechanical ventilation in 11 of 14 patients who had respiratory distress on presentation. The authors⁷⁰ concluded that laser treatment provided an excellent method of resuscitating patients with lifethreatening tracheal obstruction, enabling subsequent management such as radiation therapy, chemotherapy, or tracheobronchial stenting. Laser bronchoscopy may also facilitate weaning from mechanical ventilation in patients with respiratory failure caused by endoluminal obstruction. Stanopoulos et al.⁷⁸ reported that laser bronchoscopy improved the clinical status of 9 of 17 mechanically ventilated patients by permitting successful extubation. This subgroup of patients had appreciably shorter requirements for mechanical ventilation and a longer survival. The initial use of Nd:YAG laser bronchoscopy for treatment of an endobronchial lesion can be debated, but the palliative use of laser therapy in an inoperable, symptomatic patient has been shown to be beneficial for relief of dyspnea, control of hemoptysis, and weaning from mechanical ventilation.

Laser bronchoscopy is clearly a valuable tool in providing immediate symptomatic relief, but its survival benefit is more difficult to demonstrate. Randomized studies⁷⁹ evaluating this palliative treatment in terminal patients have been considered unethical. Although the issue of survival is a difficult one, it appears that there may be a survival advantage for patients undergoing laser resection of malignant tracheobronchial obstruction. In a preliminary study of 19 patients treated with laser photoresection, Eichenhorn et al.⁸⁰ found a median survival of 340 d, which was greater than the 198 to 266 d found in historical control subjects using irradiation alone.^{81,82} In another study using historical controls, Brutinel et al.²³ compared 71 patients with bronchogenic carcinoma treated with Nd:YAG laser photoresection with 25 patients who would have received laser treatment had it been available. They found that 76% of the control subjects were dead within 4 months, and all were dead within 7 months. By contrast, 60% of patients in the laser-treated group were alive at 7 months and 28% were alive at 1 year. Desai et al.⁷⁹

also found a significant increase in survival in a subgroup of patients treated with emergent laser resection compared with historical control subjects who had emergent radiation therapy alone. In mechanically ventilated patients, Stanopoulos et al.⁷⁸ showed an increased survival (98 d vs. 85 d) in patients who were weaned after emergent laser resection of an obstructing lesion. The addition of brachytherapy to laser resection may also contribute to increased survival. Shea et al.⁸³ found an improved mean survival time (41 weeks vs. 16 weeks) in patients treated with both endobronchial brachytherapy and Nd:YAG laser photoresection.

Although these data suggested a survival advantage, the retrospective design of the studies makes statistical validation difficult. Furthermore, other authors⁸⁴ failed to show any overall survival benefit for patients undergoing laser treatment. Although Desai et al.⁷⁹ found improved survival in a subgroup of patients treated emergently, they did not find an overall increase in survival in patients who underwent elective laser photoresection. Clarke et al.⁷⁴ also gave no evidence that laser treatment prolongs life and suggested that patients die of progression of their primary disease rather than obstruction of the bronchi. Nevertheless, patients on mechanical ventilation or with impending respiratory failure likely represent a subgroup of patients who may have a survival benefit from laser photoresection. A survival advantage may also be seen if endobronchial brachytherapy is combined with laser resection.

Absolute survival, however, may not be the best way to judge the importance of a palliative intervention in symptomatic patients. The rapid relief of dyspnea and improved performance provide justification for laser bronchoscopy in most patients. Laser bronchoscopy has been shown to be an effective method for immediate relief of respiratory symptoms related to both benign and malignant tracheobronchial obstruction. It is complementary to other modes of therapy, such as radiation, chemotherapy, stenting, or surgery, and often provides the time necessary to initiate these treatments.

42.1 Lasers and Neurosurgery

The physical basis for most laser (Light Amplification by Stimulated Emission of Radiation) applications in neurosurgery is the conversion of laser light into heat. Laser light is monochromatic, coherent, and collimated. Laser photon absorption by tissue stimulates oscillation and rotation of tissue molecules, and subsequent inelastic collisions release kinetic energy to produce heat. Depending on the duration of irradiation, and thus the degree of heat, several biologic effects can be seen including hyperthermia $(T=45^{\circ}\text{C})$, coagulation (involving protein denaturation) $(T=65^{\circ}\text{C})$, vaporization $(T=100^{\circ}\text{C})$, and carbonization $(T>100^{\circ}\text{C})$. Both the laser-emission parameters (wavelength, fluence, and mode) as well as the exposed tissue's optical and thermal properties (water and hemoglobin content, thermal conductivity, and specific heat) are critical in determining the tissue effect (hemostasis, cutting, and vaporization). The main potential disadvantage is diffusion of heat energy resulting in thermal damage to surrounding normal tissue. Furthermore, tissue factors such as degree of vascularity affect kinetics of cooling following hyperthermia from a laser pulse. In addition, laser irradiation may kill tumor cells but of course does not remove them, which must still be done surgically.

FIGURE 42.1 Cooper model 500Z CO₂ surgical laser system setup. The laser wavelength is $10.6 \mu m$. The laser power can be varied from 1 to 50 W at the treatment site in increments of 1 W. The irradiation time can be adjusted from 10 to 990 msec either continuously or in increments of 1.0 msec. The aiming beam consists of a helium–neon laser projected to the same position and spot size as the CO₂ laser. The spot size can be varied from 0.8 to 3.5 mm.

42.2 Development of the CO₂ Laser

The world's first laser, a pulsed ruby laser, was developed in 1960.² Rosomoff and Carroll in 1966³ were the first to focus pulsed-ruby-laser beams on brain tumors and found some evidence of tumor necrosis. However, they did not attempt to use the laser to remove tumor tissue. The ruby laser did not possess desirable surgical characteristics,⁴ and its thermal effects were difficult to control. The continuous-wave CO₂ laser was introduced in 1967 and immediately replaced the ruby laser for surgical applications (Figure 42.1). The CO₂ laser was superior at vaporization, cutting, hemostasis, and sterilization, and its tissue-damage characteristics were more predictable. Stellar et al. found that precise incisions could be made with the CO₂ laser in the cat brain and spinal cord with little collateral tissue damage.⁵ They were the first to use a CO₂ laser to subtotally vaporize a glioblastoma.⁶ In the mid- to late 1970s, other surgeons began to report case series of patients who had a variety of procedures performed with the CO₂ laser.⁷⁻¹¹ From 1976 to 1979, Ascher and Heppner performed more than 250 procedures using the CO₂ laser, including 200 brain tumors and 13 spinal cord tumors.⁷⁻⁹ In 1980, Takizawa et al. reported on treatment of meningiomas with the CO₂ laser.¹¹

During the late 1970s and early 1980s, two principal technical changes dramatically increased the ease of applicability of the laser in neurosurgery. First, a helium laser was added as a pilot to target the invisible CO₂ laser; the pilot beam served as a marker for the treatment beam. Second was the coupling of the laser to the operating microscope. Initially, most of these procedures were performed with a freehand laser not attached to an operating microscope, 9,12 which made precise targeting quite difficult.

After some experience with the CO_2 laser, investigators found it particularly useful for the excision of extraaxial tumors such as meningiomas, vestibular schwannomas, and craniopharyngiomas. Poorly accessible deep brain tumors and recurrent gliomas were other common uses. The growing interest in lasers in neurosurgery culminated in the First American Congress of Laser Neurosurgery, held in Chicago in October 1981.

42.3 Development of the Nd:YAG Laser

Another laser, the neodymium:yttrium-aluminum-garnet (Nd:YAG) laser, was found to have unique biologic properties, suggesting applications within neurosurgery distinct from the CO₂ laser.¹³ In particular, its selective absorption by blood and blood vessels suggested its use in neurovascular surgery. Early experimental studies had shown that it was possible to perform blood-vessel microanastomosis and repair with the Nd:YAG laser.^{14–16} Experimental comparison of CO₂ and Nd:YAG lasers applied to rabbit brains demonstrated that the Nd:YAG laser penetrated more deeply and also had a stronger effect on vascular tissue.¹⁷ This led to the clinical use of the Nd:YAG laser by Beck et al.¹⁰ and Takeuchi et al.,¹⁸ especially in the excision of vascular meningiomas and arteriovenous malformations. It was also used to perforate sphenoid bones in transsphenoidal surgery by Takeuchi et al.¹⁸ The primary advantage noted was that blood loss was lower than with conventional techniques or with the CO₂ laser due to the superior coagulating ability of the Nd:YAG laser.¹⁹

Subsequently, Sundt and colleagues carried out experimental and clinical studies of the Nd:YAG laser.^{20,21} In studies on cat brains, they found a blood:brain absorption ratio of 100:1, indicating selective absorption by hemoglobin and concurrent selective heating of blood compared with brain tissue.²⁰ This clarified the role and technique for using the Nd:YAG laser in hemostasis.

One of the only studies specifically reporting complications of the use of the Nd:YAG laser was published by Jain in 1985. ²² In a review of 32 patients who underwent brain-tumor procedures with the Nd:YAG laser, five complications were presented. Two mortalities, one due to intratumor explosion and the other to heat necrosis of the brainstem following laser irradiation of a fourth ventricular ependymoma, were described. Protection of normal tissue from thermal spread-induced damage during use of the laser was emphasized, with adequate venting of hot gases created by vaporization of tissue and covering surrounding normal tissue with moist cottonoids.

42.4 Development of the Argon Ion Laser

The initial use of the argon ion laser was in ophthalmology for the treatment of retinal detachment.¹³ Its water transmissibility, good hemostatic ability, and small size made it ideal for ophthalmologic procedures. Subsequently, it was introduced into otolaryngology.²³ Glasscock et al.²⁴ were the first to report use of the argon laser in removal of vestibular schwannomas.

In preclinical studies, Boggan et al.²⁵ directly compared the response of brain tissue to argon vs. CO_2 lasers. Pulses were given at identical power densities to 32 rat brains. Although there was an initial larger increase in blood-barrier defect caused by the CO_2 laser, by 1 month after injury there was no difference in the size of the core of coagulation necrosis and surrounding gliosis.

Powers et al.²⁶ described the use of the argon laser in 68 procedures including tumors, spinal-cord fenestration for syringomyelia, and production of dorsal root entry zone (DREZ) lesions for pain control. They emphasized that the useful characteristics of the argon laser as a microneurosurgical instrument included a small laser spot size (0.15 to 1.5 mm), a single laser-aiming and treatment beam, the transmission of the argon laser light through aqueous media, and excellent hemostasis. At the same time, however, the same group²⁷ compared standard microsurgical techniques, the CO₂ laser, and the argon laser in a rat gliosarcoma model and found identical gross total resection and rate of tumor recurrence by all three methods. Therefore, in the case of malignant glial tumors, it was not clear that the option of laser therapy had any particular advantage over standard microsurgical techniques.

42.5 Development of the KTP Laser

The potassium-titanyl-phosphate (KTP) laser was initially developed as a second-generation laser to the argon laser but has been little used. Gamache and Morgello²⁸ compared the histopathologic effects of

the KTP laser vs. the CO₂ laser on canine brain and spinal cord. Each laser led to a central zone of tissue vaporization surrounded by coagulation necrosis; the only difference appeared to be slightly more histologic evidence of hemorrhage in CO₂-laser-induced lesions. Clinical experience with this laser has been limited.²⁹

42.6 Meningiomas

In 1980, Takizawa et al.¹¹ reported on the treatment of meningiomas with the CO₂ laser. Beck¹⁰ described 51 cases of meningiomas treated with the Nd:YAG laser, but outcome was not reported. Later, Roux et al.30 described treatment of 17 meningiomas with a combined CO₂ and Nd:YAG laser. They noted that the combined laser penetrated more deeply than the CO2 laser alone with the same power and the hemostasis was contributed by the Nd:YAG component. Outcome was not reported. Lombard et al.31 studied 220 meningiomas operated on with a laser or with conventional techniques and examined postoperative morbidity and mortality. Both patients in the conventional-surgery and laser groups improved after surgery, but there was a significantly better outcome for patients with meningiomas located in functional areas treated with a laser compared to conventional surgery. Desgeorges et al.32 reported on 164 meningiomas treated with various lasers over 6 years. Complete tumor removal was documented in 83% of cases, and mortality was 3%. They commented particularly on the ability to remove deep meningiomas that might be difficult with conventional microsurgery. Specific advantages included reduced brain retraction, ability to operate with smaller exposures, reduced mechanical manipulation, and decreased intraoperative blood loss. Waidhauser et al.³³ reported on 43 patients with frontobasal meningiomas. In this series, they used the Nd:YAG laser for contact-free shrinkage of the tumor, lysis of the dural and bony attachments, and coagulation (in addition to standard bipolar cautery). In their experience, the Nd:YAG laser facilitated microsurgical dissection and reduced blood loss.

42.7 Vestibular Schwannomas

Several authors have described laser-assisted excision of vestibular schwannomas. 26,34,35 In this procedure, preservation of cranial nerve function is critical. Irrigation with suction of the laser plume has been used to minimize thermal injury to structures around the tumor. In 1993, Eiras et al. 35 compared a group of 12 cases of giant vestibular schwannomas operated with the CO_2 laser to a group of 12 similar cases undergoing conventional microsurgery. In this small study, the main finding was that while duration of surgery was slightly longer with the use of the CO_2 laser, other parameters studied, such as facial nerve preservation, were slightly better in the laser-treated group.

42.8 Pituitary Tumors

Takeuchi et al. ¹⁸ were the first to use the Nd:YAG laser to penetrate the sellar floor during transsphenoidal pituitary operations. Subsequently, Oekler et al. ³⁶ reported 15 cases of pituitary adenomas in which the sellar floor was irradiated with the Nd:YAG laser to minimize bleeding from the capsule. Powers et al. ²⁶ reported resection of a fibrous prolactinoma with the aid of the argon laser. In this case, the laser was used to open the sellar floor, cut through the dura, and vaporize the tumor. However, the application of lasers in pituitary tumors is likely to be limited in most cases to brief focal photocoagulation since thermal spread to adjacent structures (optic nerves, optic chiasm, cavernous sinus, internal carotid artery) could be devastating.

