Parsons et al., in one of the earliest genitourinary applications of thermal laser technology, used the ruby laser for the treatment of carcinoma of the penis. The patient was treated with pulsed laser energy in two sessions. In the first, black shoe polish was applied to the lesion to enhance absorption. Although the treatment proved less than completely successful, the author clearly showed the potential for laser energy to be used for the treatment of the neoplastic process of the penis.⁵² Rosemberg reported the first case of CO₂-laser tumor vaporization for a patient with Erythroplasia of Queyrat.⁵³ Rosemberg subsequently published his results on the treatment of three cases of penile cancer in which both the CO₂ and Nd:YAG lasers were used. In two of the cases, the CO₂ laser was used as a scalpel to perform partial penectomy, while in the other laser energy was used to vaporize and ablate the neoplastic lesions.⁵⁴ Bandieramonte et al. used laser microsurgery for the treatment of superficial lesions of the penis, some of which were nonneoplastic or premalignant. The CO₂ laser was used in conjunction with the operating microscope for resecting lesions. The aim of the procedure was to remove tissues while preserving the architecture for pathologic evaluation. The investigators felt that this approach served both aims well in addition to maintaining cosmesis.⁵⁵

Between 1977 and 1981, Hofstetter utilized the Nd:YAG laser in 17 patients with T1 and T2 penile carcinomas; 7 of these patients had no local relapse or metastases in 4 years of follow-up.⁵⁶ Seeking to preserve penile integrity, Rothenberger utilized the Nd:YAG laser as an adjunct to local surgical resection in 19 patients (13, T1:6, T2). Immediately after surgical resection of all gross tumor, the tumor bed and a 0.5-cm margin were treated with the laser using 45 W for 3 sec. A total of 17 of the 19 patients evaluated at 1 year were free of disease.⁵⁷ Malloy et al. treated 16 men (5 TIS, 9 T1, and 2 T2) with squamous-cell carcinoma of the penis with the Nd:YAG laser. Laser irradiation was applied with a focusing hand piece, and iced saline was applied to prevent surface carbonization. Within the follow-up period ranging from 18 to 36 months none of the TIS patients had a recurrence, while 6 of the 9 T1 patients were free of disease. Neither of the T2 patients was free of cancer, and one of these had developed a urethrocutaneous fistula at the site of therapy.⁵⁸ Malek reported the Mayo Clinic experience on the use of the CO₂₂ Nd:YAG,

and KTP lasers for the ablation of premalignant and malignant penile lesions. A total of 25 of 30 patients had either premalignant carcinoma or CIS. Although the number of T1 and T2 lesions was small, the author concluded that laser treatment was clinically equal and functionally superior to standard surgical therapy.⁵⁹

These studies suggest that thermal lasers are capable of eradicating superficial neoplasms of the penis with excellent cosmetic and functional results. One caveat is that patients must be informed of the prolonged healing time, which may be up to 3 to 4 months when the Nd:YAG laser is used.

45.3.1.2 Prostate Cancer

Carcinoma of the prostate is the most common neoplasm in men over the age of 50. Although both radiation therapy and radical prostatectomy have proved to be excellent forms of therapy, alternative methods of treatment are being pursued. To date, thermal lasers have not been widely applied for the treatment of carcinoma of the prostate.

A series of articles by Beisland et al. explored the use of thermal lasers (Nd:YAG) for residual prostate ablation subsequent to "radical" transurethral resection of the prostate (TURP). In the initial study, 5 patients (3 T1; 2 T2) were treated with transurethral Nd:YAG laser energy (50 to 55 W, 4 sec) 4 to 6 weeks after TURP. The laser tip, introduced through a standard cytoscope, was rotated between 12 and 6 o'clock and gradually drawn back from the bladder neck toward the prostatic apex. No bleeding, perforations, or infection was encountered.⁶⁰ In a subsequent report, 16 patients were treated. A technique modification had been added in which the laser endoscopic was introduced through a suprapubic cystostomy. This was done to facilitate treatment of the prostatic apex. 61 In a third publication, the number of patients increased to 63 (36 T1, 27 T2). Rectal temperatures were monitored with a thermistor. In addition, transrectal ultrasound was used to determine whether an ultrasound signature of thermally treated prostate could be ascertained. The investigators found none. With a mean follow-up of 22 months, 56 patients were "free of disease." Unfortunately, prostatic-specific antigen (PSA) was not measured, and clinical follow-up was short.⁶² Although this approach to the treatment of prostate cancer is appealing, the inability to adequately monitor temperatures in the critical areas, such as the prostatic capsule, bladder neck, and prostatic apex, is a drawback. However, adjunctive technologies, such as transrectal MRI or interstitial thermistors, may make this approach feasible.

The standard treatment of metastatic carcinoma of the prostate is hormonal manipulation with the aim of lowering serum testosterone to anorchid levels. The use of luteinizing hormone-releasing hormone (LHRH) agonists has supplanted oral estrogen therapy. Some men with metastatic prostate cancer, however, are treated with bilateral orchiectomy. Wishnow and Johnson reported on the use of the CO₂ laser for subcapsular orchiectomy. This surgical approach to castration has the putative advantage of fewer complications such as bleeding and pain. The authors used a CO₂ laser as a surgical knife to incise the scrotum, dartos fascia, and tunica albuginea of the testicle. The testicular parenchyma was then removed by dissection with a moist sponge. The visceral surface of the tunica albuginea was ablated with the laser to assure complete removal of testicular tissue and assure hemostasis. Of the 13 patients so treated, one developed a scrotal hematoma. Postoperative serum testosterone levels were in the anorchid range.⁶³ Bolton and Costello used the same approach on 17 patients. Their mean operating time was 32 min. None of the patients developed complications. Beta human chorionic gonadotrophin stimulation (5,000 U) administered to 10 patients confirmed the adequacy of orchiectomy.⁶⁴

45.3.1.3 Bladder Cancer

Thermal lasers have been widely used in the treatment of bladder tumors. The Nd:YAG, argon, and Ho:YAG lasers have all been used in the treatment of bladder tumors. Because there is no fiber system for transmission of CO₂ laser energy, the CO₂ laser has minimal usefulness for the treatment of bladder tumors. The development of a new cystoscope that enables the transmission of a CO₂ laser beam in a CO₂-gas-filled bladder may render this laser useful in the future.⁶⁵

Smith and Dixon reported on the treatment of 11 patients with superficial transitional-cell carcinoma (TCC) of the bladder with the argon laser. Of these 11 patients, 9 had low-grade papillary lesions, while

2 patients had CIS. Follow-up revealed no local tumor recurrence in the nine patients with papillary lesions. However, three patients had remote tumor recurrence outside the treatment area. One patient with CIS had persistent lesions and positive cytology on follow-up. The authors concluded that the argon laser should be limited to patients with known low-grade, low-stage TCC in whom histologic confirmation is not necessary. Lesions treated in this manner should be either less than 1.0 cm in size or CIS.⁶⁶

The Nd:YAG laser is the most widely used laser for the treatment of bladder neoplasms. This laser can be used without general anesthesia and is associated with minimal blood loss and obturator-nerve stimulation. Catheter drainage is usually not necessary, and tumor ablation can often be done on an outpatient basis.^{67–70}

It has been postulated that the "no touch" technique of the Nd:YAG bladder-tumor ablation decreases exfoliation of tumor cells and therefore decreases tumor recurrences. Several series have compared the number of tumor recurrences after standard transurethral electrosurgical resection (TUR) to those seen after the use of the Nd:YAG laser. Hofstetter found a significantly decreased (p < 0.001) rate of recurrence in 66 patients (Ta-T2) treated with the Nd:YAG compared to standard laser. He also observed a decreased local recurrence rate of 1% with the Nd:YAG vs. 40% with TUR. The Beisland and Seland in a prospective randomized study of 122 patients with stage Ta-T2 disease showed a decreased local recurrence rate of 4.8% with the Nd:YAG compared to 31.6% with TUR. However, the appearance of new foci of TCC outside the area of previous resection or ablation was similar with the Nd:YAG and TUR (20 vs. 22%) despite the "no touch" approach of the former. Beer et al. found similar results, with a 7% recurrence rate for the "no touch" Nd:YAG ablation and 25% recurrence after TUR. Neither technique offered a clear benefit to preventing the appearance of new lesions outside the original margin of resection.

Johnson reported on the use of Ho:YAG in the treatment of 15 patients with superficial bladder cancer. Follow-up revealed 27% of patients had no recurrent disease; 53% had out-of-field recurrences, and 20% had in-field recurrences.⁷⁴ The local recurrence rate is higher than the 4.8% reported for the Nd:YAG.⁷² Further clinical experience should clarify the efficacy of the Ho:YAG laser in the treatment of bladder cancer.

Muscle-invasive bladder cancer is usually treated by radical cystectomy; however, in selected cases the Nd:YAG laser, because of its deep coagulation effects, can be used for treatment. The Nd:YAG laser has the potential to treat these lesions. Two problems exist limiting the effectiveness of the Nd:YAG for the general treatment of muscle-invasive disease — (1) errors in staging and (2) inability of the Nd:YAG to reliably and consistently achieve full-thickness penetration of the bladder. Smith reported on 21 patients treated with the Nd:YAG for muscle-invasive bladder cancer. Patients had clinical stages B1 to D disease. Patients were preselected because they were either poor surgical risks or they refused cystectomy. On follow-up he obtained negative biopsies in 80% of B1 lesions, 50% of B2 lesions, 25% of C lesions, and 0% of D lesions. McPhee's results were not as encouraging. He had recurrences or residual disease in 41.6% of his stage T2(B1) lesions, 57% of T3a(B2) lesions, and 100% of his T3b® lesions. Beisland and Sander treated 15 patients with the Nd:YAG laser for stage T2 disease. Of these 15 patients, 4 failed treatment. These authors concluded that laser treatment for invasive TCC should be reserved for selected patients who are either poor surgical candidates for cystectomy or who refuse cystectomy.

Clinical data have not proved the laser more efficacious in reducing overall tumor recurrence rates as compared to TUR, although there is evidence of decreased local tumor recurrence in the laser-treated area. The laser is effective in eradicating small superficial lesions and is a viable option when the pathologic stage is apparent and no tissue is needed for staging. Radical cystectomy remains the standard treatment for muscle-invasive bladder cancer; however, laser treatment may be an alternative treatment option for high-risk surgical candidates or for those refusing cystectomy.

45.3.1.4 Ureteral and Renal Pelvis Carcinoma

The traditional approach to the treatment of transitional-cell carcinoma of the ureter and renal pelvis has been nephroureterectomy. However, it has been recognized for some time that conservative (parenchymal sparing) procedures (e.g., partial ureterectomy for ureteral tumors) have their place in the management of patients with upper-tract urothelial cancers.⁷⁹ This is especially true in patients with

compromised renal function, bilateral cancer, or solitary kidney. Survival after ureteral resection for low-grade lesions is comparable to those achieved with nephroureterectomy. The widespread availability of small urologic endoscopic instruments, both flexible and rigid, facilitating access to the entire collecting system has naturally led to the use of thermal lasers for endoscopic upper-urinary-tract-tumor ablation. Both percutaneous and transureteral approaches have been used.

Schilling et al. treated 13 ureteral tumors in ten patients transureteroscopically using the Nd:YAG laser (40 W, 1 to 3 sec). They reported excellent patient tolerance with no complications. Complete healing of the lasered site was documented in one patient who underwent nephroureterectomy 3 weeks following laser therapy. The authors noted that the small working space within the ureter limited the approach to the tumor to a tangential one creating a shadow area within the targeted tissue. Si Smith et al. reported on percutaneous treatment of renal pelvic tumors in nine selected patients. The investigators first gained access to the renal pelvis using standard percutaneous techniques and then undertook tumor resection using electrocautery. Subsequently (2 to 28 d later), Nd:YAG laser treatment (15 to 20 W, 2 sec) of the previously resected site was undertaken. Within the short mean follow-up (9.5 months), five patients remained free of tumors. However, adjunctive intraluminal chemotherapy/immunotherapy was also used in some patients. No conclusions could be reached regarding the additional benefit of laser ablation. Si

Schmeller and Hofstetter found 36 ureteral tumors between 1984 and 1987 of which endoscopic treatment was attempted in 20 using the laser alone or in combination with electrocautery. A 600-µm fiber was used to deliver between 20 and 30 W of power for no longer than 3 sec. The authors noted that when tumors were greater than 5 mm, complete laser coagulation was difficult. In these cases, the superficial coagulated neoplastic tissue was removed by "scratching" it away with the tip of the fiber. Stents were placed after treatment and removed 4 to 6 weeks later, at which time ureteroscopy was repeated with biopsy and, if necessary, retreatment. One patient treated for a circumferential tumor developed narrowing at the treatment site. In the 8 patients treated with laser therapy only, 2 developed recurrent tumors within the median follow-up of 22 months.⁸³

Of 12 patients with upper-urinary-tract urothelial tumors felt to be candidates for endoscopic ablation, Grossman et al. were able to treat 8. Of the 4 not treated, 2 had tumors found to be too large, while 2 had tumors within the renal pelvis not endoscopically accessible with the rigid instruments available to the investigators. Tumors were treated with an Nd:YAG laser (30 W) using a 600-µm fiber. When necessary, an internal ureteral stent was left after treatment and removed several days later. No serious complications or strictures developed. As would be expected, recurrences were common (5 of 7 not lost to follow-up). The authors concluded that transureteroscopic laser therapy was appropriate for low-grade superficial ureteral tumors. However, renal pelvis tumors were not felt to be amenable to transureteral rigid endoscopic laser therapy because of limited accessibility.⁸⁴

Kaufman and Carson selected 9 patients with low-grade, low-stage ureteral tumors to treat endoscopically. Using cold-cup forceps, tumors were first avulsed and debulked. The base of the removed tumor was then treated with 30 W of Nd:YAG laser energy through a 400-µm fiber. Ureteral stents were placed in all patients. Using this approach, 8 of 9 patients had no recurrences with a mean follow-up of 28 months. Two "minor" strictures developed that were subsequently treated with balloon dilatation. The investigators conclude that the combination of tumor debulking and Nd:YAG laser ablation is an effective treatment in selected patients with ureteral tumors.⁸⁵

At the Mayo Clinic 44 patients with transitional carcinoma of the upper urinary tract were treated either with electrofulguration or Nd:YAG laser energy. Of the 44, 21 had tumors of the renal pelvis and 23 of the ureter. Patients with tumors greater than 2 cm were excluded from this approach. Both the percutaneous (24%) and the transureteroscopic (76%) approach utilizing rigid and flexible instruments were used for tumors of the renal pelvis. Ureteral tumors were treated without prior avulsion by cold-cup forceps. Adjunctive intraluminal chemo/immunotherapy was used in some patients. Three patients treated transureteroscopically with the laser developed strictures. Tumor-recurrence rates — 33% using Nd:YAG laser and 44% using electrocautery — were not statistically different. The authors conclude that in selected patients the endourological approach is an acceptable treatment of upper-tract neoplasms.⁸⁶

The use of the Ho:YAG laser for the treatment of ureteral tumors has been explored by Bagley and Erhard. The very limited tissue penetration of energy of this wavelength led the investigators to use the laser to resect small tumors.⁸⁷ In a subsequent article, this laser was used alone and in combination with the Nd:YAG for endoscopic tumor ablation and coagulation.⁸⁸

As evidenced by the above studies, the use of the laser for endoscopic removal of ureteral and renal pelvic tumors is gaining acceptance in the urologic community. It appears to be associated with minimal morbidity and excellent tumor control.

45.3.1.5 Renal Tumors

In the last decade, there has been increasing interest in partial (renal sparing) nephrectomy in the treatment of carcinomas arising in the renal parenchyma. To this end, there has been interest in the use of the laser both as a tool for incising the renal parenchyma and as an adjunct to resection for thermal ablation of the surgical bed.

Malloy et al. reported on the use of the Nd:YAG laser for partial nephrectomies in six patients. In three patients with invasive TCCs arising in either the upper- or lower-pole calyx, a small pyelotomy was first made in the exposed renal pelvis, and a flexible nephroscope and laser were then introduced and used to ablate/coagulate visible tumor. Polar nephrectomies were then performed using the laser to aid in hemostasis of the cut surface of the kidney. Three patients with renal-cell carcinomas underwent partial nephrectomies. In these patients, the perimeter of the tumor was first "treated" with laser energy with the aim of sealing draining lymphatics. Subsequently, the laser was used as an aid in tumor enucleation or partial nephrectomy. In none of the six patients was blood transfusion necessary.⁸⁹

Contact-Nd:YAG-laser incision, in combination with regional hypothermia and renal artery occlusion, was used for partial nephrectomy in six patients with renal-cell carcinoma by Korhonen et al. These investigators felt that clamping the renal artery limited the extent of laser-energy damage in the surrounding normal parenchyma. With a mean follow-up of 15.3 months, no recurrences or metastasis occurred.⁹⁰

In a report by Merguerian and Seremetis, KTP and Nd:YAG lasers were used in combination for partial nephrectomies in patients with bilateral Wilms' tumors. The KTP (40 W, 0.5-mm spot size) laser was used to incise, while the Nd:YAG (50 W, 0.5-mm spot size) laser was used to coagulate blood vessels. Blood loss was minimal in both cases. The authors point out that the small size of the blood vessels in the pediatric kidney is ideally suited for laser coagulation.⁹¹

45.3.2 Photodynamic Therapy

PDT is a two-step procedure based on the localization of an administered drug (photosensitizer) within targeted tissue and the subsequent excitation of the photosensitizer with light of the appropriate wavelength to generate toxic photoproducts. To achieve the desired effect, sufficient amounts of the photosensitizer, oxygen, and light must be present at the optimal time (determined by the pharmacokinetics of the sensitizer) for light delivery.

45.3.2.1 Photosensitizers

Hematoporphyrin derivative (HPD), the first synthetic photosensitizer, has been the predominant photosensitizer for PDT of malignant tissues. HPD is a mixture of porphyrins, hematoporphyrin, and its dehydration products. The putative active component of HPD has been identified as dihematoporphyrin ether (DHE, porfimer sodium) and is currently marketed as Photofrin[®]. HPD and DHE are excited from their ground-state energy levels to higher energy levels by red light of 630-nm wavelength. Return to the ground-state energy level results in energy transfer to molecular oxygen and subsequent tissue destruction. The depth of the photodynamic effect, and thus tissue necrosis, is limited by the tissue penetration depth of red light at this wavelength. The skin, which can retain the drug for 6 weeks or longer, is especially troublesome because patients must limit sun exposure for significant periods of time.

Second-generation photosensitizers with absorption peaks at higher wavelengths, higher chemical purity, and the potential for less prolonged photosensitivity have been developed and tested in preclinical and clinical studies. Newer sensitizers currently in clinical development include benzoporphyrin derivative (BPD), tin ethyl etiopurpurin (SnET2), 5-animolevulinic acid (ALA), meso-tetra (hydroxyphenyl) chlorin (mTHPC), and lutetium texaphyrin (Lutex) (Figure 45.1). Of these, ALA is unique in that it requires metabolization to its active form, protoporphyrin IX (PpIX), before becoming a photosensitizer.

45.3.2.2 Light Sources and Dosimetry

Tunable-dye lasers, principally the argon pumped-dye laser, producing light of 630 nm to match an absorption peak of HPD have been the most widely used lasers. Other dye-laser systems that have been used include frequency-doubled KTP/dye, dye/Nd:YAG lasers, copper-vapor/dye lasers, excimer/dye lasers, and gold-vapor lasers. Most dye lasers are expensive and bulky, require special cooling, and are difficult to maintain. Samaller and less expensive diode lasers that are easier to handle and maintain may be able to overcome these problems. In preclinical and clinical studies, diode lasers have proved to be just as effective as dye lasers in inducing tissue destruction after sensitization with the photosensitizers BPD, Lutex, CASPc, and SnET2. S-97

Although shorter wavelengths (e.g., 514 nm) of light have proved effective in the destruction of cultured human bladder cells, the minimal depth of penetration at these wavelengths has prevented their clinical use. 98 On average, red light at 630 nm used for clinical PDT with DHE or ALA penetrates between 1 and 3 mm. 99 Light wavelengths from 700 to 850 nm penetrate nearly twice this depth, making longer visible wavelengths more attractive for photodestruction of tumors, particularly solid tumors. The total light dose is usually delivered in one session using continuous-light application. The optional properties of targeted tissue must be considered to optimize treatment plans in PDT. The bladder acts as a light-integrating sphere and must be considered as such when planning treatment dosimetry.

45.3.2.3 Clinical Studies

45.3.2.3.1 Patient Selection

The indications for the use of PDT in treatment of bladder cancer have yet to be clearly defined. Most studies have been performed in patients with recurrent bladder cancer confined to the mucosa (Ta), submucosa (T1), or carcinoma *in situ* (Tis). The majority of treatments reported in the literature were performed in "worst-case" patients who had failed other conventional bladder-cancer therapies such as instillation therapy (BCG or mitomycin) or transurethral resection. ^{100,101} In general, long-term results have documented that patients with tumor stages greater than T1 are not good candidates for PDT. The best results have been obtained in patients with Tis. ¹⁰²

45.3.2.3.2 PDT Technique for Bladder Cancer Treatment

A number of photosensitizers have been proposed for the PDT of bladder cancers, but HPD and DHE have been the most widely investigated. Table 45.1 summarizes the results of 11 recent studies performed with 2.5 to 5 mg/kg HPD or 1.5 to 2 mg/kg DHE. ^{103–113} The interval between drug administration and light treatment was usually 24 to 72 h. The homogenous application of light to the bladder wall to achieve a uniform and consistent illumination of each part of the bladder has been problematic. ¹¹⁴ For whole-bladder irradiation (integral PDT) several methods have been tested to achieve a more homogenous light distribution. Laser-light scattering optics, ¹¹⁵ light-diffusing medium, e.g., intralipid, ^{116,117} or specific catheters for light application in the bladder have been developed. ¹¹⁴

For focal therapy of lesions a flat-cut fiber (front-end light emission) is suitable, whereas for whole-bladder irradiation spherical bulb-type diffusers produce a homogenous light distribution. Scattering of light during whole-bladder treatment increases the actual light dose by a factor of five to six in a bladder model, and there is considerable interpatient variability in light scattering. 118,119

The treatment surface area, treatment time, and power density must be calculated individually to achieve the optimal treatment. ^{102,120} Intravesical light treatment was usually performed under general or spinal anesthesia. ^{102,120} For focal tumor treatment a light dose of approximately 150 J/cm² has been reported as sufficient. ¹⁰⁰ Commonly only 15 to 25/30 J/cm² light are necessary for whole-bladder

 TABLE 45.1 Clinical Experiences with PDT for Bladder Cancer

Author/ Ref. No.	Indication	N	Drug and Dose	Light Energy	Results at 3 Months	Long-Term Results	Adverse Effects
Nseyo ¹⁰³	Recurrent Ta to T3 and CIS	23	DHE 2 mg/kg	5–60 J/cm ²	CR 7 (30%) PR 10 (43%)	Not reported	All patients with urgency, frequency, nocturia, bladder spasms; 4 patients with bladder shrinkage
Prout ¹⁰⁴	Recurrent and newly diagnosed Ta to T1	19	DHE 2 mg/kg	Focal: 100–200 J/cm ² Whole bladder: 5.5 J/cm ²	CR 9 (47%) PR 9 (47%)	Not reported	18 (95%) with adverse events
Heng Li ¹⁰⁵	Bladder	50	HPD 5 mg/kg	<u>Focal</u> : 100–300 J/cm ²	CR 40 (80%) PR 4 (8%)	Not reported	Not reported
Jocham ¹⁰⁶	Recurrent multifocal Ta/T1	20	DHE 1.5–2 mg/kg HPD 3 mg/kg	Whole bladder: 15–70 J/cm ²	CR 83% of tumors	6 NED* up to 5 years	All patients with pollakisuria, dysuria, and temporary bladder shrinkage
Naito ¹⁰⁷	Recurrent multifocal Ta/T1 and CIS	35	HPD 3 mg/kg DHE 2 mg/kg	Whole bladder: 10–30 J/cm ²	CR 24 (69%) PR 5 (14%)	10 NED average of 20.9 months (5 months to 5 years)	All patients with bladder irrigation including hematuria, frequency, and burning urination
Windahl ¹⁰⁸	Recurrent Ta to T3 and CIS	11	HPD 2.5 mg/kg DHE 2 mg/kg	Whole bladder: for HPD: 30–53 J/cm ² for DHE: 15 J/cm ²	CR 8 (73%) PR 1 (9%)	4 NED for 12–30 months	9 (82%) patients with bladder symptoms: frequency, urgency and dysuria, hematuria
D'Hallewin ¹⁰⁹	Multifocal Ta and CIS	15	DHE 2 mg/kg	Whole bladder: 75–100 J/cm ²	CR 15 (100%)	9 NED at 36 months	All patients with irritative symptoms: bladder shrinkage (2 patients required cystectomy for permanent fibrotic shrinkage)
Kriegmair ¹¹⁰	Recurrent Ta to T1 and CIS	21	DHE 2 mg/kg	Whole bladder: 15–30 J/cm ²	CR 12 (57%)	5 NED for 15–42 months	19 (90%) patients with dysuria and urgency; 1 patient with bladder shrinkage
Uchibayashi ¹¹¹	Recurrent Ta to T1 and CIS	34	HPD 3 mg/kg DHE 2 mg/kg	Whole bladder: dose not reported	CR 25 (74%)	4 NED at 24 months	34 (100%) hematuria, burning, frequency; temporary bladder shrinkage
Walther ¹¹²	Recurrent Ta to T1 and CIS	20	DHE 1.5–2 mg/kg	Whole bladder and focal: 5.1–25.6 J/cm ²	CR 9 (45%)	4 NED average of 36.3 months (23–56 months)	20 (100%) urgency, frequency, and suprapubic pain
Nseyo ¹¹³	Recurrent Ta to T1 and CIS	58	DHE 1.5–2 mg/kg	Whole bladder: 10–60 J/cm ²	CR 75–90%	3 NED average of 50 months (9–110 months)	Not reported

^{*}NED = No evidence of disease.

PDT.^{100,114,121} Usually a power density of less than 50 mW/cm² and bladder-filling pressure lower than 30 cm H₂O are adequate.¹²¹

45.3.2.3.3 Results

As noted in Table 45.1, recent studies demonstrate the excellent short-term responses of PDT in highrisk populations with complete tumor-remission rates between 30 and 100% at 3 months post treatment. 103–113 Patients with no evidence of disease for up to 10 years after PDT have been reported. 113 However, the majority of patients with initial complete responses experienced recurrence of the cancer. Recurrences occurred more frequently in patients with large tumors, higher tumor stages, and higher tumor grades and less frequently in patients with carcinoma *in situ*.

45.3.2.3.4 Adverse Reactions

Increased and prolonged skin photosensitivity is the most frequent treatment-related adverse event in PDT.^{122–124} Photosensitivity or phototoxic reactions resemble sunburns or erythemas of different severity grades from reddening to the occurrence of edema or bulla formation.¹²⁵ Unfortunately, the documentation of these events is inconsistent in the literature, which results in reported frequencies of skin photosensitivity reactions in 10 to 100% of patients treated with photodynamic therapy.^{103,104,112,122–124,126–128} Skin-photosensitivity reactions are reported to occur within days to months after photosensitization.^{124,129–131} Depending on the pharmacological properties of the photosensitizer, patients should avoid direct sunlight and bright indoor light and wear protective clothing for 6 to 8 weeks following PDT with DHE, or 1 to 2 weeks following BPD-PDT.^{124,131}

The most frequent local side effect of PDT in the bladder is irritability of various degrees starting immediately after the treatment and usually lasting for up to 4 weeks, in rare cases for several months. 103,106,107,109,112 Almost all patients experience urinary frequency, urgency, and mild hematuria. 107,120 These acute inflammatory-type reactions seem to be light-dose-dependent and are more severe if the bladder has extensive disease or has undergone previous radiation therapy.^{103,108,109} One immediate consequence of the inflammatory response is a temporary decrease in bladder capacity and compliance. Bladder capacity can be reduced by 20 to 80% within the first few days after PDT but usually returns to pretreatment values. The loss of capacity seems to correlate with the light dose/drug doses applied and the resulting amount of tissue damage. 106,107,109 Some authors have recommended excluding patients with bladder capacities less than 200 ml from PDT.¹⁰⁷ While most of these changes are reversible, cases of permanent fibrotic changes of the bladder wall requiring cystectomy have been reported. 108,132,133 Patients who have undergone radiation therapy for bladder cancer are at a higher risk for irreversible fibrosis of the bladder. 108 However, the problem of permanent bladder fibrosis may reflect overtreatment with light, drug, or both. 120 Choosing the correct treatment parameters should reduce damage to the bladder muscle layers. 120,134 Other rare local adverse effects reported include bladder calcifications presumed to occur because of tissue injury and rectovesical fistula. 108,112 Almost all side effects are reversible except fibrotic bladder shrinkage.100

45.3.2.3.5 PDT after Intravesical ALA Instillation

More recently, PDT after intravesical instillation of ALA has been advocated as an effective treatment for superficial bladder cancer. ^{135,136} This technique may reduce the problem of long-term detrusor-muscle damage and skin photosensitivity. Patients retained a 30-ml sodium bicarbonate solution containing 5 g ALA for 4 to 8 h in their bladders. Thereafter bladders were illuminated with green (514 nm) and red light (635 nm) with the patients under general or spinal anesthesia. ¹³⁶ At 3 months after therapy four of ten patients had a complete and two of ten had a partial response. No skin phototoxicity or bladder-capacity reduction was observed. All patients reported dysuria and pollakiuria and six had a macrohematuria. Long-term results have yet to be reported.

45.3.2.3.6 Photodynamic Detection (PDD) of Bladder Cancer

The fluorescent properties of several photosensitizers have been studied for their use in the detection of neoplastic diseases. Fluorescence is the emission of light from an excited molecule and has been used to determine the uptake of a photosensitizer by malignant tissues. 99,137–139 Fluorescence detection after tumor

sensitization with a photosensitizer has been investigated for its potential to increase the diagnostic accuracy of cystoscopy for bladder cancer. Ho-143 Preclinical and clinical studies have confirmed increased fluorescence of bladder tumor tissue. A sensitivity of 97% in detection of bladder tumors has been reported for fluorescence cystoscopy as compared to standard white-light cystoscopy (73% sensitivity), while the specificity did not differ significantly. However, the value of this technology is controversial, and it remains to be integrated as a standard tool into the diagnostic armamentarium for bladder cancer detection.

Acknowledgment

The research for this chapter was supported in part by the Stranahan Chair for Oncologic Research, Medical College of Ohio Foundation.

46.1 Introduction

The use of lasers in the field of gastroenterology has evolved mainly because of the availability of flexible endoscopes that allow easy access to the lower and upper gastrointestinal (GI) tract. Laser energy may be easily delivered using a fiber optic passed through the working channel of the endoscope. In general, lasers have been used for either therapeutic or diagnostic applications. This review focuses on the therapeutic application of lasers in gastroenterology.

The major therapeutic applications of lasers in gastroenterology have been for ablation of early and advanced cancers, stopping of hemorrhage from ulcers, treatment of vascular malformations, and lithotripsy.

46.2 Lasers for Destruction of Tumors

In general, these lasers can be categorized as either photodynamic therapy (PDT) lasers or thermal lasers. PDT lasers are used to activate a specific photosensitizer in the tumor. Thermal lasers deliver concentrated laser energy to the tissue, resulting in coagulation or vaporization of tumors.

46.2.1 Lasers for PDT

PDT is a new class of cancer treatment that uses a combination of photosensitizer and laser light to destroy malignant tissues. First, a photosensitizer is administered, typically intravenously. After the photosensitizer accumulates in the tumor, light from a laser is delivered to the tumor, resulting in a reaction between the photosensitizer and the oxygen in the tissue. The resulting singlet oxygen, or free radicals, is highly cytotoxic, causing necrosis of the tissue. PDT for palliation of dysphagia in patients with partially or completely obstructing esophageal cancer has been reported.¹⁻⁴ Photofrin® (porfimer

sodium) from Axcan Pharma, Inc. (Mont-Saint-Hilaire, Quebec, Canada) is currently the only photosensitizer approved by the U.S. Food and Drug Administration for treatment of esophageal cancer and endobronchial lung cancer. There have also been reports of PDT in the GI tract for patients with early esophageal cancer and dysplasia in Barrett's esophagus.^{5,6} The phase III multicenter clinical study for treatment of patients with high-grade dysplasia in Barrett's esophagus was recently completed.

An important component of PDT is the delivery of light to the tumor. This chapter discusses different lasers and light-delivery devices used for PDT of premalignant and malignant conditions in the GI tract. The choice of laser is determined by the photosensitizer in addition to the desired depth of necrosis. For example, porfimer sodium is activated at a wavelength of 630 nm. Meta-tetrahydroxyphenylchlorin (mTHPC), a second-generation photosensitizer, is typically activated at 652 nm. These wavelengths are in the red region of the spectrum and penetrate the tissue effectively. On the other hand, a specific laser may be employed to limit the depth of necrosis in the treated tissue. An argon laser at a single wavelength of 514 nm may be used to produce minimal depth-of-tissue necrosis, thereby minimizing the risk of perforation in treatment of superficial lesions in the esophagus.

In gastroenterology, laser light must be delivered to the tissue using optical fibers. Different fiber configurations and light-delivery devices have been developed for treatment of different conditions. Following the discussion of PDT lasers, light-delivery devices for treatment of advanced esophageal cancer, dysplasia, and early cancer in Barrett's esophagus, gastric cancer, and colorectal tumors will be reviewed.

46.2.1.1 Argon-Pumped Dye Laser (Argon/Dye Laser)

The most widely used laser for PDT has been the continuous-wave (CW) argon-pumped dye laser (argon/dye laser). Argon/dye lasers can generate powerful monochromatic light that can effectively be coupled into an optical fiber for delivery to the tissue. In addition, the wavelength of the dye laser can be adjusted to match the optimum absorption of the photosensitizer. For example, porfimer sodium and its older versions hematoporphyrin derivative (HPD) and dihematoporphyrin ether (DHE) are activated at 630 nm generated from an argon/dye laser.^{3–5,7–13} Aminolevulinic acid (ALA)-induced protoporphyrin IX (PpIX) is activated at 635 nm,¹⁴ which can easily be obtained from the same argon/dye laser with minor adjustment to the birefringent filter in the dye laser. An argon/dye laser tuned at a wavelength of 652 nm can be used to activate mTHPC.^{15,16}

The amount of power from a dye laser is mostly a function of the size of the pumping argon laser. High-power argon lasers, in the range of 20 W, are typically required to obtain sufficient power conversion from the dye laser.³ Different laser manufacturers such as Spectra Physics (Mountain View, CA) make scientific argon/dye laser that have been used extensively.^{7,15} Scientific lasers require frequent minor optical adjustments for optimal performance.

Lumenis, Inc. (Santa Clara, CA) formerly known as Coherent, manufactures a clinical argon/dye laser, Lambda plus PDT laser, specifically designed for PDT with Photofrin.^{4,17} This laser can generate 2.7 W of 630-nm light. All optical adjustments are done automatically during the warm-up period, which takes about 2 min.

46.2.1.2 KTP-Pumped Dye Laser (KTP/Dye Laser)

KTP/dye laser is a clinical PDT laser system manufactured by Laserscope (San Jose, CA). It is a quasi-CW (25 kHz) pulsed laser system (consisting of a KTP laser and a dye module) that several studies have shown to be equivalent to a CW light source such as argon/dye laser. ^{18,19} The dye module is designed to operate at various wavelengths. This laser has been used at 630 nm for activation of Photofrin, ⁵ at 652 nm for activation of mTHPC, ²⁰ and at 635 nm for activation of ALA-induced PpIX. ^{21,22}

The Laserscope system employs a commonly used surgical KTP laser (532 nm). The 532-nm light from the KTP laser is used to optically pump a specially designed dye laser (600 Series dye module), which generates the 630 nm. Two models are available. The standard model has a maximum power of 3.2 W when pumped by a 700 Series KTP laser. The high-power XP 600 Series dye module has a maximum power of 7 W when pumped by 30 W of 532 nm from an 800 Series KTP laser. A high-power system is

useful when treating a long segment of Barrett's esophagus using a 7-cm balloon.⁵ An advantage of this system is the application of a KTP to pump a dye module. The laser energy from the KTP laser is delivered to the dye module using a fiber that allows independent movement of the dye module and the KTP laser. A PDT dye module can be purchased as an accessory to the KTP laser.

46.2.1.3 Gold-Vapor Laser

Gold-vapor lasers generate a monochromatic 627.8-nm pulsed light with a typical repetition-rate range of 5 to 15 kHz.^{23–26} Gold-vapor lasers have been used for activation of ALA-induced PpIX and Photofrin (and HPD and DHE). Nakamura et al.²³ used a gold-vapor laser to treat early gastric cancer using HPD PDT. Mlkvy et al.^{27,28} used a gold-vapor laser to activate Photofrin and ALA-induced PpIX for treatment of a variety of GI tumors. The use of this laser eliminated the need for a dye laser. However, since the beam diameter of a gold-vapor laser is large, a 600-µm-diameter fiber is typically required for efficient coupling of the laser beam to the fiber.²⁹ Since gold-vapor lasers are pulsed, several studies have shown their equivalence to the CW argon/dye laser in inducing PDT response.^{24–26,29}

46.2.1.4 Copper-Vapor Pumped Dye Laser

While gold-vapor lasers can produce high powers at a single wavelength of 627.8 nm for activation of Photofrin, their use for activation of other photosensitizers is limited. However, gold-vapor lasers can be modified into copper-vapor lasers that in turn can be used to pump a dye laser to generate suitable wavelengths for PDT.²⁹ Barr et al.³⁰ showed that a copper-vapor pumped dye laser produced the same PDT effect in the normal rat colon as that produced with a CW argon/dye laser.

46.2.1.5 Diode Lasers

Diode lasers are semiconductor light sources that are compact, user-friendly, and less expensive than conventional lasers. Diode lasers have been available at longer wavelengths such as 664 nm for activation of tin ethyl etiopurpurin, or SnET2 (Miravant Medical Technologies, Santa Barbara, CA) for treatment of metastatic breast cancer and Kaposi's sarcoma. Diode lasers with sufficient power at 630 nm (for activation of Photofrin) have been more difficult to manufacture. Diomed (Andover, MA) manufactures a diode laser with a wavelength of 630 nm ± 3 nm with a maximum calibrated power of 2.0 W from the fiber-optic delivery system. An internal power meter allows measurement of power from the fiber delivery system. Diomed also manufactures diode lasers at other wavelengths such as 635, 652, and 730 nm. All diode lasers operate on standard electrical power supply and require no water cooling. They are mobile and rugged, require less maintenance, and are cheaper than other PDT lasers.

46.2.1.6 Argon Laser

The choice of laser is sometimes dictated by the desired depth of tissue necrosis. Most photosensitizers can be effectively activated at both short and long wavelengths. Therefore, a suitable short wavelength that is strongly absorbed by tissue may be used to limit depth of necrosis in the treated area. Green light (514 nm) from an argon laser has a limited penetration depth in tissue due to its strong absorption by hemoglobin. Using mTHPC, 514-nm green light from an argon laser has been recommended to eliminate the possibility of through-the-wall necrosis in the esophagus. 9,15,16 In contrast, esophageal perforations after mTHPC PDT were reported when using 652-nm red light. 9,15,16

46.2.2 Light-Delivery Devices for PDT

Light-delivery devices for GI PDT are fiber optics with special configurations for treatment of various tissue sites. Historical data on the evolution of devices will be presented with emphasis on the most recent developments.

46.2.2.1 Esophageal Cancer

Before the development of cylindrical diffusers many investigators used a straight-tip bare fiber that delivered the laser light from the tip of the fiber, illuminating the surface of the lesion.^{3,4,10,12} These fibers were passed

through the scope, and the tip of the fiber was held at a specific distance from the tissue during the treatment. Often the fiber tip was inserted into the tumor for interstitial treatment of the tumor.^{4,10,12}

Cylindrical diffusers were developed for endoscopic intraluminal treatment of partial or completely obstructing esophageal cancers.^{3,10,31} Cylindrical diffusers circumferentially illuminate a specific length of the inner surface of a tubular organ such as the esophagus. The distal end of the fiber is modified such that the light is emitted uniformly in a circumferential manner throughout the length of the diffuser section. These fibers are manufactured at different lengths of 1, 1.5, 2.0, 2.5, and 5 cm for treatment of esophageal cancer and endobronchial cancers (Optiguide, Fibersdirect.com, Kirkland, WA). The choice of diffuser length is dictated by the length of the tumor. These fibers are semirigid but can easily be passed through a standard GI scope and may be implanted into a tumor such as in completely obstructing esophageal cancer. Typical light dose for palliation of dysphagia in advanced esophageal cancer is 300 J/cm. These diffusers are designed for use at 630 nm.

Flexible cylindrical diffusers have been developed for intraluminal illumination of tissue (CardioFocus, Inc., West Yarmouth, MA). Flexible diffusers are available in several lengths (1 to 5 cm). These fibers are easily passed through the scope regardless of scope angulation. They are especially useful in endobronchial PDT, where the bronchoscope channel is much smaller.