42.9 Intraaxial Brain Tumors

While there was initial enthusiasm over the use of lasers in the treatment of intraaxial brain tumors, conventional microsurgery, especially with modern image-guidance techniques, seems more appropriate

in most cases. For example, there is no clear advantage to performing the corticotomy required to expose brain tumors with a laser. However, Kelly et al. integrated a CO_2 laser into a computer-assisted volumetric stereotactic system for the resection of intraaxial neoplasms.^{37–40} Other investigators have demonstrated the ability to remove intraaxial brain neoplasms with lasers.^{26,41,42} Devaux et al. recently reported on the new high-power semiconductor diode laser in the treatment of intraaxial brain tumors.⁴³ There remains no clearly demonstrated advantage to lasers for intraaxial tumors that can be reached with conventional techniques.

42.10 Spinal Lesions

42.10.1 Intramedullary Tumors

CO₂ and argon lasers have been used for the excision of intramedullary spinal-cord tumors. ^{9,26,34,41,44} Usually, the myelotomy is made with the laser followed by laser vaporization of the spinal tumor. While theoretically attractive, it is not clear that outcome following laser treatment of intramedullary tumors is better than with conventional techniques, from the point of view of either reduced damage to surrounding tissue or increased efficacy of tumor removal.

42.10.2 Lipomas

Lasers have more commonly been used in the treatment of spinal lipomas and lipomyelomeningoceles. With these lesions, the goal is to untether the spinal cord and nerve roots from the lipoma. However, the fibroadipose tissue of the lipoma may have a large and poorly defined border with the conus medullaris and nerve roots. In this regard, the $\rm CO_2$ laser has proven to be quite effective at vaporization of fat. McLone and Naidich⁴⁵ reported a series of 50 cases of pediatric spinal lipoma treated with $\rm CO_2$ laser. They found that use of the laser reduced the length of the operation, intraoperative blood loss, and degree of manipulation of spinal cord and nerve roots. In addition, many patients' neurologic function improved postoperatively including recovery of urinary continence and improved motor function. Likewise, Maira et al.⁴⁶ reported using the $\rm CO_2$ laser to remove large spinal lipomas in two adult patients.

42.10.3 Laser Discectomy

The surgical treatment of herniated intervertebral discs has progressively improved with the development of less invasive techniques.⁴⁷ While nearly all operations are performed open, endoscopic methods of discectomy have been introduced.^{48,49} Distinct procedures have been developed to perform percutaneous discectomy with the use of lasers.^{50–53} Choy et al. first reported percutaneous laser discectomy in 12 patients using the Nd:YAG laser introduced through an 18-gauge needle.^{52,53} Unfortunately, 5 of the initial 12 patients ultimately required open operation. Mayer et al.⁵⁰ used a rigid endocope with a flexible Nd:YAG laser fiber to perform discectomy in six patients. No study has yet been done comparing percutaneous laser discectomy with open microdiscectomy in an appropriately selected patient population. The current clinical role of percutaneous discectomy is negligible compared with open discectomy.

42.11 Arteriovenous Malformations

As described above, the development of the Nd:YAG laser was found to have superior properties to the CO₂ laser for coagulation of blood vessels and hemostasis. It was first used as an adjunct in treatment of arteriovenous malformations (AVMs) by Beck et al. in 1980.¹⁰ In this case, it was used selectively to coagulate feeding vessels. Subsequently, Fasano et al.⁵⁴ reported on the combined use of the CO₂ laser and Nd:YAG laser in the treatment of three vascular malformations. In a larger follow-up study, Fasano et al.⁵⁵ used either the Nd:YAG or the argon laser to photocoagulate six AVMs. Sundt et al. demonstrated the use of the Nd:YAG laser in the resection of ten arteriovenous malformations (AVMs).²¹ In these cases,

the laser was found helpful for defining the plane between the AVM and brain and for achieving hemostasis of the bed following AVM resection but could not arrest high-flow bleeding from the thin-walled vessels of the AVM and did not appreciably reduce operating time. Similarly, Powers et al.²⁶ found the argon laser helpful in removal of a low-flow AVM but not a large, high-flow AVM. Zuccarello et al.⁵⁶ resected ten AVMs with the Nd:YAG laser, studied the histologic effect of the laser on AVMs, and found shrinkage of collagen in the AVM vessels leading to vessel narrowing.

Strugar and Chyatte reported five cases of spinal dural AV fistulas treated by microsurgical exposure of the dural nidus followed by nidus treatment with the Nd:YAG laser. Satisfactory obliteration was confirmed with postoperative angiography, and there were no complications.⁵⁷

42.12 Interstitial Laser Thermotherapy

Hyperthermia has been a much-studied adjunctive therapy in the treatment of malignant brain tumors.^{58–60} It has been produced by ultrasound, microwaves, radiosurgery, and indwelling probes. Interstitial laser thermotherapy using the Nd:YAG laser as a thermal source has been studied both in animal models and in humans.^{61–65} Conical sapphire-tipped optical fibers delivering a point source of Nd:YAG laser energy can be positioned at any point within a tumor.⁶¹ As with typical laser tissue effects, the size of the lesion depends on the energy and exposure time.⁶⁶ However, despite some encouraging results in the treatment of glioblastoma,⁵⁹ the current role of hyperthermia in clinical neurosurgery is limited.

42.13 Laser-Assisted Vascular Anastomosis

In the mid-1960s, Yahr et al.14 and Yahr and Strully15 were the first to demonstrate laser-assisted vascular anastomoses. 14,15 This was initially done with microvessels (0.7- to 2.0-mm diameter) and subsequently performed on larger vessels (3- to 8-mm diameter). Exactly how laser treatment welds blood vessels together is unclear, but apparently denaturation of collagen in the blood vessel walls is partially responsible.^{67,68} In 1979, Jain and Gorisch¹⁶ reported repair of small blood vessels (0.3 to 1.0 mm) in the rat with the Nd:YAG laser. In 1985, Frazier et al.⁶⁷ compared end-to-end anastomoses of femoral arteries (1.6-mm diameter) in miniature swine done with CO₂ laser vs. conventional microvascular suture anastomosis and found that the laser anastomosis was shorter (20 vs. 30 min) and patency rates were superior for laser anastomosis. Quigley et al.⁶⁹ showed that intimal hyperplasia was reduced in laserassisted compared with suture anastomosis. However, a very important finding was the association of laser treatment with the development of aneurysms in the laser-joined vessels.⁷⁰ Shapiro et al.⁷¹ demonstrated successful end-to-side anastomosis of rat carotid arteries using the Nd:YAG laser. While anastomotic patency was 86%, aneurysm formation occurred in 23% of anastomoses. This high rate of laserinduced aneurysm formation and the efficacy of conventional microsurgical anastomosis undermined enthusiasm for any clinical role for laser-assisted vascular anastomosis in neurosurgery. However, Tulleken and colleagues have since developed a novel high-flow bypass procedure using an excimer laser to revascularize the ischemic brain and shown excellent patency without aneurysm formation.⁷²⁻⁷⁴ Another application under study is the potential use of lasers in reversing cerebral vasospasm.^{75–77}

42.14 Laser-Assisted Nerve Repair

Despite refinements in microsurgical nerve repair, results can be unsatisfactory and may include fascicle mismatching, scar formation, foreign-body response to suture material, and neuroma formation.⁷⁸ Therefore, investigators have been interested in the potential for using the laser in nerve repair (laser neuror-rhaphy).^{79–88} Almquist et al. first reported the use of the argon laser to repair peripheral nerves in rats and monkeys in 1984.⁷⁹ Fischer et al.⁸⁰ found similar results using the CO₂ laser in rat sciatic-nerve repair. Maragh et al.⁸¹ compared standard microsurgical vs. laser nerve repair in a rat-sciatic-nerve model and

found better nerve conduction velocities in the microsuture group. Bailes et al. 82 compared CO_2 laser with 9–0 nylon perineurial neurorrhaphy in a primate model of sural to peroneal nerve graft and found comparable results on nerve conduction velocity and histology at 5, 8, 10, and 12 months. Seifert and Stolke 83 demonstrated feasibility of microsurgical CO_2 laser–assisted repair of the oculomotor nerve in the cat. Campion et al. 84 claimed to demonstrate improved neuromuscular function of argon laser-assisted nerve repair compared to conventional microsurgical epineurial-suture repair in a rabbit model. Huang et al. 85 compared microsuture vs. CO_2 laser repair of transected sciatic nerves in rats and found similar results on EMG and nerve conduction velocities. Korff et al. 86 found a similar amount of regeneration 2 months after repair of severed rat sciatic nerves repaired with suture or laser. More recently, Menovsky et al. 88 have compared CO_2 laser-assisted nerve repair with fibrin glue or absorbable sutures in the ratsciatic-nerve model. There were no significant differences in motor function at 16 weeks and no significant histologic differences.

Taken together, the above preclinical studies demonstrate both advantages and disadvantages of laser nerve repair. Advantages include reduced neuroma and scar formation and shorter repair time. The main disadvantages are inferior tensile strength and the cost associated with laser treatment. While these studies demonstrate that laser-assisted nerve repair is feasible, application of the technique is likely to be limited if the outcome is not shown to be superior to conventional microsurgical neurorrhaphy.⁸⁹

42.15 Fluorescence Imaging and Photodynamic Therapy

Surgical resection of malignant astrocytomas improves quality of life and survival. However, complete resection of these tumors is frequently not possible because tumor margins are not readily distinguished from normal brain tissue. Laser-induced fluorescence (LIF) spectroscopy and imaging have been used to distinguish neoplastic from normal tissue.90 Normal brain tissue has a characteristic pattern of fluorescence when exposed to laser light.⁹¹ This is due to endogenous fluorophores present in normal brain tissue (autofluorescence). By combining autofluorescence with diffuse-reflectance spectroscopy one can readily distinguish tumor from infiltrated brain tissue. Lin et al. recently published their results with this method in 26 brain-tumor patients. 90 The sensitivity and specificity for differentiating normal brain from tumor and tumor-infiltrated brain was 100 and 76%, respectively. In order to enhance the demarcation further, exogenous fluorophores can be administered. Phthalocyanine tetrasulfonate is an exogenous fluorophore that accumulates preferentially in brain tumors. In a rat glioma model, surgical resection was guided by LIF.92 Thirty percent of animals in the LIF resection-guided group were tumor-free at 2 weeks compared to none in the visual-resection group. A high contrast ratio (40:1) between normal brain and tumor was achieved. A similar technique was used by Stummer et al. in 52 malignant-glioma patients.93 They utilized 5-aminolevulinic acid (5-ALA) to induce fluorescence of tumor cells in 52 glioblastoma patients and demonstrated that fluorescence-guided resection increased completeness of resection on postoperative MRI. Sensitivity and specificity of fluorescence-guided tumor identification of tumor were 85 and 100%, respectively.94

Despite the ability of LIF to demonstrate tumor margins, resection is sometimes not possible because the tumor has infiltrated functional (eloquent) brain tissue. Many of the fluorescent agents used for LIF diagnosis and resection guidance can also be used for photodynamic therapy (PDT). In PDT, laser light is used to activate a photosensitizing molecule to produce cytotoxic singlet oxygen that can result in selective destruction of microscopic tumor cells. The most common photosensitizer used for brain-tumor therapy has been hematoporphyrin derivative (HPD).⁹⁵ Studies indicate that when HPD is activated by laser light at 630 nm, patients with brain tumors can show significant tumor responses.^{96–98} Two large clinical studies for patients with recurrent gliomas demonstrated that PDT with laser light at 630 nm can increase survival.^{96,97} Higher laser-light doses appeared to be associated with increased survival.⁹⁷ The most common cause of treatment failure was local recurrence, which is most likely secondary to the limited tissue penetration of laser light at 630 nm. Muller and Wilson recorded light penetration of 630 nm laser light in human brain and gliomas intraoperatively.⁹⁹ The mean penetration depths for tumor,

tumor-infiltrated brain, and normal brain were 2.9 ± 1.5 mm, 2.4 ± 1.2 mm, and 1.5 ± 0.4 mm, respectively. 99 In general, increasing the wavelength of the activating laser light increases the penetration in brain tissue. However, the laser-light absorption of HPD over 630 nm is limited. Newer photosensitizers that can absorb laser light at longer wavelengths may allow for deeper tissue penetration and might be able to improve local recurrence rates. Benzoporphyrin derivative (BPD) is a second-generation photosensitizer that can effectively absorb laser light at 680 nm. 100 This could result in improved local tumor control but may also result in increased toxicity to normal brain tissue. In a canine glioma model, normal-brain-tissue toxicity occurred at high photosensitizer doses with Photofrin, a purified HPD. 95 This study illustrated that reducing the photosensitizer dose limited normal-brain-tissue toxicity without abrogating therapeutic efficacy. Animal studies with BPD indicate that the increased tissue penetration does not result in increased toxicity. 100

Encouraging results have been obtained with the application of lasers in LIF and PDT of brain tumors. Other light sources are being developed but are limited to broad-spectrum light output and low-energy light. The development of cheaper diode lasers and photosensitizers that absorb light at longer wavelengths for fluorescence-guided resection and adjuvant PDT after maximal resection could potentially improve the results of prior studies.

42.16 Lasers in Stereotactic and Functional Neurosurgery

As mentioned above, Kelly and colleagues integrated a CO₂ laser into a computer-assisted volumetric stereotactic system for the resection of intraaxial neoplasms.^{37–40,102,103} In 1986, they described this system³⁸ and its results in 41 patients. It involved initial reconstruction of tumor volume from computed tomography (CT) and magnetic resonance imaging (MRI) imaging data followed by a computer-monitored, stereotactically directed CO₂ laser to vaporize the intracranial tumor. A computer terminal was used to monitor the position of the laser in relation to reformatted planar slices through the tumor. In a separate paper, Kelly et al.³⁹ reported on 83 computer-assisted stereotactic laser procedures for tumor in 78 patients. No direct comparison to standard freehand microsurgery was performed, but the authors comment that the stereotactic laser technique was particularly useful in aggressive resection of deep-seated tumors from eloquent brain areas with acceptable postoperative results.¹⁰⁴ Kelly et al. also reported excellent results in excision of 12 colloid cysts of the third ventricle using this stereotactic microsurgical laser technique.¹⁰⁵

Neuroablative properties of lasers have also been used in functional neurosurgery. DREZ lesions and commissural myelotomies have been made by laser. 106-109 DREZ lesions, originally described by Nashold, 110 are used primarily for intractable pain following spinal-cord injury or brachial plexus avulsion, postherpetic neuralgia, and phantom limb pain. While the DREZ lesion is most often accomplished with radiofrequency ablation, lasers were used in several cases. For example, Powers et al. 109 used argon and CO₂ lasers to produce DREZ lesions in 21 patients with denervation pain syndromes.