Van den Bergh³² described a reusable light-delivery device called esophageal light distributor based on the standard Savary-Gilliard dilator with a diameter of 15 mm. The distal end of the light distributor is shaped like a Savary-Gilliard dilator. The illuminating section is rigid and allows either 180 or 240° noncircumferential illumination of the esophageal lumen. This design was recommended over a circumferential illuminator to reduce stenosis after PDT.^{9,15,32} This esophageal light distributor is typically used under general anesthesia.³²

46.2.2.2 Barrett's Esophagus and Early Esophageal Cancer

Several techniques have been used to treat superficial cancer of the esophagus and dysplasia in Barrett's esophagus. Before development of cylindrical diffusers and balloons, a straight-tip fiber was used to treat early esophageal cancer. Later, cylindrical diffusers were developed to treat a specific length of the esophagus. Overholt et al. Used a 2-cm cylindrical diffuser to treat two patients with early invasive cancer in Barrett's esophagus. Laukka and Wang used a 2-cm cylindrical diffuser for treatment of patients with dysplastic Barrett's mucosa. Long segments were treated sequentially in 2-cm intervals by repositioning of the diffuser. Barr et al. used a 3-cm cylindrical diffuser in a specially designed 10- to 14-mm perspex dilator to provide even light distribution. Long segments were treated by withdrawing the light source and repeating the treatment with some overlapping of the fields. Gossner et al. used a 2-cm cylindrical diffuser for treatment of short segments of Barrett's and early cancer. Long segments were treated sequentially by repositioning of the diffuser.

Grosjean et al. 15 and Savary et al. 9 used a previously described cylindrical light distributor with 180 and 240° windows and a diameter of 15 mm to treat patients with early squamous cell carcinoma of the esophagus. They indicated that by using a noncircumferential light-delivery device the incidence of stenosis was reduced by limiting tissue damage to part of the lumen. The design of the cylindrical light distributor has been described. 32

A balloon light-delivery device was specifically developed for treatment of Barrett's esophagus.³³ The balloon was constructed from a polyurethane membrane and had a diameter of 25 mm to effectively flatten the esophageal folds to allow uniform illumination of specific length of the esophagus. Increasing the balloon diameter reduced the blood flow in tissue, resulting in no PDT injury even at higher light doses.³⁴

A balloon with a 2- or 3-cm window was first used clinically to treat four patients.¹⁷ A 2-cm cylindrical diffuser was used in the 2-cm windowed balloon. A 2.5-cm cylindrical diffuser was used in the 3-cm windowed balloon (3-cm diffusers were not available). Long segments were treated sequentially by repositioning of the balloon. This balloon was used to determine the proper light dosimetry and for developing the methodology.³⁵

PDT of long segments of Barrett's using a 2- or 3-cm windowed balloon required sequential treatments of the esophagus during each session. Later, 5- and 7-cm-long windowed balloons were developed to allow treatment of a longer segment of the Barrett's esophagus without repositioning of the balloon.^{5,36} Flexible 5- or 7-cm cylindrical diffusers were used in, respectively, the 5- and 7-cm windowed balloons. In addition, the balloon design was modified for guidewire positioning of the balloon in the esophagus. The light dose of 175 to 200 J/cm using these balloons is typically required for destruction of high-grade dysplasia in Barrett's esophagus.

These balloons were modified with a 180° window to illuminate half the circumference of the lumen. While the concept of semicircumferential treatment was demonstrated in the canine esophagus,³⁷ it was never used clinically because suitable cases were not found. We believe that the entire circumference of the esophagus should be treated to eliminate all Barrett's mucosa. While this increases the likelihood of potential complications from strictures, it improves results in the ultimate goal of eliminating all Barrett's mucosa.

The above balloon was modified for the phase III multicenter study for treatment of high-grade dysplasia in Barrett's esophagus. The interior surface of the distal and proximal capped portions of the balloon was coated with a reflective material (Wilson-Cook Medical, Inc., Winston-Salem, NC). A cylindrical diffuser 2 cm longer that the window length was used inside the central channel, extending 1 cm proximally and 1 cm distally beyond the window margins. Using this diffuser/balloon configuration, the uniformity of light emitted from the balloon window was improved (unpublished data from QLT). In addition, laboratory testing and canine studies showed that the light intensity emitted from the balloon window was 1.5 times higher using the reflective-balloon design vs. that from the initial balloon design (M. Panjehpour et al., unpublished data). Using this balloon, a light dose of 130 J/cm was used for treatment of high-grade dysplasia in Barrett's esophagus. The reflective balloons were available for the study in window lengths of 3, 5, and 7 cm. The balloon material was changed to nonstretchable polyethylene terephthalate (PET). It is critical to inflate the balloon to about 20 mm Hg to reduce the pressure on the esophageal wall, minimizing the reduction of oxygen supply to the tissue.⁵

46.2.2.3 Gastric Cancer

Straight-tip bare fibers have been used for treatment of gastric cancer. 4,11,12 These were simple fiber optics with cleaved and polished ends that allowed surface illumination of the tumor by positioning the fiber tip at a specific distance from the tissue. Often, the fiber tip was inserted into the tumor for intralesional (interstitial) illumination of tumors. 5,12 In most recent works, microlens fibers have been developed to deliver light to the surface of gastric tumors. 14,20 Microlens fibers generate a circular beam of light with excellent edge-to-edge uniformity and a well-defined illumination field. Microlens fibers are routinely used for cutaneous PDT. It should be noted that the beam diameter (and ultimately the energy density) is strongly dependent on the distance between the tissue and the tip of fiber when using a microlens fiber (or bare straight-tip fiber). Therefore, endoscopic illumination of a lesion should be performed taking into account the relative movements of fiber and tissue inherent in any endoscopy procedure.

46.2.2.4 Lower-GI-Tract Cancers

The use of PDT has been reported for treatment of a variety of lower-GI malignancies. Much of the treatments were delivered using a bare straight-tip fiber. Loh et al.¹³ used a bare fiber by removing the cladding from the distal end. They inserted the tip of the fiber into villous adenomas and treated the polyps intralesionally. Mlkvy et al.²⁷ used a bare fiber and inserted the tip 1 to 2 mm deep into adenomatous polyps. Patrice et al.⁴ used bare fibers to either superficially or intralesionally treat rectosigmoid adenocarcinoma in inoperable patients. In the case of superficial treatment, the tip of the fiber was positioned 2 to 2.5 cm from the surface of tumor during the treatment. For intralesional treatment, the tip of the fiber was implanted into the tumor. Mlkvy et al.²⁸ treated colorectal and duodenal tumors using a bare fiber placed interstitially or intraluminally using a 1-cm cylindrical diffuser.

46.2.3 Lasers for Thermal Ablation of Tumors

46.2.3.1 Neodymium:Yttrium-Aluminum-Garnet (Nd:YAG) Laser and Argon Laser

The initial application of laser in gastroenterology was for thermal ablation. Laser energy is always delivered through the working channel of an endoscope using an optical fiber. The tissue effect depends on several parameters including the wavelength, power density, and energy density of the laser delivered to the tissue. Vaporization of tissue is achieved when the power density is sufficiently high. However, tissue ablation is also possible at lower power densities where coagulation is achieved, resulting in tissue necrosis. The necrotic tissue is either sloughed or can be debrided endoscopically at a later session. While several lasers have been applied, the Nd:YAG laser has been the most widely used system. Nd:YAG lasers are solid-state lasers that can generate high powers in the range of 60 to 120 W at a wavelength of 1064 nm. The laser energy is easily transmitted through a 600-µm quartz fiber, which is passed through the biopsy channel of the endoscope.

Fleischer et al.³⁸ reported the first palliative application of Nd:YAG for esophageal carcinoma. Significant clinical, endoscopic, and radiographical improvements were noted in all patients. Jensen et al.³⁹ compared the Nd:YAG laser and electrocautery technique for palliation of esophageal cancer. They concluded that electrocautery and the Nd:YAG laser were similar for treatment of circumferential tumors, while the laser was more effective for treatment of noncircumferential tumors.

The Nd:YAG laser has typically been delivered as a noncontact technique using a quartz fiber where the tip of the fiber is held about 1.5 cm from the tissue during the laser application. Later, contact probes were introduced by Joffe⁴⁰ to allow more precise application of laser energy to the lesions by touching the probe to the tissue. The contact probe is attached to the distal end of a quartz fiber. The contact probes are constructed from synthetic sapphire crystal that has proven superior to conventional noncontact quartz fiber for delivery of Nd:YAG. The advantages of using the contact technique include greater precision in delivering the laser, protection of the quartz-fiber tip from damage, and lower power requirement from the laser. In addition, there is less smoke generated using the contact technique. Contact probes are geometrically designed for each specific application and desired effect (coagulation, vaporization, cutting). The rounded contact probe is typically used for coagulative endoscopic applications using a laser power of 12 to 15 W vs. the noncontact technique requiring 80 to 100 W of laser power.⁴¹ Overholt⁴² has provided a clinical review of both contact and noncontact laser ablation for esophageal cancer. Regardless of technique, multiple sessions of laser therapy are required to establish an open lumen in esophageal cancer patients. While laser therapy is not intended to increase survival, Karlin et al.⁴³ reported significantly longer survival in esophageal cancer patients who were treated with Nd:YAG laser.

Another technique was described by Sander and Poesl⁴⁴ for delivering Nd:YAG laser energy for coagulation of tissue. In this technique, a water jet was used to guide the laser energy to the tissue. The advantages of this technique include ease of use, absence of smoke and carbonization, reduction in organ distention, and deeper coagulation in tissue. They suggested the use of a water-jet Nd:YAG laser for treatment of tumors in the GI tract.

While surgery remains the standard treatment for patients with colorectal cancers, lasers have been used for palliation of symptoms in inoperable or high-risk patients. The majority of treated tumors are in the rectum or rectosigmoid due to better access and less patient preparation. The typical laser power is about 100 W using a noncontact laser.⁴⁵ Mathus-Vliegen⁴⁶ has thoroughly reviewed the application of lasers for colorectal cancer. In general, lasers were effective for those with bleeding tumors. There was 75% efficacy in palliation of obstructing colorectal cancers. While the majority of laser applications have been for palliation of symptoms in advanced lower GI cancers, Lambert et al.⁴⁷ reported successful treatment of early colorectal cancer using laser.

Thermal lasers have also been used for treatment of benign lower-GI lesions. Brunetaud et al.⁴⁸ reported using argon laser and Nd:YAG laser for rectal and rectosigmoid villous adenomas. Total tumor ablation was achieved in 92% of patients.

Yasuda et al.⁴⁹ reported on the use of Nd:YAG laser for treatment of early gastric cancer. They indicated that the Nd:YAG laser was curative in 96% of 28 cases of early gastric cancer. They recommended using laser therapy for those cases that were confirmed as mucosal lesions by endoscopic ultrasound.

46.2.3.2 Mid-Infrared Lasers

Mid-infrared lasers such as the erbium:YAG laser (2.94 μm) and thulium-holmium-chromium:YAG (THC:YAG) laser (2.15 μm)⁵⁰ may also be applied endoscopically because the laser energy can be transmitted through quartz fibers. In addition, as with CO₂ lasers a large absorption peak of water in the 2- to 3-μm range makes these lasers attractive for precision cutting. Treat et al.⁵⁰ reported preclinical results using the above lasers in human colon (*in vitro*) and in rabbit stomach (*in vivo*). They indicated that the depth of penetration was controllable with minimal spreading of injury 24 h after treatment. Bass et al.⁵¹ compared pulsed THC:YAG laser with a clinical Nd:YAG laser in canine colonic mucosa and concluded that the THC:YAG laser created significantly less collateral thermal damage as compared with the Nd:YAG laser. They recommended this laser to reduce the risk of perforation when removing sessile polyps. Similarly, Nishioka et al.⁵² tested a flashlamp-excited pulsed holmium-yttrium-scandium-gal-lium-garnet laser (2.1-μm, 250-μsec pulses) in rabbit liver, stomach, and colon. They indicated that this laser produced less thermal necrosis than the Nd:YAG laser and the ablation rate could be controlled in a more precise manner; they recommended it as an alternative method for endoscopic ablation of tissues.

46.3 Lasers for Endoscopic Control of Hemorrhage in Ulcers

Both the argon and Nd:YAG lasers have been used for photocoagulation of hemorrhage from peptic ulcers.^{53–55} However, the Nd:YAG has proven to be superior to the argon laser and has been used most commonly. Typically, the Nd:YAG laser is delivered to the hemorrhage via a quartz fiber at a high power of 70 to 90 W using the noncontact method where several applications are delivered around the ulcer. The efficacy of laser therapy for hemorrhaging ulcers was reported by Swain et al.⁵⁵ and Rutgeerts et al.⁵⁶ where the need for emergency surgery and mortality was effectively reduced. The exact role of laser for this application is not clear because other nonlaser techniques, such as bipolar electrocoagulation, have been shown to be as effective at a lower cost.⁵⁷

46.4 Lasers for Treatment of Vascular Malformations

Angiodysplasia and vascular malformations associated with hereditary hemorrhage telangiectasia (HHT) are the major causes of hemorrhage in the GI tract. Surgical treatment of these types of hemorrhage has been associated with considerable morbidity and mortality and is not an option for patients with multiple lesions throughout the GI tract. The argon and Nd:YAG lasers have been used for endoscopic treatment of such vascular lesions.

The argon laser has the advantage that its blue-green light is strongly absorbed by hemoglobin, resulting in relatively shallow treatment depth. This may reduce the risk of perforation given a careful control of delivered energy. However, deeper lesions within the submucosa may not be treated effectively. Waitman et al.⁵⁸ used an argon laser for treating hemorrhage secondary to telangiectasia, indicating that two thirds of patients had no recurrence of bleeding. Jensen et al.⁵⁹ used an argon laser for treatment of GI angioma. They reported a significant reduction in bleeding and transfusions after laser therapy.

The Nd:YAG laser has better penetration in tissue than the argon laser. Therefore, the Nd:YAG laser can coagulate vessels that are deeper within the submucosa. Rutgeerts et al.⁶⁰ used an Nd:YAG laser to treat vascular lesions in the upper and lower GI tract. The laser therapy resulted in significant reduction in bleedings as well as the need for transfusions. The treatment was most effective for patients with angiodysplasia. The treatment was not effective in patients with HHT. Bown et al.⁶¹ used both the argon laser and the Nd:YAG laser for treatment of vascular lesions (HHT, single and multiple angiodysplasias).

The majority of patients required minimal transfusions after one or more laser therapies. The Nd:YAG laser appeared to achieve better long-term results due to its greater depth of penetration for destroying submucosal vessels.

Lasers have also been used for treating hemorrhage from other vascular lesions such as watermelon stomach and radiation-induced vascular lesions. Gostout et al.⁶² reported using an Nd:YAG laser for treatment of watermelon stomach. Reduction in bleeding was achieved in 92% of patients. Bjorkman and Buchi⁶³ used an argon laser to effectively treat watermelon stomach within the mucosal layer. Viggiano et al.⁶⁴ used an Nd:YAG laser for treating radiation-induced proctopathy. After laser therapy, the number of patients with daily bleeding was reduced from 85 to 5%.

46.5 Lasers for Lithotripsy

High-energy pulsed lasers may be used to deliver a large amount of optical energy, resulting in the shattering of the biliary stones. The laser energy is delivered to the stone using a small optical fiber. The laser fiber should be in direct contact with the stone to improve the efficiency of fragmentation. The efficacy of stone fragmentation also depends on other laser parameters such as pulse duration.⁶⁵ Longer pulses have a reported tendency to melt renal stones⁶⁶ rather than fragment them. However, pulse durations ranging from 20 nsec to 2 msec have been used effectively.

Several pulsed lasers have been used for fragmenting stones in the common bile duct or intrahepatic ducts. Ell et al.⁶⁷ used a pulsed Nd:YAG laser to treat patients with large common bile-duct stones. The laser energy was transmitted through a 200-µm quartz fiber under direct visualization through a choledochoscope. Two thirds of patients were completely cleared of their stones. In another study by Cotton et al.,68 a pulsed tunable dye laser at a wavelength of 504 nm was used for treating patients who were unresponsive to standard treatments. The pulse duration was 1 µsec. Some degree of fragmentation was detected in 92% of patients. A total of 8% of patients had clearance of their stones. The authors concluded that laser lithotripsy was a safe but challenging alternative to surgery in patients with large bile-duct stones. Dawson et al.69 also used a pulsed tunable dye laser at a wavelength of 504 nm to fragment stones in the hepatic ducts or common bile duct. The pulse energy was 60 mJ. They concluded that laser lithotripsy was a safe nonsurgical alternative for patients who had failed standard treatments. Ell et al. 70 described a smart system that could detect whether the delivery fiber was in contact with a stone or tissue during treatment. If the tip of the probe came into contact with tissue, the laser treatment was terminated to minimize tissue injury. Using a flashlamp-pumped tunable dye laser to fragment biliary stone in vitro, Nishioka et al. 71 showed that the energy threshold was increased when the wavelength was increased from 450 nm to 700 nm. However, changing the pulse duration from 0.8 to 360 μsec did not affect the efficacy of fragmentation. The efficiency of lithotripsy was enhanced if the procedure was performed in an aqueous medium.⁷¹ Due to the complexity of the procedure and the expense of the system, laser lithotripsy is used in a small percentage of patients with common bile-duct stones that have not responded to standard treatments.

While not a lithotripsy application, an interesting use of a high-power pulsed laser is worth noting here. Lam et al.⁷² reported use of a holmium:YAG laser for fragmenting a denture that was impacted in the esophagus of a patient. After disimpacting the denture into the stomach, the laser was used to successfully fracture the denture into three pieces. The pieces were then successfully removed from the stomach.

46.6 Closing Remarks

This chapter reviewed the use of therapeutic lasers in gastroenterology. PDT is the newest development in the use of lasers in gastroenterology; hence, emphasis on the use of lasers and techniques for PDT in the esophagus was noted. This chapter is not intended as a thorough review of clinical literature but rather as an introduction to various applications of lasers in gastroenterology.

47.1 Introduction

Approximately 570,000 new cases of breast cancer occur in the world each year, and breast cancer is the second leading cause of cancer death in women.¹ Breast cancer survival rates are extremely variable, with a current 5-year survival in the U.K. of 68%. This compares poorly with the rest of Europe (average 73%)² and the United States (average 84%).³ No other cancer produces such an emotive response among the general public, due mainly to increased public education and high-profile coverage in the popular press. With ever increasing activity of patient-advocacy groups, attention has been refocused on all aspects of breast cancer care, causing renewed efforts to improve prevention, detection, and treatment. Despite many recent advances, however, a universal cure for breast cancer is still some way off. Research is currently under way to determine if laser treatment has a role to play in the treatment of breast cancer, but at present it can only be regarded as a research technique. Benign conditions of the breast attract much less media attention, but laser therapy appears particularly promising for the treatment of fibroadenomas of the breast, a common condition that causes hard lumps to appear in the breasts of young women.

47.2 Breast Cancer

47.2.1 Surgery

Little has changed substantively over the past century in the surgical treatment of breast cancer in terms of technology. Most surgeons still perform the operation with a scalpel, some technique like cautery to control bleeding and sutures. What has changed is a move toward more conservative, breast-preserving surgery. This shift has essentially taken place only in the last 20 years. This has followed the publication of several large studies that evaluated the long-term survival after localized surgery in conjunction with radiotherapy vs. traditional mastectomy alone. ⁴⁻⁶ Breast-conservation surgery generally means the excision of the cancer with a surrounding rim of normal tissue. Most would accept that a 1-cm margin

around the tumor is adequate, although there is still much debate about this. Although local recurrence rates are higher with lumpectomy as compared with wide local excision, overall survival remains the same.⁴ There is a trade-off between removing enough tissue to keep local recurrence to a minimum against removing too much, with a resultant poor cosmetic outcome.

Lesion size is the main predictor of whether breast-conservation surgery is possible. An arbitrary cutoff figure of less than 4 cm is often quoted, but it is highly dependent on the relative size of the breast
and the position of the lesion, i.e., excision of a moderate-sized tumor in a small breast may have a worse
outcome than a larger lesion in a large breast. Also, excision of tumors in the lower aspect of the breast
often has a poorer cosmetic outcome than those in the upper part due to a pulling down of the nipple
through removal of supporting tissue and contraction of the scar.

What is evident from these trials is that surgery to remove the primary breast tumor serves only to achieve local control of disease and may have little effect on the overall outcome. Any technique that can destroy tumor tissue in the breast equally well without surgical excision has obvious attractions.

47.2.2 Thermal Ablation

The use of heat to treat breast cancer has been documented as far back as 3000 to 2500 B.C. with mention of "cauterization with a fire stick." As heat has the obvious ability to destroy tissue, early physicians saw its potential to destroy cancerous lesions, with the added benefit of achieving cautery to blood vessels at the same time. Thermal destruction of tissue can occur in two ways. Traditionally, any thermal ablative technique has relied on explosive vaporization (true ablation) by using a high-power energy source to cause intracellular water to reach 100°C and therefore vaporize, causing rupture of the cell membrane. The second method is by protein denaturing (thermal coagulation), which utilizes a lower power source to raise the temperature above 50°C for a set period of time. It has been shown that temperatures as low as 41 to 42°C will cause cell death if exposure is prolonged, but as the temperature is increased the time to achieve this decreases. As a rule of thumb, the time required to kill tissue halves for each 1°C increase in temperature. The mechanism of tissue destruction is complex but most probably is related to reduced pH, hypoglycemia, vasoconstriction, increased capillary permeability, and edema. Temperature changes in the opposite direction are also effective. Extreme cold has been used for many years as a method for destroying tissue. Indeed "frostbite" can be just as damaging to tissue, if not more so, than a burn.

As the precision and sophistication of energy-delivery devices has evolved, interest in interstitial thermal therapy has increased. This is the direct delivery of heat into lesions in the center of solid organs, minimizing the effects in the overlying normal tissues. The rate of heat delivery is much slower than with techniques for immediate vaporization of tissue to avoid explosive effects deep within a solid organ, but the precision is usually much better. This is the "gentle-casserole" rather than the "flame-grilled" effect. Such methods are gaining interest for the treatment of a variety of benign and malignant tumors where evaporative ablation is undesirable. All interstitial therapy is critically dependent on imaging to define the limits of the lesion to be treated, to insert the energy-delivering device, and to monitor the efficacy of treatment. Appropriate imaging techniques are evolving rapidly¹² and are discussed later in this chapter.

47.2.2.1 Thermal Ablative Techniques

There are five main methods of tissue ablation by changing tissue temperature, all of which can be adapted for minimally invasive use. Three of these — laser photocoagulation, radio-frequency heating, and microwaves — use electromagnetic radiation. The other two are ultrasound (pressure waves) and cryotherapy (direct damage by freezing). For interstitial use laser and radio-frequency heating are the most convenient because the probes can be inserted into tissue through thin needles. To some extent this is also true for microwaves, but cryotherapy requires a wide enough probe to permit circulation of a coolant such as liquid nitrogen. Therapeutic ultrasound is usually delivered via phased arrays of transducers, and thus it is not necessary to insert anything into the tissue, but it is difficult to produce effects accurately more than a few centimeters deep in tissue or if there are extra tissue planes through which the beam must pass before reaching the target lesion. The discussion in this chapter will be limited to interstitial laser photocoagulation (ILP).

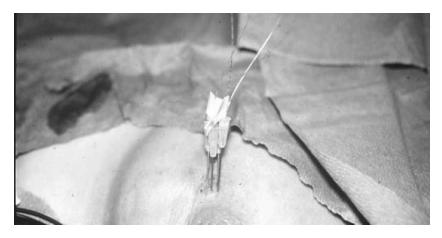

FIGURE 47.1 Needles inserted into breast with fibers passed through needles into the tumor to be treated.

47.2.2.2 Interstitial Laser Photocoagulation

This procedure was first described in 1983.¹³ Simply put, the concept involves a laser fiber (typically 0.2-to 0.4-mm core diameter) being inserted directly into the target tissue (usually through a needle of about 18 gauge) so that light is delivered to the tissue from the end of the fiber as a point source (bare-tip fiber) or emitted from the end section of the fiber (diffuser fiber, where the diffuser section can be up to several centimeters long). The energy is absorbed within the surrounding tissues, causing local thermal necrosis. One or more fibres can be used.¹⁴ Various lasers have been tried, but the most convenient are either a semiconductor diode or a neodymium:yttrium-aluminum-garnet (Nd:YAG) laser, at wavelengths between 805 and 1064 nm. The technique is sometimes referred to as laser interstitial thermal therapy (LITT) or interstitial laser thermal therapy (ILTT).

For treatment of breast tumors, the procedure can be carried out under local anesthetic and mild sedation. Up to four needles can be placed directly into the tumor either under ultrasound or MR guidance (Figure 47.1). Optical fibers are then inserted through each needle. Once the fibers are in place the needle is withdrawn slightly so that the bare ends of the fibers lie within the tumor. Previous work has demonstrated that the size of the laser-induced necrosis is more predictable when the bare end of the fiber is precharred before insertion. 15,16 This leaves a deposit of carbon particles on the tip of the fiber that absorb the laser energy, making the fiber tip a point source of heat. Without this precharring, some patients have shown no discernible treatment effect, probably because the available energy is absorbed in a larger volume of tissue so there is not enough energy per unit volume of tissue to produce a biological effect. The volume of tissue treated from each fiber position can be increased by using diffuser fibers instead of bare-tip fibers, although these are usually larger in diameter than the bare-tip ones and thus require larger needles for insertion. This causes more trauma to the overlying tissue through which the needle must pass to reach the target lesion. Diffuser fibers are also relatively difficult to manufacture in such a way that they tolerate the high temperatures generated during light delivery. Once the fibers are safely secured in position in the target tissue the laser is activated, typically for 10 min at 2 to 3 W per fiber. This gives a characteristic zone of tissue destruction (necrosis) with central charring (sometimes with liquefaction), a surrounding area of heat-fixed tissue consistent with coagulative necrosis, and an outer hemorrhagic rim. These changes are seen in surgical specimens removed a few days after ILP.

Microscopically, the central area contains carbonized and necrotic debris. Within the surrounding heat-fixed zone, the features are of morphologically normal cells but with featureless, heavily stained nuclei consistent with coagulative necrosis (Figure 47.2). Within the hemorrhagic peripheral zone the cells are less severely disrupted, with the only indication of cell damage being some increased staining in the nuclei. Also within this zone are proliferating fibroblasts (cells that lay down scar tissue) and damaged blood vessels with extravasation of red blood cells. It has been shown using enzyme histochemical

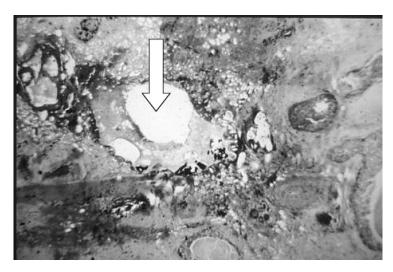

FIGURE 47.2 Photomicrograph of a breast cancer treated with ILP and removed by surgery a few days later. A small amount of charring is visible around the needle track (arrow) with coagulation of the cancer glands outside this zone.

staining (NADH-diaphorase) that all these areas contain dead tissue.¹⁷ These findings have been confirmed recently by a group at Stanford University that is evaluating radio-frequency ablation of breast tumors.¹⁸

47.2.2.3 Clinical Results

The earliest reported case of a laser-treated breast cancer was by Steger et al. in 1989.¹⁹ Since then several studies investigating the feasibility of treating breast cancers in this way have been published.^{15,17,20,21} In all cases, the laser treatment was either purely a research procedure (in which case ILP was followed by surgical removal of the treated cancer for microscopic examination of the treated tissue) or a palliative procedure undertaken when other treatments such as surgery or radiotherapy had failed or the patient had refused alternative treatments.

Harries et al.¹⁵ treated 44 patients with breast cancer prior to routine surgical excision. Predictable areas of tumor necrosis (median diameter 14 mm) were achieved using a precharred fiber. Only one minor complication occurred — a small bleed from the puncture site. Mumtaz et al.¹⁷ reported the outcomes of a further 20 patients with similar results but with more sophisticated imaging, as discussed below.

More recently, a group in Ukraine²⁰ presented its results in the treatment of 35 breast-cancer patients. The researchers used an Nd:YAG laser at slightly higher power outputs (2.5 to 6 W). A total of 28 patients underwent laser therapy prior to surgery, and a further 7 had ILP as their only invasive treatment. All tumors again showed laser-induced necrosis, with increasing diameter of destruction with increasing power and energy levels. There were slightly more complications, however, with four minor skin burns and one gaseous rupture. These were probably related to the increased power employed. As the first two studies have shown, 2.5 W is adequate to produce cell death without evaporative ablation. Of the seven patients who did not undergo surgery, three were postmenopausal with severe coexisting medical disease. Following ILP they all showed a good response to treatment with tumor shrinkage A further three patients with metastases at the time of diagnosis underwent palliative ILP. Two of the three showed a reasonable local response to treatment. The third, however, showed no change in tumor size. The final patient was a young woman who refused surgery. Unfortunately, she progressed quickly with aggressive metastatic disease. Overall, however, their results were again encouraging with few complications.

The most recent study by Dowlatshahi et al.²¹ reported the results of 36 patients with tumors less than 2 cm in diameter treated with an 805-nm diode laser. They employed a single water-cooled diffusing fiber that allowed light to spread from the tip equally in all directions and also maintained the temperature below 100°C to avoid charring, although this type of fiber is considerably larger in diameter than those

used in the earlier studies. All patients underwent surgery 8 weeks later. Examination of the excised tissue showed that there was complete tumor ablation in 66% of cases. Only two minor skin burns were encountered with no serious complications.

The only other study of thermal ablation of human breast tumors *in vivo* was by Jeffrey et al. who described the effects of radio-frequency ablation prior to routine surgery in five patients. ¹⁸ Using a single 15-gauge electrode they demonstrated partial tumor ablation in all patients with no complications. The aim was to assess the feasibility of destroying breast tumors by this method, and they intentionally left part of the tumor untreated to evaluate the margin between ablated and nonablated tissue. The size of necrosis was similar to laser therapy, although the treatment times were much longer — 30 min vs. an average of 10 min for ILP.

These studies have demonstrated the feasibility of producing local destruction of breast cancers using thermal ablative techniques. None of the studies set out to completely destroy breast cancers, although this was achieved in some cases.

Having shown that interstitial therapy can ablate cancerous tissue in the breast, clinicians now face the next major challenges — to produce a noninvasive means of assessing *in vivo* whether the cancer ablation is complete or whether viable malignant tissue has been left behind and to be sure that laser-treated areas heal safely. These aspects are addressed in the following sections of this chapter.

47.2.2.4 Imaging for ILP of Breast Cancer

The main goal of any thermal treatment is to achieve complete local destruction of tumors with minimal damage to surrounding normal tissues and fewer complications than after conventional surgery. One of the key factors is the ability to accurately assess the extent of tumor destruction *in vivo*, either at the time of treatment or shortly afterwards. The gold standard for assessing completeness of tumor clearance is microscopic examination of surgically excised tissue to show that there is no residual cancer at the resection margins. The challenge for those advocating interstitial therapy is to find an equally reliable way of detecting residual viable cancer after treatment without having to remove the treated tissue from the patient. An ideal imaging modality would provide real-time assessment of the extent of tissue destruction. This would allow adjustment of treatment parameters (laser power and treatment time) or repositioning of probes/fibers during treatment to ensure complete ablation of the tumor with a "safe" surrounding rim of normal tissue. Alternatively, it may be easier to look some time after treatment to detect tumor persisting or recurring in the treated area.

Four imaging modalities are being evaluated for assessing the immediate and longer-term efficacy of ILP: ultrasound scanning (US), computerized tomography scanning (CT), magnetic resonance imaging (MRI), and positron emission tomography (PET). US is the simplest option and was tried in the early work with ILP on the liver and breast. ^{15,19,22} Steger found US was useful for placing the needles and fibers prior to treatment; he also found that some changes could be detected during energy delivery. However, US images did not give an accurate indication of the extent of thermal damage either at the time of treatment or subsequently. The studies by Amin²² and Harries¹⁵ reported similar findings. In the more recent study by Dowlatshahi, it was suggested that by using an intravenous contrast agent (Optison), US could detect the loss of blood flow in coagulated tissue,²¹ although there is some doubt about how accurately the boundaries of the necrosed tissue could be defined as the US results were not correlated with histological findings. The same study presented data on the use of PET scanning pre- and postlaser treatment. They found reasonable correlation between isotope uptake and residual tumor, but this was only done on four patients because it is an expensive and time-consuming option.

Before the widespread availability of MRI, dynamic enhanced CT was investigated for determining the extent of tissue destruction and residual tumor after ILP.^{15,22} Characteristically, the necrotic tissue appeared as avascular areas (no uptake of contrast material injected intravenously). This was confirmed by core-cut biopsies, which did not find any residual viable tumor in these areas. The paper by Harries reported six patients who had CT with subsequent histopathological correlation on the resected specimen. This showed reasonable accuracy for detecting the volume of treated tissue. However, there have been no larger trials evaluating CT in the breast. CT is not a conventional imaging modality for breast cancer,

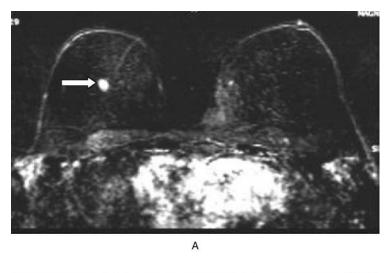

and it exposes patients to ionizing radiation, which ultrasound and MRI do not, so it is unlikely to become the investigation method of choice for this indication. CT has proved much more effective for assessing the results of ILP on liver tumors.²²

It now appears that MRI has the best chance of achieving the main goals required for monitoring breast-cancer ILP. This applies both to real-time monitoring to see the extent of tissue damage as the laser is firing and for follow-up imaging to look for persistent or recurrent cancer. Thermally destroyed tumors show signal change on both T1- and T2-weighted MRI sequences.^{23,24} For breast MRI other than at the actual time of light delivery, an intravascular paramagnetic "enhancement" agent (usually containing gadolinium) is used. This concentrates preferentially within breast tumors (most likely in regions of angiogenesis, the new blood vessels that develop in the regions where cancers are spreading into adjacent normal tissues) and therefore appears as a bright area on the image (increased signal intensity). Characteristically, thermally coagulated tissue loses this enhancement, whereas in residual viable tumor the increased signal intensity is maintained. The use of dynamic fast-sequence scanning (taking repeated scans at intervals of a minute or two after injection of the contrast agent) allows the enhancement characteristics of specified areas to be studied. There has been much debate about the ability of variations in signal intensity with time to differentiate between benign and malignant enhancing lesions, but for follow-up after ILP the most important aspect is to see if any of the tumor enhancement that was present prior to ILP remains after treatment. Care must be taken when interpreting the images in the first month or so after treatment to see if there is an inflammatory reaction in the surrounding tissue at the edges of the ILP-treated zone, which may itself give rise to a zone of increased uptake of contrast agent (Figure 47.3). There are not yet enough data available to allow for judgment on whether dynamicenhancement characteristics will have any role to play in determining the nature of residual enhancement after ILP.17

There have been a multitude of papers in the recent literature exploring the possibilities of using MRI to guide, monitor, and follow up thermally ablated tumors, although only one has specifically assessed its accuracy following ILP in breast cancer.¹⁷ Pre- and post-treatment scans were performed and compared to the pathological specimen following routine surgical excision a few days after ILP. Imaging immediately after ILP did not show good correlation with the final histology, whereas delayed imaging (more than 24 h after ILP) was much more accurate (Figure 47.4).

Contrast-enhanced imaging gives an accurate picture of viable cancer in the breast, but it cannot be used to follow real-time changes during light delivery because the time taken for the contrast agent to clear after one injection is comparable to the time required for laser-light delivery, so it is only possible to get an image of the situation at one point in time. Further, it has been well documented that contrast-enhanced scans taken within a few hours of ILP do not give a true picture of the extent of tumor destruction; this takes a day or two to evolve. However, MRI can also be used without administration of a contrast agent for real-time temperature mapping during treatment. The MRI parameters that vary with temperature are signal intensity on T1-weighted images, ²⁵ signal intensity change due to diffusion, ²⁶ and signal phase change due to proton-frequency shift. ²⁷ Most investigators have concentrated on T1 signal-intensity change and proton resonance-frequency shift (PRFS). Both have their relative merits but also certain disadvantages.

With increasing temperature, the T1 relaxation time lengthens, and signal intensity decreases. This occurs in a relatively linear fashion until the temperature reaches around 60°C, when a plateau is reached. Acquisition times are fast (around 3 sec per slice), and thermal color-coded images can be obtained (Thermo-TurboFLASH, Siemens). The main disadvantage with this method is the antagonistic decrease in T1 relaxation time within coagulated tissue. This fact has led some investigators to concentrate on frequency-shift imaging because this is dependent on temperature change only. PRFS has also been shown to be more accurate than signal-intensity change for temperature mapping. The main drawbacks are slow acquisition times (up to 1 min per slice) and marked sensitivity to motion artefacts. These problems can be partly overcome with faster imaging (spoiled-gradient echo — 20 sec per slice) and immobilization of the tissue in question. The need for sub-20-sec imaging is also questionable as most coagulation methods have treatment times extending over several minutes. Of greater concern, however,

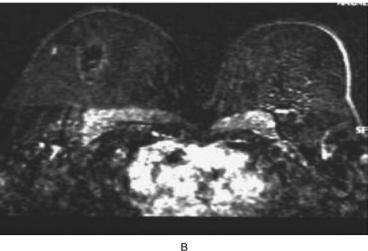

FIGURE 47.3 Pre- and post-laser contrast-enhanced MRI scans of a small breast cancer. (A) Pretreatment scan showing marked enhancement at the site of the cancer (arrow). (B) Scan 2 d after ILP showing loss of enhancement in the cancer with a new, fainter ring of enhancement around the treated area indicating inflammatory changes in the surrounding normal tissue as a result of the treatment.

is the difficulty of using this technique in tissues (like the breast) that contain fat as this causes temperature-induced susceptibility changes.²⁷ This makes signal-intensity changes more suitable for monitoring thermal ablative methods within the breast.

Careful studies in normal rat liver have shown good correlation between real-time MR images and the extent of ILP-induced thermal necrosis.³⁰ Figure 47.5, from this study, shows the MRI changes at the end of a 500-sec treatment and an image taken 360 sec after the laser was turned off, when the tissue temperature had returned to normal. A subsequent clinical paper from the same group reported real-time MR images of ILP being applied to liver metastases and showed that the extent of laser-induced necrosis correlated well with contrast-enhanced CT scans taken a few days later.³¹

Real-time dynamic imaging (looking at the temperature changes) is the ideal option for monitoring ILP in the breast as the images can be compared with contrast-enhanced images taken prior to ILP. However, much research remains to be done to establish what changes on the scans really mean in terms of whether or not the tissue being imaged is viable. The MRI demonstrates changes due to the increase

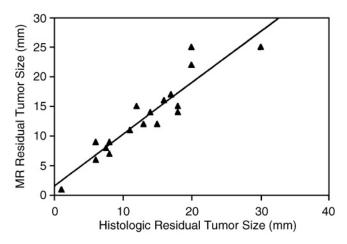

FIGURE 47.4 Graph correlating the maximum diameter of remaining viable cancer after ILP as measured by contrast-enhanced MRI and by conventional histology on the tumor removed surgically a few days after ILP. (From Mumtaz, H. et al., *Radiology*, 200, 651, 1996. With permission.)

in tissue temperature and the consequent biological changes, but it is difficult to be sure how severe these changes need to be to indicate a loss of tissue viability, which depends on both the temperature reached and the time for which that temperature increase is maintained. The ultimate aim is to continue energy delivery until the extent of thermal tissue destruction covers the entire tumor volume, together with a surrounding rim of normal tissue (in an attempt to ablate nests of cancer cells that may have spread beyond the cancer volume detected on the scans). This is still some way in the future and requires further developments in MRI scanners. Adjusting the position of laser fibers during ILP requires an open-magnet scanner (to give easy access to the tissue being treated), but current open magnets have magnetic fields only up to 0.5 T, which is not really high enough. Good dynamic imaging of temperature changes requires around 1.5 T, which is currently only available in larger closed scanners, although this is likely to change in the relatively near future.

Thus, contrast-enhanced MRI is the most accurate technique for documenting the extent of thermal necrosis in the tumor, but it cannot give answers at the time of treatment. If residual cancer is found some time after ILP, treatment would have to be repeated. ILP does have the major attraction that, unlike radiotherapy, it can be repeated at the same site, several times if necessary.

47.3 Treatment of Benign Fibroadenomas and Healing of Breast Tissue after Interstitial Laser Photocoagulation

Until MRI or some other form of noninvasive imaging makes it possible to ascertain with confidence whether or not laser ablation of a cancer in the breast is complete, it would be unethical not to follow laser treatment by surgical excision. This makes it impossible with the current state of knowledge to follow how laser-treated breast cancers heal. An ethical way around this dilemma is to treat benign lesions in the breast and follow how the zone of thermal necrosis heals as the body's response to any dead tissue in the breast, cancer or otherwise, is likely to be the same. By serendipity, this approach has led to the realization that ILP is an attractive option for treating fibroadenomas.