Lasers have been used in adjunctive management of epileptic syndromes. Kelly et al.¹¹¹ treated 18 patients with medically intractable epilepsy with stereotactic amygdalohippocampectomy using a CO₂ laser. In addition, the same group reported on stereotactic laser treatment of epileptogenic lesions associated with tuberous sclerosis.¹¹² While effective, it is not clear that the laser technique has any advantage over conventional microsurgery in the treatment of epileptic syndromes.

42.17 Lasers in Neuroendoscopy

Endoscopic techniques in neurosurgery most commonly involve procedures to treat obstructive hydrocephalus. This includes endoscopic third ventriculocisternostomy and procedures to provide communication between loculated ventricular cavities. Lasers have been used to assist with these procedures. Powers¹¹³ used the argon laser to perform endoscopic fenestration in two infants with hydrocephalus and compartmentalization of the lateral ventricles due to ventriculitis. He later reported using the argon laser and a flexible steerable endoscope to accomplish endoscopic intraventricular cyst fenestration in seven patients.¹¹⁴ Bucholz and Pittman¹¹⁵ used an Nd:YAG laser to endoscopically coagulate the choroid plexus

in an infant with hydrocephalus. Vandertop et al.¹¹⁶ performed endoscopic laser third ventriculocisternostomy with an Nd:YAG laser and a new-generation diode laser in 33 patients without morbidity. Recently, Buki et al.¹¹⁷ used a newly developed combined pulsed holmium-YAG (Ho:YAG) and Nd:YAG laser to perform a variety of endoscopic procedures successfully.

Other investigators have coupled lasers with endoscopic systems to treat other lesions as well. Zamorano et al. 118,119 integrated image-guided stereotaxis with rigid–flexible endoscopy and the Nd:YAG laser (endoscopic laser stereotaxis) and found this system useful in cystic and intraventricular lesions. Similarly, Otsuki et al. 120,121 used a stereotactic guiding tube and endoscopes to deliver laser irradiation to deepseated brain tumors.

42.18 Summary

Initial experiments with ruby, CO2, Nd:YAG, and argon lasers led to many preclinical and a few clinical studies of laser application in various neurosurgical procedures. 122,123 The major advantages described include improved precision, reduction of surgically related mechanical trauma, reduction of blood loss, and decreased operative time. 10,124 Disadvantages include collateral thermal damage, potential danger to operating-room personnel, cost, and complexity. While effective cutting, vaporization, and hemostasis have been demonstrated, there are few instances where lasers are routinely used in modern clinical neurosurgery. In isolated instances, lasers are a useful adjunct therapy in tumor, vascular, and functional procedures. Lasers may be particularly useful in the treatment of lesions situated in critical areas (e.g., brainstem), or lesions that are difficult to reach surgically (such as intraventricular meningiomas or extraaxial skull-base tumors). However, the efficacy of bipolar cautery, ultrasonic aspiration, radiofrequency lesion making, and radiosurgery have left little room for application of lasers in current neurosurgical practice. Future applications of lasers in neurosurgery may involve evaluation of more precise thermal and nonthermal interactions with brain tissue. New high-power diode lasers may offer superior tissue-cutting and hemostatic properties as well as reduced cost.⁴³ Combined laser and ultrasound aspiration units are in development that could combine tissue disruption by ultrasound with coagulation by laser. 125 Furthermore, a new technique of "cold" laser ablation is being studied that involves ultrashort laser pulses to cause plasma-induced ablation of tumor tissue with minimal thermal spread.^{123,126}

43.1 Laser Surgery of the Anterior Segment of the Eye

43.1.1 Introduction

The eye is a transparent organ, and for the past 200 years its structural elements could be viewed by optical devices such as ophthalmoscopes and slit-lamp biomicroscopes. With the emergence of coherent-light sources, early efforts were made to use such sources in order to affect disease processes in the eye. Early on, other properties of laser were found to be helpful in the treatment of eye disease. Small spot sizes made it possible to avoid exposing unwanted structures. Coherence of light was found to be synonymous with a significant decrease of collateral damage to surrounding tissues. The ability to reflect visible laser light off mirrors made it possible to treat ocular structures that would otherwise be unreachable. The ability to drive coherent light through flexible optical fibers also made it possible to use lasers in the operating room, both with "open-sky" and endoscopic techniques.

At the same time that range lasers were developing, intraocular surgery techniques, which had been performed with magnifying eyeglasses, started being performed with operating microscopes. These microscopes, along with slit lamps and ophthalmoscopes, became the obvious delivery systems for coherent light into the eye. They were modified to allow coaxial placement of the light source along with the optical system and an aiming beam, mostly HeNe lasers of power small enough not to damage eye structures.

This chapter focuses on how different structures in the eye can be treated with different lasers; brief descriptions of the most common diseases involved are provided.

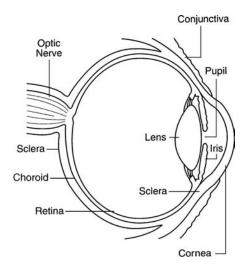

FIGURE 43.1 Cross section of the eye.

43.1.2 Functional Anatomy of the Eye

Figure 43.1 shows a cross section of the eye where the cornea is anterior and the optic nerve is posterior. The eye is arbitrarily divided into an anterior segment and a posterior segment whereby the dividing line between the two is a vertical line tangent to the posterior end of the ciliary body.

The cornea is a transparent organ responsible for most of the refracting power of the eye. There are no blood vessels within the cornea. Transparency is achieved by a structure of collagen-fiber packs that are perfectly parallel to one another. The bundles appear to be at various angles to one another in a two-dimensional view. However, in a three-dimensional (3D) view, they are parallel to each other. The cornea is continued by the sclera, which is made of collagen arranged in intersecting fibers. It is therefore nontransparent and serves as a wall protecting the inner structures of the eye. It has several holes within it to allow passage of several nerves and blood vessels, the largest of which is the optic nerve.

Behind the cornea is a space called the anterior chamber (AC). It is filled with fluid leaked from vessels in the ciliary body. These fluids travel in the space between the lens and iris, access the AC through the pupil, and are drained out of the eye via a drainage system located at the anterior chamber angle (ACA). A cross-section view shows that the ACA is located at the junction between the backside of the cornea and the periphery of the iris. A decreased rate of fluid drainage out of the eye does not reduce leakage; this produces a buildup in intraocular pressure called glaucoma. If excessive pressure is allowed to remain, blindness can result. Decrease in drainage may be induced by a disturbance in the structures of the ACA, hence the name open-angle glaucoma. If an eye has an inherent narrow access to the ACA and pressure builds up, it is called narrow-angle glaucoma. With a narrow angle, due to the buildup in pressure, the iris may be pushed forward and obstruct fluid access to the ACA. This condition is called angle-closure glaucoma. This condition is urgent and requires prompt treatment; otherwise, the eye could lose vision. A similar acute condition known as pupillary block can be induced by blockage of the passage between the iris, lens, and pupil.

The iris consists of two muscles designed to vary the diameter of the central aperture, the pupil. The sphincter decreases pupil size, while the dilator increases it. Behind the iris is a system consisting of the ciliary body and the lens. Both are connected by a network of thin fibers called zonules. The base of the ciliary body is anchored solidly to the sclera. The lens is made of a "bag" or capsule containing proteins of different densities. With respect to the cornea, the 3D molecular arrangement of both capsule and contents makes the lens transparent. The contraction and relaxation of the ciliary body makes the lens stretch and relax. This movement induces a change of the curvature of the front surface of the lens, making it possible to vary the focal distance of the refracting system of the eye (cornea and lens). This

capability decreases with age because of the decreased flexibility of the lens (presbyopia), hence the need for near correction with glasses. The lens can also become more opaque (cataract). When the opacity induces a significant decrease in vision, the lens is removed and replaced with a prosthetic lens. Behind the plane formed by the ciliary body and the back of the lens is a space filled by the vitreous. The posterior segment of the eye is comprised of clear vitreous gel and the back wall of the globe. The anatomic features of the back wall are the retina, choroids, and sclera. The vitreous cavity occupies four fifths of the volume of the globe. The vitreous gel is transparent, consisting of 99% water, mucopolysaccharide, and hyaluronic acid. It absorbs laser energy negligibly within the visible-light spectrum (Table 43.1).

The retina processes light into electrical impulses, which are transmitted by a network of nerves and fibers to the back of the brain (the occipital lobe), where these data are processed into images. The retina can be divided into the central retina, which includes the optic-nerve exit, and the macula. The macula has a higher density of retinal cells than the rest of the retina. As a result, it is responsible for better visual acuity with better resolution and color vision. The peripheral retina provides peripheral vision with less resolution and night vision. The retina is comprised of two layers: (1) an inner transparent neurosensory retina, consisting of neural (photoreceptors), glial, and vascular elements, and (2) an outer pigmented layer called retinal pigment epithelium (RPE), consisting of hexagonal-shaped cells important in the metabolic maintenance of the neurosensory retina. Of note, the cytoplasm of RPE cells contains multiple round and ovoid pigment granules or melanosomes. The retina has no physical attachment to the next layer, the choroid. It is maintained in place by capillarity. Therefore, if the retina breaks and fluid is allowed to invade the space between the retina and the choroid, the retina will detach (retinal detachment).

The choroid — the posterior portion of the uveal tract — nourishes the outer portion of the retina. It is a highly vascularized structure consisting of multiple layers of blood vessels and is separated from the RPE by Bruch's membrane, which is not a true membrane but rather a layer of PAS positive material. Bruch's membrane presents a barrier to large molecules and blood vessels but is permeable to small molecules.

The sclera is an essentially avascular structure consisting of dense connective tissue, fibroblasts, collagen, and ground substance.

43.1.3 Laser Surgery of the Cornea

The goal of laser surgery of the cornea is either to make incisions (linear,¹ curved, or circular) or, most commonly, alter the curvature of the front surface of the cornea. Table 43.1 details the relevant physical properties of the cornea. These numbers make clear that the anterior surface of the cornea has the greatest influence on the refractive power of the eye. This, combined with easy access, makes the anterior surface of the cornea the obvious target organ for surgery designed to alter the refraction of the eye.

43.1.3.1 Ultraviolet Lasers

Srinivasan² and Trokel supplied the basic ideas and tools to apply excimer lasers to refractive corneal surgery. Their experiments made it clear that the 193-nm ArF excimer laser provides a smooth ablation pattern, minimal thermal damage, and exquisite control of the depth of ablation. Based on the simplified Munnerlyn³ formula, an ablation depth (t_0) of 12 µm per diopter (D=1) is carried out for an ablation diameter, or optical zone (Z) of 6 mm that reflects the tight tolerances of such a system in order to be accurate.

TABLE 43.1 Optical Properties of the Cornea and Lens Based on Gullstrand's "Schematic Eye"

Diameter	12 mm
Thickness	0.55 mm
Refracting power, anterior surface	48.83 D
Refractive power, posterior surface	-5.88 D
Total refracting power of eye	58.64 D

$$t_0 = \frac{Z^2 \cdot D}{3} \tag{43.1}$$

The first clinical models of excimer lasers for refractive surgery were built by Meditec (Oberkochen, Germany), VISX (Santa Clara, CA), and Summit Technologies (Greenwood Village, CO). They included a delivery system similar to an operating microscope and a system of quartz lenses to guide the beam from the laser chamber to the eye. The laser beam was delivered via a scanning mechanism (Meditec) and as a broad beam (VISX and Summit). Beam-shape control was achieved with the use of physical masks (Meditec) and a shutter mechanism designed to vary the diameter of the beam (VISX and Summit). When these were used, a lens-like profile could be obtained, thereby flattening the central cornea and correcting spherical myopia.

An additional challenge in refractive surgery with the excimer laser was the correction of astigmatism. This involved an ablation pattern that would transform a toroidal surface into a spherical surface. This problem was solved by combining a variable slit opening to the shutter mechanism (VISX) and by interposing a proprietary "erodible mask" designed to vary the ablation profile in a customized fashion (Summit).

Additional strategies needed to be devised to treat high refractive errors. In the case of high myopia, an ablation pattern varying the optical zone has been devised. It allows for the significant reduction of the ablation depth by decreasing the size of the zone as the ablation becomes more central. Indeed, an ablation pattern of 6 mm initially reduced to 5 mm in mid-depth and to 4 mm at the deepest could save significant amounts of corneal tissue. Barraquer⁶ recognized the limit of ablation depth beyond which a significant number of complications would occur. The thickness of the residual cornea underlying the laser treatment area cannot be thinner than 250 μ m.

Additional refinements in the delivery of the beam to the target organ included a scanning wide beam (Nidek EC5000) and a combination of the same with an Axicon-type prism (VISX)⁷ designed to increase the ablation diameter to 9 mm to treat hyperopia (far sightedness). Indeed, the ablation profile for hyperopia involves steepening the original corneal profile. To accomplish this most of the ablation must be performed in the periphery of the ablation zone, thereby allowing a minimum of a 4- to 5-mm optical zone.

Further improvements in the delivery system included the technology of randomly applying a laser spot with a diameter of 1 mm. This method can theoretically create any possible ablation pattern over any size optical zone. The use of larger optical zones can in many cases reduce night glare if the border of the zone exceeds the diameter of the dilated pupil as it occurs in the dark. This delivery method carries with it the need for precise spot application and centration of the ablation pattern, hence the need for a tracking device of the eye as ablation proceeds.⁸ Alcon Autonomous Technologies (Fort Worth, TX) was the first to develop such a system and have it approved by the U.S. Food and Drug Administration (FDA) for all refractive surgical applications. Other manufacturers of lasers with similar technology are Bausch & Lomb (Rochester, NY) (Technolas 217) and LaserSight (Green Bay, WI).