Benign fibroadenomas have probably caused more unnecessary anguish to young women than any other breast problem. They are by far the most common cause of a discrete breast lump in young women and reach a peak incidence between the ages of 20 and 30,³² although they are not an uncommon finding in older women. They are often only discovered through routine screening mammography, where they appear as well-circumscribed lesions, often with characteristic "popcorn calcification." Originally classified as a true benign tumor, they are now regarded as an aberration in the normal changes that occur

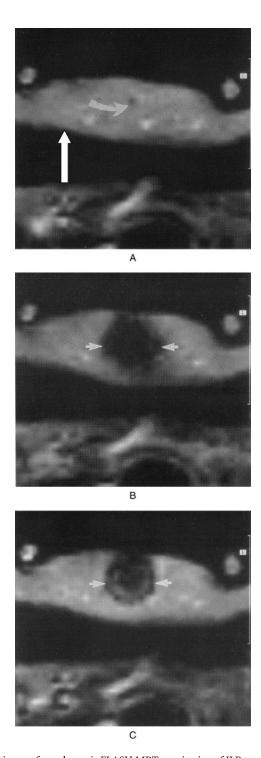

FIGURE 47.5 Representative images from dynamic FLASH MRT monitoring of ILP to a normal rat liver. Under general anesthesia, the abdomen of the rat was opened and a lobe of liver (straight arrow) gently eased out of the abdominal cavity onto the skin. (A) Baseline showing site of insertion of fiber (curved arrow). (B) 500 sec after turning on laser to deliver 1 W of laser light at 805 nm through a bare-tip fiber. (C) 360 sec after laser had been turned off. The limits of the laser-induced effects in (B) and (C) are shown with arrows and corresponded closely to subsequent microscopic examination of the treated tissue. (From Roberts, H.R.S. et al., *Minimally Invasive Ther. Allied Technol.*, 6, 41, 1997. With permission.)

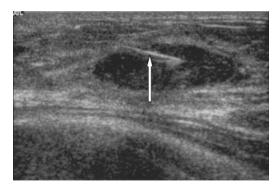

FIGURE 47.6 Ultrasound scan showing a laser fiber (arrow) positioned in a fibroadenoma.

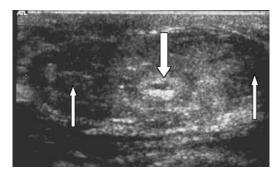

FIGURE 47.7 Ultrasound scan to show a partly treated fibroadenoma. The central area (thick arrow) has been treated and has a bright echo pattern. The sections on either side (thin arrows) have not been treated and have very few echoes.

in the breast throughout life. This has led to the introduction of the term ANDI (aberrations of normal development and involution). Much debate has arisen in recent years about the natural history of fibroadenomas, raising the question of which ones should be treated. In simple terms, around a third will get larger, a third smaller, and a third will remain the same size.^{33–35} There is no evidence that they ever turn into cancer, although the two diseases can coexist.

It can be argued that all but the most rapidly growing fibroadenomas should receive a trial of conservative management (i.e., no active treatment), and this is becoming normal practice in the U.K. There is, however, a subgroup of women who request early excision due to fear of leaving a lump *in situ* or of cancer being missed. Others request surgical treatment at some point down the line should their lump fail to resolve spontaneously. Few women would admit to being totally happy about leaving a fibroadenoma indefinitely, especially if it is particularly prominent.

As these lesions are benign, it is not critical that 100% of the lesion be treated, as residual fibroadenoma tissue does not pose a danger to the patient and can be treated again later if required. Further, the lesions have well-defined margins, unlike cancers, from which nests of cancer cells may infiltrate the tissue surrounding the main bulk of the tumor. This makes imaging simpler, so ultrasound scanning, which is cheaper and more readily available than MRI, can be used for guiding ILP and for follow-up assessment (Figure 47.6). For larger fibroadenomas multiple fibers can be used (typically up to a maximum of four). These are spaced as equally as possible within the tumor. It is important to check the position of each needle in two planes prior to light delivery because although a needle can appear central on one view, it can in fact be near the edge of the target lesion in another plane. For very large fibroadenomas, it is sometimes not feasible to coagulate it all at one sitting. Areas of coagulated fibroadenoma can, however, be distinguished from nontreated areas on ultrasound scans (Figure 47.7).

The original aim of treating fibroadenomas was to see how zones of thermally coagulated tissue in the breast healed, and this has been assessed by serial US scans. These have shown the change in size of the lesions and the characteristics of laser-coagulated tissue. Typically, ILP-treated areas of fibroadenoma become hyperechoic (bright echo pattern) compared to the normal hypoechoic (dark echo) pattern (Figure 47.7). After ILP some of the smaller fibroadenomas can become quite indistinct and difficult to distinguish from the normal surrounding breast tissue, presumably because the area of coagulation extended into the surrounding normal tissue. Nevertheless, the remarkable finding has been that the coagulated tissue is gradually absorbed by the body's normal healing processes over a period of months. As long as the lump has been completely treated, in due course it disappears entirely, although this may take up to 1 year. Patients comment on some soreness in the treated area for a few days after treatment, and the lump may initially swell (due to edema) before shrinking, but the patients do not feel generally unwell in any way.

There have only been two published studies using ILP for fibroadenomas. Lai et al.³⁶ treated 29 fibroadenomas with a mean diameter of 25 mm (range 14 to 35 mm). These patients were scheduled for conventional surgical excision but were offered ILP as an alternative, on the understanding that they could still have surgery at a later date if they so wished. Of the 29 lesions treated, 28 decreased in size on serial US. Only six patients continued with the original plan of surgery, and most of these chose surgery soon after ILP. It later became apparent that if they had waited longer, the fibroadenomas would probably have shrunk as a result of the ILP. The remaining patients were happy with the gradual reduction in size following ILP and declined further intervention. The average decreases in size documented were 38, 60, and 92% at 3, 6, and 12 months, respectively. Fourteen patients were followed up for 1 year, by which time none had a palpable lump and only one lesion was still detectable on US. There were no serious complications. Three patients had minor skin burns around the puncture site, either because the fiber slipped during treatment or the fiber had been positioned too superficially in the breast. This problem has been solved in more recent treatments by cooling the skin with iced water during light delivery.

Basu et al.³⁷ used a similar technique, the only real difference being the use of an Nd:YAG laser operating at 1064 nm rather than the semiconductor diode laser (805 nm) used by Lai et al.³⁶ A total of 27 patients were treated for lesions averaging 16 mm in diameter, smaller than those in Lai's study. Follow-up was shorter (8 weeks), but there was a larger average decrease in size at this time point (60%). Ten patients with residual lumps underwent excision biopsy. Again no serious complications were observed, although eight patients had minor skin burns around the puncture sites and two had a sterile, self-limiting discharge.

These papers have demonstrated the safety and efficacy of ILP for treating fibroadenomas. The smaller number of skin burns in the first study is probably attributable to the use of an oblique course for needle placement when the lumps were superficial, rather than going directly through the skin overlying the lesion. Also, cooling of the breast with cold saline may play a positive role in preventing this complication. Both studies demonstrated an increase in size over the first 2 weeks after ILP, presumably due to swelling from an inflammatory response, before a gradual decrease in size over the following months. It is important to warn patients undergoing ILP that this is likely to happen.

47.4 Interstitial Laser Photocoagulation in Other Organs

Much of the early experimental work on ILP was done on normal animal livers, as the liver is a forgiving organ and heals well after a localized thermal insult. In consequence, the first clinical studies were for the treatment of isolated metastatic tumors in the liver, most often in patients who had previously had cancers of the colon removed surgically.¹⁹ Amin et al. described their experience in the treatment of 55 liver tumors in 21 patients. A total of 82% of patients fulfilled the UICC (Union Internationale contre le Cancer) criteria for at least a partial response (>50% reduction in tumor volume).²² Recent results have concentrated on the long-term outcome in over 500 treated patients with a median survival of 27 months and a 5-year survival rate of 26%. This is comparable to patient outcomes following operative

treatment for liver metastases at the same institution of 33-month median survival and 30% 5-year survival, respectively.³⁸ Another group reported a mean survival of 35 months³⁹ after ILP for liver metastases.

Some work has been published on the treatment of benign prostatic hyperplasia. Here, the aim of treatment is to reduce the volume of the prostate gland to improve urinary flow,⁴⁰ although there is some doubt about whether ILP is really any better than the conventional surgical approach of shaving out the part of the prostate causing obstruction. Another promising clinical use is in the treatment of moderate-sized uterine fibroids. These are benign tumors of the womb that can cause heavy and painful periods or infertility. Two groups have shown that ILP can shrink these lesions. Law et al. demonstrated a mean reduction in tumor volume following ILP of 37.5% at 3 months in 12 female volunteers, although they gave no indication as to clinical benefit.⁴¹ Visvanathan et al. treated 30 fibroids in 24 symptomatic patients and documented shrinkage in 23 lesions.⁴² A total of 13 patients reported an improvement in symptoms of abdominal discomfort, urinary frequency, or dysmenorrhea (painful periods), and one delivered a healthy child, having been unable to conceive prior to ILP. Yet another indication is for treating osteoid osteomas. These are benign but painful tumors of bone that often occur in sites that are very difficult to get to by conventional surgery, but where it is straightforward to insert one or more needles under CT guidance for ILP. ILP gives an almost immediate cure.⁴³ It has even been used for small but inoperable lung tumors.⁴⁴

47.5 Conclusion

The idea of using ILP as an alternative to surgery for the destruction of small breast cancers is attractive, but it is important to keep a clear picture of the role it might play in the overall management of these patients. Local destruction of the cancer is only one part of the management of patients with this unpleasant disease, and most will require additional treatment such as radiotherapy, hormones, or chemotherapy, whether they have ILP or surgery. Further, it must be recognized that for surgeons not to follow ILP by a conventional surgical excision they will have to reach the point where they have enough confidence that MRI (real-time or delayed) can detect any viable cancer persisting after ILP. This stage remains in the distant future. However, if it is reached, the benefits will be the general simplicity and safety of the technique without the need for a general anesthetic and good cosmetic outcome (no scarring and minimal change in the shape and size of the breast). In an age where breast-conserving surgery is standard practice, it could provide an alternative for some patients with breast cancer. There are particular attractions for patients whose general condition is poor or who simply refuse surgery. For benign fibroadenomas, where precise imaging is not so vital, the evidence of efficacy and safety is now strong enough to offer ILP to all patients as an alternative to surgery.

48.1 Introduction

The first publications about low-power laser therapy (then called laser biostimulation) appeared more than 30 years ago. Since then, approximately 2000 studies have been published on this still controversial topic. In the 1960s and 1970s, doctors in Eastern Europe, and especially in the Soviet Union and Hungary, actively developed laser biostimulation. However, scientists around the world harbored an open skepticism about the credibility of studies stating that low-intensity visible-laser radiation acts directly on an organism at the molecular level. The coherence of laser radiation for achieving stimulative effects on biological objects was more than suspect. Supporters in Western countries, such as Italy, France, and Spain, as well as in Japan and China also adopted and developed this method, but the method was — and still remains — outside mainstream medicine. The controversial points of laser biostimulation,²⁻⁴ which were topics of great interest at that time, were analyzed in reviews that appeared in the late 1980s.

Since then, medical treatment with coherent-light sources (lasers) or noncoherent light (light-emitting diodes, LEDs) has passed through its childhood and adolescence. Most of the controversial points from "childhood" are no longer topical. Currently, low-power laser therapy — or low-level laser therapy (LLLT) or photobiomodulation — is considered part of light therapy as well as part of physiotherapy. In fact, light therapy is one of the oldest therapeutic methods used by humans (historically as sun therapy, later as color light therapy and UV therapy). A short history of experimental work with colored light on

various kinds of biological subjects can be found elsewhere.^{2,3} The use of lasers and LEDs as light sources was the next step in the technological development of light therapy.

It is clear now that laser therapy cannot be considered separately from physiotherapeutic methods that use such physical factors as low-frequency pulsed electromagnetic fields; microwaves; time-varying, static, and combined magnetic fields; focused ultrasound; direct-current electricity; etc. Some common features of biological responses to physical factors have been briefly analyzed.⁵

As this handbook makes abundantly clear, by the dawn of the 21st century, a certain level of development of (laser) light use in therapy and diagnostics (e.g., photodynamic therapy, optical tomography, etc.) had been achieved. In low-power laser therapy, the question is no longer whether light has biological effects but rather how radiation from therapeutic lasers and LEDs works at the cellular and organism levels and what the optimal light parameters are for different uses of these light sources.

This chapter is organized as follows. First, Section 48.2 briefly reviews clinical applications and considers one of the most topical issues in low-power-laser medicine today, i.e., whether coherent and polarized light has additional benefits in comparison with noncoherent light at the same wavelength and intensity.

Second, direct activation of various types of cells via light absorption in mitochondria is described. Primary photoacceptors and mechanisms of light action on cells as well as mechanisms of cellular signaling are considered (Section 48.3). Section 48.4 describes enhancement of cellular metabolism via activation of nonmitochondrial photoacceptors and possible indirect effects via secondary cellular messengers, which are produced by cells as a result of direct activation. This chapter does not consider systemic effects of low-power laser therapy.

48.2 Clinical Applications and Effects of Light Coherence and Polarization

Low-power laser therapy is used by physiotherapists (to treat a wide variety of acute and chronic musculoskeletal aches and pains), by dentists (to treat inflamed oral tissues and to heal diverse ulcerations), by dermatologists (to treat edema, indolent ulcers, burns, and dermatitis), by rheumatologists (to relieve pain and treat chronic inflammations and autoimmune diseases), and by other specialists, as well as general practitioners. Laser therapy is also widely used in veterinary medicine (especially in racehorse-training centers) and in sports-medicine and rehabilitation clinics (to reduce swelling and hematoma, relieve pain, improve mobility, and treat acute soft-tissue injuries). Lasers and LEDs are applied directly to the respective areas (e.g., wounds, sites of injuries) or to various points on the body (acupuncture points, muscle-trigger points). Several books provide details of clinical applications and techniques used.^{1,6,7}

Clinical applications of low-power laser therapy are diverse. The field is characterized by a variety of methodologies and uses of various light sources (lasers, LEDs) with different parameters (wavelength, output power, continuous-wave or pulsed operation modes, pulse parameters). Figure 48.1 presents schematically the types of light therapeutic devices, possible wavelengths they can emit, and maximal output power used in therapy. The GaAlAs diodes are used in both diode lasers and LEDs; the difference is whether the device contains the resonator (as the laser does) or not (LED). In recent years, longer wavelengths (~800 to 900 nm) and higher output powers (to 100 mW) have been preferred in therapeutic devices.

One of the most topical and widely discussed issues in the low-power-laser-therapy clinical community is whether the coherence and polarization of laser radiation have additional benefits as compared with monochromatic light from a conventional light source or LED with the same wavelength and intensity.

Two aspects of this problem must be distinguished: the *coherence of light* itself and the *coherence of the interaction* of light with matter (biomolecules, tissues).

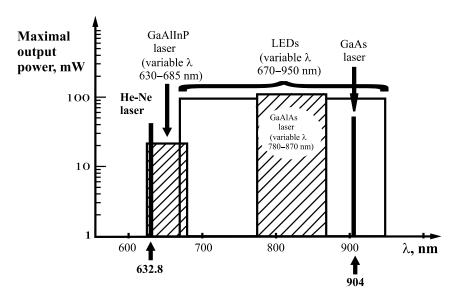

FIGURE 48.1 Wavelength and maximal output power of lasers and LEDs used in low-power laser therapy.

48.2.1 Coherence of Light

The coherent properties of light are described by *temporal* and *spatial* coherence. Temporal coherence of light is determined by the spectral width, Δv , since the coherence time τ_{coh} during which light oscillates at the point of irradiation has a regular and strongly periodical character:

$$\tau_{\rm coh} \cong \frac{1}{\Delta \nu}$$
(48.1)

Here Δv is the spectral width of the beam in Hz. Since light propagates at the rate $c = 3 \times 10^{10}$ cm/sec, the light oscillations are matched by the phase (i.e., they are coherent) on the length of light propagation $L_{\rm coh}$.

$$L_{coh} = \frac{c}{\Delta v [Hz]}$$
 (48.2)

$$L_{coh} = \frac{1}{\Delta v \left[cm^{-1} \right]} \tag{48.2}$$

 L_{coh} is called longitudinal coherence. The more monochromatic the light, the longer the length where the light field is coherent in volume. For example, for a multimode He-Ne laser with $\Delta \nu = 500$ MHz, $L_{coh} = 60$ cm. But for a LED emitting at $\lambda = 800$ nm (= 12,500 cm⁻¹), $\Delta \nu = 160$ cm⁻¹ (or $\Delta \lambda = 10$ nm), and $L_{coh} = 1/160$ cm⁻¹ $\cong 60$ μ m, i.e., L_{coh} is longer than the thickness of a cell monolayer (≈ 10 to 30 μ m).

Spatial coherence describes the correlation between the phases of the light field in a lateral direction. For this reason, spatial coherence is also called lateral coherence. The size of the lateral coherence (ℓ_{coh}) is connected with the divergence (ϕ) of the light beam at the point of irradiation:

$$\ell_{\rm coh} \cong \frac{\lambda}{\Phi} \tag{48.3}$$

For example, for a He-Ne laser, which operates in the TEM_{00} mode, the divergence of the beam is determined by the diffraction:

$$\varphi \cong \frac{\lambda}{D} \tag{48.4}$$

where D is the beam diameter. In this case, ℓ_{coh} coincides with the beam diameter, since for the TEM₀₀ laser mode the phase of the field along the wave front is constant.

With conventional light sources, the size of the emitting area is significantly larger than the light wavelength, and various parts of this area emit light independently or noncoherently. In this case, the size of the lateral coherence $\ell_{\rm coh}$ is significantly less than the diameter of the light beam, and $\ell_{\rm coh}$ is determined by the light divergence, as shown in Equation 48.3.

An analysis of published clinical results from the point of view of various types of radiation sources does not lead to the conclusion that lasers have a higher therapeutic potential than LEDs. But in certain clinical cases the therapeutic effect of coherent light is believed to be higher. However, when human peptic ulcers were irradiated by a He-Ne laser or properly filtered red light was irradiated in a specially designed clinical double-blind study, equally positive results were documented for both types of radiation sources (for a review, see Reference 3).

48.2.2 Coherence of Light Interaction with Biomolecules, Cells, and Tissues

The coherent properties of light are not manifested when the beam interacts with a biotissue on the molecular level. This problem was first considered several years ago.² The question then arose of whether coherent light was needed for "laser biostimulation" or was it simply a photobiological phenomenon. The conclusion was that under physiological conditions the absorption of low-intensity light by biological systems is of purely noncoherent (i.e., photobiological) nature because the rate of decoherence of excitation is many orders of magnitude higher than the rate of photoexcitation. The time of decoherence of photoexcitation determines the interaction with surrounding molecules (under normal conditions less than 10^{-12} sec). The average excitation time depends on the light intensity (at an intensity of 1 mW/cm² this time is around 1 sec). At 300 K in condensed matter for compounds absorbing monochromatic visible light, the light intensity at which the interactions between coherent light and matter start to occur was estimated to be above the GW/cm² level.² Note that the light intensities used in clinical practice are not higher than tens or hundreds of mW/cm². Indeed, the stimulative action of various bands of visible light at the level of organisms and cells was known long before the advent of the laser. Also, specially designed experiments at the cellular level have provided evidence that coherent and noncoherent light with the same wavelength, intensity, and irradiation time provide the same biological effect.⁹⁻¹¹ Successful use of LEDs in many areas of clinical practice also confirms this conclusion.

Therefore, it is possible that the effects of light coherence are manifested at the macroscopic (e.g., tissue) level at various depths (L) of irradiated matter. Figure 48.2 presents the coherence volumes (V_{coh}) and coherence lengths (L_{coh}) for four different light sources. Figure 48.2A presents the data for two coherent-light sources (He-Ne and diode lasers as typical examples of therapeutic devices). Figure 48.2B presents the respective data for noncoherent light (LED and spectrally filtered light from a lamp). Figure 48.2 illustrates how large volumes of tissue are irradiated only by laser sources with monochromatic radiation (Figure 48.2A). For noncoherent-radiation sources (Figure 48.2B) the length of the coherence, L_{coh} , is small. This means that only surface layers of an irradiated substance can be achieved by coherent light.

The spatial (lateral) coherence of the light source is unimportant due to strong scattering of light in biotissue when propagated to the depth L>> l_{SC} , where ℓ_{SC} is the free pathway of light in relation to scattering. This is because every region in a scattering medium is illuminated by radiation with a wide angle ($\phi \approx 1$ rd). This means that $\ell_{coh} \cong \lambda$, i.e., the size of spatial coherence ℓ_{coh} , decreases to the light wavelength (Figure 48.2).

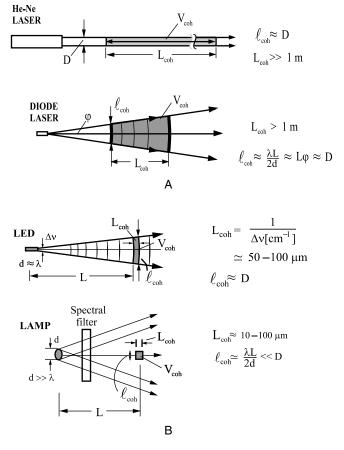

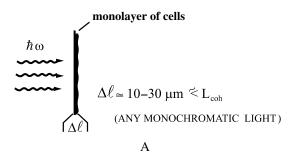

FIGURE 48.2 Coherence volumes and coherence lengths of light from: (A) laser and (B) conventional sources when a tissue is irradiated. $L_{coh} = length$ of temporal (longitudinal) coherence, $\ell_{coh} = size$ of spatial (lateral) coherence, D = longth diameter of light beam, D = longth diameter of noncoherent-light source, D = longth diameter of light beam, D = longth diameter of noncoherent-light source, D = longth diameter of noncoherent-light source, D = longth diameter of light beam, D = longth diameter of noncoherent-light source, D = longth diameter of light beam, D = longth diameter of noncoherent-light source, D = longth diameter of light beam, D = longth diameter of noncoherent-light source, D = longth diameter of light beam spectral width.

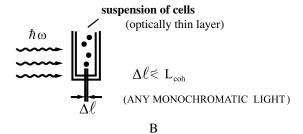

Thus, the length of longitudinal coherence (L_{coh}) is important when bulk tissue is irradiated because this parameter determines the volume of the irradiated tissue, V_{coh} . In this volume, the random interference of scattered light waves and formation of random nonhomogeneities of intensity in space (speckles) occur. For noncoherent-light sources, the coherence length is small (tens to hundreds of microns). For laser sources, this parameter is much higher. Thus, the additional therapeutic effect of coherent radiation, if this indeed exists, depends not only on the length of L_{coh} but also, and even mainly, on the penetration depth into the tissue due to absorption and scattering, i.e., by the depth of attenuation. Table 48.1 summarizes qualitative characteristics of coherence of various light sources, as discussed above.

The difference in the coherence length L_{coh} is unimportant when thin layers are irradiated inasmuch as the longitudinal size of irradiated object $\Delta \ell$ is less than L_{coh} for any source of monochromatic light (filtered lamp light, LED, laser). Examples are the monolayer of cells and optically thin layers of cell suspensions (Figure 48.3A and B). Indeed, experimental results^{9–11} on these models provide clear evidence that the biological responses of coherent and noncoherent light with the same parameters are equal. The situation is quite different when a bulk tissue is irradiated (Figure 48.3C). The coherence length L_{coh} is very short for noncoherent-light sources and can play some role only on surface layers of the tissue with thickness $\Delta \ell_{surface}$. For coherent-light sources, the coherence of the radiation is retained along the entire penetration depth L. The random interference of light waves of various directions occurs over this entire distance in bulk tissue ($\Delta \ell_{bulk}$). As a result, a speckle pattern of intensity appears. Maximum values of

TABLE 48.1 Comparison of Coherence (Temporal and Spatial) of Various Light Sources Used in Clinical Practice and Experimental Work

	Qualitative Characteristics of Coherence			
		Length of		
		Longitudinal		Volume of
	Temporal	(Temporal)	Spatial	Spatial (Lateral)
Light Source	Coherence	Coherence, L _{coh}	Coherence	Coherence, $\ell_{\rm coh}$
Laser	Very high	Very long	Very high	Large
LED	Low	Short ($>>\lambda$)	High	Small (very thin layer)
Lamp with a spectral filter	Low	Short ($>>\lambda$)	Very low	Very small
Lamp	Very low	Very short (≈λ)	Very low (≈λ)	Extremely small $(\approx \lambda^3)$

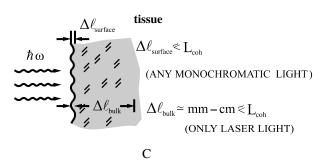

FIGURE 48.3 Depth $(\Delta \ell)$ in which the beam coherency is manifested and coherence length L_{coh} in various irradiated systems: (A) monolayer of cells, (B) optically thin suspension of cells, and (C) surface layer of tissue and bulk tissue.

the intensity appear at the random constructive interference. The minima (i.e., regions of zero intensity) occur at the random destructive interference. The dimensions of these speckles at every occurrence of directed random interference are approximately within the range of the light wavelength, λ . The coherent effects (speckles) appear only at the depth L_{coh} . These laser-specific speckles cause a spatially nonhomogeneous

deposition of light energy and lead to statistically nonhomogeneous photochemical processes, an increase in temperature, changes in local pressure, deformation of cellular membranes, etc.

For nonpolarized coherent light the random speckles are less pronounced (they have lower contrast) as compared to the speckles caused by coherent polarized light. A special feature of nonpolarized coherent radiation is that the regions with zero intensity appear less often as compared with the action of coherent polarized light. Thus, the polarization of light causes brighter random intensity gradients that can enhance the manifestation of the effects of light coherence when the tissue is irradiated.

Thus, perhaps in scattering biotissue, the main role is played by coherence length (monochromaticity of light) inasmuch as this parameter determines the depth of tissue where the coherent properties of the light beam can potentially be manifested, depending on the attenuation. This is the spatial (lateral) coherence of the beam, i.e., its directivity, which plays the main role in the delivery of light into biotissue. In addition, the direction and orientation of laser radiation could be important factors for some types of tissues (e.g., dental tissue) that have fiber-type structures (filaments). In this case, waveguide propagation effects of light can appear that provide an enhancement of penetration depth.

Considered within the framework of this qualitative picture, some additional (i.e., additional to those effects caused by light absorption by photoacceptor molecules) manifestation of light coherence for deeper tissue is quite possible. This qualitative picture also explains why coherent and noncoherent light with the same parameters produce the same biological effects on cell monolayer, hin layers of cell suspension, 10,11 and tissue surface (e.g., by healing of peptic ulcers). Some additional (therapeutic) effects from the coherent and polarized radiation can appear only in deeper layers of the bulk tissue. To date, no experimental work has been performed to qualitatively and quantitatively study these possible additional effects. In any case, the main therapeutic effects occur due to light absorption by cellular photoacceptors.

48.3 Enhancement of Cellular Metabolism via Activation of Respiratory Chain: A Universal Photobiological Action Mechanism

48.3.1 Cytochrome c Oxidase as the Photoacceptor in the Visible-to-Near-Infrared Spectral Range

Photobiological reactions involve the absorption of a specific wavelength of light by the functioning photoacceptor molecule. The photobiological nature of low-power laser effects^{2,3} means that some molecule (photoacceptor) must first absorb the light used for the irradiation. After promotion of electronically excited states, primary molecular processes from these states can lead to a measurable biological effect at the cellular level. The problem is knowing which molecule is the photoacceptor. When considering the cellular effects, this question can be answered by action spectra.

A graph representing photoresponse as a function of wavelength λ , wave number λ^{-1} , frequency ν , or photon energy e is called an action spectrum. The action spectrum of a biological response resembles the absorption spectrum of the photoacceptor molecule. The existence of a structured action spectrum is strong evidence that the phenomenon under study is a photobiological one (i.e., primary photoacceptors and cellular signaling pathways exist). ^{12,13}

The first action spectra in the visible-light region were recorded in the early 1980s for DNA and RNA synthesis rate, 14,15 growth stimulation of *Escherichia coli*, 10,16 and protein synthesis by yeasts 16 for the purpose of investigating the photobiological mechanisms of laser biostimulation. In addition, other action spectra were recorded in various ranges of visible wavelengths: photostimulation of formation of E-rosettes by human lymphocytes, mitosis in L cells, exertion of DNA factor from lymphocytes in the violet–green range, 17 and oxidative phosphorylation by mitochondria in the violet–blue range. 18 All these

spectra were recorded for narrow ranges of the optical spectrum and with a limited number of wavelengths, which prevented identification of the photoacceptor molecule.

Full action spectra from 313 to 860 nm for DNA and RNA synthesis rate in both exponentially growing and plateau-phase HeLa cells were also recorded in the early 1980s^{19,20} (for a review, see References 2 and 4). The question of the nature of the photoacceptor molecule has since remained open. It was suggested in 1988²¹ (see also Reference 4) that the mechanism of low-power laser therapy at the cellular level was based on the absorption of monochromatic visible and NIR radiation by components of the cellular respiratory chain. Absorption and promotion of electronically excited states cause changes in redox properties of these molecules and acceleration of electron transfer (primary reactions). Primary reactions in mitochondria of eukaryotic cells were supposed to be followed by a cascade of secondary reactions (photosignal transduction and amplification chain or cellular signaling) occurring in cell cytoplasm, membrane, and nucleus²¹ (for a review, see References 4 and 22). In 1995, an analysis of five action spectra suggested that the primary photoacceptor for the red-NIR range in mammalian cell is a mixed-valence form of cytochrome *c* oxidase²³ (for a review, see Reference 22).

It is remarkable that the five action spectra that were analyzed had very close (within the confidence limits) peak positions in spite of the fact that these processes occurred in different parts of the cells (nucleus and plasma membrane). However, there were differences in peak intensities. Three of these action spectra only for the red-to-NIR range (wavelengths that are important in low-power laser therapy) are presented in Figure 48.4A, B, and C. Two conclusions were drawn from the action spectra. First, the fact that the peak positions are the same suggests that the primary photoacceptor is the same. Second, the existence of the action spectra implies the existence of cellular signaling pathways inside the cell between photoacceptor and the nucleus as well as between the photoacceptor and cell membrane.

Five action spectra were analyzed, and the bands were identified by analogy with the absorption spectra of the metal-ligand system characteristic of this spectral range²³ (for a review, see References 22 and 25). It was concluded that the ranges 400 to 450 nm and 620 to 680 nm were characterized by the bands pertaining to a complex associated with charge transfer in a metal-ligand system, and within 760 to 830 nm these were d-d transitions in metals, most probably in Cu (II). The range 400 to 420 nm was found to be typical of a π - π * transition in a porphyrin ring. A comparative analysis of lines of possible d-d transitions and charge-transfer complexes of Cu with our action spectra suggested that the photoacceptor was the terminal enzyme of the mitochondrial respiratory chain cytochrome c oxidase. It was suggested that the main contribution to the 825-nm band was made by the oxidized Cu_A, to the 760-nm band by the reduced Cu_B, to the 680-nm band by the oxidized Cu_B, and to the 620-nm band by the reduced Cu_A. The 400- to 450-nm band was more likely the envelope of a few absorption bands in the 350- to 500nm range (i.e., a superposition of several bands). Analysis of the band shapes in the action spectra and the line-intensity ratios also led to the conclusion that cytochrome c oxidase cannot be considered a primary photoacceptor when fully oxidized or fully reduced but only when it is in one of the intermediate forms (partially reduced or mixed-valence enzyme)23 (for a review, see Reference 22) that have not yet been identified.

Taken together, the terminal respiratory-chain oxidases in eukaryotic cells (cytochrome c oxidase) and in prokaryotic cells of E. coli (cytochrome bd complex²⁶) are believed to be photoacceptor molecules for red to NIR radiation. In the violet-to-blue spectral range, flavoproteins (e.g., NADH-dehydrogenase^{5,21} in the beginning of the respiratory chain) are also among the photoacceptors and terminal oxidases.

One important step in identifying the photoacceptor molecule is to compare the absorption and action spectra. For recording the absorption of a cell monolayer and investigating the changes in absorption under irradiation at various wavelengths of monochromatic light, a sensitive multichannel registration method was developed.^{27,28} Figure 48.4D presents an absorption spectrum of a monolayer of HeLa cells dried in air. In these cells, cytochrome *c* oxidase is fully oxidized. A comparison of the peak position of the spectrum in Figure 48.4D and the action spectra in Figure 48.4A, B, and C shows that the peaks near 620, 680, and 820 nm are present in all four spectra, but the peak near 760 nm is practically absent in the absorption spectrum of dry monolayer HeLa cells. Note the suggestion that this peak belongs to Cu_B in reduced state.²³

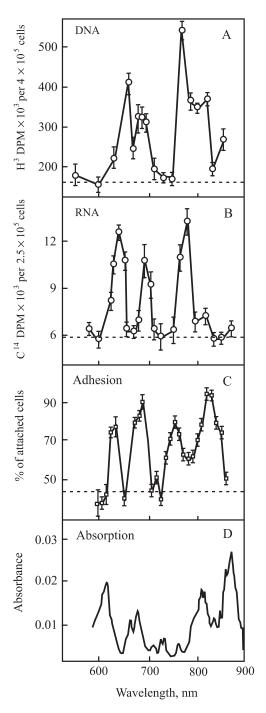

FIGURE 48.4 Action spectra of (A) DNA and (B) RNA synthesis rate; (C) plasma membrane adhesion of exponentially growing HeLa cells for red to NIR radiation; (D) absorption spectrum of air-dried monolayer of HeLa cells for the same spectral region. (Modified from Karu, T.I. et al., *Nuov. Cim. D*, 3, 309, 1984; Karu, T.I. et al., *Dokl. Akad. Nauk (Moscow)*, 360, 267, 1998; and Karu, T.I. et al., *Lasers Surg. Med.*, 18, 171, 1996.)

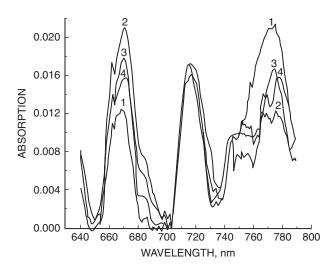

FIGURE 48.5 Absorption spectrum of monolayer of HeLa cells recorded in open vial immediately after removal of the nutrient medium (curve 1) and following exposure to radiation with $\lambda = 820$ nm for the first time (curve 2), second time (curve 3), and third time (curve 4), with each exposure lasting 10 sec for a dose 6.3×10^3 J/m². (Modified from Karu, T.I. et al., *Dokl. Akad. Nauk (Moscow)*, 360, 267, 1998.)

Later, the absorption spectra were recorded in the monolayer of living HeLa cells, and redox absorbance changes after laser irradiation at different wavelengths were recorded. These experiments were performed in open or closed vials. These two conditions differ by, respectively, the partial pressure of oxygen in nutrient medium of cells and by the oxidation state of cytochrome c oxidase.

The absorption spectra of a monolayer of living cells in open flasks clearly show the bands at 670 and 775 nm as well as a less distinct band shoulder in the vicinity of 750 nm and band at 718 nm.²⁷ Exposing the sample for 10 sec to laser radiation with a wavelength of 670 nm and dose of 6.3×10^3 J/m² caused changes in its absorption bands around 670, 750, and 775 nm, with the absorption band at 718 nm remaining unchanged. In the action spectra, the band in the neighborhood of 670–680 nm supposedly belongs to the chromophore Cu_B in the oxidized state, while that in the vicinity of 760–770 nm belongs to the chromophore Cu_B in the reduced state.²³ If there is a correspondence between the action spectra bands (Figure 48.4A, B, and C) and the absorption spectra bands recorded in Reference 27, the results are quite natural: as laser irradiation increases absorption in the band at 670 nm — and hence the concentration of the chromophore in the oxidized state, represented by the absorption near 750–770 nm (and the concentration of the reduced chromophore) — decreases.

The exposure of the cellular monolayer to laser light with $\lambda = 820 \text{ nm}^{27}$ was also observed to cause changes in the absorption bands in the vicinity of 670 and 775 nm (Figure 48.5). Note that the action-spectrum band at around 825 nm is supposedly associated with the oxidized chromophore Cu_A .²³ Following the first exposure (curve 2), a sharp increase in absorption is observed to occur in the band near 670 nm (and a correspondingly sharp reduction of absorption in the band near 775 nm in comparison with the control, curve 1). The second (curve 3) and the third (curve 4) exposures cause no sharp changes in absorption, which could be due to an equilibrium being established between the oxidized and reduced forms of the chromophore Cu_B .

In another set of experiments, the HeLa-cell monolayer was irradiated in the closed vial where the cells had been grown for 72 h.^{28} Under these conditions, the respiratory chains are supposedly more reduced as compared with the chains in the previous experiments.²⁷ The spectrum recorded before the irradiation had strong absorption peaks at 739, 757, and 775 nm and weak maxima at 795, 812, 831, and 873 nm, as well as at 630 nm (Figure 48.6A). A comparison of two sets of spectra^{27,28} allows for a rough estimation that the peaks in the red (620 to 680 nm) and NIR regions (812 to 870 nm) are characteristic of the absorption spectra of the more oxidized cytochrome c oxidase, and the peaks in the 730- to 775-nm

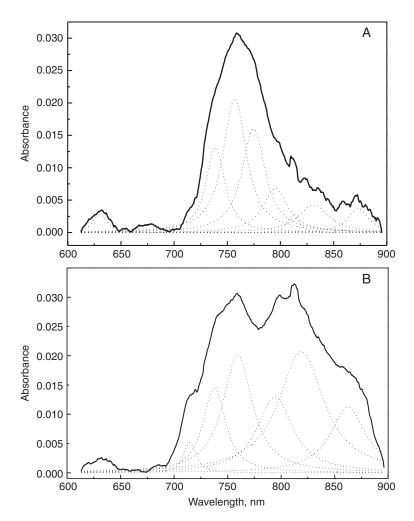

FIGURE 48.6 Absorption spectra of HeLa monolayer: (A) before and (B) after irradiation at 820, 670, 632.8, and 670 nm in the closed vial (dose at every wavelength 6.3×10^3 J/m², irradiation time 10 sec). The dashed lines present the data of Lorentzian fitting of the spectra. (Modified from Karu, T.I. et al., *IEEE J. Sel. Top. Quantum Electron.*, 7, 982, 2001.)

range are characteristic of the spectra of the more reduced cytochrome c oxidase. Irradiation of the same HeLa cell monolayer in closed vials at 820, 670, and 632.8 nm and once more at 670 nm caused remarkable changes for the peaks at 739 to 799 nm and at 812 to 873 nm. There were practically no changes in absorption bands in the red region (600 to 700 nm), and a few changes occurred in the green region (peaks at 545 to 581 nm) (Figure 48.6B). It was concluded that cytochrome c became more oxidized due to irradiation. The fact that cytochrome c oxidase became more oxidized when the tissue or whole cells were irradiated indicates that the oxidative metabolism had been increased. Remarkable redox absorbance changes near 750 to 760 and 820 to 870 nm suggest that irradiation induces structural and functional changes near Cu_A and Cu_B chromophores, respectively. The alteration of peak parameters (width, height, area) at 750 to 760 nm indicates that the structure of the a_3 -Cu_B site (probably due to ligand-metal interactions) changes. Recall that the irradiation of prokaryotic cells E coli with a HeNe laser also caused partial oxidation of the terminal part of the respiratory chain, cytochrome bd complex, while flavoproteins became slightly reduced.

Changes in the absorption of HeLa cells were accompanied by conformational changes in the molecule of cytochrome c oxidase (measured by circular dichroism [CD] spectra^{32,33}). In the visible spectral range,

(1) ACTION SPECTRUM = ABSORPTION SPECTRUM OF MITOCHONDRIA

(2) ACTIVATION IS ACHIEVED WHEN THE MITOCHONDRIAL AREA OF A CELL IS IRRADIATED BY MICROIRRADIATION TECHNIQUE

(3) IN EXPERIMENTS PERFORMED BY MICROIRRADIATION TECHNIQUE, INHIBITORS OF RESPIRATORY CHAIN ALTER THE RADIATION EFFECTS

FIGURE 48.7 Experimental data obtained from irradiation of excitable cells indicating photoacceptors are located in the mitochondria.

distinct maxima in CD spectra (the spectra were recorded from 250 to 780 nm) of control cells were found at 566, 634, 680, 712, and 741 nm. After irradiation at 820 nm the most remarkable changes in peak positions as well as in CD signals were recorded in the range 750 to 770 nm — an appearance of a new peak at 767 nm and its shift to 757 nm after the second irradiation. Also, the peaks at 712 and 741 nm disappeared, and a new peak at 601 nm appeared. It was suggested that the changes in degree of oxidation of the chromophores of cytochrome c oxidase caused by the irradiation were accompanied by conformational changes in their vicinity. It was further suggested that these changes occured in the environment of Cu_B . Seven small structural changes in the binuclear site of cytochrome c oxidase control both rates of the dioxygen reduction and rates of internal electron- and proton-transfer reactions.

The results of various studies^{27,28,32,33} support the suggestion made earlier²¹ that the mechanism of low-power laser therapy at the cellular level is based on the increase of oxidative metabolism in mitochondria, which is caused by electronic excitation of components of the respiratory chain (e.g., cytochrome *c* oxidase). Our results also provide evidence that various wavelengths (670, 632.8, and 820 nm) can be used for increasing respiratory activity. The wavelengths that were used in experiments described in References 27, 28, 32, and 33 were chosen in accordance with the maxima in the action spectra (Figure 48.4A and B). Note that 632.8 nm (He-Ne laser) and 820 nm (diode laser or LED) are the most common wavelengths used in therapeutic light sources.