The most recent advance in laser vision correction involves the use of wavefront technology in an attempt to correct higher-order optical aberrations. Most laser manufacturers have included this capability into their systems. In the United States, Alcon Autonomous Technologies and VISX are proceeding with FDA-guided clinical trials. The procedure includes obtaining data pertaining to higher-order aberrations as produced by a Tchernig Aberrometer or a Hartman Schack device. These data are used to modify the ablation pattern accordingly. Once the prospective trials are complete, an assessment could be made as to whether this technology improves visual acuity or quality.

There are two procedures for performing laser vision correction: photorefractive keratectomy (PRK) and laser-assisted *in situ* keratomileusis (LASIK). A third procedure, laser-assisted subepithelial keratomileusis (LASEK), has recently become popular.

PRK consists of removal of the superficial layer of the cornea (epithelium), either manually or by laser ablation. The refractive portion of the laser ablation is performed on the bulk of the cornea (stroma). A contact lens is inserted, and under the contact lens the epithelium regrows over the ablated area.

LASIK consists of using a mechanical device called a microkeratome to perform a partial-thickness round cut of the cornea. The cut is intentionally incomplete so that a hinge of tissue is left securing the flap of tissue thus formed in place. The flap is then lifted and the ablation performed on the exposed corneal stroma. The flap is replaced, and the anterior surface flattens or steepens as the flap conforms to the new profile made by the laser ablation. LASEK requires carefully displacing the corneal epithelium from the stroma after loosening the attachment between the two layers with diluted alcohol. A flap of epithelium secured by a hinge is formed and reflected. Ablation then proceeds on the underlying stroma. The epithelium is then replaced and smoothened.

Both procedures have pros and cons. PRK is simpler, and the surgery is safer because it does not involve the use of a microkeratome. After surgery, significant pain is experienced for 24 to 48 h. The healing is slow and may take several weeks. Superficial hazing of the cornea is relatively common, especially with higher corrections. LASIK is relatively less safe as it involves the use of a microkeratome with the complications specific to that surgical procedure. This is outweighed by very little pain after surgery and a fast recovery of optimal vision. With LASEK, no microkeratome is used. There is less pain than with PRK, and visual recovery time is better than with PRK but slower than with LASIK.

43.1.3.2 Infrared and Other Lasers

The use of ultraviolet lasers is complicated by the fact that they are gas lasers. Solid-state lasers could be simpler to build and maintain. Such systems could be miniaturized with relative ease. In addition, solid-state lasers within certain ranges of infrared could be used for other ophthalmic procedures on the iris, ACA, and lens.

The Novatec laser⁸ is a proprietary solid-state laser with a wavelength of $0.2 \mu m$, fluence of 100 mJ/cm^2 , a variable spot size between 10 and 500 μm , and optical zone of up to 10 mm. The laser showed promise in initial clinical trials but ultimately was not produced. Other infrared solid-state lasers were built for PRK and LASIK, but they were not commercially produced.

Other strategies of using infrared lasers for vision correction included shortening the pulse width of the beam. Earlier models showed that in addition to performing corneal surgery on the surface of the end organ, the beam could be focused inside the cornea and tissue altered with relatively little collateral tissue damage. Picosecond⁹ lasers were used with some success but never came to market. One of the most recent attempts at using this strategy is the emergence of a femtosecond laser (Intralase, Irvine, CA). The system can create a corneal flap without using a mechanical device and remove tissue within the deeper corneal stroma to create a change in curvature. Clinical trials are ongoing to assess the safety and efficacy of the system.

The Hyperion solid-state infrared laser produced by Sunrise Technologies (Winston-Salem, NC) 9 uses a different strategy and is FDA approved to correct hyperopia. It is a solid-state holmium:YAG (Ho:YAG) laser operating at a wavelength of 2.13 μ m and pulse duration of 250 μ sec. The spot size is 500 to 600 μ m. The treatment strategy (laser thermokeratoplasty, or LTK) consists of applying 8 to 16 simultaneous applications on the cornea in a ring pattern at a given distance from the corneal center, thereby inducing central steepening and correcting hyperopia by inducing collagen shrinkage around the laser applications. It is simple to perform and carries relatively low intraoperative risk. At the same time, the amount of correction is not as controlled as with excimer-laser procedures. The range of correction is limited, and in many cases regression of the correction occurs over time.

43.1.4 Laser Surgery of the Anterior Chamber Angle

Laser procedures here are designed to treat open-angle glaucoma. They target a collagen meshwork called the trabecular meshwork. This is the initial part of the system that drains fluid out of the eye. The surgical technique consists of driving a laser beam through a slit-lamp delivery system into a reflecting mirror. From there the beam travels at an angle into the target organ. Of the 360° of the ACA, 180° are treated at one time with an average of 50 applications per treatment. The mechanism of action is unclear. The most plausible explanation is that collagen shrinks at the treatment area, stretching wider open the

meshwork adjacent to the laser spots. The success rate of the procedure is reportedly up to 90% in the short term and decreases to 50% at 5 years after surgery.

The argon laser has been exclusively used for the past 20 years for this type of treatment, hence the name argon laser trabeculoplasty (ALT). The treatment parameters range as follows: energy = 800 to 1000 mW, spot size = 50 μ m, and exposure time = 0.1 sec. Recently, a new treatment modality of the ACA was introduced using a 532-nm, frequency-doubled, Q-switched neodymium:yttrium-aluminum-garnet (Nd:YAG) laser (Selecta 7000 model, Lumenis, Inc., Santa Clara, CA). The treatment strategy is similar to that of ALT, using 54 to 55 spots per treatment. Treatment parameters are as follows: spot size = 400 μ m, pulse duration = 3 nsec, and energy = 0.6 to 1.2 mJ. The mechanism of action is purported to produce a biological effect by targeting pigmented cells within the trabecular meshwork, hence the name selective laser trabeculoplasty (SLT). During FDA-guided trials, a 70% success rate was reported.

43.1.5 Laser Surgery of the Iris

Several laser surgical procedures are performed on the iris. There are three main goals with this type of surgery: (1) create a bypass between the space behind the iris and the AC to reduce eye pressure, (2) enlarge the approach to the ACA, and (3) enlarge pupil size. The argon laser described above and Nd:YAG lasers can be used. The Nd:YAG lasers (wavelength = 1064 nm) are mostly of the fundamental Q-switched type, paired with a HeNe laser for aiming. They induce photodisruption, which in turn releases a shockwave, thereby creating disruption of the iris fibers. The argon lasers induce mostly thermal damage of the tissue. Iris color is directly related to the efficacy of the two lasers. Argon lasers are more efficient in more pigmented (darker color) irides, whereas in lighter irides, the Nd:YAG laser is preferred. A collimating lens placed on the eye can reduce laser energy.

43.1.5.1 Laser Iridotomy

This procedure is designed to create a bypassing hole in the iris to allow fluid trapped behind it to flow to the AC. Fluid blockage occurs due to closure of the ACA or to pupillary block. Both argon 12 and Nd:YAG 13 lasers can be used — separately or in combination. Laser parameters for the argon laser are energy = 800 to 1000 mW, diameter = 50 μ m, and exposure time = 0.1 sec. A total of 40 to 80 applications are used. For the Nd:YAG laser, energy = 3 to 7 mJ, and four to ten applications are used.

43.1.5.2 Laser Iridoplasty (Gonioplasty)

This procedure 14 is designed to enlarge the approach to the ACA by thinning the peripheral iris using the thermal damage to tissue induced by the argon laser. Thermal damage is followed by atrophy of the tissue and therefore is thinned. Several applications are made in a 360° circular pattern. One or more rows can be applied. Laser parameters are energy = 400 to 600 mW, diameter = 400 μm , and exposure time = 0.2 to 0.4 sec.

43.1.5.3 Laser Photomydriasis

This procedure is designed to increase the size of the pupil by using a technique similar to laser iridoplasty. Laser applications are guided as close as possible to the margin of the pupil. The same type of laser—tissue interaction eventually induces atrophy of the iris muscle, which closes the pupil (iris sphincter). A small pupil can be induced by drugs or by previous disease, causing adhesion of the iris to the lens. Its enlargement is sought mainly to better view the inside of the eye.

43.1.6 Laser Surgery of the Ciliary Body

The ciliary body is the structure least accessible to viewing and laser treatment because of its location, which is immediately behind the peripheral iris. The goal of laser treatment of the ciliary body is to decrease intraocular pressure. Indeed, vessels in this structure leak fluid into the eye, and a decrease in

fluid outflow could regulate better eye pressure. There are three approaches to laser treatment of the ciliary body.

43.1.6.1 Laser Cyclophotocoagulation

Direct treatment of the ciliary body with the argon laser is possible only if a sector of the iris was previously removed by surgery. Typical laser settings are mean energy = 400 mW, diameter = 100 μ m, and exposure time = 0.1 to 0.2 sec.

43.1.6.2 Endolaser Cyclophotocoagulation

In this procedure,¹⁵ the ciliary body is visualized and treated via a fiber optic with the argon laser. This involves a major surgical procedure, as the surrounding vitreous must be removed. The treatment cannot be applied if the lens has not been removed.

43.1.6.3 Transscleral Cyclophotocoagulation

The third approach to the ciliary body involves using a laser beam to irradiate the overlying sclera. Laser energy is transmitted via the sclera to the ciliary body. Laser–tissue interaction reflects mostly transformation of laser energy to thermal energy. Two methodologies can be applied: noncontact treatment can be provided with an Nd:YAG laser. A typical treatment consists of 32 applications of 8 J each to the 360° circumference of the ciliary body. The LASAG Microruptor® laser can be used for the treatment. Contact transscleral treatment (the probe is applied to the sclera overlying the ciliary body) can be performed with a gallium-aluminum-arsenide diode laser emitting at 810 nm. In Inc.

43.1.7 Laser Surgery of the Lens

The lens may become opaque over time, leading to a condition called cataract. Modern cataract surgery involves opening the lens capsule (bag), liquefying and aspirating the protein contents, and inserting a prosthetic lens implant into the remaining bag. After surgery the back of the bag (posterior capsule) may get opaque, and an opening must be made to recover good vision. Lasers can be used for both liquefying and aspirating (phakoemulsification) and for perforating the posterior capsule (capsulotomy), if needed later.

43.1.7.1 Laser Phakoemulsification

Erbium YAG (Er:YAG)¹⁸ and Nd:YAG¹⁹ laser systems are available for lens emulsification. The Nd:YAG system is manufactured by A.R.C. Laser AG (Jona, Switzerland) and is named The Dodick Photolysis System® after its inventor. The energy is delivered through a handheld probe containing a quartz fiber optic and is focused on a titanium target within the probe tip. Each pulse releases 12 mJ over 14 nsec. The pulse impacts the titanium target, leading to plasma formation. The ensuing shockwave fragments the lens proteins, which are aspirated through the same hand piece. The Er:YAG system is made by several manufacturers. It includes a hand piece containing a zirconium fluoride fiber optic to drive laser energy and an irrigation and aspiration system. Because of the water content of the lens, this laser can effectively emulsify this tissue. Data published for the Aesculap-Meditec MCL 29 model show that application frequency was between 20 to 60 Hz. For a typical phakoemulsification, the mean number of pulses was 1740, mean total energy was 38.5 J, and mean treatment time was 3 min.

43.1.7.2 Laser Posterior Capsulotomy

This procedure²⁰ was the first application of the Nd:YAG laser in ophthalmology and is now a well-established routine procedure. The system consists of an Nd:YAG laser delivered via a slit lamp and guided with a HeNe beam. A collimating lens can be applied to the eye to decrease the energy necessary to induce a central rupture of the posterior capsule. Typical settings are energy = 2 to 3 mJ and number of applications = 5 to 20. The laser–tissue interaction includes plasma formation followed by tissue disruption, mostly by the shockwave induced.

43.2 Laser Surgery of the Posterior Segment of the Eye

43.2.1 Pathophysiologic Considerations

Diseases within the posterior segment of the eye can be classified as conditions that (1) overlie the neurosensory retina, (2) lie within the neurosensory retina, (3) lie completely through the neurosensory retina, and (4) underlie the neurosensory retina. Various laser therapies have been developed to address all these conditions.

Abnormal tissue growth above the neurosensory retina can be vascular tissue or fibrous tissue. Such disease conditions include epiretinal membranes and abnormal neovascularization (known as neovascular proliferation) associated with retinal ischemia (i.e., diabetic retinopathy, sickle-cell retinopathy, and retinopathy of prematurity). The various laser treatments discussed below have been designed to remove such abnormal tissue.

Disease processes that occur within the substance of the neurosensory retina are typically associated with abnormal leakage of serum or incompetence from retinal vascular. Leakage into the neurosensory retina causes damage to the normal retinal architecture, thereby destroying vision. Many vascular diseases, such as diabetic macular edema, retinal-vein occlusions, retinal-vessel telangiectasia, and retinal-arterial macroaneurysms, can cause this type of direct damage to the neurosensory retina.

Disease processes that involve the entire neurosensory retina are typically retinal holes or retinal tears. These conditions are significant because they can develop into retinal detachments, which are vision-threatening conditions.

Lastly, abnormal conditions can develop below or under the neurosensory retina, causing retinal disease and vision loss. Abnormal vascular tissue (choroidal neovascular membrane) can grow under the retina, causing damage to the normal retinal architecture and resulting in vision loss. Examples of these conditions include exudative macular degeneration, myopic degeneration, and ocular histoplasmosis. In addition, abnormal tumor cells and other tissues (hamartomas), such as choroidal melanoma, metastatic carcinomas, and choroidal hemagioma, can grow under the neurosensory retina.

43.2.1.1 Light Absorption

Melanin, hemoglobin, and macular xanthophyll represent the three most significant light absorbers in the retina and choroid. Melanin is the most significant chorioretinal light absorber. Its light absorption gradually decreases with increasing wavelength, thereby allowing longer laser wavelengths, such as krypton, red light, and diode infrared light, to produce deeper chorioretinal lesions than occurs with shorter-wavelength argon green laser light (Figure 43.2).

Hemoglobin is the next most effective light absorber. Hemoglobin absorption also decreases with increasing wavelength; however, there are two peaks in the absorption spectrum of oxyhemoglobin (542 nm, green; 577 nm, yellow) and one absorption peak for reduced hemoglobin (555 nm, yellow). Hemoglobin absorbs blue, green, and yellow light well but has poor red-light absorption.

Xanthophyll in the macular region of the retina is the least effective light absorber. Macular xanthophylls absorb blue-wavelength light well, green light minimally, and yellow to red light poorly.

43.2.1.2 Temperature Changes

Various forms of laser photocoagulation cause different temperature rises within the retina. Melanin within the RPE and choroid acts as the primary light absorber in retinal photocoagulation. Light absorption converts laser radiation into heat energy, increasing the temperature of light-absorbing tissues. Temperature rise is proportional to retinal irradiance (laser power/area) for a particular wavelength, spot size, and exposure duration.²¹ Heat conduction spreads temperature increases from the light-absorbing RPE and choroid to contiguous tissues. For very long exposures, heat convection, because of choroidal blood flow, moderates chorioretinal temperature rise.

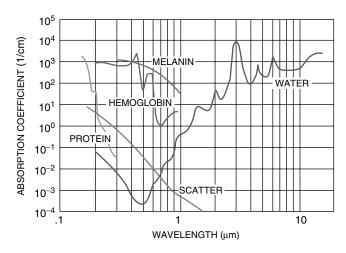

FIGURE 43.2 Laser absorption and tissue penetration.

43.2.2 Tissue Photocoagulation

Conventional short-pulse photocoagulation is a highly suprathreshold procedure, associated with temperature increases of 40 to 60°C above normal body temperature of 37°C.²¹ Most ophthalmic lasers in use today exemplify this concept of short-pulse tissue photocoagulation. Various laser wavelengths are used to accomplish this: (1) argon blue (488 nm), (2) argon blue/green (514.5 nm), (3) krypton red (647 nm), (4) dye (577 to 630 nm), (5) diode (810 nm), and (6) frequency-doubled Nd:YAG (532 nm).

This concept of short-pulse tissue photocoagulation has been successfully applied to treat a wide variety of ocular conditions. In essence, they can be divided into five broad categories:

- Focal treatment of leaking microvascular or macrovascular abnormalities. Focal-tissue obliteration
 of leaks and grid-laser treatment to damage leaking capillary beds are used. Examples are diabetic
 macular edema, branch-vein occlusion, radiation retinopathy, and idiopathic perifoveal telangiectasias.^{22,23}
- 2. Panretinal photocoagulation for treatment of proliferative retinopathies or neovascularization of the iris. Examples include proliferative diabetic retinopathy, sickle cell retinopathy, central retinal-vein occlusion with rubeosis, proliferative disease following radiation retinopathy, and proliferation associated with branch-vein occlusion.^{24–26}
- 3. Treatment or prevention of retinal detachment. Examples include treatment of retinal breaks, demarcation of subclinical retinal detachment, and treatment of lattice degeneration.²⁷
- 4. Treatment of ocular tumors and neoplasms. Examples include choroidal melanoma, retinoblastoma, choroidal cavernous hemangioma, and angioma (Von Hippel disease).^{28,29}
- 5. Treatment of choroidal neovascular membrane or focal choroidal lesions. Examples include central serous retinopathy, age-related macular degeneration (AMD), presumed ocular histoplasmosis, myopia degeneration, and idiopathic polypoidal choroidal vasculopathy.^{30–33}

Multiple different wavelengths have been used to treat the above conditions. Several generalities exist regarding the use of various wavelengths. Argon green appears to have advantages over blue light only if there is less damage when treatment is placed near the fovea due to less absorption by the retinal xanthophyll and there is more light scatter. Krypton red may have advantages in patients with hazy ocular media. The deeper the penetration of laser energy into the choroid (krypton red and diode), the more pain is associated with treatment.

Diode lasers emit laser energy at a wavelength of 810 nm. This longer wavelength can be absorbed by all three ocular pigments — hemoglobin, melanin, and xanthophyll — albeit inefficiently. Because of the

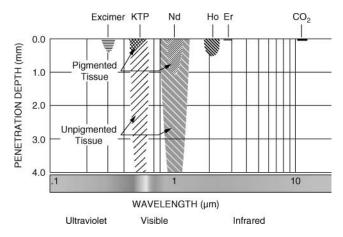

FIGURE 43.3 Tissue penetration characteristics.

inefficient absorption of this wavelength, diode-laser energy can penetrate deeper into the choroidal layer of the eye (Figure 43.3). It therefore has theoretical advantages over other wavelengths in treating retinal pathology located deeper within the eye. This theoretical advantage, however, has not been noted in clinical studies. Diode-laser photocoagulation has been used to treat all the conditions effectively treated by argon green and yellow and krypton red laser photocoagulation, with similar, but not better, results. It has proven particularly effective in the treatment of retinopathy of prematurity, a blinding condition in neonatal infants, and is the laser wavelength of choice.³⁴ Unfortunately, the deeper penetration of the diode laser energy in the eye also causes more pain stimulation than with shorter wavelengths.

43.2.3 Thermotherapy

Thermotherapy, the treatment of tissue disorders by causing a rise in tissue temperature, is another novel medical approach. Retinal temperature rise in laser therapy is proportional to retinal irradiance (laser power/area) for a particular spot size, exposure duration, and wavelength.¹ Transpupillary thermotherapy (TTT) is a low-irradiance, large-spot-size, and prolonged-exposure (long-pulse) laser treatment using infrared diode-laser energy. TTT has been successfully used to treat intraocular tumors such as choroidal melanoma and choroidal hemangioma.³5-37 Recently, long-pulse TTT has been advocated in the treatment of choroidal neovascularization in AMD.³8,39

Maximal chorioretinal temperature rise in short- or long-pulse intraocular or transpupillary photocoagulation occurs at the inner surface of the RPE and in the center of the laser spot. In long-pulse TTT for choroidal neovascularization in macular degeneration, an 810-nm infrared diode laser is used with a 3-mm-diameter retinal spot size and a 60-sec exposure. For these parameters, maximal temperature rise is roughly 10°C for a typical 800-mW clinical power setting used in treating CNVM in a lightly pigmented fundus.³⁸ In comparison, even a 50-mW 0.1-sec, 200-µm argon laser exposure produces a 42°C RPE temperature rise.⁴⁰ In photodynamic therapy (PDT), discussed later in this chapter, a 3-mm-diameter, 0.6-W/cm², 83-sec, 689-nm exposure causes a maximal RPE temperature rise of less than 2°C.²¹ Actual temperature increases are somewhat lower than maximal increases calculated for TTT and PDT because of the cooling effect of choroidal circulation.

43.2.4 Photodynamic Therapy

PDT requires administration of a photosensitizing dye and activation of the dye by light irradiation at the target tissue. This usually causes activation of the dye to a higher state, releasing singlet oxygen and causing tissue-cell injury. This process accomplishes destruction of abnormal blood vessels.

Many photosensitizing dyes are available including rose bengal, hematoporphyrin, Photofrin®, benzoporphyrin, tin etiopurpura, chlorinae 6, bacterochlorinae, and chaloalimium sulfonated phthalocyanine.

The laser light used to activate the photosensitized dye coincides with the absorption maximum of the photosensitizer. A better dye would localize preferentially to the target, minimizing collateral damage. An additional desirable feature would be a relatively short half-life, thereby minimizing the potential general side effects of environmental light exposure.

In ophthalmology, PDT lends itself to treatment of CNVMs and tumors. The photosensitizing dye can be allowed to accumulate in these pathologic tissues without accumulating in normal tissues and structures. In CNVM and tumor treatment, the damage is done by singlet-oxygen damage of the endothelial wall, which leads to vessel closure. PDT is therefore a nonthermal treatment. Today, only Vertiporphyrin (VisudyneTM, QLT Pharmaceuticals, Vancouver, Canada) has been approved for clinical use for the treatment of classic CNVM in AMD.^{41–44}

43.2.5 Selective Retinal Pigment Epithelial Photocoagulation

Micropulse laser treatment, with pulse durations from nanoseconds to microseconds, has been shown to cause selective damage to RPE tissue, sparing the neurosensory retina altogether. Again this has theoretical advantages over shorter-wavelength treatment, especially in conditions originating in the RPE and choroidal layers. This treatment is limited by the lack of a visible change in the retinal appearance with laser application, making it difficult to assess adequate treatment. Several laser systems have been tested to create this selective type of tissue damage including Q-switched Nd:YAG, micropulsed diode, micropulsed argon, and neodymium:yttrium-lithium-fluoride (Nd:YLF). It has been suggested that treatment above the ablation threshold may reduce untoward thermal and mechanical effects. 45,46

43.2.6 Photodisruption

Various laser systems have been used to create tissue photodisruption in the posterior segment of the eye. Practical considerations for all these systems include their method of delivery and ease of use. Fiber optics wear out or are not easily bendable without breaking their tips and can become coated, losing their effectiveness. Also, cavitation can occur, making visualization during surgery difficult.

43.2.6.1 Carbon Dioxide Laser

Wavelength of 10.6 um (infrared spectrum) has been used intraocularly to phototransect and simultaneously coagulate vitreoretinal membranes. Because of the absorption of energy by water, all of the effect is at the point of impact at the target tissue. An advantage of this wavelength is its ability to treat on top of critical structures. The $\rm CO_2$ laser does not require pigment to accomplish cutting or coagulation. The major disadvantage of the $\rm CO_2$ laser is that it requires direct contact with the treating tissue. With too much pressure, a tear in the retina may occur. It cannot be delivered easily by fiber optic, an additional disadvantage. 47,48

43.2.6.2 Ho:YAG Laser

Wavelength of 2.12 µm can be transmitted by flexible optical fibers with little power attenuation. Due to transmission, the beam must be shielded to prevent underlying retinal burns or hemorrhage. It has been used successfully to cut experimental vitreous membranes in rabbits.⁴⁹

43.2.6.3 Sapphire-Tipped Nd:YAG Laser

Sapphire crystal has been used at the tip of various laser probes to deliver energy to the target tissue. The sapphire crystals do not alter the laser energy or transmission. The crystal has a high meeting point and low thermal conductivity and is mechanically strong. This tip can deliver Nd:YAG and argon energy. The Nd:YAG has been used clinically to coagulate retina and internally to transect vitreoretinal membranes.⁵⁰

43.2.5.4 Er:YAG Laser (2.94 µm)

The Er:YAG laser offers almost complete absorption of laser energy in water with little transmission. It has been used through intraocular fiber-optic delivery systems to photovaporize membranes in rabbits. In addition, it has been used in humans in two clinical studies, treating elevated membranes and vascularized diabetic preretinal membranes, creating retinotomies, and ablating epiretinal membranes. Recent trials showed that ablation was time-consuming and coagulation poor. Complications noted included hemorrhage, retinal breaks, and intraocular lens damage.^{51,52}

43.2.5.5 Picosecond Nd:YLF Laser

A power level of 1053 nm (operating in picoseconds) may have high power, short pulse, and high repotion and may reduce breakdown of ocular tissues adjacent to target tissue. A pulse rate of 1000 per second for up to 10 sec allows segmentation of tissue near the retinal surface and has been used clinically in diabetic patients.⁵³

43.2.5.6 Nd:YAG Phototransection (1.06 µm)

Vitreoretinal membranes may be cut in vitreous or AC. Because of explosive cutting, this should not be used within 3 mm of the retina. A contact lens is used to focus, and burst mode is used to cut. A 100-psec Nd:YAG laser pulsing at 50 to 200 Hz achieved optical breakdown and vitreous cutting using only 70 uJ of energy.^{54,55}

43.3 Summary

Coherent-light sources with novel laser-energy delivery systems are well suited in the treatment of many ophthalmologic conditions. Various laser-energy wavelengths have been used effectively in ophthalmic medicine and continue to be the mainstay of many treatment therapies. Novel uses of new laser-energy sources and wavelengths will undoubtedly become possible in the future.

44.1 Introduction

The laser and its role in otolaryngology begin just after Theodore Maiman made the first ruby laser on May 16, 1960.¹ In the early 1960s, as ophthalmologists² and dermatologists³,⁴ experimented with lasers, otolaryngologists first considered different methods of using pulsed-laser systems in the middle ear and labyrinth.⁵,⁶ During this time, Geza Jako began studying the effects of laser energy on human vocal folds.⁶ His first attempts at tissue ablation were made with the neodymium-glass laser, with a wavelength of 1.06 μm. The absorption characteristics of the tissue were not suitable for precise excision with this wavelength of light. In 1965, Strully and Yahr tried to enhance the absorption of the tissue by painting the tissue with a copper sulfate solution.⁶ The results were still unsatisfactory. They found at least three problems associated with using the laser: (1) they needed higher intensity levels; (2) they could produce only small lesions; and (3) they were left with significant thermal destruction of the tissue surrounding the laser-ablation site.

Starting in 1967, Polanyi experimented with the CO_2 laser in a human cadaver larynx and was encouraged by its ability to produce discrete wounds. The 10.6- μ m wavelength of the CO_2 laser is strongly absorbed by water ($\alpha = 250 \text{ cm}^{-1}$). Therefore, biological tissue, which is high in water content, absorbs laser energy well. The energy is concentrated at the point of laser impact, and comparatively minimal spread through surrounding tissue occurs. In addition, the longer wavelength at 10.6 μ m shows minimal scattering of the laser light in tissue. Polanyi's work was spurred by the development of an endoscopic delivery system that made it possible to test the laser *in vivo*. 11,12 In 1972, Jako⁷ and Strong and Jako¹³ reported the initial use of this new equipment in a canine model.