It must be emphasized that when excitable cells (e.g., neurons, cardiomyocites) are irradiated with monochromatic visible light, photoacceptors are also believed to be the components of the respiratory chain. Since the publication in 1947 of a study by Arvanitaki and Chalazonitis³⁴ it has been known that mitochondria of excitable cells have photosensitivity. Some of the experimental evidence concerning excitable cells is summarized briefly in Figure 48.7. These experiments were not performed in connection with light therapy. Experimental data^{35–39} (see also Reference 40 and Chapter 5 of Reference 5) made it clear that monochromatic visible radiation could cause (via absorption in mitochondria) physiological and morphological changes in nonpigmented excitable cells, which do not contain specialized photoreceptors. Later, similar irradiation experiments were performed with neurons in connection with low-power laser therapy.^{5,40} It was shown experimentally in the 1980s that He-Ne laser radiation altered the firing pattern of nerves. In addition, it was found that transcutaneous irradiation with a He-Ne laser mimicked the effect of peripheral stimulation of a behavioral reflex and that dose-related effects existed.⁴¹ And, what is even more important, these findings were found to be connected with pain therapy.^{42,43} Later clinical developments of these findings can be found in other publications.^{1,6,7}

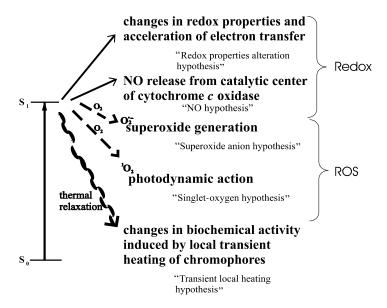

FIGURE 48.8 Possible primary reactions in photoacceptor molecules after promotion of excited electronic states. ROS = reactive oxygen species.

48.3.2 Primary Reactions after Light Absorption

The primary mechanisms of light action after absorption of light quanta and the promotion of electronically excited states have not been established. The suggestions made to date are summarized in Figure 48.8; for simplicity, only singlet states (S_0 and S_1) are shown. However, triplet states are also involved.

Historically, the first mechanism, proposed in 1981 before recording of the action spectra, was the "singlet-oxygen hypothesis." Certain photoabsorbing molecules like porphyrins and flavoproteins (some respiratory-chain components belong to these classes of compounds) can be reversibly converted to photosensitizers. Based on visible-laser-light action on RNA synthesis rates in HeLa cells and spectroscopic data for porphyrins and flavins, the hypothesis was put forward that the absorption of light quanta by these molecules was responsible for the generation of singlet oxygen $^{1}O_{2}$ and, therefore, for stimulation of the RNA-synthesis rate⁴⁴ and the DNA synthesis rate. This possibility has been considered for some time as a predominant suppressive reaction when cells are irradiated at higher doses and intensities.

The next mechanism proposed was the "redox properties alteration hypothesis" in 1988.²¹ Photoexcitation of certain chromophores in the cytochrome c oxidase molecule (like Cu_A and Cu_B or hemes a and a_3^{23}) influences the redox state of these centers and, consequently, the rate of electron flow in the molecule.²¹

The latest developments indicate that under physiological conditions the activity of cytochrome *c* oxidase is also regulated by nitric oxide (NO).⁴⁶ This regulation occurs via reversible inhibition of mitochondrial respiration. It was hypothesized⁴⁷ that laser irradiation and activation of electron flow in the molecule of cytochrome *c* oxidase could reverse the partial inhibition of the catalytic center by NO and in this way increase the O₂-binding and respiration rate ("NO hypothesis"). This may be a factor in the increase of the concentration of the oxidized form of Cu_B (Figure 48.5). Recent experimental results on the modification of irradiation effects with donors of NO do not exclude this hypothesis.⁴⁸ Note also that under pathological conditions the concentration of NO is increased (mainly due to the activation of macrophages producing NO⁴⁹). This circumstance also increases the probability that the respiration activity of various cells will be inhibited by NO. Under these conditions, light activation of cell respiration may have a beneficial effect.

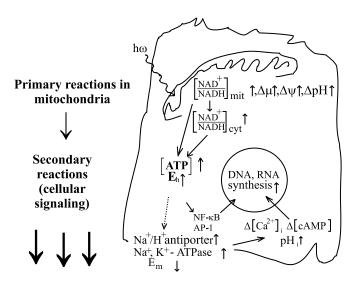

FIGURE 48.9 Scheme of cellular signaling cascades (secondary reactions) occurring in a mammalian cell after primary reactions in the mitochondria. $E_h \uparrow = \text{shift}$ of the cellular redox potential to more oxidized direction; the arrows \uparrow and \downarrow indicate increase or decrease of the respective values, brackets [] indicate the intracellular concentration of the respective chemicals.

When electronic states are excited with light, a noticeable fraction of the excitation energy is inevitably converted to heat, which causes a local transient increase in the temperature of absorbing chromophores ("transient local heating hypothesis").⁵⁰ Any appreciable time- or space-averaged heating of the sample can be prevented by controlling the irradiation intensity and dose appropriately. The local transient rise in temperature of absorbing biomolecules may cause structural (e.g., conformational) changes and trigger biochemical activity (cellular signaling or secondary dark reactions).^{50,51}

In 1993, it was suggested⁵² that activation of the respiratory chain by irradiation would also increase production of superoxide anions ("superoxide anion hypothesis"). It has been shown that the production of $O_2^{\bullet-}$ depends primarily on the metabolic state of the mitochondria.⁵³

The belief that only one of the reactions discussed above occurs when a cell is irradiated and excited electronic states are produced is groundless. The question is, which mechanism is decisive? It is entirely possible that all the mechanisms discussed above lead to a similar result — a modulation of the redox state of the mitochondria (a shift in the direction of greater oxidation). However, depending on the light dose and intensity used, some of these mechanisms can prevail significantly. Experiments with *E. coli* provided evidence that, at different laser-light doses, different mechanisms were responsible — a photochemical one at low doses and a thermal one at higher doses.⁵⁴

48.3.3 Cellular Signaling (Secondary Reactions)

If photoacceptors are located in the mitochondria, how then are the primary reactions that occur under irradiation in the respiratory chain connected with DNA and RNA synthesis in the nucleus (the action spectra in Figure 48.4A and B) or with changes in the plasma membrane (Figure 48.4C)? The principal answer is that between these events are secondary (dark) reactions (cellular signaling cascades or photosignal transduction and amplification chain, Figure 48.9).

Figure 48.9 presents a possible scheme of cellular signaling cascades, which was first proposed to explain the increase in DNA synthesis rate after the irradiation of HeLa cells with monochromatic visible light.²¹ New details have been added in recent years, ^{5,22,25} and the latest version of this scheme is presented in Figure 48.9.

Figure 48.9 suggests three regulation pathways. The first one is the control of the photoacceptor over the level of intracellular ATP. It is known that even small changes in ATP level can significantly alter cellular metabolism (55 for a review, see Reference). However, in many cases the regulative role of redox

homeostasis has proved to be more important than that of ATP. For example, the susceptibility of cells to hypoxic injury depends more on the capacity of cells to maintain the redox homeostasis and less on their capacity to maintain the energy status.⁵⁶

The second and third regulation pathways are mediated through the cellular redox state. This may involve redox-sensitive transcription factors (NF-κB and AP-1 in Figure 48.9) or cellular signaling homeostatic cascades from cytoplasm via cell membrane to nucleus (Figure 48.9).^{3,21,22} As a whole, the scheme in Figure 48.9 suggests a shift in overall cell redox potential in the direction of greater oxidation.

Recent experimental results of modification of an irradiation effect (increase of plasma-membrane adhesion when HeLa cells are irradiated at 820 nm) with various chemicals support the suggestions presented in Figure 48.9. Among these chemicals were respiratory-chain inhibitors,⁵⁷ donors of NO,⁵⁸ oxidants and antioxidants,⁵⁷ thiol reactive chemicals,⁵⁸ and chemicals that modify the activity of enzymes in the plasma membrane.⁵⁹ Recall that the overall redox state of a cell represents the net balance between stable and unstable reducing and oxidizing equivalents in dynamic equilibrium and is determined by three couples: NAD/NADH, NADP/NADPH, and GSH/GSSG (GSH = glutathione).

Recent studies have revealed that many cellular signaling pathways are regulated by the intracellular redox state (see References 60 through 63 for reviews). It is believed now that extracellular stimuli elicit cellular responses such as proliferation, differentiation, and even apoptosis through the pathways of cellular signaling. Modulation of the cellular redox state affects gene expression via mechanisms of cellular signaling (via effector molecules like transcription factors and phospholipase A₂).⁶⁰⁻⁶² There are at least two well-defined transcription factors — nuclear factor kappa B (NF-κB) and activator protein (AP)-1 — that have been identified as being regulated by the intracellular redox state (see References 60 and 61 for reviews). As a rule, oxidants stimulate cellular signaling systems, and reductants generally suppress the upstream signaling cascades, resulting in suppression of transcription factors.⁶⁴ It is believed now that redox-based regulation of gene expression appears to represent a fundamental mechanism in cell biology.^{60,61} It is important to emphasize that in spite of some similar or even identical steps in cellular signaling, the final cellular responses to irradiation can differ due to the existence of different modes of regulation of transcription factors.

It was suggested in 1988 that activation of cellular metabolism by monochromatic visible light was a redox-regulated phenomenon.²¹ Specificity of the light action is as follows: the radiation is absorbed by the components of the respiratory chain, and this is the starting point for redox regulation. The experimental data from following years have supported this suggestion.

Dependencies of various biological responses (i.e., secondary reactions) on the irradiation dose, wavelength, pulsation mode, and intensity are available (for reviews, see References 2 through 5). The main features are mentioned here. Dose-biological response curves are usually bell-shaped, characterized by a threshold, a distinct maximum, and a decline phase. In most cases, the photobiological effects depend only on the radiation dose and not on the radiation intensity and exposure time (the reciprocity rule holds true), but in other cases the reciprocity rule proves invalid (the irradiation effects depend on light intensity). Although the biological responses of various cells may be qualitatively similar, they may have essential quantitative differences. The biological effects of irradiation depend on wavelength (action spectra). The biological responses of the same cells to pulsed and continuous-wave (CW) light of the same wavelength, average intensity, and dose can vary. (See Reference 5 for a detailed review).

Figure 48.10 explains magnitudes of low-power laser effects as being dependent on the initial redox status of a cell. The main idea expressed in Figure 48.10 is that cellular response is weak or absent (the dashed arrows on the right side) when the overall redox potential of a cell is optimal or near optimal for the particular growth conditions. The cellular response is stronger when the redox potential of the target cell is initially shifted (the arrows on left side) to a more reduced state (and intracellular pH, pH_i, is lowered). This explains why the degrees of cellular responses can differ markedly in different experiments and why they are sometimes nonexistent. A jump in pH_i due to irradiation has been measured experimentally (0.20 units in mammalian cells⁶⁵ and 0.32 units in *E. coli*⁶⁶).

Various magnitudes of low-power laser effects (strong effect, weak effect, or no effect at all) have always been one of the most criticized aspects of low-power laser therapy. An attempt was made to quantify the

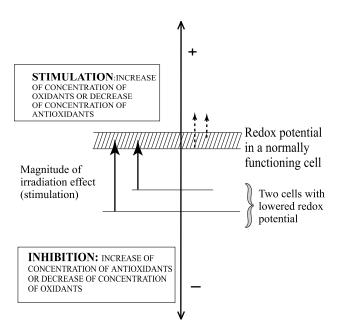

FIGURE 48.10 Schematic illustration of the action principle of monochromatic visible and NIR radiation on a cell. Irradiation shifts the cellular redox potential in a more oxidized direction. The magnitude of cellular response is determined by the cellular redox potential at the moment of irradiation.

magnitude of irradiation effects as dependent on the metabolic status of *E. coli* cells⁶⁷ (for a review, see Reference 26). Recently, the correlation was found between the amount of ATP in irradiated cells and the initial amount of ATP in control cells.⁶⁸

Thus, variations in the magnitude of low-power laser effects at the cellular level are explained by the overall redox state (and pH_i) at the moment of irradiation. Cells with a lowered pH_i (in which redox state is shifted to the reduced side) respond stronger than cells with a normal or close-to-normal pH_i value.

48.3.4 Partial Derepression of Genome of Human Peripheral Lymphocytes: Biological Limitations of Low-Power Laser Effects

Monochromatic visible light cannot always induce full metabolic activation. One such example is considered in this section. Circulating lymphocytes confronted with an immunological stimulus shift from the resting state (G_0 -phase of cellular cycle) to one of rapid enlargement, culminating in DNA synthesis and mitosis (blast transformation). The characteristics of biochemical and morphological reactions in lymphocytes under the action of mitogens (agents responsible for blast transformation, e.g., phytohemagglutinin, [PHA]) have been studied for years (for a review, see Reference 69). Cellular responses to a mitogen can be divided into short-term responses without *de novo* protein synthesis and occurring during the first seconds, minutes, and hours after contact with the mitogen starts and long-term ones connected with protein synthesis hours and days after the beginning of stimulation.

Parallel experiments with PHA treatment and He-Ne laser irradiation were carried out, and the results for these two experimental groups were compared with each other and with those of intact control. $^{70-76}$ The 10-sec irradiation with a He-Ne laser (D = 56 J/m²) induced short-term changes in lymphocytes that were qualitatively similar and quantitatively close to those caused by PHA (which is present in the incubation medium during all experiments). Among short-term responses compared in this set of experiments were Ca²+ influx, RNA synthesis, accessibility of chromatin to acridine orange (a test characterizing the chromatin template activity and its transcription function), and steady-state level of *c-myc* mRNA. $^{70-73}$ Also, ultrastructural changes of the nucleus 74 and chromatin 75 were found to be similar in

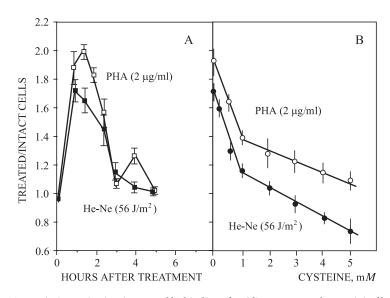

FIGURE 48.11 Transcription activation (measured by binding of acridine orange to chromatin) of human peripheral lymphocytes: (A) after irradiation with He-Ne laser (10 sec, 56 J/m²) or treatment with phytohemagglutinin (PHA, 2 μ g/ml); (B) decrease of transcription activation 1 h after irradiation or PHA treatment depending on concentration of cysteine added immediately after the irradiation or adding PHA. (Modified from Fedoseyeva, G.E. et al., *Lasers Life Sci.*, 2, 197, 1988.)

two experimental groups during the first hours after stimulation. These changes were interpreted as an activation of rRNA metabolism, including its synthesis, processing, and transport.⁷⁴

Two characteristic features of laser-light action were established. First, transcription function was activated in T-lymphocytes but not in B-lymphocytes. At the same time, PHA was stimulative for both types of lymphocytes. Fecond, despite the similarities in the early responses of lymphocytes to PHA and He-Ne laser radiation, the irradiated lymphocytes did not enter the S-phase of the cell cycle. This means that full mitogenic activation did not occur in the irradiated lymphocytes. It is quite possible that the period of irradiation (10 sec in our experiments) was too short to cause the entire cascade of reactions needed for blast transformation. But this time was long enough to cause a boosting effect of blast transformation in PHA-treated lymphocytes. The number of blast-transformed cells in the sample, which was irradiated before the beginning of PHA treatment, was 120 to 170% higher depending on PHA concentration. This may also be a conditioning (priming) effect of certain subpopulations of lymphocytes. This may also be a conditioning (priming) effect of certain subpopulations of lymphocytes. It is possible that this is a redox priming effect. Two lines of evidence allow for this suggestion.

First, it is believed that lymphocyte activation under laser radiation starts with mitochondria, as described in Section 48.3.1. This suggestion is supported by experiments showing that ATP extrasynthesis and an increase of energy charge occur in irradiated lymphocytes.⁷⁷ Formation of giant mitochondrial structures in the irradiated cells indicated that a higher level of respiration and energy turnover occurred in these cells.⁷⁸ But recording of action spectra is needed for further studies of photoacceptors in lymphocytes.

Second, the early transcriptional activation of lymphocytes both by PHA and He-Ne laser radiation (Figure 48.11A) can be eliminated by a reducing agent, cysteine (Figure 48.11B).⁷⁰ As seen in Figure 48.11B, the effect depends on the concentration of cysteine. Cysteine also cancels blast transformation of lymphocytes.⁷⁹ The activation events in T-lymphocytes and monocytes, which are mediated through translocation of the transcription factor NF-κB, depend on the redox state of these cells.⁸⁰ A basal redox equilibrium tending toward oxidation was a prerequisite for the activation of T-lymphocytes

and U937 monocytes; both constitutive activation as well as that induced by mitogens were inhibited or even canceled by treatment of cells with reducing agents or antioxidants.^{79,80}

Partial mitogenic activation of lymphocytes under He-Ne laser radiation is not the only example of limited activation. For example, silent neurons of *Helix pomatia* did not respond to He-Ne laser irradiation, while the spontaneously active neurons responded strongly under the same experimental conditions. ⁴⁰ Only 25 to 27% of 3T3 fibroblasts responded to NIR radiation by extending their pseudopodia toward the monochromatic-light source. ⁸¹

The results of experiments with E. coli batches showed that they contained a subpopulation that, in response to the irradiation, rapidly began a new cycle of replication and division. 5,26 The number of cells in this subpopulation depended on the cultivation conditions, being smaller in faster-growing populations (e.g., the glucose-grown culture) and larger in slower-growing populations (e.g., the arabinose-grown culture). Presumably, in cells of this light-sensitive subpopulation, the particular metabolic state necessary for the division could be established. Irradiation is what enables the cells to achieve this active state rapidly. Also, this set of experiments 5,26 clearly proved that there is a limit to the specific growth rate of all populations (0.80 h⁻¹) that does not depend on growth conditions, and in addition that populations that are already growing at this rate cannot be stimulated. This was also found to be the reason why E. coli growth was maximally stimulated not in summer but rather in winter. In autumn and winter, the intact culture featured relatively slow growth. In spring and summer, when the growth of that culture accelerated and the growth rate of the control culture was almost comparable to that of the culture exposed to the optimum dose of red light in the autumn-winter period, irradiation had but little effect.³

One conclusion from experiments with cultured cells was that only proliferation of slowly growing subpopulations could be stimulated by irradiation. Also, the experiments with HeLa cells demonstrated that one of the effects of He-Ne laser irradiation of these cells was a decrease of the duration of the G_1 period but not other periods of the cell cycle⁸² (for a review, see Reference 83).

Taken together, there exist certain biological as well as other limitations connected with the physiological status of an irradiated object.

48.4 Enhancement of Cellular Metabolism via Activation of Nonmitochondrial Photoacceptors: Indirect Activation/Suppression

The redox-regulation mechanism cannot occur solely via the respiratory chain (see Section 48.3). Redox chains containing molecules that absorb light in the visible spectral region are usually key structures that can regulate metabolic pathways. One such example is NADPH-oxidase of phagocytic cells, which is responsible for nonmitochondrial respiratory burst. This multicomponent enzyme system is a redox chain that generates reactive oxygen species (ROS) as a response to the microbicidal or other types of activation. Irradiation with the He-Ne84-87 and semiconductor lasers and LEDs52,88-91 can activate this chain. The features of radiation-induced nonmitochondrial respiratory burst, which was quantitatively and qualitatively characterized by measurements of luminol-amplified chemiluminescence (CL),84-91 must be followed. First, nonmitochondrial respiratory burst can be induced both in homogeneous cell populations and cellular systems (blood, spleen cells, and bone marrow) by both CW and pulsed lasers and LEDs. Figure 48.12 presents some examples. Qualitatively, the kinetics of CL enhancement after irradiation is similar to that after treatment of cells with an object of phagocytosis, Candida albicans. Quantitatively, the intensity of induced by radiation CL is approximately one order of magnitude lower (Figure 48.12B). This is true for He-Ne laser radiation⁸⁴ as well as for radiation of various pulsed LEDs.^{88,91} Second, irradiation effects (stimulation or inhibition of CL) on phagocytic cells strongly depend on the health status of the host organism. 85-90 This circumstance can be used for diagnostic purposes. Third, there are complex dependencies on irradiation parameters; irradiation can suppress or activate the nonmitochondrial respiratory burst.⁸⁸⁻⁹¹ These problems have been reviewed in detail elsewhere.⁵

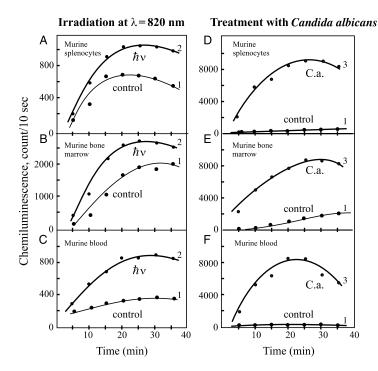

FIGURE 48.12 Kinetic curves of chemiluminescence of murine splenocytes (A, D), bone marrow (B, E), and blood (C, F) after irradiation (A–C) or treatment (D–F) with *Candida albicans*. Curve 1 denotes everywhere the spontaneous chemiluminescence of control cells; curve 2 is chemiluminescence after irradiation of samples in dose 800 J/m² (I = 51 W/m^2 , f = 292 Hz); and curve 3 marks the chemiluminescence induced by the treatment with *C. albicans* ($5 \times 10^7 \text{ particles/ml}$). The measurement error is $\leq \pm 5\%$. (From Karu, T.I. et al., *Lasers Surg. Med.*, 21, 485, 1997.)

Finally, reactive-oxygen species, the burst of which is induced by direct irradiation of phagocytes, can activate or deactivate other cells that were not directly irradiated. In this way, indirect activation (or suppression) of metabolic pathways in nonirradiated cells occurs. Cooperative action among various cells via secondary messengers (ROS, lymphokines, cytokines, ⁹² and NO⁹³) requires much more attention when the mechanisms of low-power laser therapy are considered at the organism level.

This chapter did not consider systemic effects of low-power laser therapy at the organism level. The mechanisms of these effects have not yet been established. Perhaps NO plays a role as a secondary messenger for systemic effects of laser irradiation. A possible mechanism connected with the NO-cytochrome c oxidase complex was considered earlier (Section 48.3.2). In addition, mechanisms of analgesic effects of laser radiation⁹⁴ and systemic therapeutic effects that occur via blood irradiation⁹⁵ could be connected with NO.

Recent studies have demonstrated that a number of nonphagocytic cell types, including fibroblasts, osteoblasts, endothelial cells, chondrocytes, kidney mesangial cells, and others, generate ROS (mainly superoxide anion) in low concentrations in response to stimuli. The function of this ROS production is not yet known. It is believed that an NADPH-oxidase (probably different from that in phagocytic cells) is present in nonphagocytic cells as well. To date, the effects of irradiation on this enzyme have not yet been studied.

Another example of important redox chains are NO-synthases, a group of redox-active P450-like flavocytochromes that are responsible for NO generation under physiological conditions.⁹⁷ So far, the irradiation effects on these systems have not been investigated.

48.5 Conclusion

This chapter considered three principal ways of activating individual cells by monochromatic (laser) light. The photobiological action mechanism via activation of the respiratory chain is a universal mechanism. Primary photoacceptors are terminal oxidases (cytochrome c oxidase in eukaryotic cells and, for example, cytochrome bd complex in the prokaryotic cell of E. coli) as well as NADH-dehydrogenase (for the blue-to-red spectral range). Primary reactions in or with a photoacceptor molecule lead to photobiological responses at the cellular level through cascades of biochemical homeostatic reactions (cellular signaling or photosignal transduction and amplification chain). Crucial events of this type of cellmetabolism activation occur due to a shift of cellular redox potential in the direction of greater oxidation. Cell-metabolism activation via the respiratory chain occurs in all cells susceptible to light irradiation. Susceptibility to irradiation and capability for activation depend on the physiological status of irradiated cells; cells whose overall redox potential is shifted to a more reduced state (e.g., certain pathological conditions) are more sensitive to irradiation. The specificity of final photobiological response is determined not at the level of primary reactions in the respiratory chain but at the transcription level during cellular signaling cascades. In some cases, only partial activation of cell metabolism happens (e.g., priming of lymphocytes). All light-induced biological effects depend on the parameters of the irradiation (wavelength, dose, intensity, radiation time, CW or pulsed mode, pulse parameters).

Other redox chains in cells can also be activated by irradiation. In phagocytic cells irradiation initiates a nonmitochondrial respiratory burst (production of reactive oxygen species, especially superoxide anion) through activation of NADPH-oxidase located in the plasma membrane of these cells. The irradiation effects on phagocyting cells depend on the physiological status of the host organism as well as on radiation parameters.

Direct activation of cells can lead to the indirect activation of other cells. This occurs via secondary messengers released by directly activated cells: reactive oxygen species produced by phagocytes, lymphokines and cytokines produced by various subpopulations of lymphocytes, or NO produced by macrophages or as a result of NO-hemoglobin photolysis of red blood cells.

Coherent properties of laser light are not manifested at the molecular level by light interaction with biotissue. The absorption of low-intensity laser light by biological systems is of a purely noncoherent (i.e., photobiological) nature. At the cellular level, biological responses are determined by absorption of light with photoacceptor molecules. Coherent properties of laser light are unimportant when the cellular monolayer, the thin layer of cell suspension, and the thin layer of tissue surface are irradiated. In these cases, the coherent and noncoherent light with the same wavelength, intensity, and dose provides the same biological response. Some additional (therapeutic) effects from coherent and polarized radiation can occur only in deeper layers of bulk tissue.

Acknowledgments

I am indebted to Prof. V.S. Letokhov for helpful comments and discussions about the effects of coherent and noncoherent light. Partial financial support from the Ministry of Science, Industry, and Technology of the Russian Federation (grant 108-12(00)) and the Ministry of Science and Technology of the Moscow Region and Russian Foundation of Basic Research (grant 01-02-97025) are acknowledged.

49.1 Introduction

Surgery is rooted in a basic inherent conflict. The Hippocratic Oath commands surgeons to abstain from whatever causes harm to the patient, yet the essence of surgery is to invade the body — and therefore to inflict injury. The majority of all surgical research has focused on techniques that alter the balance between improving the lot of the patient suffering from disease and minimizing the mortality and morbidity attendant on the therapeutic act.

Much of the morbidity associated with surgery is incurred during the development of situational knowledge by the surgeon while performing surgery. For a surgeon to reach a lesion the opening into the body must afford both access to the lesion and an appreciation of location. Surgeons use landmarks visualized during dissection to provide course corrections that eventually bring them to the target of choice. Once at the target the opening must be large enough to allow the surgeon to effectively deal with the lesion in an appropriate fashion, which often consists of removing the diseased tissue. The therapeutic ratio between the efficacy and injury of a procedure is therefore a function of the quality of visualization of the surgeon of anatomy during surgery and the efficacy of the instruments, or effectors, at hand to deal with the pathology once visualized. Any technology that holds the promise of improving both visualization and the effectiveness of surgery will therefore have a dramatic effect on the therapeutic ratio and be eagerly embraced by both surgeons and their patients. A prime example of such a technology is image-guided surgery.

Surgeons have always looked to alternative ways of providing visualization without exposing anatomy. The development of medical imaging has revolutionized surgery, enabling many procedures to be performed

that were hitherto impossible due to safety concerns and localization difficulties. Soon after development of the first imaging modality (radiographic x-ray imaging by Roentgen in 1895) surgeons employed the technology within the operating room (OR) to reduce the invasiveness of surgery. For the first time a surgeon could visualize skeletal injuries and malformations and plan their repair or correction prior to commencing a surgical procedure. Radiography also enabled localization of dense masses or foreign objects inside the body cavity, expediting their removal and minimizing iatrogenic trauma arising from exploratory procedures. In addition, the ability to visualize bony anatomy also enabled the surgeon to use this as a frame of reference when it was not feasible to expose the target site, such as in neurosurgical procedures in which lesions are made within the brain to restore function.

In such neurosurgical procedures, the highest degree of precision is essential to avoid iatrogenic injury to structures adjacent to the target site. The need for accuracy in the insertion of instruments inspired neurosurgeons to develop the field of stereotactic surgery (from *stereos*, meaning solid, as in three-dimensional (3D), and either the Greek *taxis*, meaning ordered or arranged, or the Latin *tactus*, meaning touch), in which the surgical instruments are precisely guided to a selected target within the patient by equipment that uses the patient's image data for navigational reference. Zernov first proposed the concept of a mechanical stereotactic guidance device in 1890,¹ and several clinically employed devices were produced following the invention of radiology.

Stereotactic frames were literally bolted to the patient's head by means of screws driven into the skull, which thus provided a rigid frame of reference within which the exact 3D coordinates of instruments and target could be defined. The surgeon would choose a target and an entry point, and a small calculator would be used to calculate how to set the angles of the moveable arcs attached to the frame. Once these were correctly positioned, an instrument passed through the holder would be restricted to travel only from the entry point to the desired target, with the frame acting to constrain the surgeon to the preset surgical path.

In most of these frame-based coordinate systems, the head ring of the frame defines the plane of origin, with the x and y coordinates describing a unique point within that plane. The z-axis is usually perpendicular to the plane of origin, and any point in the anatomy of the patient can be precisely described using three numbers consisting of the respective x, y, and z coordinates. Examples of frames that are coordinate-based include the Leksell, Talairach, and Hitchcock frames. The Leksell is an arc-centered system in which navigation during the procedure is confined by a probe carrier held by a series of easily adjustable arcs. The target point in such a system is at the center of the arc system. In non-Cartesian frames, such as the popular Brown-Roberts-Wells frame, targets and trajectories are defined by four angles and a length, and any point within the patient can be reached regardless of its relation to the center of the coordinate system. The latter frame was developed after computers became available, so Cartesian scanner coordinates could be readily converted into spherical coordinates.

However, plain radiographs of the body, consisting of two-dimensional (2D) images depicting the 3D structure of the body, are inherently limited by the loss of information in reducing three dimensions to two. Unfortunately, during the first half of the 20th century, the only image data available for surgical-planning purposes were 2D radiographs obtained preoperatively from several perspectives. A further limitation was that such radiographs did not depict the soft tissue within the skull. Because radiographs do not show the location of the brain without the introduction of a contrast agent, pneumoencephalography was commonly performed prior to a stereotactic procedure to show the location of the ventricles. Fortunately, the third ventricle has two points— the anterior and posterior commissures— that are easily identified on lateral skull radiographs, allowing the position of the third ventricle to be determined accurately. Stereotactic atlases of human cranial anatomy were then developed based on these points. They were adequate for localizing the ventricles, but their accuracy left something to be desired when it came to locating structures such as the cortex that were lateral to the midline. Thus, early stereotactic procedures could be performed with precision only near the midline and in patients with normal anatomy not affected by the presence of space-occupying lesions. Stereotactic surgery was thus of value to neurosurgeons who selected targets close to the midline to restore lost neurological function, but other

neurosurgeons still needed to expose large amounts of normal anatomy in order to see the anatomical landmarks required to guide them to their desired targets.

Though stereotactic frames were highly successful, they had several limitations. First, the target and trajectory parameters were usually calculated with respect to preoperative image data and did not necessarily take into account intraoperative changes in anatomy. Also, many surgeons found the frames to be cumbersome and obstructive. These limitations led to the development of devices that could determine position in 3D space without the need for mechanical arcs and calipers. These devices are called 3D digitizers. They assign coordinates to each selected point, enabling coregistration of patients, images, and instruments within the same coordinate system. Finally, the limitation associated with 2D imaging was resolved by the advent of 3D imaging techniques such as computed tomography (CT) and magnetic resonance imaging (MRI). With the advent of 3D imaging and intraoperative localization devices it has become possible to almost completely replace stereotactic frames with frameless navigational systems. These frameless systems are discussed later, but it is first necessary to examine the advances in imaging techniques that have allowed image-guided navigation techniques to achieve their current level of ubiquity.

49.2 Advances in Imaging Technology

49.2.1 Computed Tomography and Magnetic Resonance Imaging

While radiographs are clearly still invaluable in many medical applications, they have generally been superseded for image-guidance purposes by other imaging modalities, predominantly CT and MRI. CT is excellent for imaging vascular and skull-base lesions and ideal for trauma cases. However, MRI offers superior tissue contrast and is therefore extremely useful for imaging brain tumors in soft tissues and organs, for example. The 2D images acquired with these modalities can be manipulated by relatively inexpensive computer technology into 3D virtual models of the patient's anatomy. Such virtual models can be rotated and examined from all angles to enable the surgeon to determine the best approach to the target. These visualization techniques have thereby markedly increased the range of applications for stereotactic techniques. Preoperative images can also be supplemented by the use of intraoperative imaging, allowing the surgeon to evaluate the progress of the operation and decide if changes to the surgical plan are necessary due to movement of tissue.

49.2.2 Functional Imaging

Functional imaging technology, which detects changes in metabolism produced by function and produces images showing the location of such functional activity, has experienced an upsurge in use in recent years. Currently, the main functional imaging modalities are positron emission tomography (PET), single photon emission tomography (SPECT), magnetic source imaging (MSI), functional magnetic resonance imaging (fMRI), and mass spectroscopy. The latest development in this area is magnetoencephalography (MEG), which may be used for mapping normal and continuous abnormal function. It can already identify motor and sensory cortex in the brain, and new algorithms may enable detection of speech activity as well.

In functional imaging, alterations in function, rather than structure, serve as the basis for the imaging. For example, CT develops an image based on the absorption of x-rays by the tissue within the x-ray beam. fMRI detects differences in blood flow while the patient is at rest vs. performing a specific task. Such changes in blood flow are usually induced by the demands of a specific part of the brain performing a specific task. The resultant image is therefore a depiction of the anatomical location of a specific function. Knowledge of the location of function, rather than anatomy, can be particularly useful in procedures either targeting abnormal function for correction (such as in surgery for epilepsy intractable to medical intervention) or in the removal of lesions close to critical areas of the brain such as the motor cortex. As neurosurgery evolves from techniques designed to remove lesions to those designed to restore

function it is anticipated that functional imaging will be increasingly used as the imaging modality of choice for image-guided surgery.

While functional imaging has considerable potential, it does have limitations. The images usually demonstrate only function, and the relationship between function and anatomy is not necessarily obvious. Therefore, to detect an abnormality in a specific patient it may be necessary to acquire data from normal controls for comparison purposes or refer to an atlas that delineates the relationship of function to anatomy. Therefore, the use of functional imaging almost always uses a technique called image fusion, in which two different images of the same 3D object are precisely overlaid onto each other to render an image comprised of information from both sources. To perform such an overlay the two images must be related to each other through a process of registration in which points or geometry depicted on both images are used to align the images with each other. The process of registration is key for image-to-image fusion and for image-to-patient fusion and will be covered later in this chapter.

49.3 Segmentation and Deformation of Images

When imaging a patient for surgical planning purposes the entire anatomy of part of the patient, such as the head, is normally depicted. Usually, however, only a specific area is of interest for a particular case, and it is desirable to separate this region from the remainder to allow study of the shape and size of the tissue in question. This process is called segmentation and can be accomplished by matching the patient's image to a standardized printed atlas or an electronic atlas that has specific structures already segmented. This process can be rendered very inaccurate due to the significant differences between individual brains. This discrepancy may be further exacerbated by the presence of tumors, abscesses, or accidental trauma that distorts the normal anatomy, making it difficult to identify or orientate the patient's image data relative to the atlas example. A solution is to use an elastic deformation technique to resize and warp the atlas to match the patient's anatomy. This approach constrains the points on the patient image and atlas plate that must be connected but otherwise leaves the structures free to deform to a template. This enables more precise preoperative planning and is valuable if the surgical plan must be updated intraoperatively to reflect brain shift or if ambiguous structures are encountered that must be identified before proceeding further. Several deformable atlases have now been produced for neurosurgical applications, ^{2,3} though there is still some skepticism in conservative circles about their value.

At first, limited computing capacity meant that digitized data had to be manually segmented. Manual segmentation of images by humans is time-consuming and tedious. Fortunately, initial studies suggest that automated segmentation techniques are as reliable as manual segmentations. Automated techniques are much faster and are robust with respect to diverse disease entities. Use of such automated techniques may avoid the need for invasive monitoring prior to functional neurosurgical procedures. For example, when planning a surgical intervention for epilepsy, it has been necessary to surgically insert depth electrodes to record abnormal activity. Automated segmentation coupled with functional-to-anatomical image fusion may eliminate the need for such complex and costly evaluation prior to surgery. The technique could also accommodate structural lesions such as tumors. After segmenting out the lesion, the brain is deformed to what it would look like without the lesion. First the atlas is deformed to the brain, then the tumor can be grown back into the image dataset. Although this process is very experimental, it might allow for the depiction of the location of pathways altered by the presence of mass lesions.

49.4 Registration

The fundamental concept underlying all image-guided surgery is registration. This is the method used for mapping the detailed bits of imaging data of a specific patient in such a way as to relate the bits of data both to one another and to the physical space/anatomy of the patient. Registration has been traditionally performed by identifying and aligning points, called fiducials, seen on the sets of images to their location on the patient in physical space; this process is termed paired-point registration.

In conventional frame-based stereotactic surgery, markers placed on the frame during imaging allowed for the registration of the images to the operative field. Paired-point-based methods have now been supplemented with curve- and surface-matching methods, moment and principal fixed-axes methods, correlation methods, and atlas methods.⁴

49.4.1 Paired-Point Methods

The most straightforward method for achieving coregistration of coordinate spaces is to use a set of markers that are visible in the patient's image data set and that can be pointed to by a localization device or digitizer (see below). While only three points (in a nonlinear arrangement) are required to relate two 3D objects to each other, using more points improves the accuracy of the subsequent registration and reduces the risk of failure should one of the markers move relative to the others or become obscured and undetectable by the digitizer.

Some investigators (notably in the radiosurgical field) have used clearly defined anatomical features as reference markers.⁵ However, there is a degree of ambiguity associated with feature-based registration, and most neurosurgeons prefer to use artificial markers applied to the patient prior to imaging. Different types and sizes of artificial fiducials are available and may be fixed to the patient's skin using adhesive or embedded directly in the bone. Markers applied to the skin cause no discomfort to the patient but may be dislodged between preoperative imaging and surgery and are more prone to localized movement relative to each other. This can have deleterious effects on the accuracy of both registration and target localization. In contrast, bone-implanted fiducials offer the highest accuracy of any registration technique, including stereotactic frames,⁶ because they cannot move relative to the patient's bone and, once implanted, remain in place until the surgery is completed. Implanted markers are most frequently used in procedures involving the skull, spine, or pelvis. However, the trauma and subsequent pain associated with implantation of fiducials in bone militates against their routine use. The inability to fixate fiducials to soft tissue like the liver has essentially prevented any application of image guidance to organs that are not confined to a rigid structure such as the skull.

Regardless of the type of marker used for paired-point registration, the resultant accuracy of the registration process depends not only on the markers but also on how they are distributed over the volume being registered. Regardless of their number, markers arranged within a line will never allow for 3D registration. Further, coplanar markers will allow for registration but will have little accuracy in the z dimension perpendicular to the plane of the markers. For the best possible registration the markers should be spread as widely over the entire 3D volume as possible and as far from each other in each coordinate dimension.

49.4.2 Contour and Surface Mapping

As an alternative to matching isolated detectable points, it is also possible to obtain a registration by matching contours obtained from the surface of the patient. Surface contours can be extracted from image data sets using intensity-based segmentation algorithms. Using a digitizer, a random contour from the patient can be matched to the contour from the imaging study. The computer can then align these features with areas of maximum curvature that are the most useful for the process. A further development is to dispense with point matching altogether and simply match large surface areas. In neurosurgical procedures, the surfaces imaged by PET, CT, or MRI can be matched directly with the scalp as imaged in the OR. This permits rapid registration immediately prior to the surgery, obviating the need for repeating preoperative diagnostic imaging with fiducials in place. This saves both time and money, though care must be taken to ensure that the diagnostic images are of sufficient quality to justify relying on them for surgical planning and guidance. Frequently diagnostic images lack the fine spacing needed between images to allow for accurate intraoperative guidance. There is some variation in the degree to which surface-matching techniques can be automated. The best-known surface-matching strategy is that of Pelizarri and Chen,⁷ but a number of alternative approaches have been published.

Existing surface-based registration techniques are generally less accurate and less reliable than fiducial marker-based techniques and require considerably more technical support and time. The application accuracy achieved for surface matching is usually in excess of 3.0 mm.⁸ Further, it is important to note that contour matching is incapable of registering two perfect spheres using their contours; therefore, points for the registration process should be obtained wherever there is a departure of normal anatomy away from a sphere, such as the area around the face and nose.

A combination of rapid contour mapping with fully automated segmentation would result in a system permitting frequent, rapid, and accurate updates of the registration information at each stage of the surgical procedure, though the technology required for this is still under development.

49.5 Frameless Systems

49.5.1 Early Approaches to Frameless Localization

As mentioned earlier, stereotactic frames have now been almost completely replaced by frameless navigation systems for most neurosurgical procedures. Among the earliest attempts at 3D localizers were articulated arms with potentiometers at the joints between the links. These sensors determined the angles of the joints by measuring resistance, enabling the orientation of the distal section and location of the tip to be determined. The first reported use of a passive localization arm of this type for neurosurgical guidance was by Watanabe,⁹ who used an arm with six joints. A widely used commercial model is the ISG Viewing Wand (ISG Technologies, Toronto, Canada). Guthrie and Adler¹⁰ developed a similar series of arms in which optical encoders replaced the potentiometers to improve accuracy. These arm-based systems are simple and do not require a clear line of sight. However, they can interfere with the surgeon's movements and are difficult to use with surgical instruments.

Another early approach used ultrasound emitters and microphone arrays in a known configuration to localize the position of the instruments. Position was determined on the basis of the time delay between emission of an ultrasonic pulse by the emitter and its detection by each microphone. In 1986, Roberts et al.¹¹ applied a version of this approach to an operating microscope and developments continue to this day. Barnett et al.^{12,13} developed a system in which ultrasonic emitters are fitted to a hand-held interactive localization device (Picker International, Highland Heights, OH), and the detecting microphone arrays are fitted to the side rails of a standard operating table. However, ultrasound-based digitizing systems are limited by their requirement for a clear line of sight between the emitters and detectors, and the systems may be confused by echoes, environmental noise, and the effects of fluctuating air temperature. On the positive side, they are relatively inexpensive, costing no more than half as much as an optical digitizer, can be set up rapidly, and can cover a very large working volume. Also, it is easy to affix the emitters to all kinds of instruments and other equipment.

49.5.2 Optical Digitizers

Modern navigation systems make use of light-emitting diodes (LEDs) to track the location of instruments within the operative space and were first developed by Bucholz. The LEDs used in such systems emit near-infrared light that can be detected by at least two charge-coupled-device (CCD) cameras positioned in the OR. Inside the cameras, light from the LEDs is focused onto a layer of several thousand CCD sensor elements, and the infrared energy is converted into electrical impulses. These digital signals may be further processed or converted to analog form. Through triangulation the point of light emission can be calculated with 0.3-mm accuracy.

Optical triangulation techniques are highly accurate and robust. A useful comparison of their properties with those of sonic digitizers has been published.¹⁴ Like sonic digitizers, optical systems require a clear line of sight, but they are unaffected by temperature fluctuations and do not appear to be compromised by surgical light sources. The infrared light is not visible to the surgical team and causes no harmful effects.

A variation on the infrared detection approach uses passive reflectors instead of active emitters, with an infrared source illuminating the operative field. The reflected light is detected as before. Instruments fitted with passive reflectors do not need to have electrical cables attached and are thus easier to sterilize. However, the passive markers cannot be "turned off" and thus appear simultaneously to the CCD cameras at all times. This can confuse the navigation system if multiple instruments are being used and a large number of reflectors are present in the operative field at once. Another passive approach substitutes an ultraviolet (UV) source as the field illuminator, with fluorescent markers reirradiating the UV light at visible frequency levels. However, there is concern that prolonged exposure to UV light in this context may pose a health hazard.

49.5.3 Reference Systems

With stereotactic frames the mounting of surgical instruments on the base ring ensured that they were accurately positioned relative to the patient's anatomy. Frameless devices provide no such safeguarded connection between the instruments and the patient's anatomy, which can lead to error if the position of the patient is not accurately known.

An important benefit of surgical navigation systems is the ability to change the patient's position following registration. To avoid the need for reregistration, some means of tracking the head relative to the detection mechanism is required. This is commonly achieved with a reference arc or similar device fixed directly to the patient's head or to the head holder, assuming that the head does not move in relation to the holder. The reference device has at least three emitters that are detectable by the digitizer employed in the design of the system; for optically based systems, a multiplicity of LEDs serves this function, allowing one or more LEDs to be blocked and still allow the position of the head to be determined prior to localization of the surgical instruments.

By monitoring the relative positions of the instrument and the reference arc, the navigation system correlates the position of the instrument to the patient's anatomy on a continuous basis, regardless of the frequent movements of the patient that occur during a standard operation.

49.5.4 Effectors

The term effector simply refers to those instruments used by a surgeon to perform surgery on the patient. Although surgical instruments comprise the largest portion of such devices, an effector can also be anything used to treat the patient surgically including surgical microscopes, endoscopes, genetic material, drug polymers, and robots. Such effectors rely on precise positioning to produce the maximal benefit for the patient, so integration of navigational technology is critical to their success.

Essential components of a surgical navigation system are the instruments that, through modifications by the addition of LEDs or reflectors, permit localization. Because the LEDs or spheres must be visible to the camera array at all times, they cannot be mounted on the tip of an instrument, as this will not be visible to the cameras during surgery. Instead, the LEDs or spheres are usually located at a given distance from the tip in the handle of the instrument. If the instrument is essentially linear, such as a forceps, then the minimum requirement for localization is two LEDs mounted in alignment with the tip. Reflective spheres generally do not localize well if they are placed in a linear alignment, as reflective systems experience difficulty when the view of the spheres partially overlap, so reflective arrays usually consist of at least three spheres in a nonlinear arrangement. Given the relatively large size of reflective spheres, LEDs are usually the detector of choice for microsurgical instrumentation.

A bayoneted instrument is commonly employed to allow surgery through a small opening. The offset design of a bayonet instrument allows the handle to be placed off the axis of the line of sight of the surgeon, and its geometry is ideal for use in conjunction with a navigational system. Similarly, for instruments with complex 3D shapes, LEDs or spheres must be placed off axis to allow tracking.

When a specific trajectory into the brain is desired, rigid fixation of instrumentation is preferred to ensure that the instrumentation is aligned along the selected surgical path. Typical situations in which

this path is key include tumor biopsy, insertion of depth electrodes for epilepsy, insertion of ventricular catheters, and functional surgery. This function is carried out by a biopsy guide-tube adaptor, which is attached to the reference arc using a standard retractor arm with adjustable tension. The tube is equipped with four LEDs to provide redundancy.

The most popular frameless surgical navigation system is the Trion (formerly called the StealthStation) manufactured by Medtronic. The Trion consists of (1) a UNIX-based workstation that, by communicating with the other components of the system, displays position on a high-resolution monitor or head-mounted display; (2) an infrared optical digitizer with camera array (as described earlier); (3) a reference LED array (e.g., a reference arc) for the patient; and (4) surgical instruments modified by the addition of either passive reflectors or active emitters (usually LEDs). Optional components of the system include a robotically controlled locatable surgical microscope and surgical endoscopes modified by the placement of LEDs.

The Trion utilizes CT or MRI for intraoperative guidance. Images are typically obtained in the axial dimension, and the scanning parameters for each modality are adjusted to achieve roughly cubic voxels: Image files are transmitted from the CT or MRI scanner to the surgical workstation over an Ethernet-based local area network and then converted to a standard file format. During surgery, three standard views (the original axial projection and reconstructed sagittal and coronal images) are displayed on a monitor at all times. A cross-hair pointer superimposed on these images indicates the position of the surgical instrument, endoscope, or microscope focal point. A fourth window can alternatively display a surface-rendered 3D view of the patient's anatomy, real-time video from the endoscope or microscope, or reference data from an anatomical atlas. An alternative view, the navigational view, produces images orthogonal to the surgical instrument rather than the patient and is particularly useful for aligning the instrument with a surgical path.

An operating microscope can also be tracked relative to the surgical field and the position of the focal point displayed on the preoperative images. Certain microscopes can be robotically controlled by the system. By means of motors that move the microscope head, the workstation can drive the scope to focus on a specific point in the surgical field chosen by clicking on the spot as viewed on the workstation display.

A rigid straight fiberscope ("INCLUSIVE" endoscope, Medtronic Sofamor Danek, Memphis, TN) has also been modified to work with the Trion for intraventricular procedures. Four LEDS are attached to the endoscope near the camera mount using a star-shaped adapter, and the geometric configuration of the LEDs is programmed into the surgical navigational system along with the endoscopic dimensions.

49.6 Intraoperative Imaging

Images acquired preoperatively obviously depict the situation prior to opening of the cranium. However, the brain is elastic and usually deforms during a surgical procedure, particularly when resecting a large tumor or if a significant volume of CSF is drained. Attempts have been made to model how the brain would respond to surgery, but this is mathematically complex. An alternative solution is to use intraoperative imaging to update and correct preoperative images as the surgery progresses. In its simplest form, the same imaging modality used preoperatively could be employed intraoperatively. Alternatively, a different imaging modality could be used during a procedure and the deformation detected by this imaging modality used to elastically deform the preoperative images. Several different modalities are currently available for intraoperative imaging, and their relative advantages and disadvantages are summarized in Table 49.1.

Ultrasound has been suggested as a low-cost alternative to stereotaxis. Ultrasound data may be acquired as a single 2D image, or a 3D data set may be acquired with newer systems. However, the images are taken at oblique angles to normal anatomical axes and are often difficult to interpret. There is a high signal-to-noise ratio, and some tumors are not visible at all using ultrasound. However, it may be useful if registered to other imaging modalities that enable the recognition of specific structures. Ultrasound-to-MRI registration is accomplished by using a modified probe equipped with LEDs.

TABLE 49.1 Relative Merits of Intraoperative Imaging Modalities

Factor/Type	MRI	CT	Ultrasound	Fluoroscopy
Cost		_	+	+
Continuous duty	+		++	-
Resolution	+	+	+++	
Contrast	++	+	+	+
Distortion	_	++	+	+
Signal-to-noise ratio	++	+		-

^{+ =} advantageous, - = disadvantageous.

With the Trion ultrasound images are fed in through a video port and preoperative MR or CT images reformatted to match the ultrasound images. Color Doppler units, such as the Aloka Model 5000 (Aloka Co., Wallingford, CT), can detect the presence of vessels easily and in color. The system has a modified operative display with five active windows that enable the axial, coronal, and sagittal views to be displayed as reformatted MR or CT with or without overlaid ultrasound images.

49.7 Intraoperative System Control

As navigational systems become more complex the surgeon must increasingly interact with the system during a procedure. This need will intensify as more complex effectors, such as robots, are brought into the operating room. Furthermore, as these units proliferate in community hospitals, it will be imperative that they be controllable by a small surgical team, without the need for additional technicians to operate the systems.

Several approaches have been developed that allow the surgeon to control the system while scrubbed. One technique involves the use of touch-sensitive flat-panel displays that can be placed in a sterile bag and used for controlling the system as well as indicating position. Another solution is to incorporate voice recognition in the head-mounted display worn by the surgeon during a procedure.

As these systems become more advanced, it will be important to improve the diversity and utility of the information presented. Rather than being limited to simply showing where a surgeon is within a patient's anatomy, these systems can be employed to compare the patient's anatomy to that of previous patient's functional anatomy. This function is served through the use of an atlas of functional anatomy.

49.8 Current Applications

Image-guided surgery techniques have proved valuable in diverse procedures including tumor removal and ablation, treatment of arteriovenous malformations, functional neurosurgery for the treatment of epilepsy or tremor-inducing conditions, and implantation of devices to control hydrocephalus (for example). Image guidance also provides significant assistance in various orthopedic procedures including spine surgery, pelvic fixation, and joint replacement.

49.8.1 Tumors

Image guidance is of great value for planning tumor-removal procedures. The actual location of certain types of tumor with distinct margins is usually apparent in preoperative imaging, though some forms of tumor are not so easily delineated. In most cases, image guidance facilitates a more complete resection of the tumor during the initial surgery, and subsequent imaging will reveal whether follow-up surgery is necessary to remove any residual material or recurrent growth.

Another application of image guidance for tumor therapy is the placement of radioactive seeds directly inside tumors that are otherwise inoperable or where surgery may result in unwanted side effects. In general, this technique is used to palliate rather than cure a lesion. One area in which this technique has

been used successfully is in the management of malignant tumors of the prostate that commonly occur in patients incapable of tolerating extensive resective surgery.

49.8.2 Vascular Malformations

Intracerebral vascular malformations normally require surgical intervention to prevent a future hemorrhage and the attendant neurological deficits. Excision of such malformations is particularly difficult when they occur in eloquent areas of the brain such as those responsible for speech or motor-sensory functions. Image-guidance technology enables the malformation to be modeled in three dimensions and thus permits the optimal resection to be planned, taking into account the relationships of the feeding and draining vessels.

49.8.3 Ventriculostomy

The most common application of endoscopy within the head is in the performance of third ventriculostomies in patients with obstructive hydrocephalus or aqueductal stenosis.^{15–17} Once the endoscope is successfully inserted, it is frequently possible to proceed on the basis of visual guidance. However, image guidance can ensure a straight trajectory from the burr hole through the foramen of Monroe to the floor of the third ventricle and help avoid unseen branches of the basilar artery. Image guidance is also of particular value in cases of abnormal anatomy or where orientation becomes difficult owing to bloody or blurry cerebrospinal fluid.¹⁸ Recent developments in the field of virtual endoscopy promise to aid in the planning and conduct of these procedures.¹⁹

49.8.4 Functional Neurosurgery

Patients with medically intractable epilepsy are now frequently referred for functional neurosurgery to alleviate their condition. To treat the condition surgically the seizure focus must first be identified and localized within the brain. Once localized, the region can be eradicated. These processes require accurate spatial localization during preoperative imaging and electrophysiological investigations, and accurate coregistration of the patient data with the surgical field is essential to prevent destruction of uninvolved tissue.

While the advent of CT and MRI had a significant impact on epilepsy management, the more recent developments of PET, SPECT, fMRI, and magnetic source imaging (MEG) has enabled greater understanding of the underlying neurophysiology and has permitted refinement of treatment protocols. The ability to coregister each of the imaging modalities with the others (and with the patient) is fundamental to the process of determining the nature of the pathology in a given patient.

Video EEG recordings of actual seizure events also provide vital information for determining which cases are suitable for surgery. Invasive recording techniques are used to evaluate more difficult cases, and placement of the required recording hardware can be facilitated by image guidance. A common approach involves the insertion of depth electrodes into critical mesial structures to localize the seizure origins.²⁰ Another evaluation technique requires the placement of subdural strip electrodes on the cortical surface. Accurate placement of subdural strips is crucial, and frameless image guidance is potentially of great assistance in the process, though many centers still place the strips without such guidance.

Therapeutic procedures for treating seizure disorders associated with structural lesions have been highly successful in producing seizure-free outcomes.^{21,22} All such surgical interventions for seizure disorders benefit considerably from image guidance as it is desirable to fully eliminate the causative lesion while minimizing damage to surrounding tissue. It is likely that in the future we will see the development of noninvasive source localization that will obviate the need for surgical implantation of recording electrodes. However, image guidance in therapeutic surgery will still be required. Improvements in noncontact registration should enable the registration of patient image data to be accomplished and updated more rapidly.

49.8.5 Stereotactic Radiosurgery

Another area where image guidance has been of considerable assistance is stereotactic radiosurgery in which one or more highly collimated beams of radiation are directed at a tumor. This is usually an outpatient, nonsurgical procedure using the LINAC Scalpel, Gamma Knife, or, more recently, proton-beam therapy.^{23,24} For certain types of brain tumor this treatment is an effective alternative to conventional surgery. However, the radiation does not remove the tumor (although it may shrink it), and resulting scar tissue may make any future surgery more difficult. In this technique, the patient first undergoes the application of a stereotactic frame to establish a reference system upon his or her anatomy. The target of interest is then defined by imaging the patient with the frame in place, and the coordinates of the target are calculated using conventional stereotactic techniques. A focused beam of irradiation is then sent through the target point, and the patient or the beam is moved, and the beam repeated, as in LINAC-based stereotactic radiosurgery. Alternatively, the patient's head is precisely placed at the center of numerous intersecting beams such that all of the beams intersect within the target, as in Gamma Knife radiosurgery. Both devices embrace the key concept of image guidance in terms of maximal functionality with minimal invasiveness.

49.9 Conclusions

Image guidance directly supports minimally invasive surgery techniques by enabling the surgeon to view the operative site directly without the need for extensive exposure of normal anatomy. In the hands of a well-trained surgeon, the use of image guidance can markedly reduce the risk associated with critical interventions when compared to the situation before navigation was widely adopted.

Based on the advances made in imaging, image guidance has gone from a few applications limited to the midline of the brain to being used in nearly every cranial procedure imaginable, and fusion of intraoperatively acquired ultrasound images to preoperative MRI data may mean that expensive imaging equipment is unnecessary to bridge the gap between the preoperative and intraoperative situations.

As this technology improves, and as more effectors are built that rely on precise placement, image guidance will become the standard of care for all cranial interventions and many other surgical procedures.

50.1 Optical, Physical, and Thermal Properties of Dental Hard Tissues

50.1.1 Optical Properties of Dental Hard Tissue in the Visible and Near-Infrared

References

Dental enamel is an ordered array of rods of inorganic apatite-like crystals surrounded by a protein/lipid/ water matrix. The crystals are approximately 30 to 40 nm in diameter and can be as long as 10 μ m. The crystals are clustered together in 4- μ m-diameter rods (or prisms), which are roughly perpendicular to

the tooth surface. Dentin is honeycombed with dentinal tubules of 1 to 3 μ m in diameter. Each of these tubules is surrounded by a matrix of needle-shaped, hydroxyapatite (HAP)-like crystals in a protein matrix composed largely of collagen. Because of the complex nature of these materials, the scattering distributions are generally anisotropic and depend on tissue orientation relative to the irradiating light source¹⁻⁴ in addition to the polarization of the incident light.

The optical properties of biological tissue can be quantitatively described by defining the optical constants — the absorption (μ_a) and scattering coefficients (μ_s) — that represent the probability that the incident photons will be absorbed or scattered, as well as the scattering phase function $\Phi(\cos\theta)$, which is a mathematical function that describes the directional nature of scattering.⁵⁻⁸ When these parameters are known, light transport in dental hard tissue can be completely characterized and modeled. The optical parameters for normal enamel and dentin have been reported in the wavelength range of 200 to 700 nm. For enamel, absorption is very weak in the visible range $(\mu_a < 1 \text{ cm}^{-1}, \lambda = 400 \text{ to } 700 \text{ nm})$ and increases in the ultraviolet (UV) $(\mu_a > 10 \text{ cm}^{-1}, \lambda < 240 \text{ nm})$. For dentin in the 400- to 700-nm wavelength range, the absorption coefficient is essentially wavelength independent, with a value of $\mu_a \sim 4 \text{ cm}^{-1}$. Scattering in enamel is strong in the near-UV and decreases $\sim \lambda^3$ with increasing wavelength to a value of only 2 to 3 cm⁻¹ at 1550 nm. In contrast, scattering in dentin is strong throughout the near-UV, visible, and near infrared (NIR).

Accurate description of light transport in dental hard tissue relies on knowledge of the exact form of the phase function $\Phi(\cos\theta)$ for each tissue scatterer at each wavelength. Therefore, direct measurement of the phase function is necessary. It is important to note that the empirically derived Kubelka-Munk (KM) coefficients that are commonly used in dentistry are not fundamental optical constants and are not appropriate for describing light transport in tissue with forward-directed scattering such as enamel and dentin, particularly in the NIR.^{5–8,13} Scattering in most biological tissues can be represented by a Henyey–Greenstein (HG) function with values of g greater than $0.8.^5$ The scattering anisotropy (g) should be determined within the context of an appropriate phase function based on the nature of the scatterers in the tissue^{5,13} and subsequently validated through comparison of simulated scattering distributions with measured distributions of various thickness. Measured angular-resolved scattering distributions could not be represented by a single scattering phase function $\Phi(\cos\theta)$ and required a linear combination of a highly forward-peaked phase function, an HG function, and an isotropic phase function represented by the following equation:

$$\Phi(\cos\theta) = f_d + (1 - f_d) \left(\frac{(1 - g^2)}{(1 - g^2 - 2g\cos\theta)^{3/2}} \right)$$
 (50.1)

The parameter f_d (fraction diffuse) is defined as the fraction of isotropic scatterers. The average value of the cosine of the scattering angle (θ) is called the scattering anisotropy (g), and at 1053 nm g=0.96 and g=0.93 for enamel and dentin, respectively.³ Note that Zijp and ten Bosch¹ and Zijp et al.⁴ reported values of g=0.4 for dentin and g=0.68 for enamel, calculated by taking the ratio of the forward- and backward-scattered light. This latter approach is prone to error due to the contribution of surface scattering.³ At 1053 nm the fraction of isotropic scatterers, (f_d), was measured to be 36% for enamel and less than 2% for dentin. The phase function changes with wavelength; therefore, the phase function must be independently determined at each wavelength.

Increased backscatter from the demineralized region of early caries lesions is the basis for the visual appearance of white spot lesions. ¹⁴ Increased porosity of the lesion leads to increased scattering at the lesion surface and higher scattering in the body of the lesion, producing an increase in the magnitude of the diffuse reflectance. ¹⁵ Attempts at measuring the optical properties of dental caries have been limited to measurements of backscattered light from optically thick, multilayered sections of simulated caries lesions. ^{15–17} In those measurements, empirical KM coefficients were calculated representing the diffusion

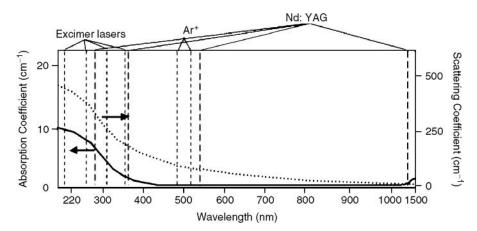

FIGURE 50.1 The scattering coefficient μ_s (dotted line) and the absorption coefficient μ_a (solid line) of dental enamel from the UV-NIR. Laser wavelengths of interest are indicated by the vertical dashed lines. (Compiled from References 9, 11, and 12.)

of light through the tissue. Ko et al.¹⁷ recently proposed that the optical scattering power, the product of the KM scattering parameter and the lesion depth, is a good estimate of enamel demineralization.

Enamel exhibits double refraction or birefringence upon illumination in the visible and NIR.¹⁸ The apatite crystals in dental enamel are highly oriented along the long or c-axis of the enamel prismatic structures. The major source of birefringence in dentin is the highly oriented collagen fibrils in the collagen; the collagen fibers are positively birefringent, while the apatite crystals are negatively birefringent. Demineralized enamel and dentin appear black under observation through crossed polarizers due to depolarization of the incident polarized light. Theuns et al.¹⁹ have related changes in the birefringence of dental enamel during demineralization to mineral content. Polarized-light microscopy measurements over the past several decades on thin sections have demonstrated that caries lesions rapidly depolarize incident polarized light.

50.1.2 Optical Properties of Dental Hard Tissue in the Infrared

In the mid-infrared, scattering is negligible, and with accurate knowledge of the absorption coefficient and the reflectivity the light deposition can be described using Beer's law. The magnitude of the absorption coefficient is high in the mid-infrared due to resonant absorption by molecular groups in water, protein, and mineral. The reflectivity can exceed 50% at wavelengths coincident with mineral-absorption bands due to the large increase in the imaginary component of the refractive index (see Section 50.1.3). Coefficients corresponding to carbon dioxide (CO₂) laser lines that could be obtained using conventional transmission were determined to be 1168 ± 49 cm⁻¹ at 10.3 μ m and 819 ± 62 cm⁻¹ at 10.6 μ m for enamel and 1198 ± 104 cm⁻¹ at 10.3 μm and 813 ± 63 cm⁻¹ at 10.6 μm for dentin. Enamel-absorption coefficients corresponding to Er:YAG (2.94 μm) and Er:YSGG (2.79 μm) were calculated to be 768 ± 27 cm⁻¹ and 451 ± 29 cm⁻¹, respectively. The absorption coefficient of dentin at 2.79 μ m was calculated to be 988 \pm 111 cm⁻¹. These absorption coefficients were based on the Beer-Lambert law accounting for Fresnel reflectance losses. Conventional transmission measurements were not possible for the determination of the optical properties of enamel and dentin at 9.3 and 9.6 µm; therefore, alternative methods, such as angular-resolved reflection measurements of polarized light and time-resolved radiometric measurements, were necessary. Duplain et al.20 measured absorption coefficients of 18,700, 31,300, 6,500, and 5,200 cm⁻¹ at 9.3, 9.6, 10.3, and 10.6 µm, respectively, using angular-resolved reflection measurements of polarized light. The magnitude of the coefficients of these researchers in the wavelength range in which

direct transmission measurements were possible, 10.6 and 10.3 µm, are not consistent with the dental-enamel-absorption coefficients determined using direct-transmission measurements (1168 and 819 cm⁻¹ for 10.3 and 10.6 µm, respectively). Moreover, those values are also not consistent with observed surface-modification thresholds based on the known melting range of dental enamel (800 to 1200° C). More recent measurements employing time-resolved radiometry measurements coupled with numerical simulations of thermal relaxation in the tissue²¹ are a factor of five to six times lower. Those values are shown in Figures 50.2 and 50.3 for enamel and dentin along with the absorption depth, reflectance, and corresponding thermal relaxation times computed from the absorption depth and thermal property data shown in Table 50.1. These latter values are consistent with time-resolved temperature measurements during laser irradiation and surface-melting thresholds.²⁶

TABLE 50.1 Thermal and Mechanical Properties of Dental Hard Tissues

Tissue Property	Enamel	Dentin
Density (g/cm³)	2.8	2.0
Specific heat (J/g °C)	0.71	1.59
Thermal conductivity (W/cm °C)	0.0093	0.0057
Coeff. linear expansion (µm/°C)	27	
Melting point (°C)	1280	
Compressive strength (MPa)	250-550	300-380
Tensile strength (MPa)	10-70	50–60

Data compiled from References 23 through 25.

50.1.3 Infrared Reflectance of Dental Hard Tissue

At CO2 wavelengths, the reflection losses during enamel irradiation are substantial and reduce the laser energy absorbed by the target surface; losses are minimal near 3.0 μm. The fraction of incident laser light reflected at the surface of the tooth is described by the Fresnel reflection formula, $R = [(n_r - 1)^2 + k^2]/(n_r + k^2)$ $[(n_r + 1)^2 + k^2]$, where (n_r) is the real component of the refractive index and (k) is the attenuation index. The absorption coefficient, (μ_{α}) , (k), and the wavelength (λ) are related by the expression $\mu_{\alpha} = 4\pi k/\lambda$. Thus, the reflectance of materials can increase markedly and approach 100% in regions of strong absorption, e.g., some metals have absorption coefficients >106 cm⁻¹ and reflectance > 99% in the visible and infrared. The reflectance of dentin and enamel was measured at the $\lambda = 2.79, 2.94, 10.6, 10.3, 9.6,$ and 9.3 µm wavelengths (see Figures 50.3 and 50.4). 20,27,28 The reflectance of enamel is substantially higher at $\lambda = 9.6$ and 9.3 µm than at $\lambda = 10.6$ µm, near 50%, and must be accounted for when calculating ablation efficiencies, ablation thresholds, and heat deposition in the tooth. Transient and permanent changes in the reflectance of enamel and dentin were observed during and after laser irradiation.²⁷ These changes resulted in increased energy coupling during irradiation at $\lambda = 9.3$ and 9.6 µm for fluences that raised the enamel surface temperature several hundred degrees. The reflectance of dentin at $\lambda = 9.6 \mu m$ permanently increased by as much as 30% as a result of laser irradiation. This change can be attributed to an increase in the mineral density and loss of organics.²⁷

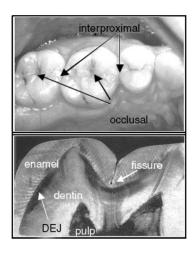

FIGURE 50.4 Top: The primary (high-risk) sites for dental decay are in the pits and fissures of the posterior teeth and the approximal contact sites between teeth. Bottom: A typical fissure with a diameter of 200 μm in a tooth cross section.

50.2 Optical Caries Diagnostics

During the past century the nature of dental decay or dental caries in the United States has changed markedly due to the introduction of fluoride to the drinking water, the advent of fluoride dentifrices and rinses, and improved dental hygiene. In spite of these advances, dental decay continues to be the leading cause of tooth loss in the U.S.^{29–31} By age 17, 80% of children have experienced at least one cavity.³² In addition, two thirds of adults age 35 to 44 have lost at least one permanent tooth to caries. Older adults suffer tooth loss due to the problem of root caries. The nature of the caries problem has changed dramatically, with the majority of newly discovered caries lesions being highly localized to the occlusal pits and fissures of the posterior dentition and the interproximal contact sites between teeth (Figure 50.4). These early carious lesions are often obscured or "hidden" in the complex and convoluted topography of the pits and fissures or are concealed by debris that frequently accumulates in those regions of the posterior teeth. Moreover, such lesions are difficult to detect in the early stages of development. By definition, early caries lesions are those lesions confined to the enamel or incident on the dentinal—enamel junction (DEJ).

In the caries process, demineralization occurs as organic acids generated by bacterial plaque diffuse through the porous enamel of the tooth, dissolving the mineral. If the decay process is not arrested, the demineralization spreads through the enamel and reaches the dentin where it rapidly accelerates due to the markedly higher solubility and permeability of dentin. The lesion spreads throughout the underlying dentin to encompass a large area, resulting in loss of integrity of the tissue and cavitation. Caries lesions are usually not detected until after the lesions have progressed to the point at which surgical intervention and restoration are necessary, often resulting in the loss of healthy tissue structure and weakening of the tooth. Carious lesions also occur adjacent to existing restorations, and diagnostic tools are needed to diagnose the severity of those lesions and determine if an existing restoration needs to be replaced. The diagnostic and treatment paradigms that were developed in the past such as radiography are adequate for large, cavitated lesions; however, they do not have sufficient sensitivity or specificity for the diagnosis of early noncavitating caries, root surface caries, or secondary caries.

New diagnostic tools are needed for the detection and characterization of caries lesions in the early stages of development. In a recent consensus statement released by the NIH entitled The Diagnosis and Management of Dental Caries throughout Life, the development of new devices and techniques for caries diagnosis was identified as one of five major areas in which additional research was needed.³² Caries lesions are routinely detected in the United States using visual/tactile (explorer) methods coupled with radiography. Unfortunately, these methods have numerous shortcomings and are inadequate for the detection of the early stages of the caries process.^{33–35} Radiographic methods do not have the sensitivity for early lesions, particularly occlusal lesions, and by the time the lesions are radiolucent they have often progressed well into the dentin, at which point surgical intervention is necessary.^{35–37} At that stage in the decay process, it is far too late for preventive and conservative intervention, and a large portion of carious and healthy tissue must be removed, which often compromises the mechanical integrity of the tooth. If left untreated, the decay will eventually infect the pulp, leading to loss of tooth vitality and possibly extraction. The caries process is potentially preventable and curable. If carious lesions are detected early enough, it is likely that they can be arrested/reversed by nonsurgical means through fluoride therapy, antibacterial therapy, dietary changes, or by low-intensity laser irradiation.^{32,38} Therefore, one cannot overstate the importance of detecting decay in the early stage of development at which point noninvasive preventive measures can be taken to halt further decay.

In a recent review of conventional methods of caries diagnosis, ten Cata³⁷ indicated that visual and tactile caries diagnosis was far from ideal and that visual diagnosis of occlusal caries typically has a very low sensitivity. Sensitivities scatter around a value of 0.3, implying that only 20 to 48% of the caries present (usually into the dentin) are found.^{37,39,40} The specificity typically exceeds 0.95. The poor sensitivity can be attributed to the "hidden" nature of the majority of occlusal lesions. The area of the lesion accessible for visual and tactile inspection is typically confined to the upper region of the fissure. The bulk of the lesion is not accessible and is most often not detected unless it is so extensive that it is resolvable radiographically.

50.2.1 Optical Transillumination (Interproximal Lesions)

Interproximal areas between teeth are generally inaccessible for visual inspection. Bite-wing radiographs are the standard method of diagnosis. Unfortunately, as much as 25% of the interproximal areas of bite-wing x-rays is unresolved due to the overlap with healthy tooth structure on adjoining teeth. ^{41,42} Values for sensitivity (0.38 and 0.59) and specificity (0.99 and 0.96) are reported for visual and radiological diagnosis, respectively. ⁴³

Optical transillumination was used extensively before the discovery of x-rays for detection of dental caries. Recently there has been renewed interest in this method with the availability of high-intensity fiber-optic-based illumination systems for the detection of interproximal lesions. 41,44–47 During fiber-optic transillumination (FOTI) a carious lesion appears dark upon transillumination because of decreased transmission due to increased scattering and absorption by the lesion. A digital fiber-optic transillumination system, called DIFOTI, which uses visible light for the detection of caries lesions, has been developed by Electro-Optics Sciences (Irvington, NY)⁴⁸ and recently received U.S. Food and Drug Administration (FDA) approval.

50.2.2 Fluorescence (DIAGNOdent™ and QLF)

Teeth naturally fluoresce upon irradiation with ultraviolet (UV) and visible light. Alfano et al.^{49,50} and Bjelkhagen and Sundstrom⁵¹ demonstrated that laser induced-fluorescence (LIF) of endogenous fluorophores in human teeth could be used as a basis for discrimination between carious and noncarious tissue. Upon illumination with near-UV and visible light and imaging of the emitted fluorescence in the range of 600 to 700 nm, carious/demineralized areas appear dark. The origin of the endogenous fluorescence in teeth in this particular wavelength range has not been established.

Hafstroem-Bjorkman et al. 52 established an experimental relationship between the loss of fluorescence intensity and extent of enamel demineralization. The method was subsequently labeled the QLF method, for quantitative laser fluorescence. An empirical relationship between overall lesion demineralization (ΔZ) vs. loss of fluorescence was established that can be used to monitor lesion progression on smooth surfaces. $^{53-55}$ Recent measurements suggest that QLF may be useful for determination of the degree of hydration of the lesion that, in turn, may be indicative of the lesion activity. 56 Unfortunately, it is difficult to apply QLF to occlusal and interproximal lesions, which constitute the majority of carious lesions. Furthermore, the fluorescence method cannot be used to provide information about the subsurface characteristics of the lesion.

Bacteria produce significant amounts of porphyrins, and dental plaque fluoresces upon excitation with red light.⁵⁷ A novel caries detection system, the DIAGNOdent™ (KaVo, Biberach, Germany), was recently developed and received FDA approval in the U.S. This device uses a diode laser and a fiber-optic probe designed to detect the NIR fluorescence from porphyrins.⁵⁸ This low-cost diagnostic tool is a major step toward better caries detection in occlusal surfaces, greatly aiding in the detection of "hidden" occlusal lesions, i.e., lesions that have progressed into the dentin and are too small to show up on a radiograph.⁵⁹ It is important to note that the DIAGNOdent has poor sensitivity (~0.4) for early lesions confined to enamel, and it cannot provide information about the lesion depth and the degree of severity.^{60,61}

50.2.3 Optical Coherence Tomography for Caries Imaging

Optical coherence tomography (OCT) is a sensitive method for resolving changes in light scattering in early caries lesions. The first OCT images of soft- and hard-tissue structures of the oral cavity were acquired by Colston et al.⁶²⁻⁶⁴ Baumgartner et al.^{65,66} presented the first polarization-resolved images or polarization sensitive-OCT images (PS-OCT) of dental caries; however, the penetration depth was limited and the image quality was poor due to limited source power. Feldchtein et al.⁶⁷ presented high-resolution dual-wavelength 830- and 1280-nm images of dental hard tissues, enamel and dentin caries, and restorations *in vivo*. Wang et al.⁶⁸ measured the birefringence in dentin and enamel and suggested

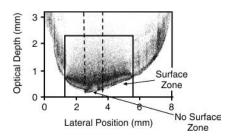

FIGURE 50.5 Fast-axis PS-OCT scan (orthogonal polarization state) of an obvious smooth-surface interproximal lesion (white spot lesion).^{71,72} The scan was taken perpendicular to the long axis of the tooth from the facial to lingual surface. The dark areas on the tooth surface indicate the position of the lesion. The lesion, which is enclosed in the box, appears more active between the dotted lines and lacks a surface zone of reduced scattering. The surface of the lesion contains a thin surface zone of reduced scattering outside of the dotted lines that may indicate remineralization. (From Fried, D. et al., *J. Biomed. Opt.*, 7(4), 618, 2002. With permission.)

that the enamel rods act as waveguides. The following year, Everett et al.⁶⁹ presented polarization-resolved images using a high-power 1310-nm broadband source and a bulk optic PS-OCT system. In those images, changes in the mineral density of tooth enamel were resolvable to depths of 2 to 3 mm into the tooth. An important advantage of PS-OCT is that the structure of the carious lesions can be resolved in fine detail. Figure 50.5 shows a fast-axis or S-axis scan — detected polarization orthogonal or perpendicular to incident linear polarization — of an early interproximal lesion. Areas of reduced scattering near the surface may be indicative of remineralization, and those regions of the lesion may be inactive. In the area between the dotted lines, the scattering near the surface of the lesion is very strong. This may be indicative of an active area of the lesion that is progressing. Being able to access the activity of the lesion, i.e., whether it is active and needs intervention or if it has been arrested and can be left alone, is extremely important to the clinician, and no currently available diagnostic technology is capable of such a diagnosis.

According to Kidd,⁷⁰ 75% of operative dentistry involves the replacement of existing restorations, and secondary caries is the most common reason given for replacing both amalgam and composite fillings. PS-OCT is well suited for the detection of secondary caries because restorative materials have markedly different scattering properties compared to dental hard tissues. Colston et al.⁶⁴ and Feldchtein et al.⁶⁷ have shown that OCT can be used to differentiate between restorative materials and enamel and detect decay around the periphery of a restoration. Recent studies have demonstrated that composite can be distinguished from dentin and enamel using PS-OCT and that the degree of demineralization underneath composite restorations can be quantified.^{71,72}

Root caries are an increasing problem among our aging population and are the principal cause of tooth loss after the age of 44. The scattering coefficient of dentin is much higher than enamel; therefore, the penetration depth is more limited than for enamel. However, early root caries are localized on the surface of the dentin and cementum. It is difficult to obtain intact thin sections through natural root caries lesions without damaging the fragile, poorly mineralized regions of the lesion. High-resolution xray tomography (XTM) can be used to acquire tomograms of tooth mineral density with a resolution of 9 µm.^{73,74} Figure 50.6 shows XTM and PS-OCT scans taken from the crown to the root across a small root caries lesion located just below the cementum-enamel junction on a human tooth. The principal advantage of XTM is that tissue slices representing the mineral density vs. position can be extracted from the x-ray tomogram with any desired orientation to match the OCT scan geometry. The XTM image of the area scanned by the PS-OCT system is shown on the right side of Figure 50.6. Taking into account that the high refractive indices of dentin and enamel result in compression of those areas of the image, the agreement between the two imaging modalities is excellent. The entire lesion morphology is reproduced in the fast-axis OCT image, with the characteristic lesion semicircle shape clearly visible. The fastaxis image provides the best match because the confounding influence of the surface reflection and residual coherence are markedly reduced.

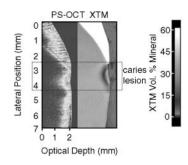

FIGURE 50.6 (Color figure follows p. 28-30.) Comparison of the PS-OCT fast-axis image (orthogonal polarization state) with the corresponding x-ray tomogram (XTM) of the mineral density taken from the same region of the tooth (right).^{71,72} A small root caries lesion is present just below the cementum–enamel junction shown in the box. The intensity of the OCT images ranges from 12 dB to –45 dB; areas with regions of intensity greater than –5dB are shown in red, and those areas of less than –35 dB are shown in blue. In the XTM image on the right, normal dentin is yellow, enamel is white, the water outside the tooth is indicated in red, and the demineralized area of the lesion is blue (color bar on right). (From Fried, D. et al., *J. Biomed. Opt.*, 7(4), 618, 2002. With permission.)

50.3 Therapeutic Applications on Dental Hard Tissues

Since the initial investigations of Stern and Sognnaes⁷⁵ more than 30 years ago several unique laser dental applications have evolved for restorative dentistry, i.e., laser ablation of dental hard tissue,⁷⁶ caries-inhibition treatments by localized surface heating,⁷⁷ and surface conditioning for bonding.⁷⁶ For several years medical lasers have been approved by the FDA for soft-tissue vaporization, and even though hard tissue applications have been investigated for over 30 years, only recently have the first lasers been approved for hard-tissue use in the United States. The first lasers to receive approval were the CenturiTM Er:YAG and the MillenniumTM Er:YSGG introduced by Premier Laser (Irvine, CA) and Biolase Technology (San Clemente, CA), respectively.

50.3.1 New Preventive and Conservative Approaches to Restorative Dentistry

Several developments in dentistry are driving the shift to new more conservative approaches to restorative dentistry than the classical G.V. Black approach that has been the standard for cavity preparation since the 19th century. These include the development of new more effective adhesive restorative materials, a more thorough understanding of the caries process, the now recognized role of fluoride as a remineralizing agent, new and more sensitive methods of caries detection, and the public's demand for more aesthetic restorations. Over the past 50 years, the nature of dental caries has changed, with the majority of new lesions, 90%, occurring in the pits and fissures (occlusal surfaces) of posterior teeth (see Figure 50.4).^{78,79}

New caries diagnostic procedures such as those described above are becoming available that enable the dentist to identify early caries lesions before they have spread extensively into the underlying dentin. For lesions of this magnitude, it is too early to use conventional restorations that require the removal of large amounts of healthy tissue. As part of the more conservative approach to restorative dentistry, some experts have revised the G.V. Black cavity-classification scheme to emphasize the importance of early pit and fissure sites. This new conservative approach emphasizes micropreparation with minimal removal of healthy tissue. The laser is ideally suited for this approach for the following reasons.

- 1. Laser pulses can preferentially ablate carious tissue due to the higher volatility of water and protein that are present in carious tissue at a higher ratio than in normal tissue.
- 2. They can be tightly focused to drill holes with very high aspect ratios (depth/height) well beyond those obtainable by the dental drill, which is limited by the size of the dental burr (>1 mm). Conservation of enamel structure is paramount for preservation of the natural dentition for retention of sealants and to limit exposure to wear.