The most common application of the medical laser in otolaryngology is for tissue ablation. It is therefore not surprising that the most commonly used laser in otolaryngology is the CO_2 laser. The 10.6- μ m light from the CO_2 laser can create intense localized heating sufficient to vaporize both extra- and intracellular water, producing a coagulative necrosis. ^{14–16}

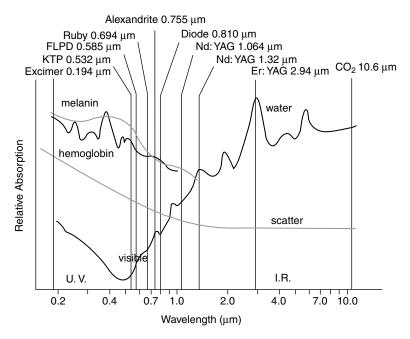

FIGURE 44.1 The electromagnetic spectrum from the ultraviolet, through the visible, to the mid-infrared. The absorption spectra of major tissue chromophores, hemoglobin, melanin, and water are shown. The limit of penetration depth due to scatter is shown. The wavelengths of several important medical lasers have been added.

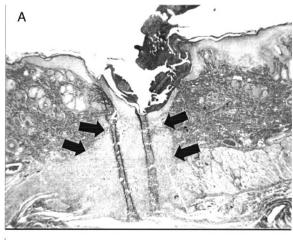

44.2 Laser Use

The tissue effects produced by the laser vary with the wavelength and pulse structure of the laser (Figure 44.1). The interaction of laser energy with living tissue can produce at least three distinct reactions. First, the laser energy can be absorbed by chromophores within the tissue. ^{17,18} For example, water is the chromophore for the CO_2 laser, and hemoglobin is often the chromophore for the potassium-titanyl-phosphate (KTP or KTP/532) laser. The absorption of the light energy by the tissue is then converted into heat. This is the thermal effect used today with most conventional surgical laser systems.

The second reaction, the radiant energy of a laser, can stimulate or react with molecules within a cell. 19-22 These molecules, after the absorption of the light energy, effect a biomolecular chemical change within the cell. This change is termed photochemical. An example of a photochemical process is the reaction that occurs with the injection of a photosensitizing drug into tissue and the subsequent biochemical effect that is produced when the drug is activated by the laser energy.

Third, the use of short pulses of high-intensity laser light can disrupt cellular architecture because of the production of stress-transient waves or photoacoustic shockwaves. The short burst of light causes rapid heating and thermal expansion of a small volume of the tissue. The expansion causes an acoustic wave to propagate from the source. This mechanical disruption of tissue is an example of a nonthermal tissue effect.²³

Several studies comparing the histologic and tensile properties of wounds after laser and scalpel-produced incisions on experimental animals have been performed (Figure 44.2). As early as 1971, Hall demonstrated that the tensile strength in a CO₂ laser–induced incision was less than the scalpel incision up to the 20th day of healing and became the same by the 40th day. Later, in 1981, Norris and Mullarky studied the healing properties of CO₂ laser incisions using a porcine model histologically. They showed that scalpel-induced incisions exhibited better tissue reconstruction than laser-induced incisions up to the 30th day, after which time both incisions exhibited similar results. In a similar study presented in

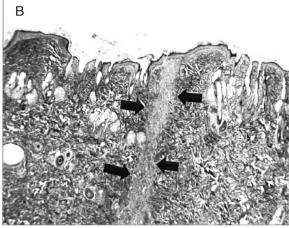

FIGURE 44.2 Histological sections of incisions made to rat skin after (A) CO_2 laser incision made with 5-W, 0.2-sec repeat-pulse mode and focused to 125 μ m and (B) scalpel incision. The wounds were harvested 7 d after the incisions were made. A wide band of denatured collagen (marked with arrows) is shown in (A). The tissue has reepithelialized, and a large amount of coagulum is seen on the surface. A narrow band of new collagen (marked with arrows) is shown in (B). The laser incision (A) shows the most pronounced delay in wound healing at its early (7-d) time point.

1983, Buell and Schuller created CO₂ laser incisions in pigs and compared them to scalpel incisions.²⁵ They found the laser wound to be weaker in tensile strength than the scalpel wounds for the first 3 weeks. For all the advantages of the laser, including hands-off operation and hemostasis, the delay in wound

healing caused by the lateral thermal damage remains a problem. When the otolaryngologist decides to use the laser, all of the advantages must be weighed against the disadvantages and the potential for increased morbidity. Thus, the surgeon must be informed and aware of how the laser interacts with the tissue.

44.2.1 Types of Lasers

Various types of lasers are currently used in otolaryngology head and neck surgery. Each laser will be explained and the range of applications given. Of course, this list is constantly changing. In general, any laser is first tried in many different applications, and use becomes better defined and more specific as the surgeon gains experience with the laser.

44.2.1.1 The Argon Ion Laser

The argon ion laser (frequently called the argon laser), with wavelengths of 514 nm (green in color) and 488 nm (blue in color), is operated in the continuous-wave (CW) mode, can be delivered through optical fibers, and is used in cutaneous applications as well as stapedotomies. This laser normally has special electrical-power requirements and needs tap water for cooling the laser. The argon laser energy is poorly absorbed by clear liquids. Hemoglobin and melanin strongly absorb the laser light. The argon laser can be used to treat vascular cutaneous lesions because of its absorption by melanin and hemoglobin.²⁶

Focusing the argon laser beam to a small spot size results in high-power densities sufficient to vaporize tissue. Otologists have used the argon laser to perform stapedectomy procedures because of its ability to be focused to the small spot size and the optical-fiber delivery system.^{27,28} Another otologic application of this laser is the lysis of middle ear adhesions.²⁹

44.2.1.2 The KTP/532 Laser

Like the argon laser, the KTP or KTP/532 laser emits light at 532 nm (green color) in a quasi-CW mode and can be delivered through optical fibers. The single wavelength of the KTP laser is centered on a hemoglobin-absorption band. The laser normally does not have any special power requirements and does not require external water to cool the laser. The lasing source is a neodymium:yttrium-aluminumgarnet (Nd:YAG) laser. The Nd:YAG laser rod is continuously pumped with a krypton arc lamp and Q-switched. The Q-switching process changes the CW operation to quasi-CW. The light is emitted in a series of short pulses that repeat so quickly that the light appears to the human eye to be CW. The pulsed 1.06-µm light traverses a frequency-doubling KTP crystal, yielding the quasi-CW 532-nm green light.

Like the argon laser, the radiant energy from the KTP laser is readily transmitted through clear aqueous tissues because it has a low water-absorption coefficient. Certain tissue pigments, such as melanin and hemoglobin, absorb the KTP-laser light effectively. When low levels of green laser light interact with highly pigmented tissues, a localized coagulation takes place within these tissues. The KTP laser can be selected for procedures requiring precise surgical excision with minimal damage to surrounding tissue, vaporization, or photocoagulation. The power density chosen for a given application determines the tissue interaction achieved at the operative site.

The KTP laser is transmitted through a flexible fiber-optic delivery system, which can be used in association with a micromanipulator attached to an operating microscope or freehand in association with various hand-held delivery probes having several different tip angles. These hand-held probes facilitate use of the KTP laser for functional endoscopic sinus surgery and other intranasal,³⁰ otologic,³¹ and microlaryngeal applications.³² The optical-fiber delivery of the 532-nm laser light can be manipulated through a rigid pediatric bronchoscope as small as 3.0 mm, facilitating lower tracheal and endobronchial lesion treatment in infants and neonates.³³ Examples of handheld KTP laser applications include tonsillectomy,^{34–38} stapedectomy,^{39,40} excision of acoustic neuroma,⁴¹ and excision of benign and malignant laryngeal lesions.⁴²

44.2.1.3 The Nd:YAG Laser

The Nd:YAG laser at 1.06 µm (near-infrared [NIR] region of the spectrum) has the deepest penetration depth of any of the common surgical lasers. This laser can produce a zone of thermal coagulation and necrosis that extends up to 4 mm from the impact site. The CW light can also be delivered through optical fibers. The laser normally does not have any special power requirements and does not need external cooling water.

The primary applications for the Nd:YAG laser in otolaryngology head and neck surgery include palliation of obstructing tracheobronchial lesions,^{43–47} palliation of obstructing esophageal lesions,⁴⁸ photocoagulation of vascular lesions of the head and neck,^{49,50} and photocoagulation of lymphatic malformations.⁵¹ The Nd:YAG laser has several distinct advantages in the management of obstructing lesions of the tracheobronchial tree. Hemorrhage is a frequent and dangerous complication associated with laser bronchoscopy, and its control is extremely important. Control of hemorrhage is more secure with this laser because of its deep penetration in tissue. Nd:YAG-laser application through an open, rigid

bronchoscope allows for multiple distal suction capabilities simultaneous with laser application and rapid removal of tumor fragments and debris to prevent hypoxemia.

The major disadvantage of the Nd:YAG laser is its less predictable depth of tissue penetration. This laser is used primarily to photocoagulate tumor masses rapidly at power settings in the upper and lower aerodigestive tract of 40 to 50 W and 0.5- to 1.0-sec exposures. Whenever possible, the laser beam is applied parallel to the wall of the tracheobronchial tree. The rigid tip of the bronchoscope is used mechanically to separate the devascularized tumor mass from the wall of the tracheobronchial tree.

44.2.1.4 Other Lasers

Other lasers include the flashlamp excited-dye laser (FEDL). This laser operates at 585 nm with pulses of light approximately 0.4 msec long. The parameters have been optimized for the selective treatment of vascular lesions with minimal damage to the dermis. The light is delivered through an optical fiber. The laser normally requires 220 V and cooling water. Another laser developed for cutaneous applications is the argon pumped-dye laser. 52,53 Here the wavelength can be varied from 488 nm through the red region of the spectrum (800 nm). The CW light is delivered through an optical fiber. This laser has special electrical requirements and requires a significant flow of tap water for cooling.

Recent investigations have considered the diode laser. These small lasers operated in the red to NIR region of the spectrum. They are small and require no water for cooling. The lasers operate in CW mode, and the light is delivered through an optical fiber. The intensities are relatively low. They have been investigated for photodynamic therapy and tissue welding.^{54–56} The diode laser has also been investigated to shrink the tonsillar tissue without damaging the overlying mucosal layer.⁵⁷ This is the first step toward tonsillectomies that are relatively painless and with no loss of blood.

44.2.1.5 The CO₂ Laser

The workhorse of surgery, the CO_2 laser operates at 10.6 μ m. The invisible infrared CO_2 laser beam has a coaxial helium-neon laser or diode laser beam to act as a pointing beam. This laser does not have special electrical requirements and is normally air-cooled. The wavelength of the CO_2 laser is strongly absorbed by water. Therefore, the light energy of this laser is well absorbed by all tissues of high water content. The mid-infrared light at 10.6 μ m cannot propagate through glass or sapphire optical fibers and is normally delivered through an articulated arm. In addition, silver halide optical fibers for the CO_2 laser as well as waveguides have recently been introduced to the market. The laser energy can be delivered to tissue either through a hand piece for macroscopic surgery or adapted to an operating microscope for microscopic surgery. The universal endoscopic coupler also allows for delivery of the laser energy through a rigid bronchoscope. The universal endoscopic coupler also allows for delivery of the laser energy through a rigid bronchoscope.

44.3 Microscopic Applications

Laser technology is being coupled with additional new instrumentation for the laser surgeon, especially newer devices that have recently been introduced to deliver the laser beam. Often hospitals will update their equipment on a regular basis. It is mandatory for the surgeon to be completely familiar with the laser unit and the delivery system before any patient application is attempted. Power output, spot size, and, therefore, power density can vary and cannot always be extrapolated from one unit to another.

The lasers and the wavelengths presented above may all be adapted for use with the binocular operating microscope. The argon, KTP, diode, and Nd:YAG lasers may be used with optical-fiber delivery probes that are threaded through a suction catheter. The optical fibers are used in either a contact or noncontact mode. The CO₂ and KTP lasers have the added feature of being delivered by an optical system with a micromanipulator. This allows precise, noncontact delivery at a predetermined focal length.

Microscopic delivery systems for the CO₂ laser have evolved since the initial endoscopic couplers. Several problems, including parallax error and a large spot size, have been overcome in the newest generation of micromanipulators. Perhaps the most significant change in the micromanipulator has been the addition of the partially reflective dichroic mirror. This mirror allows reflection of the CO₂ laser while

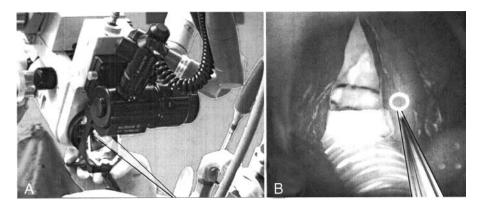

FIGURE 44.3 (A) A scanning device is coupled with a microscope micromanipulator for laryngeal surgery. This scanner scans the beam in a spiral pattern. (B) The area that will be ablated is shown by the circle drawn by the aiming beam. This area ablation is effective for removing papilloma. The beam is aiming at the vocal fold. A laser-safe endotracheal tube is used, and the cuff is protected by saline-soaked cottonoids.

permitting transmission of almost 75% of visible light.⁶¹ The larger beam diameter possible with the dichroic mirror also allows the spot size to be reduced from 800 μ m to 200 to 250 μ m.⁶² As the thermal effects of laser applications have become better understood the desirability of using a smaller spot size for tissue interaction has become evident.

Two devices that work with the micromanipulator to scan the beam in a straight line or over a circular pattern are now available (Figure 44.3). These devices allow the lasers to operate in the superpulse mode and significantly reduce lateral thermal damage. They also permit an even fluence of laser energy to impact the tissue. Although it seems that these devices should offer many advantages, few clinical reports are available at present.

44.3.1 Laryngeal Surgery

Over the past 10 years, the role and limitations of lasers in microlaryngoscopic applications have become better understood. The CO_2 laser remains the laser of choice for many microlaryngoscopic applications. Certain benign laryngeal diseases, such as the removal of recurrent respiratory papillomatosis, retain the laser as the instrument of choice. The surgeon is quick to realize the advantages of microscopic control and decreased postoperative edema. Although there was early disappointment when the laser failed to cure the papillomatosis, the disappointment has been overcome by the laser's ability to precisely remove papilloma and spare normal laryngeal tissue. Other applications appropriate for the CO_2 laser include subglottic stenosis, webs, granuloma, and capillary hemangiomas. Surgery for other benign laryngeal disease processes, such as polyps, nodules, leukoplakia, and cysts, may also be performed with the CO_2 laser; however, cold-knife excision has been shown to produce equal, if not improved, postoperative results. Surgery in the pediatric group for webs, subglottic stenosis, and capillary meningiomas has all been significantly improved by the precision, preservation of normal tissue, and decreased postoperative edema associated with the CO_2 laser.

The Nd:YAG laser has much more limited application with regard to intralaryngeal use. However, there are applications where the Nd:YAG is appropriate and often superior to the CO₂ laser. Specifically, increased tissue absorption with an increased depth of penetration make the Nd:YAG laser ideal for the treatment of vascular lesions, such as cavernous hemangiomas, where hemostasis and vessel coagulation are the treatment goals.

44.3.1.1 Stenosis

Stenotic lesions appropriate for endoscopic management have certain features in common as determined by retrospective analysis.⁶³ First, all lesions treated with endoscopic techniques must have intact external

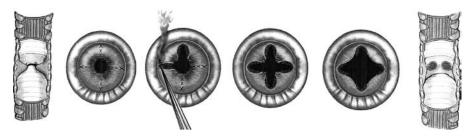

FIGURE 44.4 On the far left, a subglottic stenosis is shown in the trachea with an exposed view. The images progressing from left to right represent the stenosis as viewed by the otolaryngologist. The radial incisions are made with the laser and then dilated. The resulting airway is shown at the far right with a cutaway view of the trachea.

cartilaginous support. Attempted endoscopic incision or excision of areas of tracheomalacia can have disastrous results if surrounding structures are perforated. Second, lesions appropriate for endoscopic management are usually less than 1 cm in vertical length. Favorable results, however, have been reported for lesions up to 3 cm in length when endoscopic incision is combined with prolonged stenting. Finally, total cervical tracheal or subglottic stenosis does not usually respond well to endoscopic management. Again, however, successful case reports exist for endoscopic management when it is combined with prolonged stenting of the stenotic area. Finally, total cervical tracheal or subglottic stenosis does not usually respond well to endoscopic management.

Still, the management of laryngotracheal stenosis is a difficult problem for the otolaryngologist. The first decision — whether open management is necessary or if endoscopic techniques alone are adequate — is probably the most demanding question. All patients with laryngotracheal stenosis need staging direct laryngoscopy and bronchoscopy to determine the extent and degree of stenosis. The CO₂ laser should always be available during the staging laryngoscopy. With the laser on standby, any scarring can be easily removed or incised with the CO₂ laser. Supplemental dilation with the bronchoscope or stent placement may then be beneficial in further management of the stenotic area.⁶⁴

Endoscopic management of laryngotracheal stenosis relies on mucosal preservation. The two techniques advocated for this task are radial incision with bronchoscopic dilation⁶⁴ and the microtrapdoor flap.^{66–69} In bronchoscopic dilation, the laser is used to make radial incision, like the spokes of a wheel, in the stenotic area (Figure 44.4). Bronchoscopes are then sequentially passed through the stenosis to dilate it. The microtrapdoor flap is more complicated but uses a flap of mucosa to drape over the excised tissue.

44.3.1.2 Recurrent Respiratory Papillomatosis

The CO₂ laser has become the standard treatment modality for patients with recurrent respiratory papillomatosis. Some surgeons have reported successful treatment results with the KTP laser for this disorder; however, the less predictable depth of penetration and, therefore, increased potential for thermal injury in surrounding normal tissue make it less than ideal.⁷⁰ As stated above, the CO₂ laser cannot cure the disease. The greater absorption and decreased scatter potential in laryngeal tissue of the 10.6-µm wavelength of the CO₂ laser account for its greater effectiveness in preserving normal laryngeal structures and maintaining the airway.

CO₂ laser treatment should be directed at removing as much papilloma as possible from one vocal cord and then as much as possible from the other. Although some papilloma may remain, it is important to preserve a 2- to 3-mm strut of covering over the anterior part of one vocal cord. This decreases the possibility of creating an anterior web. The papilloma overlying the true vocal cord can be vaporized to the vocal ligament. Following the initial removal of papilloma by CO₂ laser, a planned repeat operation should be performed in approximately 6 weeks. In a series reported by Ossoff et al., 22 patients underwent 105 CO₂ laser excisions. The intraoperative soft-tissue complication rate was zero. The delayed soft-tissue complication rate, consisting of two patients with slight true vocal-fold scarring and one patient with a small posterior web, was 13.6%.⁷¹ This compares favorably with other published complication rates of 28.7 and 45%.^{72,73}

Two further considerations regarding the treatment of recurrent respiratory papillomatosis are worthy of mention. First, considerable attention has been given to the possible detection of papilloma virus in the laser plume. Conflicting reports exist on both sides of the issue.^{74,75} Both surgeons and anesthesiologists have been treated for the disease that was manifest only after clinical exposure. Current recommendations to lessen the potential risk of exposure include the use of adequate smoke evacuation and high-filtration facemasks. The second issue is the management of patients who require multiple repeat laser laryngoscopies for excision on a frequent basis. Treatment intervals can then be based on the rate of reexpression. There are a number of adult and pediatric patients, however, who cannot be placed into clinical remission with this regimen. Therapeutic trials with interferon alpha n-3 have shown no long-term benefit of administration. An investigation with interferon alpha n-1, however, seems to show more promise in producing remission after a 3- to 6-month drug trial.⁷⁶

44.4 Laser-Assisted Uvulo-Palatoplasty

Laser-assisted uvulo-palatoplasty (LAUP) is a technique that was developed by Dr. Yves-Victor Kamami in Paris, France in the late 1980s.⁷⁷ The procedure is designed to correct snoring caused by airway obstruction and soft-tissue vibration at the level of the soft palate by reducing the amount of tissue in the velum and uvula. The procedure can be performed in an ambulatory setting under local anesthesia and is performed over several stages.

The patient should first be evaluated completely to determine the degree of severity of airway obstruction during sleep. Apnea cannot be ruled out on the basis of history and physical appearance alone.^{78,79} If the patient is found to have apnea, then treatment of this condition is mandatory.

One can consider this the equivalent of a dental procedure. If the patient needs subacute bacterial endocarditis prophylaxis, it will need to be administered in conjunction with this procedure. The procedure is performed with the patient sitting in an exam chair in the upright position. A local anesthetic is administered. The procedure is performed using a CO_2 laser. The laser is delivered with a hand piece equipped with a backstop to protect the posterior pharyngeal wall from stray laser energy. The CO_2 laser was selected because of its high efficiency for making incisions. Additionally, the high absorption of the infrared light creates very fine incisions, and the tissue interactions are favorable for this type of procedure. Although the CO_2 laser is not the best coagulating laser available, it has adequate coagulation for the diameter of most vessels encountered in the soft palate. The CO_2 laser is used at a power setting of between 15 and 20 W in continuous mode. The beam is used focused for cutting and defocused for ablation and vaporization.

Once the adequate level of anesthesia has been achieved in the soft palate, the CO₂ laser is then used to make bilateral vertical incisions through the palate at the base of the uvula (Figure 44.5). The uvula can be reduced by approximately 50% of its length and is reshaped in a curved fashion. One can retract the tip of the uvula anteriorly and vaporize the central portion of the uvula muscle while leaving the mucosa intact. Maintaining the mucosa results in less postoperative pain and less delay in wound healing.

After the initial visit, the patient is scheduled for a subsequent treatment 4 weeks later. When the patient returns to the clinic, she is requested to report on the amount of pain experienced, any changes in voice or swallowing, and bleeding and infection. Subjective improvements in the patient's sleep are also elicited, as are any objective changes in snoring. The subsequent procedures are basically the same as the initial procedure. During the treatment course, the otolaryngologist should always examine the palate and determine if attention is needed in other areas. As the retraction occurs, the palate will advance anteriorly and superiorly, and this may tether the posterior tonsillar pillars, causing them to medialize. Should this occur and the pillars themselves begin to obstruct the airway, they can be released by making a horizontal incision at the superior aspect of the pillar, through and through the pillar. If the tonsils are still present, they can be superficially vaporized after this surface is first anesthetized. A crescent-shaped incision can be made vaporizing lateral to the incision; this may also prevent some of the side-to-side healing that would tend to take place in the palate with just simple through and through incisions. When

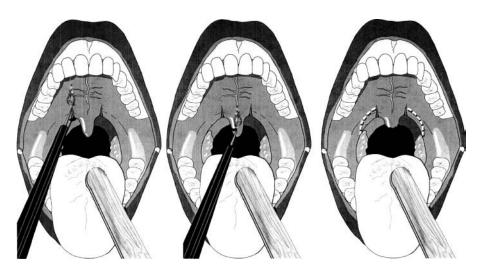

FIGURE 44.5 The steps of the laser-assisted uvulo-palatoplasty. From left to right, first the vertical incisions are made using a laser hand piece with a backstop. Next, the uvula is trimmed. If necessary, incisions can be made along the dashed line if tissue contraction pulls the airway closed.

side-to-side healing is reduced, more retracting of the palate occurs; over the course of the treatment sessions, this will reduce the number of sessions necessary to achieve the end result.

The endpoint for this procedure is determined by any one or a combination of the following factors: (1) if the snoring has stopped; (2) if the patient is satisfied — unfortunately, many patients accept a small improvement; or (3) if the patient is unable to make a snorting sound. The patient might continue to have noisy breathing but be unable to make a snorting sound. At this point the procedure should stop. Further resection of the soft palate after the patient is no longer able to snort runs the risk of excising too much tissue and creating velopharyngeal incompetence. The patient may experience noisy breathing from the vibration of other tissues, such as in the region of the base of the tongue, and not necessarily at the soft palate.

The complication rate for this procedure has been extremely low. There has been some bleeding in the immediate postoperative period that has responded to silver-nitrate cauterization. Permanent voice changes, velopharyngeal insufficiency, temporary or permanent nasal reflux, and dehydration from the inability to take food or liquid orally have not been observed with this procedure.

Although there is pain associated with the procedure, it is not of an incapacitating nature, and patients are able to attend classes or work in their normal routine. Most patients report some degree of weight loss, at most between 10 and 15 lb over the course of the treatment. In most of our patients, this has been a desirable side effect.

44.5 Limitations of Laser Use

Prior to any surgical procedure, the surgeon must consider whether the laser is the best method for treating a particular laryngeal disorder. As noted earlier, such entities as vocal nodules may require no therapy whatsoever. Although the laser is a highly precise instrument, thermal injury and carbonaceous debris may stimulate submucosal fibrosis that may be unacceptable in certain types of patients such as the professional voice user. If the laser is felt to be the optimal method of treatment, limitations may be imposed by the patient's particular anatomic configuration. Mandible size and position as well as spinal-column flexibility may limit the type of laryngoscope that can be used and thereby affect visualization of the larynx. Patients with cervical arthritis, retrognathia, prominent teeth, or hypertrophy of the base of the tongue may be difficult candidates for endoscopy. Patients with ischemic cardiovascular disease

may not withstand the prolonged laryngoscopic suspension that stimulates the vagus nerve and may produce subsequent cardiac arrhythmias as well as silent myocardial infarctions. Even in ideal circumstances, laser laryngoscopy may require more time to complete than other surgical techniques. For example, a patient with unstable cardiac disease suspected of having a laryngeal tumor may well be treated best with operative visualization and biopsy by conventional techniques rather than with the laser.⁸⁰

Patients with chronic obstructive or restrictive pulmonary disease may be difficult to ventilate. In such situations, an endotracheal tube may be mandatory and by its presence may limit laryngeal visualization and access.

The precise tissue interaction and the relatively minimal morbidity rate associated with endoscopic CO₂ laser surgery results in only three contraindications for use. First, patients with circumferential stenosis of the trachea wider than 1 cm in length will probably have unfavorable results. Therefore, endoscopic management of these patients should be limited to the initial diagnostic procedure. The second contraindication to CO₂ laser bronchoscopy is tracheomalacia. In patients suffering from tracheal stenosis caused by tracheomalacia or loss of tracheal cartilaginous support, use of the laser bronchoscope can be dangerous. It may result in perforation of the trachea wall with subsequent mediastinitis or rupture of a great vessel. This complication obviously can be devastating. The third and final contraindication to CO₂ laser bronchoscopy is in patients with airway obstruction caused by extrinsic compression of the tracheobronchial tree. Extrinsic compression is not amenable to any form of endoscopic treatment.

44.6 Conclusions

The laser continues to be an important tool for the otolaryngologist. In surgery, the importance of the laser results from the ability to direct the beam and make precise incisions. The more recent additions of computer-controlled microscanners will add to the usefulness of the laser. The microscanners permit precise control and the ability to ablate lines or patterns with minimal loss of material. They can also reduce lateral thermal damage and thus reduce the delay in wound healing often associated with the laser.

The user must be appropriately trained before using any laser and fully understand all the advantages and possible complications. Appropriate safety measures are also necessary to prevent unnecessary morbidity and mortality.

Finally, the laser–tissue interactions must be understood. The otolaryngologist must always consider whether or not the laser is necessary. The benefits of laser use must always outweigh any potential problems or risks. Used appropriately the laser is both an important and a critical tool for otolaryngology.

45.1 Introduction

The modern era of urology was inaugurated when incandescent light was cystoscopically introduced into the urinary bladder. Lasers represent one aspect of the continued development and application of light technology in urology. The photothermal, photochemical, and photomechanical properties of lasers are used for both the diagnosis and treatment of urologic disease.