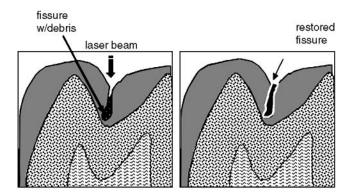

FIGURE 50.7 Cross section of a typical molar tooth with fissures. (Left) Typical fissures are about 200 μ m across and more than a millimeter in depth and may be filled with debris and bacterial plaque. Lasers are ideally suited for removing the debris and ablating the decayed (carious) tissue with minimal removal of healthy enamel. (Right) Afterwards, removal sealants can be applied directly to fill, and if a CO₂ laser is used for the preparation, the walls will have an enhanced resistance to further decay (thick white solid line).

- 3. The laser can be used to open up the neck of the fissures sufficiently to allow the entrance of flowable composite to the base of the fissure.
- 4. Laser irradiation does not produce a smear layer that must be removed; hence restorative materials can be applied directly to the ablated area without the necessity of further surface preparation and etching.⁸¹ This advantage is of great importance because fissure areas are difficult to etch by conventional means due to the unique enamel morphology. The enamel on the shoulder at the entry to the fissure is often prismless and irregular and may not accept a good etch pattern, so attachment of the resin may be tenuous. Therefore, laser preparation may be superior to the conventional acid etch in pits and fissures.
- 5. Laser radiation vaporizes water and protein and changes the chemical composition of the remaining mineral of enamel and dentin, thereby decreasing the solubility to acids around the periphery of the restoration site to leave a smooth surface with an enhanced resistance to secondary caries.^{77,82–84}
- 6. Lasers are less likely to require anesthesia and induce less noise and pain. 85–88 Therefore, they are advantageous for treating children and patients with dental phobias.

Thus, lasers are ideally suited for minimally invasive surgical intervention and have the potential for markedly reducing or eliminating the loss of adjacent healthy tissue during the removal of carious tissue from early lesions or the removal of existing composite restorations.

Figure 50.7 illustrates the principle of minimal intervention with lasers.⁸⁹ The laser can be precisely focused into the carious fissure of a molar to remove any debris and bacteria, ablate away the carious tissue, and enlarge the narrow neck of the fissure, leaving a smooth crater. If the appropriate irradiation conditions are met, the walls will have enhanced resistance to acid dissolution.^{83,84} A flowable composite can subsequently be applied for a highly conservative restoration. By taking this approach the dentist can intervene in a conservative manner before the lesion has progressed to the point that conventional surgical intervention is necessary.

50.3.2 Infrared Laser Ablation of Enamel

Enamel is a biological composite containing 12% by volume water, 85% mineral (carbonated hydroxyapatite [CAP]), and 3% protein and lipid. The mineral component is crystalline in nature comprising hexagonal crystallites approximately 40 nm in diameter, which are aligned in enamel rods roughly 5 µm in diameter that run in an S-shaped pattern from the enamel surface to the DEJ. A sheath of protein and water surrounds each rod. Approximately half of the water is bound tightly to the enamel as caged waters

of hydration, and the other half is more loosely bound and located between the individual enamel crystals and the rods. The mechanism of interaction of laser light with dental enamel is inherently complex and varies markedly with the laser irradiation wavelength and the nature of the primary absorber in the tissue, water, protein, or mineral. The principal factor limiting the ablation rate of dental hard tissue is the risk of excessive heat deposition in the tooth that may lead to eventual loss of pulpal vitality. The accumulation of heat in the tooth can be minimized through use of a laser wavelength tuned to the maximum absorption coefficient of the tissue irradiated and by judicious selection of the laser-pulse duration to be commensurate with the thermal relaxation time of the deposited energy

Several erbium-laser wavelengths have been investigated for the ablation of dental enamel, i.e., the Er:YAG, 2.94 μ m, Er:YLF, 2.81, Er:YSGG, 2.79 μ m, Er:YAP, 2.73 μ m, and CTE:YAG, 2.69 μ m. $^{91-95}$ Those wavelengths give access to the water-absorption band from 2.6 to 3.0 μ m. These lasers can be operated in either free-running mode, in which the pulse duration can be varied from tens of microseconds to almost a millisecond, or Q-switched mode, in which the pulse duration can vary from tens to hundreds of nanoseconds. Altshuler et al. 92 determined that the ablation threshold in free-running mode increased in the following order: Er:YSGG, Er:YLF, Er:YAP, and Er:YAG. The CTE:YAG ablation threshold is considerably higher than the other erbium systems because absorption in water is weaker, although the λ =2.69 μ m laser wavelength is still of significant interest because it is readily transmitted through robust, inexpensive low-OH fibers. 96,97 Three studies have investigated variation of the pulse duration during the ablation of enamel. Majaron et al. 98 observed a decrease in the ablation efficiency upon stretching the laser pulse from 200 to 1000 μ s. Zeck at al. 99 observed a twofold increase in the ablation efficiency of enamel upon reducing 400- μ s Er:YAG laser pulses to 30 μ s and a fourfold reduction in the ablation threshold. An even greater reduction in the ablation threshold was observed for Q-switched 200-ns laser pulses, particularly for Er:YSGG laser pulses used in conjunction with water.

 CO_2 lasers are the most common lasers found in clinics today and have been used for soft-tissue surgical procedures for three decades. The CO_2 laser can be designed to operate or "lase" at discrete wavelengths between $\lambda=9$ to 11 μ m. Those wavelengths correspond to specific rotational–vibrational transitions in the ground state of gas-phase CO_2 molecules. Early results with the CO_2 laser were discouraging because these studies used continuous-wave (CW) lasers operating at $\lambda=10.6~\mu m$, $^{101-111}$ and extensive thermal damage was observed. Recent studies using CO_2 -laser pulses of submillisecond duration indicate that enamel can be ablated efficiently without generating peripheral damage. $^{112-114}$ Even though the pulsed CO_2 lasers are a significant improvement over the previous CW systems, the laser parameters are still not well matched to the peak absorption of dental enamel.

Presently, 9.6- μ m pulsed CO₂ lasers are under development for use in dentistry. One system, manufactured by Argus Photonics Group (APG) (Jupiter, FL), uses transverse excited atmospheric pressure (TEA) technology and uses a pulse duration of 5 to 20 μ s. ^{115,116} Another system from ESC Medical Systems (Yokneam, Israel) uses radio-frequency (RF) technology and a pulse duration of 70 μ s. ¹¹⁷ The ESC laser has recently been tested on humans in a limited safety study, and there were no apparent adverse changes to the pulp of the laser-treated teeth. ¹¹⁷

The laser ablation of dental hard tissue is a water-mediated explosive process at 2.94 and 2.79 μ m⁹³ caused by preferential absorption by water that is localized between the rods of enamel or is intrinsic to the protein/mineral matrix of dentin. During rapid heating the inertially confined water can create enormous subsurface pressures that can lead to the explosive removal of the surrounding mineral matrix. Studies of hard-tissue ablation in the $\lambda = 3\mu$ m region indicate that large intact particles are ejected at high velocity from the irradiated tissue. Moreover, the normal highly ordered structure of dentin and enamel is conserved during the ablation process (see Figure 50.8). In contrast, the mechanism of ablation of dental hard tissue at the highly absorbed CO₂ wavelengths of 9.3 and 9.6 μ m is apparently mineral-mediated, and SEM micrographs show that the tissue morphology is markedly changed after irradiation step Figure 50.8). Surface temperatures at the ablation threshold for enamel indicate that the mechanism of ablation is thermal and occurs at approximately 300 to 400°C for Er:YAG, 800°C for Er:YSGG, and 1200°C for CO₂ lasers. Hough it is advantageous to ablate enamel at lower surface temperatures to avoid heat deposition, it may also be useful to heat the tissue peripheral to the ablation

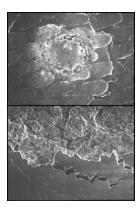

FIGURE 50.8 Top: SEM image (5000×) of an enamel surface irradiated by a pulsed 9.3- μ m CO₂ laser near the surface-modification threshold.²⁸ The enamel prisms are beginning to fuse together as a result of melting of the mineral phase. Bottom: SEM image (2000×) of an enamel surface irradiated by a pulsed 2.94- μ m Er:YAG laser just above surface modification threshold. Intact enamel prisms are ejected without melting of the surface.

site to temperatures exceeding 400°C. This creates a zone of increased acid resistance around the restoration site, which may occur to a greater degree after Er:YSGG and CO₂ laser irradiation¹²⁰ than with Er:YAG laser irradiation.

50.3.3 Safety Issues

Heat may accumulate in the tooth to dangerous levels during multiple pulse-laser irradiation. Hence, it is necessary to measure accumulation of heat in the tooth during ablation. The 1965 study by Zach and Cohen on the effect of heat on the pulp of Rhesus monkeys indicated that a temperature rise of 5.5°C in the pulp caused irreversible pulpitis in 15% of the pulps.¹²¹ This 5.5°C temperature rise is typically used as a temperature threshold that should not be exceeded. Higher temperatures may cause thermal damage to the pulp. The accumulation of heat after use of the dental drill for cavity preparations¹²² and for the finishing of restorative materials¹²³ can raise the pulpal temperatures to dangerous levels if air/ water cooling is not used. Similarly, the use of multiple pulse irradiation without air/water cooling may also result in the accumulation of heat to levels dangerous to the pulp. Subsurface thermocouple measurements, simulations of heat conduction, and histological examinations during laser irradiation show that the extent of pulpal heating is determined by the rate of deposition of the laser energy in the tooth, the distance from the laser spot to the pulp, and the rate of energy loss from the tooth. 103,105-107,124-127 Miserendino et al.¹²⁸ observed that typically the temperature excursions in the pulpal wall occurred 10 to 20 sec after irradiation of the surface of the tooth. Applying air/water cooling for 5 sec after the 5-sec CW ($\lambda = 10.6 \,\mu m$) CO₂ laser exposures of 10 to 50 J (2 to 10 W and 1-mm spot size) reduced the otherwise excessive temperature rise in the pulp chamber¹²⁸ to a safe level.

Strong acoustic waves can be generated during ablation. $^{129-132}$ These pressure waves can propagate through the tissue, radiating outward from the site of absorption. Transient stress waves may cause mechanical damage to the surface enamel or dentin surrounding the ablation site, generate cracks, and increase porosity. Generally, biological tissue has a relatively high compressive strength; however; the tensile strength is much weaker, and the tensile forces can cavitate soft tissue and generate cracks in hard tissue. A unipolar compressive stress incident on the interface with another tissue of lower density becomes a bipolar stress wave. The compressive stress wave propagates through the next medium, and a tensile wave or rarefaction wave is reflected back from the interface. It is the reflected tensile-stress wave that has the greatest potential for causing tissue damage. The additional contribution of the explosive release of inertially confined water and CO_2 during laser heating and the subsequent ablative recoil may also generate large acoustic transients. The magnitude of the stresses generated in enamel and dentin

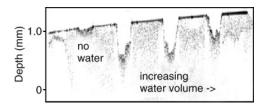

FIGURE 50.9 Optical cross sections taken with OCT of incisions produced in enamel at a fluence of 100 J/cm² with a free-running Er:YAG laser with the same number of laser pulses. The depth of the incision varies markedly with the thickness of the applied water layer. The depth of the crater is a minimum with no water and peaks for a critical water thickness and decreases with greater thickness of the water layer.

during CO_2 laser irradiation have not been measured, and the effect of varying the pulse duration, fluence, and absorption depth have not been evaluated.

50.3.4 Water Augmentation of Ablation

One of the most important and somewhat controversial aspects of hard-tissue ablation is the critical role of water in the ablation process. Initial studies of the role of water focused on preventing tissue dehydration.^{133–136} Absorption and diffusion studies in enamel indicate that approximately half of the water in enamel is actually diffusible.⁹⁰ Thermal-analysis studies indicate that the tissue must be heated to greater than 200 to 300°C before most of that mobile water is removed.²⁴ However, the rate for water diffusion is quite slow, on the order of several hours to days; therefore, it is unlikely that sample rehydration has a significant effect during laser irradiation. Several studies have shown that the ablation rate of erbium lasers can be increased by applying a water spray or a layer of water to the surface.^{137–139} This phenomena can be seen in Figure 50.9, which shows "optical" cross sections of incisions in enamel produced with a free-running Er:YAG laser with varying volume of water added to the ablation site prior to irradiation.

Several interesting mechanisms have been proposed to explain this phenomenon. One hypothesis is that cavitation bubbles are formed in the water that cut the sound enamel due to the large tensile stresses generated by the collapse of the bubble.¹³⁷ Another proposed mechanism suggests that water droplets are rapidly accelerated into the enamel by absorption of the laser beam.^{138,140} Other studies suggest that solid particles of ablated material are accelerated against the walls of the crater, resulting in a polishing effect that removes debris and any protruding sharp edges.^{141,142}

During high-intensity laser irradiation, marked chemical and physical changes may be induced in the irradiated dental enamel. These changes can have profound effects on the laser ablation/drilling process and may lead to a reduction in the ablation rate and efficiency, increase peripheral thermal damage, and even lead to stalling without further removal of tissue with subsequent laser pulses. Furthermore, thermal decomposition of the mineral can lead to changes in the susceptibility of the modified mineral to organic acids in the oral environment. Morphological changes may result in the formation of loosely attached layers of modified enamel that can delaminate, leading to failure during bonding to restorative materials. 143,144 Therefore, it is important to thoroughly characterize the laser (thermal)-induced chemical and crystalline changes after laser irradiation. The mineral CAP, found in bone and teeth, contains carbonate inclusions that render it highly susceptible to acid dissolution by organic acids generated from bacteria in dental plaque. Upon heating to temperatures in excess of 400°C, the mineral decomposes to form a new mineral phase that has increased resistance to acid dissolution.⁷⁷ Recent studies suggest that as a side effect of laser ablation the walls around the periphery of a cavity preparation will be transformed through laser heating into a more acid-resistant phase with an enhanced resistance to future decay.^{83,84,145} However, poorly crystalline nonapatite phases of calcium phosphate may have an opposite effect on plaque acid resistance146 and may increase the quantity of poorly attached grains associated with delamination failures.

Zeck et al.⁹⁹ and Rechmann et al.¹⁴⁴ observed that a loosely attached layer of fused enamel was formed during Er:YAG laser ablation if a water spray was not used. Zeck labeled this fused enamel "recrystallites."

Some of the likely sources of these phases are recondensation of vaporized enamel, spallated droplets of ejected melted enamel, and repeated melting and recrystallization of the enamel. ¹⁴⁷ Poorly crystalline-fused enamel particles and any surface protrusions or asperities in the ablation crater are likely to inhibit efficient ablation for subsequent laser pulses, leading to stalling and excessive heat accumulation. Forces imparted to the enamel surface by recoiling water particles are not of a sufficient magnitude to ablate the normal intact enamel; however, they may have sufficient strength to cleanse the surface of the crater of these poorly crystalline, loosely adherent mineral phases after the preceding laser pulses. The same recoil forces produce cavitation of the water layer ^{148–150} and energetically propel the remaining water on the surface several centimeters from the tooth.

50.3.5 Laser Ablation of Dentin and Bone

Dentin is composed of an interwoven network of water, small mineral crystals a few nanometers across, and collagen fibers. Intertubular dentin is approximately 47% by volume mineral (CAP), 33% protein (mostly collagen), and 20% water. Bone has a lower volume fraction of mineral and is less dense than dentin. Dentin contains long tubules that are 1 to 3 μ m in diameter surrounded by a collar of mineral (peritubular dentin). These tubules extend from the DEJ to the pulp. This uniform orientation of the tubules in dentin facilitates visualization of thermal damage using polarized-light microscopy. In contrast, thermal damage in bone is more difficult to visualize using polarized light due to the lack of uniform orientation of the concentric lamellae. The collagen in dentin and bone is susceptible to thermal denaturation and carbonization (charring). Carbonization and thermal denaturation of dentin may adversely affect the bonding of cements and composite restorative materials and inhibit healing. This is of particular importance for the treatment of root caries, which is an increasingly important problem for our aging population. There have been several studies of bonding restorative materials to laser-treated enamel and dentin. $^{81,151-154}$

Although the emphasis of this chapter is on caries ablation, the optical properties of bone are similar to dentin, and the laser conditions suitable for the ablation of dentin apply equally to bone. Several procedures in oral medicine require the removal and contouring of bone. Thermal damage to bone during laser cutting results in delayed healing time and bone defects. ^{155,156} Conventional technology often results in mechanical trauma, excessive thermal damage, and hemorrhage. ^{157,158} Specific areas of application include trepanation for implant placement, precise incisions for distraction osteogenesis for facial reconstruction and correction of craniofacial anomalies, and bone removal and recontouring for periodontology and oral surgery.

Free-running Er:YAG lasers can be used to ablate tissue fairly efficiently in conjunction with a water spray without significant charring of surrounding tissue. ^{135,159} Absorption in dentin and bone at erbiumlaser wavelengths is markedly higher than in enamel because of the higher water content. Absorption is confined to a depth of 4 to 5 μ m with a thermal relaxation time of 20 to 30 μ s. However, the absorption coefficient of water at 2.94 μ m drops by almost an order of magnitude upon heating from room temperature to the critical point at 374°C. ^{160,161,162} Thus, it is reasonable to assume that absorption occurs to depths greater than 5 μ m during laser irradiation; however, that must be confirmed experimentally.

Early studies using CW CO_2 lasers operated at 10.6 µm reported extensive cracking and charring of surrounding dentin and bone. ^{155,156,163–165} These disappointing initial observations caused many laser researchers to overlook the potential of CO_2 laser–based systems for hard-tissue ablation. Pulsed CO_2 lasers, however, are well suited for use on dental hard tissue due to strong absorption of water, protein, and mineral between 9 and 11 µm. Several researchers ^{112,166–170} have demonstrated that pulsed CO_2 lasers with a pulse duration of less than 20 µs can be used to avoid carbonization of the biopolymer matrix of dentin with the simultaneous application of water cooling. Figure 50.10 shows an incision in dentin with a short-pulsed 9.6-µm CO_2 laser. No charring is visible, and the peripheral thermal damage is less than 10 µm. Mineral absorption peaks at 9.6 µm, where the absorption coefficient of dentin is approximately 8000 cm⁻¹. This high absorption coefficient indicates that the incident laser light will be absorbed at a depth of under 2 to 3 µm, with a corresponding thermal relaxation time on the order of 5 µs. Ivanenko

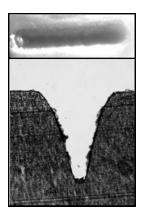

FIGURE 50.10 Top: Incision in dentin produced with a 9.6- μ m CO₂ laser with a pulse duration of 8 μ s. No char, cracks, or discoloration is visible. Bottom: A cross section viewed under polarized light indicates that the zone of thermal damage is less than 10 μ m. (From Lee, C., Ragadio, J., and Fried, D., in *Lasers in Dentistry VI*, SPIE, Vol. 3910, 2000, pp. 193–203. With permission.)

and Hering¹⁷¹ demonstrated that a mechanically Q-switched 10.6- μ m CO₂ industrial laser could be used to cut bone rapidly at 300 Hz without thermal damage; thus, rapid processing is feasible.

50.3.6 Alternative Mechanisms and Wavelengths for Hard-Tissue Ablation

The optical properties of dental hard tissues from $\lambda=0.4$ to 2.7 μ m are characterized by weak absorption and strong scattering and are not well suited for efficient ablation, which requires localization of the energy deposition to the surface of the tissue. Nevertheless, there has been some successful use of lasers emitting within this frequency range for ablation, and they warrant discussion. The absorption of laser light can be increased by adding exogenous chromophores to the surface. However, even with the added chromophore, typical ablation thresholds are still high (200 J/cm²) and ablation efficiencies low (0.03 mm³/J). There have been some successes in the removal of dentin using the fiber-coupled neodymium: YAG (Nd:YAG) laser in the contact mode. However, this laser wavelength cannot be used to remove sound enamel. Niemz¹¹9 has used picosecond laser pulses to ablate carious and noncarious enamel. The short, highly focused laser pulses generate irradiation in excess of 10¹0 W per square centimeter, and the strong electric fields ionize the tissue, forming a plasma. Plasma-mediated ablation has several advantages: it produces very clean highly machined craters with minimal peripheral thermal damage, and suitable visible and NIR lasers are available with high spatial beam quality and short pulse durations. Such laser systems, however, are expensive, sophisticated, and yield rather low ablation rates. He

UV radiation is highly absorbed by collagen and is efficiently absorbed by dentin. $^{10,183-187}$ Hennig et al. 188,189 and Rechmann et al. 190 used the frequency-doubled alexandrite laser (377 nm) to selectively ablate carious dentin. They found at least a fourfold increase in the ablation rate of carious dentin over healthy dentin. There is strong absorption and minimal penetration at $\lambda = 193$ and 248 nm; 184,191 however, the ablation efficiency is very low — 0.001 mm³/J and 0.002 mm³/J for enamel and dentin, respectively. 183,192

50.3.7 Selective Removal of Composite-Secondary Caries

Dental composites are used as adhesives and restorative materials for various dental procedures. They are composed of acrylic resins combined with quartz, zirconia silica, and fused silica filler materials. The most common application of composites is for restorative procedures, i.e., fillings. Composites are color-matched to the tooth, making it difficult for the dentist to differentiate between the enamel and the restorative material. Most restorations will eventually fail and need to be replaced. All of the existing composite from a restoration must be removed to assure proper bonding of the new composite to the

tooth structure because new composite does not bond well to residual composite. It is difficult for the clinician to differentiate between the composite of the restoration and the surrounding tooth structure, particularly near the base of the restoration. Hence the dentist frequently removes excessive amounts of healthy tooth structure to ensure complete removal of the composite. The applicability of lasers for the removal of dental composite and bone cement has been investigated for several laser systems including the free-running Er:YAG, 193,194 Nd:YAG, 195,196 XeCl (308 nm), 197 and millisecond-pulsed CO₂ lasers, 198 all of which can be used to remove composites, as indicated in the articles listed above; however; they lack selectivity, have undesirable ablation rates, or produce excessive thermal damage. Recently, greater selectivity has been demonstrated using the transverse excited atmospheric pressure (TEA) CO₂ laser operating at 10.6 µm¹⁹⁹ and the frequency-tripled Nd:YAG laser operating at 355 nm.²⁰⁰ In those studies, a TEA CO₂ laser with laser pulses of approximately 1-µs duration was used to ablate composite at a rate almost an order of magnitude higher than for enamel. Spectral analysis of the emission plume created by ablating composite and enamel identified a number of spectral lines that could be used to distinguish between the ablation of enamel and composite. However, there was measurable damage to the underlying enamel due to the similar ablation thresholds. Laser pulses of the third harmonic of the Q-switched Nd:YAG (355 nm) can be used to completely remove composite from the surface of the tooth with no discernible damage to the underlying enamel, thereby achieving the desired selectivity.²⁰⁰

50.3.8 Surface Modification for Caries Prevention — Enamel

The earliest dental laser studies of Yamamoto and Ooya²⁰¹ and Stern et al.²⁰² showed that high-intensity laser radiation rendered enamel mineral more resistant to acid dissolution.^{201–203} However, such studies utilized ruby, Nd:YAG (1064 nm), and continuous CO₂ lasers at energy levels that produced excessive heat accumulation and extensive peripheral damage, i.e., stress cracking, which prohibited their clinical implementation. More recently, pulsed infrared lasers with wavelength and pulse duration optimally matched to the optical properties of enamel have been used to demonstrate that the transformation of CAP to a more acid-resistant mineral phase is indeed practical with minimal heat deposition in the tooth, 77,203 Several studies over the past 20 years have alluded to the mechanism of inhibition. Thermalanalysis studies of Holcomb and Young²⁴ and subsequent studies by Fowler and Kuroda¹⁴⁶ indicated that there was substantial loss of carbonate and water at temperatures between 100 and 400°C, which were sufficient to change the crystallinity of the intrinsic mineral. Kuroda and Fowler²⁰⁴ observed a reduction in the carbonate content of enamel by 66% after irradiation with a CW CO₂ laser. Heat treatment between 350 and 650°C reduced the solubility of enamel to acid dissolution, 205-209 even though the permeability was increased. Featherstone et al.210 correlated the carbonate loss from enamel measured with FTIR with the inhibition of the dissolution rate, providing strong evidence for the transformation of the mineral of enamel to a purer phase. Therefore, the decreased solubility after infrared irradiation can most likely be attributed to the thermal decomposition of the more soluble CAP into the less soluble HAP with corresponding changes in the crystallinity. Other studies have suggested that the production of pyrophosphate, permeability changes, and modification of the protein matrix play a role in inhibition. 205,206,211-213

Levels of inhibition exceeding 70% have been achieved with CO₂ irradiation²¹⁴ and levels close to 100% have been achieved by combining laser treatments with fluoride application.^{77,172,215} Caries inhibition has also been demonstrated for the erbium-laser wavelengths when a water spray was not employed.¹²⁰ The inhibition after Er:YSGG (2.79 µm) laser irradiation (13 J/cm²) was 60%, which approaches the best results obtained for CO₂ laser irradiation or daily application of a fluoride dentifrice (70 to 85%).^{1–3} Studies of heat-treated and CO₂ laser–irradiated enamel have shown that significant chemical and structural changes are induced in enamel at temperatures well below the melting point.^{24,146,206,209,215,216} The principal changes are loss of water and carbonate, crystal sintering and fusion, permeability changes, and changes in the crystallinity. Therefore, it may not be necessary to melt and recrystallize the enamel for effective caries-preventive treatments.

50.3.9 Surface Modification for Caries Prevention — Dentin

Kantola et al.²¹⁷ showed 30 years ago that lasers could be used to increase the mineral content and crystallinity of dentin by preferential removal of the inherent water and protein. Since that time investigators have evaluated the susceptibility of dentin modified by various laser systems to artificial caries-like lesion formation. Nammour et al.²¹⁸ and Kinney et al.²¹⁹ used CW λ = 10.6 μ m, CO₂, and pulsed Nd:YAG lasers operating at very high intensities to irradiate dentin and create a hypermineralized layer of dentin 50 to 100 μ m thick with greater than 80% mineral composition on the outer surface. This surface layer was resistant to acid dissolution; however, extensive cracking of the surface was observed, and there was some subsurface demineralization, albeit at a somewhat reduced rate in the study of Nammour et al.²¹⁸ Apparently, the laser irradiation did not completely seal the dentinal tubule lumen in those studies; this allowed acid to diffuse through the large surface cracks created during irradiation and the tubules to a depth below the acid-resistant modified layer.

50.4 The Future

Dentists are already using lasers and optical diagnostic technology for caries detection and diagnostics and lasers for therapeutic intervention. By combining these methods future dentists may usher in a new era of conservative dentistry in which caries lesions are detected and assessed before they have progressed to the point where the removal of significant amounts of tissue is required. Subsequent to diagnosis lasers will be used to selectively, precisely, and painlessly remove the carious (decayed) tissue while minimizing the loss of healthy tissue. The mineral phase of the surrounding enamel in these high-risk areas will be transformed through laser heating into a more acid-resistant phase to have an enhanced resistance to future decay. Thus, future patients may not have to endure the current standard of treatment that results in the loss of excessive amounts of healthy tissue structure, which thereby affects the appearance and compromises the mechanical integrity of the tooth.

Acknowledgments

51.1 Introduction

Biochips and microarrays are technologies that will benefit directly from the research advances of the postsequencing era in genomics. Experimental genomics, in combination with the growing body of sequence information, promises to revolutionize the way cells and cellular processes are studied and diseases diagnosed and treated. Information on genomic sequence can be used experimentally with high-density DNA arrays that allow complex mixtures of RNA and DNA to be interrogated in a parallel and quantitative fashion. DNA arrays can be used for many different purposes, especially to measure levels of gene expression (messenger RNA abundance) for tens of thousands of genes simultaneously.¹⁻⁴ On the other hand, portable, self-contained biochips with integrated detection microchip systems have great potential for use by the physician at the point of care.⁵⁻¹¹

As a result, there has been an explosion of interest in the development and applications of biochips and microarrays. 1-5,7,11-29 Biochips are integrated microdevices designed to rapidly and inexpensively perform biochemical procedures for biomedical applications. Because of their miniaturization, low cost, and potential for large-scale automation, biochips can perform more efficiently than currently available laboratory equipment. Biochips with high- and medium-density arrays of oligonucleotides, complementary

DNAs (cDNAs), proteins, and antibodies are among the most powerful and versatile tools in genomics and proteomics for taking full advantage of the large and rapidly increasing body of information on gene structure and function. One of the greatest impacts of microarray and biochip technologies in conjunction with bioinformatics is in enabling an entirely new approach to biological and biomedical research. In the past, researchers studied one or a few genes at a time. With whole-genome sequences and new automated, high-throughput microarray and biochip technologies they can investigate a medical problem systematically and on a large scale. They can study all the genes in a genome or all the gene products in a particular tissue, tumor, or organ. Furthermore, they can investigate how tens of thousands of genes and proteins work together in interconnected networks in a living system. Such knowledge will have a profound impact on the way disorders are diagnosed, treated, and prevented and will bring about revolutionary changes in biomedical research and clinical practice.

This chapter describes the development and applications of biochip and microarray technology in biological research and medical applications. Specific applications of microarrays are described further in Chapter 52 of this handbook.

51.2 Biochips and Microarrays: Definition and Classification

51.2.1 Biochips and Microarrays: A Definition

The terms *biochip* and *microarray* have often been used indiscriminately. However, these two systems are different in design and concept. The term *biochip* was coined in analogy to the phrase *computer chip*, which, of course, refers to the silicon-based substrate used in the fabrication of miniaturized electronic circuits. Therefore, in the generic sense, the term *biochip* involves the concept of an integrated circuit (IC). However, the term has taken on a variety of meanings over the years. A biochip is often referred to as a material or substrate that has an array of probes for biochemical assays. In general, any device or component incorporating a two-dimensional (2D) array of reaction sites having biological materials on a solid substrate has been referred to as a biochip. Biochips involve both miniaturization, usually in microarray formats, and the possibility of low-cost mass production. In the literature, various terms have been used to describe this new technology: If the probes are nucleic acids, the devices are called DNA biochips, DNA chips, genome chips, DNA microarrays, gene arrays, and genosensor arrays. GeneChipTM is a registered trademark of Affymetrix, Inc., which uses this term to refer to its high-density, oligonucleotide-based DNA arrays. If the probes consist of antibodies or proteins, the devices are referred to as protein chips or protein biochips. A recently developed system with both DNA and antibody probes on the same platform is referred to as multifunctional biochip.^{7,9-11}

We define the term *biochip* in the same way that the International Union of Pure and Applied Chemistry (IUPAC) defines *biosensor*.³⁰ According to IUPAC, a biosensor is "a self-contained integrated device, which is capable of providing specific quantitative or semiquantitative analytical information using a biological recognition element (biochemical receptor), which is retained in direct spatial contact with a transduction element." The interaction of the analyte with the bioreceptor is designed to produce an effect measured by the transducer, which converts the information into a measurable effect, such as an electrical signal. Figure 51.1 illustrates the conceptual principle of the biosensing process. Biochips can be considered an array of individual biosensors that can be individually monitored and generally are used for the analysis of multiple analytes.

We group microarrays and biochips into two general classes: (1) microarray systems, which consist of arrays of probes on a substrate ("chip"), and (2) integrated biochips, which also include detector-array microchips. Microarrays (often called "chips") consist only of arrays of probes (in a chip format) but do not include sensor microchips integrated into the system. ¹⁰ Microarrays usually have separate, relatively large detection systems that are suitable for laboratory-based research applications (Figure 51.2). They can have large numbers (tens of thousands) of probes used for identifying multiple biotargets at very high speeds and high throughput by matching with different types of probes via hybridization. Therefore, array plates are very useful for gene-discovery and drug-discovery applications, which often require tens of thousands of assays on a single plate.

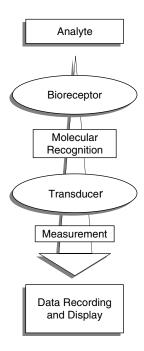

FIGURE 51.1 Principle of the biosensing process.

On the other hand, integrated biochips include an IC microsensor, which makes these devices very portable and inexpensive (Figure 51.3). These devices generally have medium-density probe arrays (10 to 100 probes) and are most appropriate for medical diagnostics at the physician's office or at the point of care in the field. The characteristic features of microarrays and biochips are summarized in Table 51.1.

51.2.2 Biochip Classification

Both microarrays and biochips use probes that consist of biological recognition systems, often called bioreceptors. Biochips can be classified either by the nature of their bioreceptors or by the type of transducer used (Figure 51.4). A detailed description of various types of bioreceptors and transducers is provided in Chapter 20 of this handbook. A bioreceptor is a biological molecular species (e.g., an antibody, an enzyme, a protein, or a nucleic acid) or a living biological system (e.g., cells, tissue, or whole organisms) that uses a biochemical mechanism for recognition. Bioreceptors are the key to specificity for biochip technologies responsible for binding the analyte of interest to the sensor for the measurement. Bioreceptors can take many forms and are as numerous as the different analytes that have been monitored using biosensors. Bioreceptors can generally be classified into five major categories: (1) antibody/antigen, (2) enzymes, (3) nucleic acids/DNA, (4) cellular structures/cells, and (5) biomimetic probes (synthetic probes that mimic receptors of living systems).

Biochips can also be classified by the type of transducers used. The conventional transducer techniques are (1) optical measurements (luminescence, absorption, surface plasmon resonance, etc.), (2) electrochemical measurements, and (3) mass-sensitive measurements (surface acoustic wave, microbalance, etc.).

51.3 Microarray Systems

51.3.1 Basic Principles

Nucleic acids have been widely used as bioreceptors for microarray and biochip technologies.^{31–38} The complementarity of adenine:thymine (A:T) and cytosine:guanine (C:G) pairing in DNA forms the basis

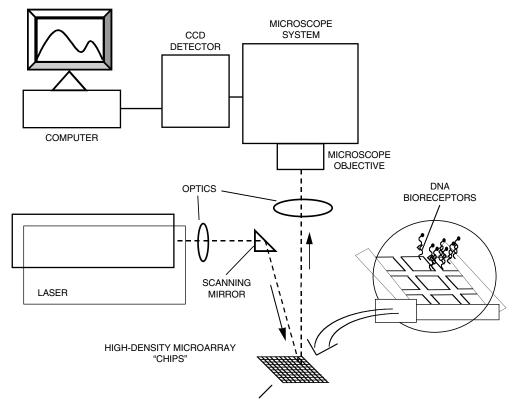

FIGURE 51.2 Schematic diagram of a microarray system. Microarrays (often called "chips") consist of high-density arrays of probes (in a chip format) but do not include sensor microchips integrated into the system. These microarrays usually have separate detection systems that are relatively large and suitable for laboratory-based research applications.

for the specificity of biorecognition in DNA biochips. If the sequence of bases composing a certain part of the DNA molecule is known, then the complementary sequence can be synthesized and labeled with an optically detectable compound (e.g., a radioactive label or a fluorescent label). When unknown fragments of single-strand DNA (ssDNA) samples, called the target, react (or hybridize) with the probes on the chip, double-strand DNA (dsDNA) fragments are formed only when the target and the probe are complementary according to the base-pairing rule. When the targets contain more than one type of sample, each is labeled with its specific tag.

The microarrays of probes serve as reaction sites, each reaction site containing single strands of a specific sequence of a DNA fragment. The DNA fragments can either be short oligonucleotides — e.g., 20- to 100-nucleotide (nt) sequences — or longer strands of cDNA. The relatively large nucleic-acid components — those longer than 100 nt — are often used in RNA expression analysis, and those with short nucleic acids — with oligonucleotides up to 25 nt — can be used for both RNA expression and sequence analysis.

Probes based on a synthetic biorecognition element, peptide nucleic acid (PNA), have been developed.³⁴ PNA is an artificial oligoamide that is capable of binding very strongly to complementary oligonucleotide sequences. A surface plasmon resonance sensor has been used to directly detect dsDNA that has been amplified by a polymerase chain reaction (PCR).

Synthetic antibody-like probes produced by molecular-imprint methods are often used as biomimetic probes. Another type of biomimetic probes is aptamers, which are artificial nucleic-acid ligands that can be produced against amino acids, proteins, and other molecules.

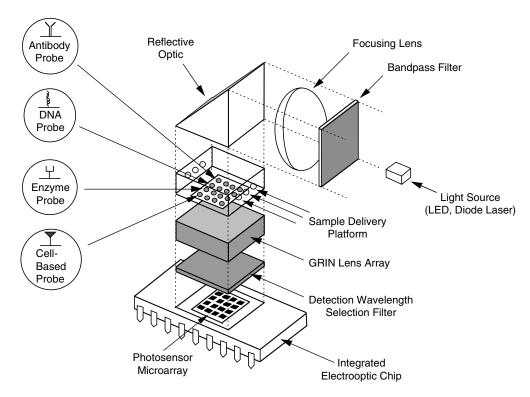

FIGURE 51.3 Schematic diagram of an integrated biochip. Integrated biochips also include an IC microsensor, which makes these devices very portable and inexpensive. These devices generally have medium-density probe arrays (10 to 100 probes) and are most appropriate for medical diagnostics at the physician's office or at the point of care in the field.

TABLE 51.I Characteristic Features of Microarrays and Biochips

Systems	Bioreceptor	Format	Probe Density	Detection System	Applications
Microarrays	DNA Antibody Proteins Cells, etc.	Array	High density (10 ³ –10 ⁵)	Separate system (laboratory system)	Research tools
Biochips	DNA Antibody Proteins Cells, etc.	Array	Low-medium density (10–10²)	Integrated system (portable)	Physician's tool Field monitor

51.3.2 Microarray Fabrication

DNA arrays, often called DNA chips, can be fabricated using high-speed robotics on a variety of substrates. The substrates can be thin plates made of silicon, glass, gel, gold, or a polymeric material such as plastic or nylon, or may even be composed of beads at the ends of fiber-optic bundles.⁴⁰ Oligonucleotide microarrays are fabricated either by *in situ* light-directed combinatorial synthesis that uses photographic masks for each chip⁴¹ or by conventional synthesis followed by immobilization on glass substrates.^{1,2,12}

Arrays with more than 250,000 different oligonucleotide probes or 10,000 different cDNAs per cm² have been produced.⁴² Sequence information is used directly to design high-density, 2D arrays of synthetic oligonucleotides. The probe arrays, made using spatially patterned, light-directed combinatorial chemical

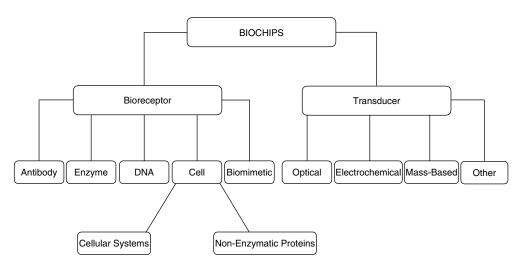

FIGURE 51.4 Biochip classification schemes.

synthesis, contain up to hundreds of thousands of different oligonucleotides on a small glass surface. The arrays have been designed and used to perform quantitative and highly parallel measurements of gene expression, to discover polymorphic loci, and to detect the presence of thousands of alternative alleles.

A maskless fabrication method of light-directed oligonucleotide microarrays replaces the chrome mask with virtual computer-generated masks. These virtual masks are relayed to a digital micromirror array capable of synthesizing microarrays containing more than 76,000 features measuring 16 μ m². A reflective imaging system forms an ultraviolet image of the virtual mask on the active surface of the glass substrate, which is mounted in a flow-cell reaction chamber connected to a DNA synthesizer. Programmed chemical-coupling cycles follow light exposure, and steps are repeated to achieve the desired pattern.⁴³

Modified chemistries should allow for other types of arrays to be manufactured using photolithography. Alternative processes, such as ink-jet⁴⁴ and spotting techniques, can also be used. ^{13,14} One method for constructing these arrays using light-directed DNA synthesis with photoactivatable monomers can currently achieve densities on the order of 10⁶ sequences/cm². One of the challenges facing the developers of this technology is to further increase the volume, complexity, and density of sequence information encoded in these arrays. An approach for synthesizing DNA probe arrays that combines standard solid-phase oligonucleotide synthesis with polymeric photoresist films serving as the photoimageable component opens the way to exploiting high-resolution imaging materials and processes from the microelectronics industry for the fabrication of DNA probe arrays with substantially higher densities. ⁴⁴

Activated DNA has been immobilized in aldehyde-containing polyacrylamide gel for use in manufacturing microarrays. ¹³ In this process, abasic sites were generated in DNA by partial acidic depurination. Amino groups were then introduced into the abasic sites by reaction with ethylenediamine and reduction of the aldimine bonds formed. It was found that DNA could be fragmented at the site of amino-group incorporation or preserved mostly unfragmented. In similar reactions, both amino-DNA and amino-oligonucleotides were attached through their amines to polyacrylamide gel-derivatized with aldehyde groups. ssDNA and dsDNA of 40 to 972 nt or base pairs were immobilized on the gel pads to manufacture DNA microarrays. ¹³

Microarrays containing PCR-amplified genomic DNA extracts from mice tumors on a Zetaprobe® membrane have been fabricated using a modified thermal ink-jet printer. This method, using a modified bubble-jet printing system, is a simple and cost-effective procedure for the fabrication of microarrays containing biological samples. Figure 51.5 shows a cross-section view of a generic bubble-jet cartridge illustrating the connection of ink channels to the printhead (Figure 51.5A) and a membrane printed with biological materials extracted from mice tumor cells with fragile histidine triad (FHIT) gene and control

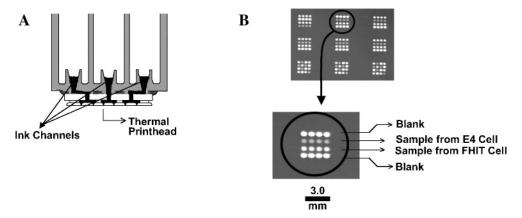

FIGURE 51.5 (Color figure follows p. 28-30.) (A) Schematic diagram of a generic bubble-jet cartridge illustrating the connection of ink channels to the printhead. (B) Membrane printed with biological materials using bubble-jet technology. For purposes of better visualization of the spotting, different fluorescent dyes were added for the preparation of this sample. (Adapted from Allain, L.R. et al., *Fresenius J. Anal. Chem.*, 371(2), 146, 2001.)

cells (cells labeled E4). For purposes of better visualization of the spotting, different fluorescent dyes were added for the preparation of this figure.⁴⁵ Because of their mass-produced design, ink-jet printers are a much cheaper alternative to conventional spotting techniques.