45.2 Nonmalignant Urologic Disease

45.2.1 Lasers for the Treatment of Urinary Lithiasis

Although early investigators demonstrated the feasibility of the use of laser energy for stone fragmentation, the first effective clinical application of laser lithotripsy was reported in 1987. A pulsed-dye laser (504 nm, 1 µsec) was coupled to a 250-µm quartz fiber for endoscopic stone fragmentation. Excellent fragmentation of all but the hardest cystine and calcium oxalate monohydrate stones was achieved.¹ The mechanism of stone fragmentation was determined to be a concentrically propagating cavitation bubble created at the laser–stone interface, collapsing and producing a photoacoustic shockwave and causing the calculus to fragment.².³ There are no direct photothermal effects from the pulsed-dye laser, and ureteral trauma from the acoustic shockwave is minimal.⁴ The pulsed-dye laser continues to be a "workhorse" for urologic laser lithotripsy at many institutions with overall success rates reported between 80 and 95%.⁵

Subsequent investigations with the Q-switched neodymium:yttrium-aluminum-garnet (Nd:YAG) and alexandrite lasers demonstrated that these lasers were effective in fragmenting calculi.^{6,7} Success rates

Portions of this chapter were published in Grafstein, L.A. and Selman, S.H., *J. Clin. Laser Med. Surg.*, 16(1), 49, 1998. Reprinted with permission.

were reported in excess of 90%. However, both were limited in their clinical application by high material costs and the lack of success in the treatment of stones composed of cystine and calcium oxalate monohydrate.

Recently the holmium:YAG (Ho:YAG) laser has moved to the forefront of laser lithotripsy technology. In contrast to the pulsed-dye laser whose therapeutic efficacy is based on photoacoustic properties, the Ho:YAG laser's effectiveness as a lithotripter is related to its thermal mechanics. The energy of the Ho:YAG laser also forms a plasma vapor bubble at the fiber tip, but this bubble is pear shaped rather than concentric.8 Laser energy is transmitted efficiently through the bubble of water vapor (the so-called "Moses effect") directly to the stone itself. Water trapped in the stone interstices is then superheated, causing fracture and disintegration. The photoacoustic properties of the cavitation bubble in this case are negligible. 10 Sayer et al. in 1993 reported effective fragmentation of all varieties of stone with the Ho:YAG laser including cystine and calcium oxalate monohydrate (brushite) calculi.¹¹ Results reported by Densted et al., 12 Grasso et al., 13 Devarajan et al., 14 and others 15-17 describe stone-free success rates in excess of 90%. Equally impressive is the success this laser has had when used in combination with miniaturized actively deflectable ureteroscopes to reach the proximal ureter and even intrarenal calculi. 18,19 With a 200-µm fiber and an actively deflectable ureteroscope, the entire intrarenal collecting system is accessible for retrograde approach. Grasso has reported an 88.5% success rate in these situations clearing 23 of 26 patients of their stone burden in one session.²⁰ Other reports cite a single-session success rate of 60 to 79% for these upper-tract calculi.^{21,22} Such an approach may be prohibitively time-consuming or more technically difficult than the percutaneous approach.

The Ho:YAG laser has been shown to produce smaller stone fragments than other modes of lithotripsy.²³ In an *in vitro* study by Teichman et al., the size of stone fragments produced by the Ho:YAG was compared to stone fragments collected following treatment with the electrohydraulic lithotripter, mechanical lithoclast, and pulsed-dye laser. The Ho:YAG was the only instrument that yielded no fragments >4 mm and had a greater percentage of fragments <1 mm. Reducing the stone to "dust" or "sand" rather than fragments considerably improves the success of treatment as measured by "stone-free" status.²³ The laser itself causes very little retrograde propulsion of the stone to more proximal locations. Where proximal migration has been described in association with this laser, it is more often related to irrigation solution than the laser effect itself.^{10,14}

Concerns for the safety and integrity of surrounding mucosal lining are minimized by careful and accurate placement of the fiber tip in direct visual contact with the stone. Care must be taken to avoid blindly drilling straight through a stone into adjacent tissue, where injury may occur. If the laser is fired with the fiber tip in contact with mucosal tissue, thermal injury and perforation will result. The Ho:YAG is a "thermal" laser and does possess tissue coagulative and ablative properties. While microsecond pulsatile delivery and the high degree of energy absorption by the water medium significantly increase the margin of safety, direct-contact mucosal irradiation will vaporize tissue up to a depth of 0.5 mm. ^{10,24} For this reason it is essential that this laser be used only under direct vision. ²⁵ Side firing tips have proven useful in this regard, particularly when approaching stones in the bladder or in the renal pelvis or calyces. During percutaneous nephrolithotomy, where it may be difficult to position the laser-fiber tip perpendicular to the stone surface or where maneuverability for access is limited, a side-firing fiber will allow the endoscopist to maintain the proper 0° incident angle for efficient energy delivery. ²⁶

The most frequently reported complication following Ho:YAG laser lithotripsy has been ureteral stricture formation. In the majority of cases, this has been attributed to the semirigid ureteroscopy rather than to the laser itself. 14,16,20,24 Previous stone impaction and unsuccessful attempts at stone manipulation are also noted as contributing risk factors for subsequent stricture formation observed following endoscopic laser lithotripsy. 24 Other potential complications involve metal endoscopic stone baskets and guidewires that may be cut inadvertently with the Ho:YAG laser. Resulting sharp wire barbs may be traumatic to tissue, and therefore extreme care must be taken when using these instruments in conjunction with this laser. 27 The development of preformed soft-wire baskets have reduced the risk of injury if the wire is transected.

One interesting theoretical concern has been raised involving the thermochemical interactions of the Ho:YAG laser with uric-acid stones. As reported by Teichman et al., when uric-acid stones are heated by irradiation with Ho:YAG energy, hydrogen cyanide is released as a chemical-breakdown product.²⁸ In their series of 18 patients, there was no evidence of cyanide toxicity; however, actual blood levels were not measured. The minimum lethal oral dose of cyanide is 50 mg. *In vitro* studies, also by Teichman et al., used a 940-µm fiber at 1.0-J pulse to deliver 1 kJ of Ho:YAG irradiation to a 97% pure uric-acid stone.²⁹ As a result, 400 mg of cyanide was produced. In a clinical series, several patients with uric-acid bladder calculi received upwards of 300 kJ of energy. No apparent ill effects were observed. The absorption capacity of urothelium is not known, and irrigation fluid used during lithotripsy may play a significant role in minimizing the absorption potential. The authors conclude that there is a high margin of safety based on these findings but encourage caution in situations where increased absorption might be observed due to bleeding or high-pressure irrigation.²⁹

45.2.2 Lasers for the Treatment of Benign Prostatic Hyperplasia

Urinary frequency, incomplete bladder emptying, and nocturia can be caused by enlargement of the prostate. The surgical "gold standard" for treatment has been the transurethral electrosurgical resection of obstructing prostatic tissue. Although transurethral resection of the prostate is a minimally invasive technique, it is not without significant morbidity principally due to blood loss. Laser technology is evolving as a viable treatment option for this common problem. The Nd:YAG laser was first used for the treatment of prostatic enlargement practice in the early 1990s. Two technologies were developed, both dependent on the thermal coagulative effects of the Nd:YAG laser. The transurethral ultrasound-guided laser-induced prostatectomy (TULIP) incorporated a side-firing Nd:YAG laser that used real-time ultrasound monitoring during treatment.³⁰ Ultrasound was incorporated for optimal guidance of laser energy. The expense and complexity of the procedure led to its abandonment, although its success in treatment was reported in a multicenter trial.

Visual laser ablation of the prostate (VLAP) as introduced was more appealing to urologists in that it incorporated endoscopic rather than ultrasonic techniques for the direct application of laser energy (Nd:YAG) to the obstructing prostatic tissue. Pioneered by Costello et al., the technique incorporated a gold alloy tip at the end of the laser-delivery fiber, which allowed right-angle delivery of laser energy directly into the obstructing prostate tissue.³¹ Coagulation of treated prostatic tissue created the desired therapeutic effect. A number of reports demonstrated the utility of this approach, as evidenced by improvement in symptom scores and urinary-flow rates. However, some patients required prolonged catheterization in the postoperative period, while others developed severe irritative voiding symptoms that only slowly resolved as treated tissue gradually sloughed or resorbed. Because of these problems this technique is no longer widely practiced. As an alternative to the free-beam technology, contact Nd:YAG-laser techniques were developed for the removal of obstructing tissue.³² However, the slow pace of this technique has led to its lack of widespread acceptance.

Transurethral interstitial laser-energy application, designed to cause coagulation necrosis of obstructing prostatic tissue while preserving the urethral mucosa, is another laser-based approach to the treatment of benign prostatic hyperplasia.³³ A 600-um PTFE-coated fiber with a 1-cm diffusing tip is placed transurethrally through the urethral wall into the targeted prostatic tissue. An 830-um diode laser provides the energy for treatment. Treatment is directed at heating the targeted tissue to 100°C, and temperature in the treatment area is controlled by a feedback system. Preliminary clinical results have demonstrated an improvement in symptom scores and maximum flow rates after treatment.³⁴

A technique for enucleation of the prostate using the Ho:YAG laser has been pioneered by Gilling et al.³⁵ Sections of obstructing prostate are removed by a combination of the cutting and ablative effects of the laser. The procedure has been associated with little blood loss and creates a prostatic cavity similar to that produced by transurethral electrosurgical resection. The large pieces of enucleated material fall

into the bladder and are subsequently morcellated by a mechanical device. Extremely large obstructing prostate adenomas have been removed using this approach.³⁶

The potassium titanyl phosphate (KTP) laser has been used clinically to vaporize obstructing prostatic tissue. There are reports of its use in combination with the Nd:YAG. The KTP vaporizes the bladderneck tissue, and the Nd:YAG is used on the remainder of the obstructing tissue.³⁷ This combination of lasers has been reported to be associated with fewer irritative voiding symptoms than when the Nd:YAG is used alone. A high-power (60-W) KTP laser has been developed as the sole laser for prostate vaporization. Initial reports on this laser have been encouraging, with all men catheter free in 24 h and none requiring blood transfusion.³⁸

45.2.3 Lasers for the Treatment of Urethral Stricture Disease

Strictures of the male urethra arise from inflammatory, traumatic, or iatrogenic causes. Cicatrix formation compromises the urethra lumen, which restricts normal urinary flow. Techniques for management included periodic dilatation (bouginage), cold-knife incision, or open surgical repair with or without tissue transfer.

Bulow et al. were among the early investigators using the Nd:YAG for the treatment of urethra stricture disease.³⁹ Five patients were treated without complications; however, long-term follow-up was not reported. In 1980, Rothauge reported on the use of the argon laser in 40 patients with stricture disease. Six patients required a second treatment.⁴⁰ Again, long-term follow-up was not provided. Smith and Dixon reported on the use of the Nd:YAG in 17 patients. Of these patients, 11 (64%) suffered recurrent strictures within 6 months of treatment, leading the investigators to conclude that Nd:YAG treatment offered no advantage over conventional therapy. However, within this series all patients had undergone multiple urethral dilatations, and 13 had been treated prior to laser with cold-knife urethrotomy.⁴¹ Subsequent studies using the Nd:YAG laser have offered more optimistic results. Perkash has described the use of a contact chisel tip to achieve a 93% success rate at 28.2 months for 42 spinal-cord-injury patients.⁴² Another recent investigation has employed an 805-nm aluminum-gallium-arsenide diode laser. Kamal has reported on 22 patients treated in this manner with 23.2-month mean follow-up. A 78.6% success rate is described for those patients not previously treated. Of 8 patients with more complex strictures previously treated with cold-knife urethrotomy, 7 had further recurrence. However, the mean time to recurrence in these patients did increase from 8 to 16 months.⁴³

Bladder-neck contractures after prostatectomy represent stricture formation at the vesicourethral junction. Contact-laser ablation of the narrowed area has been reported with the use of the Nd:YAG laser. Silber and Servadio reported on 21 patients with excellent results.⁴⁴

45.2.4 Miscellaneous Use of Lasers

Sporadic use of lasers for a variety of urologic problems have been reported. Among these are posterior urethral valves, ^{45,46} bladder hemangiomas, ⁴⁷ and ureteral strictures. ^{48–50} Each of these has been studied in small series, and further long-term follow-up is needed, though the initial results have been favorable.

45.3 Urologic Oncology

45.3.1 Thermal Lasers in Urologic Oncology

Thermal lasers refer to those lasers developing heat in targeted tissue to create their therapeutic effects. The production of heat in laser-targeted tissues depends on the emitting laser wavelength and operating mode (pulsed vs. continuous) in combination with the absorbing and scattering characteristics of the

^{*}Parts of the following appeared in Grafstein, L.A. and Selman, S.H., J. Clin. Laser Med. Surg., 16(1), 49, 1998.

tissues. Thermal effects in tissues will also vary with laser-beam power density, time of irradiation, and the presence of heat sinks (blood flow). Within tissue, water content as well as the presence of absorbing pigments (chromophores) will largely determine the extent of tissue penetration and scattering of laser energy.

Tissue effects produced by thermal lasers will differ depending on the above parameters. Once laser energy is deposited in the targeted tissue the effects will vary with type of laser delivery (free beam, contact tip) as well as tissue characteristics. When temperatures within the targeted tissue rise above 60°C, protein denaturation occurs with tissue "coagulation." When temperatures rise above 100°C, intracellular water begins to boil and evaporate. This evaporation of tissue is referred to as ablation, since tissue is removed from the target as a laser plume of debris. Further heating results in tissue carbonization, the process by which carbon remains after vaporization. In a sense, the coagulative and evaporative effects are competitive in their effects on the target tissue. High power delivered over a short interval creates the ablative effects, while lower power delivered over a longer time interval creates a coagulative effect.

In some clinical situations, precise localization of thermal energy is required. Localization of thermal effects can be achieved through the use of contact tips placed on the end of quartz laser fibers. These tips convert light energy to thermal energy within the tip. This energy then serves to cut or coagulate tissue.

45.3.1.1 Carcinoma of the Penis

The challenge in the treatment of squamous-cell carcinoma of the penis is preservation of cosmetic and functional integrity while eradicating the neoplastic process. Standard surgical treatment of distal penile lesions includes circumcision for tumors of the prepuce or distal penectomy for tumors of the glans penis, while total penectomy may be necessary for penile-shaft lesions. Carcinoma *in situ* (CIS) (Erythroplasia of Queyrat) can be effectively treated with topical 5-fluorouracil cream, but in some patients severe normal-tissue reaction limits its use. It is toward the organ-preserving treatment of superficial penile cancers that thermal lasers have shown greatest promise and utility.