51.3.3 Assay Detection

Because of its inherently sensitive detection capability, fluorescence is the most commonly used technique in DNA hybridization assays. Fluorescent labels can be inserted during the PCR process; subsequently, the sample is tested for hybridization to the microarray. In general, microarray systems are based on fiber-optic probes. Glass and silica plates are used as the probe substrates and are externally connected to a photosensing system, which generally consists of a conventional detection device such as a photomultiplier or a charge-coupled device (CCD). Although the probes on the sampling platform are small, the entire device — containing excitation laser sources and detection systems (often a confocal microscope system) — is relatively large, e.g., tabletop size. The high density of the array and the small size of the probes often require powerful excitation source and high-precision scanning systems, which are also relatively large. These systems have demonstrated their usefulness in genomics research and analysis, but they are laboratory-oriented and involve relatively expensive equipment.

Other optical techniques, such as surface plasmon resonance, has also been used to monitor real-time binding of low-molecular-weight ligands to DNA fragments that were irreversibly bound to the sensor surface via Coulombic interactions. Ellipsometry confirmed that the DNA layer remained stable over a period of several days. Binding rates and equilibrium coverages were determined for various ligands by changing the ligand concentration. In addition, affinity constants and association and dissociation rates were also determined for these various ligands. A label-free optical technique, based on reflectometric interference spectroscopy, has also been used in characterization of low-molecular-weight ligand–DNA interaction.⁴⁶

Ellipsometric and interferometric detection methods have also been used for characterization of DNA probes immobilized on a combinatorial array.⁴⁷ The hybridization reaction may be solution based, or it may be driven by an electric field.⁴⁸ This technology has been successfully applied to the simultaneous assay of expression of many thousands of genes and to large-scale gene discovery as well as to polymorphism screening and mapping of genomic DNA.

Several researchers have investigated sensing-system-based sandwich-type biosensors formed from liquid-crystalline dispersions formed from DNA-polycation complexes.⁴⁹ These sandwich biosensors have

been used to detect compounds and physical factors that affect the ability of specific DNA crosslinkers, polycationic molecules, to bind between adjacent DNA molecules.

The application of the principles of atomic force microscopy (AFM) for the use of supported lipid bilayers for anchoring subcellular to the submolecular biomolecules such as DNA, enzymes, and crystalline protein arrays has been studied. ⁵⁰ Chemical force microscopy (CFM) has also been used to probe the mechanics of molecular recognition between surfaces. The technique uses DNA-modified probes to scan the interactions between short segments of ssDNA containing complementary sequences. These substrates consisted of micron-scale patterned arrays of one or more distinct oligonucleotides. ⁵¹

Raman spectroscopy has recently been used as a detection technique for gene assays. For this method, researchers developed a new type of spectral label for DNA probes based on surface-enhanced Raman scattering (SERS) detection.^{29,52–55} The SERS probes have great potential to provide both sensitivity and selectivity via label multiplexing because of the intrinsically narrow bandwidths of Raman peaks. The effectiveness of the new detection scheme was demonstrated using the *gag* gene sequence of the human immunodefficiency (HIV) virus.⁵⁵ The development of a multiarray system for DNA diagnostics using visible and near-infrared (NIR) dyes has been reported.²⁸

51.3.4 Target-Sample Amplification

An important step in DNA microarray assay involves efficient and reproducible messenger RNA (mRNA) and DNA amplification methods. Various amplification technologies are described in detail in Chapter 55 of this handbook. This section briefly discusses two main approaches: (1) a PCR-based approach that has been used to make single-cell cDNA libraries^{56,57} and (2) a method that uses multiple rounds of linear amplification based on cDNA synthesis and a template-directed *in vitro* transcription (IVT) reaction. Although the PCR technique is most widely used, the IVT method shows significant promise. Labeled material can be sufficiently produced through multiple-round cDNA/IVT amplification. The IVT technique is highly reproducible and introduces less quantitative bias than PCR-based amplification. Messenger RNA from single live neurons has been characterized using the IVT method.^{60,61}

The need for only minute amounts of starting material is a significant advantage of the microarray and biochip technologies. This feature, in conjunction with the capability of laser-capture microdissection technology to provide pure samples, has greatly enhanced the reliability and value of the DNA chip technology as a sophisticated genetic-testing technique.^{62,63} The combination of microarrays generated with DNA, or RNA extracted from pure cell populations within the tissue, and powerful amplification strategies promises to be especially important for studies that involve human biopsy material from nonhomogeneous tissue, as well as for research in developmental biology, immunology, and neurobiology.

51.3.5 DNA-Sequence Analysis

Microarray-based sequence analyses are generally performed using arrays designed to evaluate specific sequences. There are several approaches to analyzing a DNA sequence of interest for all possible changes. The first approach uses probes complementary to a significant subset of sequence changes (such as those described for the cystic fibrosis transmembrane regulator⁶⁴) and measures gain of hybridization signal to these probes relative to reference samples. The approach allows for a partial scan of a DNA segment for all possible sequence variations. Probes are designed such that the location of the interrogated target base is in the centermost position of the potential target/probe duplex and thus provides the best discrimination for hybridization specificity. The probe arrays are made using spatially patterned, light-directed combinatorial chemical synthesis and contain up to hundreds of thousands of different oligonucleotides on a small glass surface. The arrays have been designed and used to perform quantitative and highly parallel measurements of gene expression, to discover polymorphic loci, and to detect the presence of thousands of alternative alleles.⁴² In another study, the entire 297-bp HIV-1 protease gene-coding sequence from 167 viral isolates was screened for all single nucleotide changes using this gain-of-signal approach. The DNA sequence of USA HIV-1 clade B proteases was found to be extremely variable, with

47% of the 99 amino-acid positions varied.⁶⁵ Naturally occurring mutations in HIV-1-infected patients have important implications for therapy and the outcome of clinical studies.

The second approach to scanning DNA analyses involves the selective loss of hybridization signal to perfect-match probes that are complementary to wild-type sequence in a manner analogous to comparative genomic hybridization studies, 66,67 In the loss-of-signal approach, sequence variations are scored by quantifying relative losses of hybridization signal to perfect-match oligonucleotide probes relative to wildtype reference targets. Loss-of-signal analysis allows for a practical screen to be set up for virtually any sequence variation. A disadvantage of loss-of-signal analysis is that the mutation cannot be discerned; the identity of the sequence change must be established by subsequent dideoxysequencing of the region surrounding the loss-of-signal signature. This approach has been further improved by using internal standards that utilize two-color assays. In this scheme, reference targets with a known sequence can be cohybridized to the arrays along with the test target. Labeling each target with a different fluorophore allows a direct comparison of hybridization signals from the two targets to be made. High-density arrays consisting of over 96,600 oligonucleotides 20 nt in length screen for a wide range of heterozygous mutations in the 3.45-kilobase (kb) exon 11 of the hereditary breast and ovarian cancer gene BRCA1.67 Reference and test samples were cohybridized to these arrays and differences in hybridization patterns quantified by two-color analysis. The ability to scan a large gene rapidly and accurately for all possible heterozygous mutations in large numbers of patient samples will be critical for the future of medicine. DNA minisequencing assays couple target hybridization with enzymatic primer-extension reactions to provide a powerful means of scanning for all possible sequence variations.^{22,68,69}

Representational difference analysis (RDA), which compares the results for two tissue samples, is another analysis method used for DNA microarrays and biochips. Subtraction of one set of results from the other shows which genes are active in one sample but less active or completely inactive in the other. The comparison is usually performed between normal and cancer cells, or between metastatic and nonmetastatic cancers. In this way, the evaluation may pinpoint an abnormal cellular process occurring mainly (or even exclusively) in diseased cells. The evaluation may thus serve not only as a diagnostic tool but also as a means to identify therapeutic targets. RDA of cDNA was used for a comparison of the global transcript level of tumor of the larynx and the corresponding normal epithelial tissue for detecting differentially expressed genes. Overall, some 130 gene fragments were identified.⁷⁰ After further analysis, these genes could be put in functional groups such as genes whose overexpression was a result of tumor growth or dedifferentiation, genes that played major roles in signal transduction pathways, apoptosis, oncogenes, or tumor-suppressor genes in addition to new, entirely unknown genes.

51.3.6 Protein Microarrays

Recently, antibodies have received increasing interest as bioreceptors for research in proteomics. When microarray probes consist of antibodies or proteins, the microarrays are sometimes called protein chips or protein biochips. 45,71–79 The basis for the specificity of immunoassays is the antigen—antibody (Ag—Ab) binding reaction, which is a key mechanism by which the immune system detects and eliminates foreign matter. 40–82 The way in which an antigen and an antigen-specific antibody interact may perhaps be understood as analogous to a lock-and-key fit, in which the specific configurations of a unique key enable it to open a lock. In the same way, an antigen-specific antibody fits its unique antigen in a highly specific manner, so that hollows, protrusions, planes, and ridges on the antigen and the antibody molecules (in a word, the total three-dimensional [3D] structure) are complementary. Due to this 3D shape fitting, and the diversity inherent in individual antibody makeup, it is possible to find an antibody that can recognize and bind to any one of a huge variety of molecular shapes. This unique property of antibodies is the key to their usefulness in immunosensors because this ability to "recognize" molecular structures allows researchers to develop antibodies that bind specifically to chemicals, biomolecules, microorganism components, etc. Such antibodies can then be used as specific detectors to identify and find an analyte of interest that is present, even in extremely small amounts, in a myriad of other chemical substances.

Protein microarrays have received great interest because it is not sufficient just to know the genes involved and their DNA sequences.⁷¹ Proteins formed as a result of the activity of certain genes induce the symptoms of illnesses. To understand and manage disease it is important to investigate those proteins in the body that are responsible for all biological processes (growth, metabolism, disease, etc.). The number of these proteins is estimated at several hundred thousand. For this reason, microarray and biochip technologies are expected to play an important role in the investigation of proteomics.⁸³

Proteomics research has two main objectives: (1) quantification of all the proteins expressed in a cell and (2) the functional study of thousands of protein in parallel. The standard methods for identification and quantification are 2D gel separation and mass spectrometry. Microarray-based assays are being used to study protein–protein and protein–ligand interactions because the rapid development of this technology has shortened the analysis process and made it more reliable.⁸⁴

51.4 Biochips

51.4.1 The Integrated Biochip Concept

Biochips that integrate conventional biotechnology with semiconductor processing, microelectromechanical systems (MEMS), optoelectronics, and digital-signal and image acquisition and processing have received a great deal of interest. There is a strong need for a truly integrated biochip system that comprises probes, samplers, and detectors as well as amplifier and logic circuitry on board. Such a system will be useful in physicians' offices and can be used by relatively unskilled personnel.

An integrated biochip using bioreceptor probes and a detection system in a self-contained microdevice has been developed.^{5,7–9,11} As illustrated schematically in Figure 51.3, the biochip concept involves the combination of IC elements, an electro-optics excitation/detection system, and bioreceptor probes in a self-contained and integrated microdevice. A basic biochip includes (1) an excitation light source with related optics, (2) a bioprobe, (3) a sampling platform and delivery system, (4) an optical detector with associated optics and dispersive device, and (5) a signal-amplification/treatment system.

Construction of a biochip involves the integration of several basic elements of very different natures. The basic steps are (1) the selection or development of the bioreceptor, (2) the selection of the excitation source, (3) the selection or development of the transducer, and (4) the integration of the excitation source—bioreceptor—transducer system. The development of the biochip comprises three major elements. The first element involves the development of a bioreceptor probe system: a microarray of bioreceptor probes on a multiarray sampling platform. The second element involves the development of nonradio-active methods for optical detection: the fluorescence technique. The third element involves the development of an integrated electro-optic IC system on a single chip for biosensing: a photodiode-amplifier microchip using complementary metal oxide semiconductor (CMOS) technology.

51.4.2 Integrated Chip Fabrication

Most microarray detection systems are very large when the excitation source and detector are considered, making them impractical for anything but laboratory usage. For biochips, however, the sensors, amplifiers, discriminators, and logic circuitry are all built onto the chip. The integrated biochip involves integrated electro-optic sensing photodetectors. Highly integrated biosensors are possible partly because multiple optical sensing elements and microelectronics can be fabricated on a single IC. The biochips include a large-area, *n*-well integrated amplifier-photodiode array that has been designed as a single, custom IC fabricated for the biochip. This IC device is coupled to the multiarray sampling platform and is designed for monitoring very low light levels. The individual photodiodes have 900-µm² sizes and are arrayed on a 1-mm spacing grid. The photodiodes and the accompanying electronic circuitry were fabricated using a standard 1.2-micron *n*-well CMOS process. The use of this standard process allows for the production of photodiodes and phototransistors as well as other numerous types of analog and

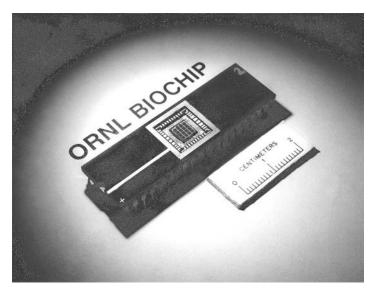

FIGURE 51.6 (Color figure follows p. 28-30.) Integrated circuit microchip for a biochip with 4×4 sensor array. (From Vo-Dinh, T., *Sensors Actuators*, B51, 52, 1998. With permission.)

digital circuitry in a single IC chip. This feature is the main advantage of the CMOS technology as compared to other detector technologies such as CCDs or charge-injection devices. The photodiodes themselves are produced using the n-well structure that is generally used to make resistors or as the body material for transistors. Since the anode of the diode is the p-type substrate material, which is common to every circuit on the IC chip, only the cathode is available for monitoring the photocurrent, and the photodiode is constrained to operate with a reverse bias. Figure 51.6 shows a $16 (4 \times 4)$ -array microchip fabricated for the DNA biochip.

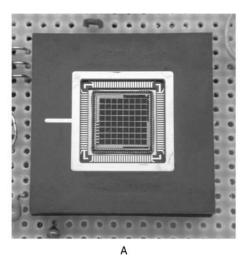

An analog multiplexer was designed to allow any of the elements in the array to be connected to an amplifier. The multiplexer is made from 16 cells for the 4×4 array device. Each cell has a CMOS switch controlled by the output of the address decoder cell. The switch is open, connecting the addressed diode to an amplifier. This arrangement makes it possible to connect a 4×4 (8×8 or 10×10) array of light sources (different fluorescent probes, for example) to the photodiode array and read out the signal levels sequentially.

Figure 51.7A shows a photograph of 64 (8×8)-array IC microchips. Figure 51.7B shows the design of the different CMOS photodiode regions and signal-processor regions of the 8×8 microchip. The CMOS technology makes possible highly integrated biosensors, partly through the capability of fabricating multiple optical sensing elements and microelectronics on a single IC. A 2D array of optical detector-amplifiers was integrated on a single IC chip.

51.4.3 Multifunctional Biochip: A Hybrid Chip for Genomics and Proteomics

The development of the first integrated DNA biochip with a phototransistor IC microchip was reported by Vo-Dinh et al. $^{5-7,85}$ This work involved the integration of 4×4 optical biosensor arrays onto an IC. The usefulness and potential of this DNA biochip was illustrated by the detection of gene fragments of the HIV system. 5

Nucleic acids are not, however, the only possible substances of interest in medical diagnosis. For example, proteins also need to be analyzed using biochips with antibody probes. These antibody-based biochips are often referred to as protein chips. In general, biochips employ only one type of bioreceptor as probes, i.e., either nucleic acid or antibody probes. A novel integrated biochip system that uses multiple bioreceptors with different functionalities on the same biochip, allowing simultaneous detection of several types of biotargets on a single platform, has been developed.^{8,9} This device is referred to as the multifunctional

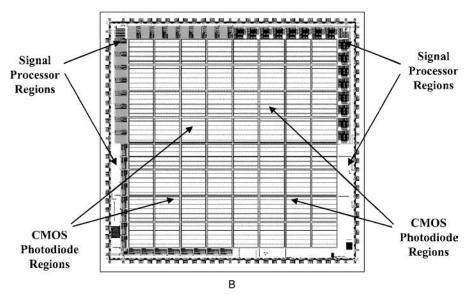

FIGURE 51.7 (Color figure follows p. 28-30.) (A) Photograph of the 8×8 integrated circuit microchip. (B) Schematic of the electronic design of the 8×8 microchip with CMOS photodiode regions and signal processor regions.

biochip (MFB). The integrated electro-optic microchip system developed for this work involved integrated electro-optic sensing photodetectors for the biosensor microchips.

The MFB allows for simultaneous detection of several disease endpoints using different bioreceptors, such as DNA and antibodies, on a single biochip system. The multifunctional capability of the MFB device is illustrated by measurements of different types of bioreceptors using DNA probes specific to gene fragments of the *Mycobacterium tuberculosis* (TB) system and antibody probes targeted to the cancer-related tumor-suppressor gene *p53* on a single biochip platform (Figure 51.8).

51.5 Applications in Biology and Medicine

51.5.1 Genomics Research

Microarray and biochip technologies provide powerful tools to identify all the genes as well as to understand their functions and how these components work together to coordinate the functions of cells

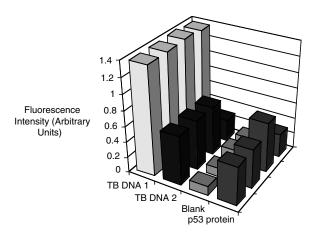

FIGURE 51.8 The multifunctional biochip used for simultaneous detection of the p53 protein (antibody probe) and the *Microbacterium tuberculosis* gene (DNA probe).

and organisms.²¹ Two important applications for the high-density DNA microarray technology involve identification of sequence (gene mutation) and determination and monitoring of expression level, e.g., mRNA abundance (gene expression).

DNA microarray and biochip technologies for genome-scaled screening and the availability of genome information will enable rapid mapping and identification of disease-related genes, which can then be analyzed in more detail. Until recently, functional studies of genes were carried out using the one-gene-one-protein-at-a-time approach. High-density microarray technology can simultaneously analyze the expression of all genes in a given organism containing thousands of different genes.

The collection of genes that are expressed or transcribed from genomic DNA (the expression profile) is a major determinant of cellular phenotype and function that changes rapidly and dramatically in response to various stimulations and during normal cellular events. Microarray hybridization has been applied for a genome-wide transcriptional analysis of cellular mitotic processes. A comprehensive identification of cell-cycle-regulated genes of the yeast *Saccharomyces cerevisiae* has been accomplished. Transcription alterations in DNA replication genes, genes involved with cell-cycle control and chromosomes, and a large collection of genes involved with smooth muscle function, apoptosis, intercellular adhesion, and cell motility have been measured.

With the human-genome-sequencing phase now completed, the postgenomics phase of research involves information analysis and experimental activities initiated as the results of genome information. For instance, the information from open reading frames (ORFs), which indicate the particular parts within the genome encoded for proteins, allows functional assignment of the given genes. Functional assignment is performed using several methods: systematic disruption of the gene to observe the effects of the absence of the functional genes, expression of the genes in transgenic animals, and expression of recombinant proteins.

51.5.1.1 Application of Human Expressed Sequence Tags and cDNA Microarrays

Human expressed sequence tags (ESTs), in combination with high-density cDNA microarray techniques, have been used to map the genome, to explore genes, and to profile downstream gene changes in a host of experiments. EST is a short strand of DNA that is a part of a cDNA molecule and can act as the identifier of a gene. ESTs represent sequences expressed in an organism under particular conditions that are often used in locating and mapping genes. For instance, in lung cancer the effects of overexpression of a tumor suppressor — the phosphatase and tensin homology deleted on chromosome 10 (PTEN) — has been studied.⁸⁹ In prostate cancer, ESTs have been used for identification of several potential markers for prostate cancer.⁹⁰ Prostate cancer tends to become transformed to androgen-independent disease over time when treated by androgen-deprivation therapy. In one study, two variants of the human prostate

cancer cell line LNCaP were used to study gene-expression differences during prostate cancer progression to androgen-independent disease.⁹⁰

The cDNA microarray technique is a unique tool that exploits this wealth of information for the analysis of gene expression. In this method, DNA probes representing cDNA clones are arrayed on a glass slide and interrogated with fluorescently labeled cDNA targets. The power of the DNA biochip technology is the ability to perform a genome-wide expression profile of thousands of genes in one experiment. In a study of breast cancer, cell lines were used for rapid identification and comparison of the differential pattern of gene expression. In an alternative approach for selecting tissue-appropriate cDNAs that could be used to examine the expression profiles of developmental processes and diseases, ESTs were employed to identify 21 neural crest-derived melanocytes in a library of 198 cDNAs for microarray analysis. CDNAs for microarray analysis.

51.5.1.2 Single-Nucleotide Polymorphism

The single-nucleotide polymorphism (SNP) is the most frequent type of variation in the human genome. Although more than 99% of human DNA sequences are the same across the population, variations in DNA sequence can have a major impact on how humans respond to disease; to such environmental insults as bacteria, viruses, toxins, and chemicals; and to drugs and other therapies. Methods are being developed to detect different types of variation, particularly SNPs, that occur about once every 100 to 300 bases. SNPs provide powerful tools for a variety of medical genetic studies. It is believed that SNP maps will help researchers identify the multiple genes associated with such complex diseases as cancer, diabetes, vascular disease, and some forms of mental illness. These associations are difficult to establish with conventional gene-hunting methods because a single altered gene may make only a small contribution to disease risk. Detection of the presence of particular mutations or polymorphisms using oligonucleotide-array-based analysis of known genomic DNA sequence was first reported in 1989. Genotype was determined nonradioactively by binding of streptavidin-horseradish peroxidase to the biotinylated DNA in a colorimetric assay that detected the signal intensity produced by each allele-specific probe.

In a large-scale survey for SNPs employing a combination of gel-based sequencing and high-density microarray DNA chips, 2.3 megabases of human genomic DNA were examined by a combination of gel-based sequencing and high-density variation-detection DNA chips. The study identified a total of over 3000 candidate SNPs. A genetic map was constructed showing the location of over 2000 of these SNPs. Prototype genotyping chips were developed that allow simultaneous genotyping of 500 SNPs. The study provides a characterization of human diversity at the nucleotide level and demonstrates the possibility of large-scale identification of human SNPs.²²

Most human cancers are characterized by genomic instability, the accumulation of multiple genetic alterations, and allelic imbalance throughout the genome. Loss of heterozygosity (LOH) is a common form of allelic imbalance, and the detection of LOH has been used to identify genomic regions that harbor tumor-suppressor genes and to characterize tumor stages and progression. Researchers have used high-density oligonucleotide arrays for genome-wide scans for LOH and allelic imbalance in human tumors. He detection of LOH and other chromosomal changes using large numbers of SNP markers should enable identification of patterns of allelic imbalance, with potential prognostic and diagnostic utility. Prototype genotyping chips have been produced to detect 400, 600, and 3000 of these SNPs. Methods have been developed for rapid genotyping of these SNPs using oligonucleotide arrays. Highdensity DNA-chip-based analysis has also been used to determine the distant history of SNPs, polymorphism detection, and genotyping in current human populations. The studies demonstrate that microarray-based assays allow for rapid comparative sequence analysis of intra- and interspecies genetic variation. He studies demonstrate that microarray-based assays allow for rapid comparative sequence analysis of intra- and interspecies genetic variation.

51.5.1.3 Gene-Expression Studies

DNA microarrays and biochips can also be used to probe gene-expression patterns throughout a genome. For this purpose the probes are selected not to cover the length of an individual gene but to have sequences

characteristic of different genes (so-called partial-sequence tags). When a gene is expressed (active), its code is transcribed into single-stranded mRNAs through which the gene transmits its instructions for cellular biosynthesis of a specific protein. Hence, a cell's cytoplasm contains a variety of messengers, depending on which genes are expressed. The messengers' hybridizations with one or another partial-sequence tag on a biochip can serve to reveal the patterns of genes being expressed. Microarray analyses have been successfully applied to identify amplified and overexpressed genes in chromosomal region 17q23, which is known to be augmented in up to 20% of primary breast cancers.⁹⁸

An important objective of current cancer research is to develop a detailed molecular characterization of gene expression in tumor cells and tissues that is linked to clinical information. One study used differential display to identify approximately one quarter of all genes that were aberrantly expressed in a breast cancer cell line. 99 Two clusters of genes, represented by *p53* and maspin, had expression patterns strongly associated with estrogen-receptor status. A third cluster that included HSP-90 tended to be associated with tumor stage, whereas a fourth cluster that included keratin 14 tended to be associated with tumor size. The expression levels of these clinically relevant gene clusters allowed breast tumors to be grouped into distinct categories. Gene-expression fingerprints that include these four gene clusters could improve prognostic accuracy and therapeutic outcomes for breast-cancer patients. 99

High-density oligonucleotide arrays were used to measure messenger RNA levels and to evaluate the transcriptional profiles of fibroblast cultures taken from donors of various ages. mRNA levels were measured in actively dividing fibroblasts isolated from young, middle-aged, and old humans and from humans with progeria, a rare genetic disorder characterized by accelerated aging. The study identified genes whose expression was associated with age-related phenotypes and diseases. The data suggest that an underlying mechanism of the aging process involves increasing errors in the mitotic machinery of dividing cells in the postreproductive stage of life. Results indicated that a central underlying process of aging involves errors in the mitotic machinery that lead to chromosomal pathologies and ultimately to misregulation of essential structural, signaling, and metabolic genes.¹⁰⁰

Complex changes in patterns of gene expression that accompany the development and progression of cancer and the experimental reversal of tumorigenicity can be investigated by microarray and biochip technologies. The tumorigenic properties of human melanoma cell line can be suppressed by introduction of a normal human chromosome 6. The introduction of this chromosome results in a reduced growth rate, restored contact inhibition, and suppressed soft agar clonogenicity and tumorigenicity in nude mice. A high-density microarray of 1161 DNA elements was used to search for differences in gene expression associated with tumor suppression in this system. Fluorescent probes for hybridization from two sources of cellular mRNA were labeled with different fluorophores to provide a direct and internally controlled comparison of the mRNA levels corresponding to each arrayed gene. The fluorescence signals representing hybridization to each arrayed gene were analyzed to determine the relative abundance in the two samples of mRNAs corresponding to each gene.³

High-density cDNA arrays have been used to detect tumorigenesis- and angiogenesis-related alterations in gene-transcript-expression profiles in ovarian cancer.¹⁰¹ In the ovary, an abundance of specific tumor markers, increased macrophage recruitment mediators, a late-stage angiogenesis profile, and the presence of chemoresistance-related markers distinguished normal and advanced ovarian-cancer-tissue samples. The detection of such parallel changes in pathway- and tissue-specific markers may prove a potential approach ready for application in reproductive-disease diagnostic and therapeutic developments.¹⁰¹

Similarly, investigators have applied general approaches to cancer classification based on gene-expression profiles monitored by DNA microarrays to a systematic characterization of gene expression in B-cell malignancies. The molecular classification of tumors on the basis of gene expression can be used to identify previously undetected and clinically significant subtypes of cancer. Description

A damaging change during cancer progression is the switch from a locally growing tumor to a metastatic killer. This switch is believed to involve numerous alterations that allow tumor cells to complete the complex series of events needed for metastasis. DNA microarrays were used to investigate this metastasis process where a defined pattern of gene expression that correlates with progression from a

locally growing tumor to a metastatic phenotype had been discerned.¹⁰³ The results demonstrated an enhanced expression of several genes involved in extracellular matrix assembly and of a second set of genes that regulate the actin-based cytoskeleton.¹⁰³

Many genes and signaling pathways controlling cell proliferation, death and differentiation, and genomic integrity are involved in cancer development. Identification of prognostic markers and prognostic parameters for renal cell carcinoma has been performed using cDNA microarray and biochip technologies.¹⁰⁴ Finally, DNA microarray technologies have been applied in genomic analysis and monitoring of the expression profiles of a host of cancerous organs including the glioma,¹⁰⁵ ovary,¹⁰¹ breast,¹⁰⁶ blood,¹⁰⁷ liver,¹⁰⁸ nasopharyngeal,¹⁰⁹ and lung.¹¹⁰

51.5.2 Gene-Profile Analysis

High-density DNA microarrays allow for massively parallel genomics profiling and gene-discovery studies and could provide researchers with information on tens of thousand of genes simultaneously. These arrays can be used to test an individual gene throughout all or part of its length for single-base variations from the gene's usual sequence. DNA chips, available from various commercial sources such as Affymetrix (Santa Clara, CA), can be used to detect single-base variations in the human genes *BRCA1* and *BRCA2* (breast-cancer-related), *p53* (a tumor-suppressor gene mutated in many forms of cancer), and *P450* (coding for a key liver enzyme system that metabolizes drugs). Other Affymetrix GeneChips analyze the HIV genome for variations within the code for the viral protease and reverse transcriptase. Predicting drug resistance of a given patient's viral strain is a possible application of these chips.

Measurements of the expression of thousands of genes in a single experiment, revealing many new and potentially important cancer genes, have become possible with techniques such as serial analysis of gene expression and cDNA microarrays. These genome-screening tools are capable of analyzing one tumor at a time. However, techniques to survey hundreds of specimens from patients in different stages of disease are often needed to establish the diagnostic, prognostic, and therapeutic importance of each of the emerging cancer-gene candidates. To facilitate rapid screening for molecular alterations in many different malignancies, a tissue microarray consisting of samples from 17 different tumor types was generated. Altogether, 397 individual tumors — such as breast, colon, kidney, lung, ovary, bladder, colon, stomach, testis head and neck, and endometrial cancer, as well as melanoma — were arrayed in a single paraffin block. The results confirmed and even extended existing data in the literature for the amplification of three extensively studied oncogenes, *CCND1*, *CMYC*, and *ERBB2*.¹¹¹

A high-throughput microarray technique that facilitates gene expression and copy-number surveys of very large numbers of tumors has been developed.¹⁵ This technique can analyze as many as 1000 cylindrical tissue biopsies from individual tumors distributed in a single tumor-tissue microarray. Sections of the microarray provide targets for parallel *in situ* detection of DNA, RNA, and protein targets in each specimen on the array, and consecutive sections permit rapid analysis of hundreds of molecular markers in the same set of specimens. Detection of six gene amplifications as well as *p53* and estrogen-receptor expression in breast cancer demonstrates the usefulness and potential of this method for identifying new subgroups of tumors.

Gene amplifications and deletions have often been associated with pathogenetic roles in cancer. Thirty thousand radiation-hybrid-mapped cDNAs provide a genomic resource to map these lesions with high resolution. Researchers report the development of a multiplex assay to detect small deletions and insertions by using a modified PCR to evenly amplify each amplicon (PCR/PCR), followed by ligase detection reaction (LDR).¹¹² This study demonstrates that microarray analysis of PCR/PCR/LDR2 products permits rapid identification of small insertion and deletion mutations in the context of both clinical diagnosis and population studies.

Another group of researchers has developed a cDNA microarray-based comparative genomic hybridization method for analyzing DNA copy-number changes across thousands of genes simultaneously.²⁶ With this procedure, DNA copy-number alterations of twofold or less could be reliably detected. The researchers have mapped regions of DNA copy-number variation at high resolution in breast cancer cell

lines, revealing previously unrecognized genomic amplifications and deletions and new complexities of amplicon structure. They have also identified recurrent regions of DNA amplification that may harbor novel oncogenes and performed comparison and correlations of alterations of DNA copy number and gene expression in parallel analyses. For breast tumors, DNA copy-number information is being compared and correlated with data already collected on *p53* status, microarray gene-expression profiles, and treatment response and clinical outcome. Genome-wide DNA copy-number information on a set of 9 breast cancer cell lines and over 35 primary breast tumors has been collected in the study.

51.5.3 Pharmacogenomics and Drug Discovery

High-throughput microarray and biochip technologies have generated increasing interest in the field of pharmacogenomics, which is aimed at finding correlations between therapeutic responses to drugs and the genetic profiles of patients. It is hoped that the discovery of genetic variances that affect drug action will lead to the development of new diagnostic procedures and therapeutic products that enable drugs to be prescribed selectively to patients for whom they will be effective and safe. Many people die each year from adverse responses to medications that are beneficial to others. Others experience serious reactions or fail to respond at all. DNA variants in genes involved in drug metabolism, particularly the cytochrome *P450* multigene family, are the focus of much current research in this area. Enzymes encoded by these genes are responsible for metabolizing most drugs, and their function affects patients' responses to both the drug and the dose. Within the next decade, researchers will begin to correlate DNA variants with individual responses to medical treatments, identify particular subgroups of patients, and develop drugs customized for those populations. This "customized medicine" approach has now come to be recognized as a significant commercial opportunity for genomics.¹⁷

A number of attempts are ongoing to treat cystic fibrosis, a lethal recessive disease affecting children in the United States and Europe, either by gene therapy or pharmacotherapy. Recently, cDNA-array technology was used in a cystic fibrosis study of human cells concerned with global gene expression and drug effects. The results provided useful pharmacogenomic information with significant relevance to both gene and pharmacological therapy. The functional similarity and specificity of different purine analogs have been determined by comparing the expression profiles of their genome-wide effects on treated yeast, murine, and human cells. Purine libraries have also been shown to be useful tools for analyzing a variety of signaling and regulatory pathways and may lead to the development of new therapeutics. 114

A method for drug-target validation and identification of secondary drug-target effects based on genome-wide gene-expression patterns using DNA biochip microarrays has been demonstrated in several experiments, which included treatment of mutant yeast strains defective in calcineurin, immunophilins, or other genes with the immunosuppressants cyclosporin A and FK506.¹¹⁵ The described method permits the direct confirmation of drug targets and recognition of drug-dependent changes in gene expression that are modulated through pathways distinct from the drug's intended target. Such a method may prove useful in improving the efficiency of drug-development programs.

The molecular mechanisms underlying the progression of prostate cancer during hormonal therapy have remained poorly understood. A study of hormone therapy for prostate cancer developed a new strategy, using of a combination of complementary cDNA and tissue-microarray technologies, for the identification of differentially expressed genes in hormone-refractory human prostate cancer.¹¹⁶

Microarray and biochip technologies, in conjunction with genomic data and bioinformatics, are expected to make drug development faster, cheaper, and more effective. Most drugs today are based on about 500 molecular targets; genomic research on the genes involved in diseases, disease pathways, and drug-response sites will lead to the discovery of thousands of new targets.

51.5.4 Toxicogenomics

The availability of genome-scale DNA-sequence information and reagents has led to the development of a new scientific subdiscipline combining the fields of toxicology and genomics.²³ This subdiscipline, often

referred to as toxicogenomics, involves the study of how genomes respond to environmental stressors or toxicants.¹¹⁷ Toxicogenomics combines genome-wide mRNA-expression profiling with protein-expression patterns using bioinformatics to understand the role of gene–environment interactions in disease and dysfunction. The goal of toxicogenomics is to find correlations between toxic responses to toxicants and changes in the genetic profiles of the objects exposed to such toxicants. For these applications, DNA microarray and biochip technologies, which allow the monitoring of the expression levels of thousands of genes simultaneously, provide an important analytical tool.²⁷ A general method by which gene expression, as measured by cDNA microarrays, can be used as a highly sensitive and informative marker for toxicity has been described.²³

Arrays containing expressed-sequence tags for xenobiotic metabolizing enzymes, proteins associated with glutathione regulation, DNA-repair enzymes, heat-shock proteins, and housekeeping genes were used to examine gene expression in response to β -naphthoflavone (β -NF), with results comparable to those of Northern blotting analysis.¹¹⁸

51.5.5 Genetic Screening of Diseases

An important area of DNA biochip application involves screening genetic diseases. Gene tests can be used to diagnose disease, confirm a diagnosis, provide prognostic information about the course of disease, confirm the existence of a disease, and, potentially, predict the risk of future disease in healthy individuals or their progeny. Currently, several hundred genetic tests are in clinical use, with many more under development. Most current tests detect mutations associated with rare genetic disorders that follow Mendelian inheritance patterns. These diseases include myotonic and Duchenne muscular dystrophies, cystic fibrosis, neurofibromatosis type 1, sickle cell anemia, and Huntington's disease.

These screening procedures are often performed prenatally. DNA biochip technology could be a sensitive tool for the prenatal detection of genetic disorders. Newborn blood cards provide high-quality DNA samples that can reliably support highly multiplexed PCRs. In a single assay, a DNA microarray facilitates the codetection of amplification products diagnostic for several genetic diseases. Initial data utilizing the model systems of sickle cell disease, an autosomal recessive condition caused by a single amino-acid substitution in the beta-globin protein, have been reported.¹¹⁹

Genetic alterations and abnormalities could lead to uncontrolled cell division and metathesis, resulting ultimately in cancer. Genetic studies have identified a number of genes that must mutate in order to induce cancer or promote the growth of malignant cells. For example, mutations in *BRCA1*, a gene on chromosome 17, have been found to be related to breast cancer. A high percentage of women with a mutated *BRCA1* gene will develop breast cancer or have an increase in ovarian cancer. A second breast-cancer gene, *BRCA2*, is located in chromosome 13. Another important gene associated with cancer is the *p53* gene, which encodes a nuclear protein that serves as a transcription factor. The *p53* gene is a tumor-suppressor gene that regulates passage of the cell from the G1 into the S phase in the cell cycle. Mutations of *p53* have been associated with a wide variety of cancers, including colon, lung, breast, and bladder cancers. DNA biochips are available for the analysis of human genes including *BRCA1*, *BRCA2*, *p53*, and *P450*.

Information on genetic abnormalities that are characteristic of certain tumor types or stages of tumor progression is provided by the rapidly expanding database of comparative genomic hybridization (CGH) publications, which already covers about 1500 tumors. CGH data have led to the discovery of six new gene amplifications as well as a locus for a cancer-predisposition syndrome. The approach based on CGH has now been established as a first-line screening procedure for cancer researchers and will serve as a basis for ongoing efforts to develop the next-generation genome-scanning techniques such as high-resolution microarray technology. Recent microarray studies have involved identification of genes involved in the development or progression of ovarian cancer, 121,122 prostate cancer, 90,123,124 breast cancer, 125 renal cell carcinoma, 104 and urinary bladder cancer. 126

With the availability of sequence data on the human gnome, it is expected that biochips will soon be used for a wide variety of other genetic tests. The use of DNA microarrays has been suggested for

evaluating renal function and disease,¹²⁷ analysis of gene expression in multiple sclerosis lesions,¹²⁸ quantitative histological analysis of Alzheimer's disease.¹²⁹

51.5.6 Pathogen Detection

Another important application of miniaturized biochip devices involves the detection of biological pathogens (e.g., bacteria and viruses) present in the environment, at occupational sites such as hospitals and offices, or in public places. To achieve the required level of sensitivity and specificity in detection, it is often necessary to use a device that is capable of identifying and differentiating a large number of biochemical constituents in complex environmental samples. DNA biochip technologies could offer a unique combination of performance capabilities and analytical features of merit not available in any other current bioanalytical system. Biochip devices that combine automated sample-collection systems and multichannel sensing capability will allow simultaneous detection of multiple pathogens present in complex environmental samples. In this application, the biochip technology could provide an important tool to warn of exposure to pathogenic agents for use in human-health protection and disease prevention.

The list of expected biochip applications could include biochips for diagnosis of infectious diseases such as HIV. Nucleic-acid arrays have been constructed for many different organisms and successfully employed in a host of various experiments. ^{130–134} In an investigation to obtain a more comprehensive view of the global effects of HIV infection of CD4-positive T cells at the mRNA level, cDNA microarray analysis was performed on approximately 1500 cellular cDNAs at 2 and 3 d postinfection (p.i.) with HIV-1. Host-cell gene expression changed little at 2 d p.i., but at 3 d p.i., 20 cellular genes were identified as differentially expressed. Genes involved in T-cell signaling, subcellular trafficking, and transcriptional regulation, as well as several uncharacterized genes, were among those whose mRNAs were differentially regulated. ¹³⁵

Current applications of microarray research involve complete profiling of the genomic sequences of microbial pathogens and hosts. Such studies will ultimately lead to sophisticated new strategies for studying host–pathogen interactions.¹³⁶ One such study looked at *Pseudomonas aeruginosa*, an opportunistic pathogen that plays a major role in lung-function deterioration in cystic fibrosis patients. To identify critical host responses during infection, the investigators used high-density DNA microarrays, consisting of 1506 human cDNA clones, to monitor gene expression in the *A549* lung pneumocyte cell line during exposure to *P. aeruginosa*. Identification of differentially regulated genes was analyzed by expression microarray analysis of human cDNAs.¹³⁷

Bacille Calmette-Guerin (BCC) vaccines are live attenuated strains of *Mycobacterium bovis* administered to prevent tuberculosis. To provide for rational approaches to the design of improved diagnostics and vaccines and better understand the differences between *M. tuberculosis*, *M. bovis*, and the various BCC daughter strains researchers studied their genomic compositions by performing comparative hybridization experiments on a DNA microarray.¹³⁸

51.5.7 The Biochip for Rapid Clinical Diagnosis

In general, because high-density microarray technologies involve relatively expensive and bulky detection systems, they are useful for laboratory applications but are not appropriate for clinical use in the physician's office. On the other hand, integrated biochip systems, having medium-density arrays (10 to 100 probes) and a miniaturized detection microchip, are most appropriate for medical diagnostics at the point of care, i.e., the physician's office. Recently, an integrated biochip device with a 16-photodiode array was developed and evaluated for the detection of HIV1 gene fragments.^{5,6} This integrated, portable system, described in Section 51.4, is an illustration of the usefulness of the DNA biochip for detection of a specific HIV gene sequence. Actual detection of HIV viruses will require simultaneous detection of multiple gene-sequence regions of the viruses. It has been observed that progression of AIDS causes an increase in the genotype diversity in HIV viruses. HIV viruses appear to defeat the immune system by producing and accumulating these gene mutations as the disease progresses. In this study, a specific DNA-sequence fragment was used as the model system for a feasibility demonstration. Other sequence fragments

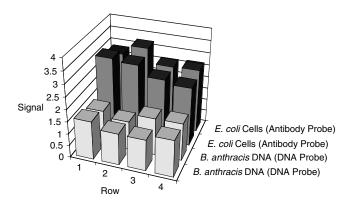

FIGURE 51.9 Detection of *E. coli* and *B. anthracis* using the biochip system. Two rows of the biochip were used for the detection of 1×10^6 *E. coli* cells via Cy5-labeled antibody probes, while the other two rows were used for the detection of the 41.2 pmol *B. anthracis* using Cy5-labeled DNA probes.

of HIV viruses or other pathogens of medical interest, such as the *M. tuberculosis* bacterium or the *p53* cancer gene, have been used on the same biochip.^{5–8}

As noted earlier, biosensors and biochips usually employ only one type of bioreceptor as probes, i.e., either nucleic-acid or antibody probes. Biochips with DNA probes are often called gene chips, and biochips with antibody probes are often called protein chips. An integrated DNA biochip that uses multiple bioreceptors with different functionalities on the same biochip, allowing simultaneous detection of several types of biotargets on a single platform, has been developed.^{8–10} This device is referred to as the MFB.

The unique feature of the MFB is its ability to perform different types of bioassay on a single platform using DNA and antibody probes simultaneously. Figure 51.9 illustrates the detection of E. coli and B. anthracis with the MFB system. Each signal bar of the graph represents the signal acquired with an individual detection element of the 4 × 4 photosensor array. Sensing arrays on half the biochip show the detection of 1×10^6 E. coli cells via Cy5-labeled antibody probes, while the other half detected the 41.2 pmol B. anthracis gene fragment via Cy5-labeled DNA probes. Hybridization of a nucleic-acid probe to DNA biotargets (e.g., gene sequences, bacteria, viral DNA) offers a very high degree of accuracy for identifying DNA sequences complementary to that of the probe. In addition, the MFB's antibody probes take advantage of the specificity of immunological recognition. Figures 51,10 and 51,11 demonstrate the quantitative capability of the biochip in monitoring the immobilization of various biomolecules of medical and environmental interest. Figure 51.10 shows a calibration curve for the detection of a segment of the Bac 816 gene of B. anthracis through hybridization of a Cy5-labeled DNA probe. Figure 51.11 shows a calibration curve for the detection of immobilized E. coli 157:H7. In contrast to the B. anthracis study described above, this screening method involved Ag-Ab interaction, analogous to the Western blot assay. This study demonstrates the feasibility of the MFB for the detection of multiple biotargets of different functionality (DNA, proteins, etc.) on a single biochip platform.

51.6 Conclusion

Rapid, simple, cost-effective medical devices for screening multiple diseases and infectious pathogens are essential for early diagnosis and improved treatments of many illnesses. An important factor in medical diagnostics is rapid, selective, and sensitive detection of biochemical substances or biological pathogens at ultratrace levels in biological samples (tissues, blood, and other body fluids).

In research laboratories, microarray technology enables massive parallel mining of biological data, with biological chips providing hybridization-based expression monitoring, polymorphism detection, and genotyping on a genomic scale. High-density microarray biochips containing sequences representative

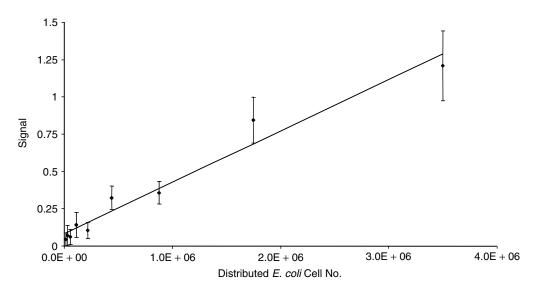

FIGURE 51.11 Calibration curve for the detection of E. coli using antibody probes.

of many human genes may soon permit the expression analysis of the entire human genome in a single reaction. These "genome chips" will provide unprecedented access to key areas of human health, including disease prognosis and diagnosis, drug discovery, toxicology, aging, and mental illness.

At the physician's office, integrated biochip systems offer several advantages in size, performance, analysis capabilities, and cost because of their integrated optical sensing microchip. The small probes (microliter to nanoliter in size) minimize sample requirement and reduce reagent requirements and waste. Highly integrated systems reduce noise and increase signal due to the improved efficiency of sample collection and the reduction of interfaces. The IC technology used in the systems will allow for large-scale production and therefore low cost. The assembly of the various components of the system is made

simple by the integration of several elements on a single chip. For medical applications, this cost advantage will allow for the development of extremely low-cost, disposable biochips that can be used for in-home medical diagnostics of diseases without the need to send samples to a laboratory for analysis.

52.1 Introduction

One of the greatest challenges in human genetics is to systematically identify and classify genetic polymorphisms and elucidate their contribution to human health and disease. During the past 20 years, the genetic components of more than 1000 human monogenetic disorders have been identified. However, many fewer genetic factors important to common polygenic diseases have been identified. These complex disorders result from the cumulative effects of many independent susceptibility loci, none of which alone is either necessary or sufficient to cause disease. Because of this, the classical mapping strategies for monogenetic disorders, particularly linkage studies, have been largely unsuccessful in identifying the principal genetic components of complex diseases.

The analysis of DNA-sequence variation is important, particularly in dissecting the genetic basis of disease and in gauging individual xenobiotic responsiveness.² Several types of DNA variants exist in the human genome: single nucleotide polymorphisms (SNPs), microsatellite markers, and deletions or insertions of single or multiple base pairs. SNPs are highly abundant (on average one per thousand bases) and generally randomly distributed across the genome. By definition the least frequent allele of an SNP occurs in 1% or more of the population, while disease markers may have a much lower frequency.³⁻⁷ The International SNP Map Working Group has recently introduced a high-density map of publicly available SNPs with the aim of providing a public resource to support human population genetic studies and to help in the identification of diagnostic and therapeutic targets for common diseases.⁸

The human genome is estimated to contain more than 3 million SNPs³⁻⁶ and, as of August 2001, 2.98 million SNPs have been deposited into the public database, dbSNP, at the National Center for Biotechnology Information (http://www.ncbi.nlm.gov/SNP). This collection includes 1.79 million nonredundant

SNPs, making this an extremely useful set of markers for a wide range of genetic studies. In particular, genotyping large numbers of SNPs in linkage or large-scale association studies is expected to provide sufficient power to detect susceptibility loci with weak penetrance in complex disease traits including common human diseases and altered drug responses. For example, high-density SNP analysis would be useful in studies to identify contributions of individual genetic polymorphisms to complex diseases such as diabetes in which many genes have some influence. New drug targets and informative genetic diagnostic tests are expected to emerge from studies of this type. However, improved technologies capable of genotyping large numbers of SNPs across large sample sets accurately, rapidly, and cost-effectively are needed to make these studies feasible.

Short tandem repeat (STR) sequences, also known as microsatellite polymorphisms, are another type of informative DNA-sequence variation. STRs consist of tandemly repeated DNA-sequence elements (2 to 5 bp) that are highly polymorphic and widely distributed throughout the human genome. These characteristics have made them ideal tools for genomic mapping and for individual identification where they have been widely applied in paternity and forensic analysis. A human microsatellite map including more than 9000 STR markers is now available. Similar maps are appearing for other organisms and have become the basis for "quantitative trait locus" (QTL) mapping, a method that can reveal levels of genetic complexity underlying observed morphological and behavioral traits. New generations of geneticanalysis devices, including instruments and methods capable of performing sensitive, high-resolution, high-throughput STR separations, will support these and future STR-based studies.

Traditionally, slab-gel electrophoresis has been widely used as an analytical technique to study genetic variation. However, increasing demand for high-throughput genotyping requires fast, parallel, high-resolution analysis of multiple targets and multiple samples. The performance of slab-gel systems is limited in throughput because they provide relatively slow separations and require significant manual intervention; thus, they do not meet current requirements. By comparison, capillary electrophoresis (CE) eliminates manual gel pouring and sample-loading steps and offers excellent separation speed and resolution. High-throughput CE analyses are possible because sample injection and gel loading can be automated and 96 capillaries can be run simultaneously in an array format. Overall throughput can be further improved by using multiplexed assay formats; for example, dyes with different fluorescence emission wavelengths to discriminate targets can be combined in a single analytical run. In the present paper, we will summarize array-based genotyping technologies and describe in particular plastic microfluidic device technology as it may be applied to achieve high-throughput screening of SNPs and STRs.

52.2 Array-Based Technologies

Array technologies are driven primarily by the need to increase throughput and automation while reducing costs by limiting consumption of expensive reagents. System miniaturization and integration are the enabling technologies that provide accurate, fast analysis of large sample sets while providing cost reduction. Array technologies provide increased throughput by increasing either the number of samples that can be analyzed simultaneously (e.g., capillary array electrophoresis) or per-sample information content (e.g., microarrays).

Oligonucleotide microarray technology enables genomic research and potentially diagnostic applications since it provides a means of simultaneously analyzing thousands of DNA sequences. DNA microarrays or DNA chips are libraries of synthetic oligonucleotides or PCR products generated form cDNA attached to a substrate such as coated glass, silicon, or plastic or nylon membranes. Arrays are organized in such a way that each sequence has a defined location. Microarrays can be used in applications that require the sequence-specific detection of nucleic acids such as gene-expression profiling and SNP scoring. There are four general types of commercially available arrays: printed filter arrays, printed glass slide arrays, *in situ* synthesized oligonucleotide arrays, and electronically addressable chip arrays. In addition, equipment and reagents for producing printed arrays are commercially available, and detailed protocols for microarray printing can be found on the Web (e.g., http://cmgm.stanford.edu/pbrown/). For a review of the available instrumentation and associated technology used to produce arrays, see Reference 12.

After hybridization, microarrays are scanned to measure the relative abundance of labeled target hybridized to complementary immobilized probes. Typical protocols for hybridizing filter arrays require that the hybridization targets (DNA or RNA) be labeled with radioisotopes, such as ³³P, which can be detected using a PhosphorImager* (Molecular Dynamics, Sunnyvale, CA) or x-ray film. Targets hybridized to plastic- or glass-slide arrays are typically labeled with one or more fluorescent dyes. Labeling methods incorporating multiple fluorescent dyes, coupled with high-resolution imaging, offer the advantage of measuring comparative signal abundance, allowing relative quantitation measurements to be made more accurately, as spot-to-spot signal variation can be normalized. In this way, more representative quantitation can be assessed for each of the hundreds to thousands of probes represented in the array.

Microarrays are valuable tools for surveying the "big picture" for biological processes by simultaneously looking at the interactions of multiple genes or polymorphisms. However, typically only one sample is processed per array analysis, and therefore large numbers of hybridization arrays are needed for most genetic association studies. In contrast, capillary array electrophoresis (CAE) provides two-dimensional multiplicity, as many measurements may be made in parallel on many samples.

The mobility-based separation mechanism of gel electrophoresis is broadly applicable to the analysis of a wide range of molecules including proteins and nucleic acids. A practical solution to the need for high-throughput analyses using CE was provided by the introduction of CAE in 1992 by Huang et al.¹³ In CAE, individual capillaries are loaded independently but bundled together for parallel, simultaneous detection using a scanning detection system that addresses the entire array of capillaries during each analytical run. Generally, small (50- to 100-µm internal diameter, 200-µm outer diameter) gel-filled capillaries are bundled near the array outlet to provide the equivalent of high-density, closely packed "gel lanes." Several CAE systems are now commercially available for medium- and high-throughput genetic analysis. These generally include a high degree of automation (sample loading, electrophoresis, and analysis) and reduced hands-on operator time. ^{12,14}

Sequenom¹⁵ has developed another array format technology that is based on matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) mass spectrometry. This DNA MassArrayTM Technology integrates sample preparation with signal detection and a low level of multiplexing (3 to 5 SNPs per assay) in a fully automated process to support high-throughput SNP analysis. In addition, readout signals can be accurately quantified, which means that DNA sample pooling can be used for estimating the allele frequencies of polymorphic markers to provide an additional degree of efficiency to the process.

In the postgenomic era, the scientific community's appetite for large volumes of biological information is unlikely to diminish, and continually more advanced approaches to high-throughput genetic analysis will be needed. Since CE was demonstrated in microfabricated devices in the early 1990s, ^{16–18} the "labon-a-chip" devices have increased the speed and throughput of genetic analysis by an order of magnitude. The precise control of injected sample plug volumes and the short separation lengths afforded by microfabricated chips relative to standard CE have significantly reduced separation time.¹⁹ Furthermore, chip-based devices provide a single platform to integrate all processing steps from sample preparation through analysis on the same platform and eventually on the same device.

52.3 Plastic Chips and Their Application to Electrophoresis

Many different manufacturing procedures and substrate materials have been investigated for microchip CE-device fabrication. Early devices were constructed using glass or quartz because these substrates are optically transparent and exhibit electroosmotic flow properties similar to those of fused silica. ^{17,20} Glass chips are generally constructed using modified processes developed to manufacture silicon chips. Disadvantages of glass devices include limitations on the geometry of etched features (imposed by the isotropic acid-etch characteristics of glass), the high temperature bonding required for sealing, and the fragile nature of the final device.

While early microfabricated electrophoretic devices used glass or silica as substrates, a few groups began exploring the use of polymeric microstructures. For example, Eckstrom et al.²¹ and Soane and Soane²² described the use of various polymers including fluoropolymers and silicone rubber. The ease

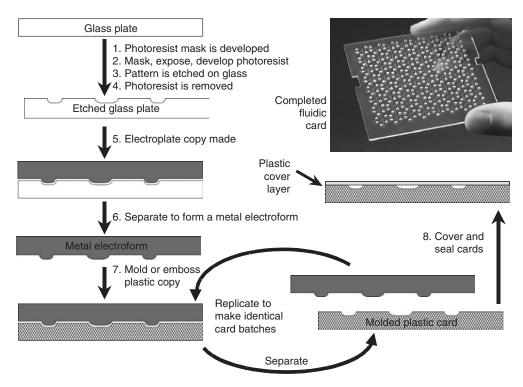

FIGURE 52.1 Plastic LabCard™ device fabrication process.

of fabrication and relatively low cost of devices manufactured from these materials have made them an attractive alternative to optical-quality glass. In particular, there has been growing interest in the application of poly (dimethylsiloxane)-based (PDMS) microchip CE devices.^{23,24} PDMS is a hydrophobic elastomer in which channels can be formed by curing the polymer over a master tool formed with the desired microchip features. Many devices can be replicated from a single master without requiring expensive clean-room facilities. To date, several groups have demonstrated CE-based separations in PDMS microchip devices.^{25–27}

ACLARA Biosciences, Inc. (Mountain View, CA) is a leading developer of plastic microfluidic array technologies, often referred to as "lab-on-a-chip" systems. ACLARA's proprietary technology targets genomic applications (RNA and DNA analysis) and high-throughput pharmaceutical drug screening. Their plastic LabCard™ microfluidic array devices are mass produced and disposable. This allows researchers to rapidly perform large numbers of biochemical measurements in a format that is inexpensive, miniaturized, automated, and free from sample cross-contamination worries.

Use of fabrication technology to manufacture miniaturized channel networks for electrophoresis in thin, plastic substrates is an expertise at ACLARA.²⁸ Microfluidic devices are made of interconnected networks of microchannels and tiny-volume reservoirs. Fluids are transported between reservoirs and through interconnected microchannels using electrokinetic mechanisms. These multichannel plastic LabCard devices are replicated from masters (typically formed in glass, silicon, or nickel) by processes that include injection molding, compression molding, casting, and hot embossing. The master is produced either by direct etching of a material (for example, acid-etching of glass) or, in the case of nickel masters, by electroplating nickel from an aqueous solution directly onto an etched substrate. The latter approach yields a robust master than can be used many thousands of times to produce molded plastic devices. The process flow to generate substrates with high-precision patterns of microsize channel features is illustrated in Figure 52.1.

Confocal laser-induced fluorescence (LIF) is used as a sensitive detection method for separations performed in microchips. The effective rejection of background fluorescence with this approach can

enhance signal-to-noise ratios, especially for plastic microfluidic devices, which frequently contain plasticizers that can yield high fluorescent background signals. Experimental procedures and the instrumental setup for scanning devices have been described in detail elsewhere.²⁹ Briefly, the "breadboard" workstations used include an inverted epifluorescence microscope and custom-built power supplies. A laser or filtered ultraviolet lamp provides the excitation source, while the fluorescent emission is detected by a photomultiplier tube or charge-coupled device (CCD).

52.4 Multiplex STR Analysis

STR polymorphisms are most easily scored by PCR amplification, followed by size separation of amplicons using denaturing electrophoresis. To address increased typing demands in biomedical research and individual identification applications, STR analyses have been converted from slab-gel systems to CE and, more recently, to CAE systems.³⁰ Microfluidic arrays offer additional advantages over traditional CAE analysis of STR markers because separation times can be dramatically reduced. High-throughput, multiplexed STR genotyping has recently been performed in multichannel plastic devices.³¹ Figure 52.2 shows the electrophoretic separation of a multiplexed STR allelic ladder (AmpFLSTR® Blue, Applied Biosystems, Foster City, CA) using a multichannel plastic LabCard device. The high-resolution separation (to 300 bp) was complete in less than 10 min, much faster than typically achieved by standard CE, CAE, or slab-gel electrophoresis.

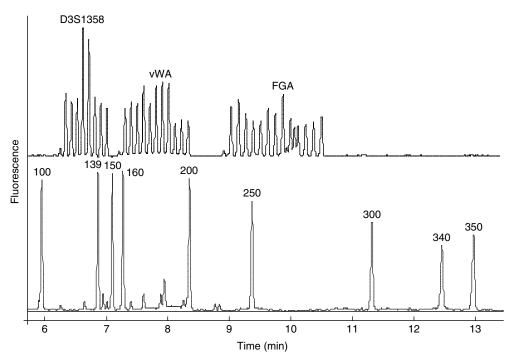

FIGURE 52.2 Simultaneous, two-color separation of three STR loci and migration standard in a 32-channel plastic LabCard[™] device. The AmpFLSTR® Blue allelic ladder standard for D3S1358, vWA, and FGA (upper panel) was combined with a comigrating sizing standard, GeneScan®-350 ROX[™] (Applied Biosystems) (lower panel) and analyzed simultaneously using a plastic LabCard device. The separation matrix used was 4% (w/v) linear polyacrylamide with 7 M urea in 1 × TTE buffer. Separation was performed at 160 V/cm and 33°C with a separation length to the detector of 4.5 cm. Fluorescent signal was measured with a laser-induced fluorescence detector, as outlined in the text. Electropherograms were plotted and analyzed using DA × 7 (Van Mierlo Software Consultancy, Eindhoven, the Netherlands). The STR sample was separated in less than 10 min. (Data courtesy of Yining Shi, ACLARA Biosciences, Inc., Mountain View, CA.)

52.5 Multiplex SNP Detection

A variety of methodologies and platforms currently exist for detecting SNPs present in genomic DNA.³² Most methods begin with polymerase chain reaction (PCR) for DNA target amplification to provide enough DNA for detection. More recently, significant progress has been made in detecting and measuring the abundance of target sequences using "real-time" PCR.³³ SNP detection using real-time amplification monitors accumulation of individual PCR products as they are synthesized and fluorescently labeled during the amplification reaction. Three basic real-time PCR product-detection methods exist: (1) labeling double stranded DNA (dsDNA) using intercalating dyes, (2) generating fluorescence-energy transfer during amplification (also known as the FRET approach), and (3) releasing quenched fluorescence during amplification (such as the Taqman® approach).

Higuchi et al.³⁴ first demonstrated the real-time PCR using ethidium bromide as a reporter. A variety of dyes are known to exhibit increased fluorescence upon binding to dsDNA. This detection method is used in conjunction with the specific amplification of wild type or mutant allele by the amplification refractory mutation system (ARMS).³⁵ The fluorescence of wild-type or mutant PCR products are continuously monitored in parallel, allele-specific reactions using ethidium bromide or SYBR® dyes (Molecular Probes, Eugene, OR), which bind to the accumulating PCR product and generate a proportional fluorescent signal. One drawback of this method is that the nonspecific binding of the dyes to proteins, residual primers, or spurious PCR products can result in false positive results or high backgrounds.

The fluorescence resonance energy transfer (FRET) technique relies on the binding of two differentially labeled fluorescent DNA probes to the target sequence. The close proximity of the two dyes on the adjacent, hybridized probes increases resonance-energy transfer from one dye to the other, leading to a unique fluorescence signal. Mismatches caused by SNPs that disrupt the adjacent binding of either of the probes results in signal loss that can be used to detect mutant sequences present in a DNA sample.³⁶ Alternatively, signal of a dual-labeled FRET probe may be quenched in free solution but detectable with allele-specific hybridization. This approach to probe design is the principle exploited in "molecular beacon" assays.

Real-time fluorescence detection of PCR-amplified products can also be accomplished using the TaqMan® assay method (Applied Biosystems).^{37,38} In this assay, probes labeled at the 5'-end with a fluorescent reporter dye and at the 3'-end with a quencher dye bind specifically to the PCR product. The 5'-3' exonuclease activity of thermostable polymerases, such as *Taq* DNA polymerase, removes the 5' dye during PCR, releasing the fluorescence from quenching. For SNP scoring, two allele-specific probes (TaqMan probes), each labeled with a different fluorescent reporter dye, are used to discriminate between alternative alleles.

The TaqMan assay design is difficult to multiplex due to the limited combination of reporter and quencher dyes and the overlapping fluorescent emissions of these dye sets. A new class of reporter molecules called eTagTM (electrophoretic mobility tag) reporters has been developed at ACLARA that allow multiplex SNP scoring in 5′-nuclease-based assays, such as TaqMan. eTag reporters are fluorescent molecules with unique mobility signatures under defined electrophoretic separation conditions. Capillary instruments and microchannel devices can be used as readout platforms for assays incorporating eTag reporter technology. These reporter molecules are released from hybridized oligonucleotide probes by enzymatic cleavage. Subsequently, released eTag reporters are electrophoretically separated and decoded based on migration time to identify the targets present in the original DNA sample.

An example of a multiplexed SNP assay using TaqMan and eTag reporter-labeled, allele-specific probes is illustrated in Figure 52.3. Large families of generic reporters are being developed and are ideally suited to electrophoretic analysis. The eTag reporter strategy for multiplexing assays provides a method for detecting one or more target nucleic-acid sequences in a mixture because the labels give each target a unique electrophoretic signature. This biochemistry can be integrated with microfluidic-based LabCard systems to provide high-throughput, multiplexed SNP genotyping.

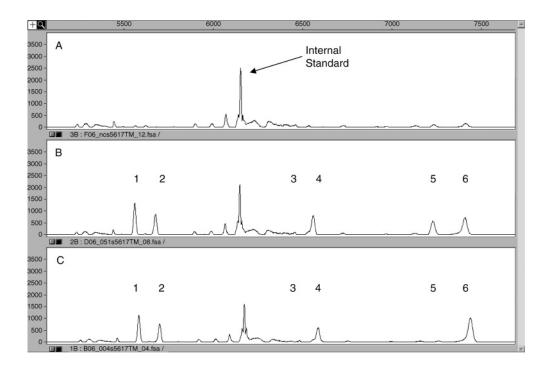

FIGURE 52.3 Electropherogram illustrating the results of a multiplexed SNP assay using the eTag reporter technology in a TaqMan assay format. A water blank served as a negative control (panel A), and two different human genomic DNA samples were analyzed (panels B and C). The six eTag reporter labels were detected by CAE using an ABI Prism® 3100 genetic analyzer. Migration position of enzymatically released reporters relative to the internal Rox-dye standard permits genotype identification. The polymorphisms evaluated using allele-specific probes were ApoB Thre71Ile, ApoB Arg3500Gln, and CETP Ile405Val, where peak 1 = ApoB Ile71, peak 2 = ApoB Thre71, peak 3 = ApoB Gln3500, peak 4 = ApoB Arg3500, peak 5 = CETP Val405, and peak 6 = CETP Ile405. Sample DNA in panel B was heterozygous for ApoB Thre71Ile (1, 2) and CETP Ile405Val (5, 6) and homozygous for ApoB Arg3500Gln (4, 4). DNA sample in panel C was heterozygous for ApoB Thre71Ile (1, 2) and homozygous for both ApoB Arg3500Gln (4, 4) and CETP Ile405Val (6, 6).

52.6 Conclusion

High-throughput genetic analysis can be achieved in plastic microfluidic chips. Aside from SNP and STR scoring, additional applications, including gene-expression analysis, dsDNA fragment separation, and DNA sequencing,²⁸ as well as protein separation,³⁹ have also been demonstrated. In the future, fully integrated LabCard devices employing interfacing structures to allow complete sample-to-answer testing, the true "lab-on-a-chip" devices, will be possible using some of the assay formats described in this chapter.

Acknowledgments

The authors thank Tracy Matray and colleagues for kindly providing eTag reporter-labeled probes and Yining Shi for his work on the microchannel separations of STR allelic ladders.

53.1 General Considerations

53.1.1 What Is DNA?

53.1.1.1 Organization of Genome

The blueprint for all cellular structures and functions is encoded in the genome of any organism. The genome consists of deoxyribonucleic acid (DNA), which is tightly coiled into narrow threads that, when completely stretched, reach a length of approximately 1.5 m yet possess a width of only \sim 2.0 nm (2 × 10⁻⁹ m). The threads of DNA are typically associated with many different types of proteins and are organized into structures called chromosomes that are housed within the nucleus of cells in most eukaryotic organisms. There are 23 pairs of chromosomes within the human genome.

DNA is composed of several different chemical units: a deoxyribose sugar unit, phosphate group, and one of four different nucleotide bases (adenine [A], guanine [G], cytosine [C], or thymine [T]). At the molecular level, it is the order of these bases that carries the code to build proteins within the cell that inevitably control the function of various cells and also determine an organism's physical characteristics. In the human genome, the 23 pairs of chromosomes contain 3 billion bases. The length of the chromosomes

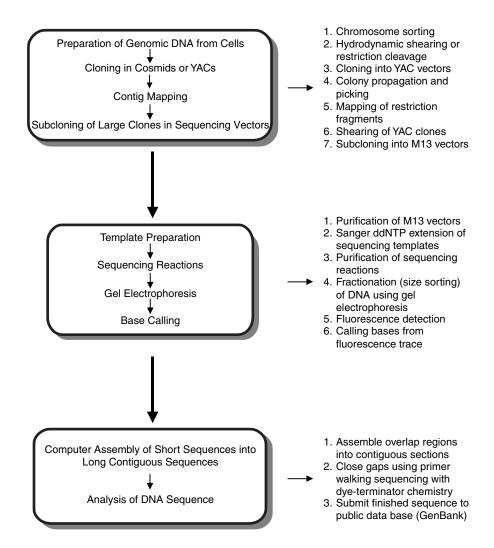

FIGURE 53.1 Flow chart showing the processing steps typically involved in sequencing DNA starting with isolating genomic DNA from cells.

(in base pairs) varies greatly, with the smallest chromosome containing 50 million bases (chromosome Y) and the longest containing 250 million bases (chromosome 1). It is the primary function of DNA sequencing to determine the order of these nucleotide bases.

53.1.1.2 Functions of Genes

The coding regions (regions that carry the information for the construction of proteins) of the genome are contained within genes. Each gene consists of a specific sequence of nucleotide bases, with three nucleotide bases (codon) directing the cells' protein-synthesizing machinery to add a specific amino acid to the target protein. It is estimated that within the human genome are approximately 30,000 genes, with the length of the genes varying greatly. However, only approximately 10% of the human genome is thought to contain protein-coding sequences.

53.1.2 What Is DNA Sequencing?

Figure 53.1 shows a flow chart depicting the important steps involved in the process of DNA sequencing. There are three primary steps — mapping, sequencing, and assembly. Within each of these three general steps are a number of substeps, which include such processes as cloning and subcloning (mapping), template preparation and gel electrophoresis (sequencing), and the computer algorithms required to assemble the small bits of sequencing data into the contiguous strings that comprise the intact chromosome. Each chromosome may consist of hundreds of millions of nucleotide bases; unfortunately, the sequencing phase of the intricate process can handle only pieces of DNA that vary from 1000 to 2000 base pairs (bp) in length. Therefore, the chromosome must typically be broken down into manageable pieces using either restriction enzymes or mechanical shearing and then cloned into bacterium to increase the copy number of the individual pieces of DNA. Following sequencing of each cloned fragment the individual pieces must be reassembled into a contiguous strand representing the entire chromosome. This process typically involves sophisticated computer algorithms to search for commonalties in the small fragments and overlap them to build the sequence of the entire chromosome.

53.1.2.1 DNA-Sequencing Factories

To accomplish the lofty goal of sequencing the entire human genome, sequencing factories have been assembled to produce large amounts of data and deposit these data into public databases for easy accessibility by the general scientific and medical communities. One such production-scale sequencing center is the Human Genome Sequencing Center at the Baylor College of Medicine (www.hgsc.bcm.tmc.edu). Some statistics on this particular sequencing center help put the sequencing demands into perspective. As of May 1999, the center had deposited over 26 Mbp (26×10^6 bp, 0.7% of the human genome) of sequence data into the public databases; in addition, the center typically runs approximately 14 automated fluorescence-based DNA-sequencing machines 12 h a day. This amounts to 50,000 sequencing reactions a month.

This chapter focuses on the sequencing phase of the genome-processing steps. It is this particular step on which fluorescence — both hardware and probe development — has had a profound impact in terms of augmenting the throughput of acquiring sequencing data. We begin by briefly introducing (or refreshing) the reader to the molecular and geometrical structure of DNA and then review the common schemes used to sequence DNA. We also discuss the various electrophoretic modes for fractionating DNA based on size, an integral component in high-throughput sequencing. We then examine common strategies of fluorescence detection used in many sequencing machines; our discussion includes hardware and probe (labeling-dye) developments.

53.1.3 Structure of DNA

53.1.3.1 Nucleotide Bases

As stated in the previous section, the basic building blocks of DNA are a deoxyribose sugar unit, a phosphate group, and the nucleotide base, of which there are four; when combined chemically, these building blocks form an individual nucleotide. Figure 53.2 shows the chemical structure of the four nucleotide units that comprise DNA. The bases are grouped into two different classes — the pyrimidines (T, C) and the purines (A, G). In the case of ribonucleic acid (RNA), the structural differences include the incorporation of a ribose sugar (inclusion of a hydroxyl group at the 2' position) and also the substitution of uracil for thymine.

Since DNA — more specifically, chromosomes — is composed of many of these individual nucleotide units strung together, the nucleotides are covalently attached via phosphodiester linkages, which occur between the phosphate group on the 5' site of one sugar unit and the 3' hydroxyl group on another nucleotide (see Figure 53.2). Therefore, DNA exists as a biopolymer, with the repeating units being deoxyribose and phosphate residues that are always linked together by the same type of linkage and form the backbone of the DNA molecule. However, the order of bases along the biopolymer backbone can vary greatly and imparts a high degree of individuality to any particular DNA molecule.

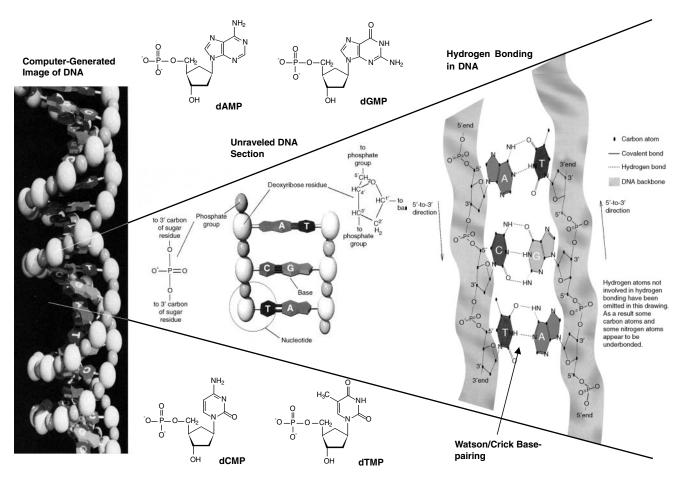

FIGURE 53.2 Chemical structures of deoxyribonucleic acid (DNA). The computer image shows the double-helical nature of DNA. Also shown are the hydrogen bonding between nucleotide bases (Watson–Crick base pairing) and the structures of the nucleotide building blocks.

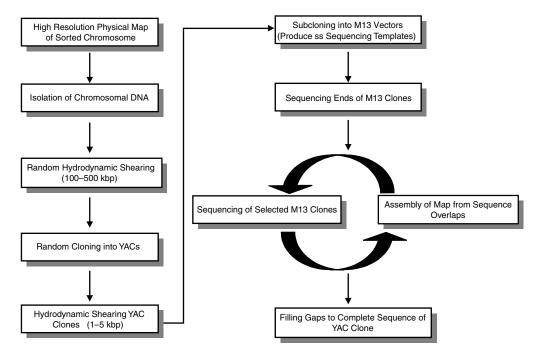

FIGURE 53.3 Processing flow chart of ordered shotgun sequencing of DNA.

53.1.3.2 Watson-Crick Base Pairing

The three-dimensional structure of DNA is known to differ greatly from that of proteins, which are also biopolymers composed of different amino acid residues. In 1953, James Watson and Francis Crick discovered that DNA existed in a double-helical structure (see Figure 53.2), with the sugar-phosphate backbone oriented on the outside of the molecule and the bases positioned on the inside of the double helix. They also surmised that the two strands of the double-stranded molecule were held together via hydrogen bonds between a pair of bases on opposing strands. From modeling, they found that A could pair only with T and C with G (see Figure 53.2). Each of these base pairs possesses a symmetry that permits it to be placed into the double helix in two different ways (A to T and T to A; C to G and G to C). Thus, all possible permutations (four) of sequence can exist for all four bases. In spite of the irregular sequence of bases along each strand, the sugar–phosphate backbone assumes a very regular helical structure, with each turn of the double helix composed of ten nucleotide units.

53.1.4 Methods for Determining the Primary Structure of DNA

The important factor to consider when developing a sequencing strategy for whole genomes is to remember that only small sections (1000 to 2000 bp) of DNA can be sequenced and that entire chromosomes are composed of well over 1×10^6 bp. The actual process of generating DNAs that can be handled by sequencing machines is typically involved and requires a number of cloning and purification steps followed by actual sequencing and then assembling the pieces into contiguous regions of the target chromosome. While this chapter does not cover these specific processes, Figure 53.3 provides a schematic diagram of a typical strategy used in many sequencing laboratories. This strategy is termed an ordered shotgun approach and starts with the mechanical shearing (breaking apart) of intact chromosomes into pieces composed of 100,000 to 200,000 bp. 2 These sheared DNAs are then cloned into yeast artificial chromosomes (YACs), one sheared section per YAC that allows one to amplify the number of copies of the insert. Cloning provides an unlimited amount of material for sequencing and serves as the basis for construction of libraries, which are random sets of cloned DNA fragments. Genomic libraries are sets of

overlapping fragments encompassing an entire genome. Once these libraries have been constructed, single inserts are extracted from the library and further sheared into fragments ranging from 1000 to 2000 bp. These fragments are then subcloned into M13 vectors to produce high-quality single-stranded DNAs (ssDNAs) appropriate for actual sequencing. Typically, M13 subclones are sequenced from both ends to allow construction of maps of the single YAC inserts, which are then used to provide a scaffold for the complete sequence analysis of the YAC insert. The important procedures that are the focus of this chapter are those that are actually used to produce the sequence data of the M13 subclones. The two most common procedures are the Maxam–Gilbert chemical degradation method and the Sanger dideoxychain-termination method.^{3,4} Both of these methods have in common the production of a nested set of fragments, all of which are terminated (cleaved) at a common base or bases.

53.1.4.1 Maxam-Gilbert DNA Sequencing

The Maxam–Gilbert sequencing method uses chemical cleavage methods to break ssDNA molecules at either one or two bases, followed by a size fractionation step to sort the cleaved products. The cleavage reaction involves two different reactions — one that cleaves at G and A (purine) residues and the other that cleaves at C and T (pyrimidine) residues. The first reaction can be slightly modified to cleave at G only and the second at T only. Therefore, one can run four separate cleavage reactions — G only, A + G, T only, A + G only, A + G

The chemical steps involved in G cleavage are shown in Figure 53.4A. In this step, dimethylsulfate is used to methylate G. After eviction of the modified base via heating the strand is broken at the exposed sugar by subjecting the DNA to alkali conditions. To cleave at both A and G residues, the procedure is identical to the G cleavage reaction except that a dilute acid is added after the methylation step (see Figure 53.4B). The reaction that cleaves at either a C or C and T residue is carried out by subjecting the DNA to hydrazine to remove the base and piperidine to cleave the sugar—phosphate backbone. The extent of each reaction can be carefully limited so that each strand is cleaved at only one site.

Figure 53.4C depicts the entire Maxam–Gilbert process. As shown in the figure, four cleavage reactions are run — G, G + A, T, T + C. Prior to chemical cleavage, the intact DNA strand is labeled (typically with a 32 P radiolabel for detection at the 5′ end). Following chemical cleavage the reactions are run in an electrophoresis gel (polyacrylamide) and separated based on size. The actual sequence of the strand is then deduced from the generated gel pattern.

53.1.4.2 Sanger Chain-Termination Method

Unlike the Maxam–Gilbert method, the Sanger procedure is an enzymatic method and involves construction of a DNA complement to the template whose sequence is to be determined. The complement is a strand of DNA that is constructed with a polymerase enzyme, which incorporates single nucleotide bases according to Watson–Crick base-pairing rules (A–T, G–C) (see Figure 53.5). The nested set of fragments is produced by interrupting the polymerization by inserting into the reaction cocktail a base that has a structural modification — the lack of a hydroxyl group at the 3′ position of the deoxyribose sugar (dideoxynucleotide, ddNTP). Figure 53.5A shows the chemical structure of a ddNTP. When mixed with the deoxynucleotides (dNTP), the polymerization proceeds until the ddNTP is incorporated.

Figure 53.5C shows the entire Sanger chain-termination protocol. The process is typically carried out by adding to the template DNA a primer that has a known sequence and anneals (binds) to a complementary site on the unknown template. This primer can carry some type of label, e.g., a covalently attached fluorochrome. However, situating the fluorescent label on the ddNTP can be done as well. Following annealing of the primer to the template, the reaction is carried out by the addition of a polymerase enzyme, all four dNTPs, and one particular ddNTP. Therefore, four reactions are carried out, each containing a particular ddNTP. Following polymerization, the reactions are loaded onto an electrophoresis gel and size-fractionated. The final step involves reading the sequence from the gel.

The Sanger method has been the preferred sequencing method for most large-scale sequencing projects because of the ease with which it prepares the nested set of fragments. Many times reactions can be run

under standard conditions without the need for chemical additions at timed intervals. In addition, the process is very conducive to automation.

53.1.5 Modes of Electrophoresis

Whatever fluorescence detection protocol is used for calling bases, the important analytical technique that is required is a fractionation step in which the DNA molecules are sorted by size. While the focus of this chapter is on fluorescence-based detection in sequencing applications, it is informative to briefly discuss some of the common gel electrophoresis platforms that are used because the fluorescence detector is integrated into the sizing step to provide online detection.

All electrophoresis formats have in common the use of an electric field to shuttle the DNAs through a maze consisting of a polymer, either static or dynamic, with pores of various sizes. In all electrophoresis experiments, the mobility of the molecule (μ , cm²/Vs, defined as the steady-state velocity per unit electric-field strength) in an electric field is determined by:

$$\mu = \frac{q}{f} \tag{53.1}$$

where q is the net charge on the molecule, and f is the frictional property of the molecule and is related to its conformational state as well as the molecular weight (MW) of the molecule. For example, proteins can be considered solid spheres; thus, $f \sim (MW)^{1/3}$. In the case of DNAs, either single-stranded or double-stranded, $f \sim (MW)^1$ because the DNA molecule acts as a free-draining coil. Since q is also related to the length of the DNA molecule, one $\mu \sim N_b^0$, where N_b^0 indicates that the mobility (in free solution) is independent of the number of bases comprising the DNA molecule. Because of this property of DNAs, the electrophoresis step must include some type of sieving medium, which can be a polymer consisting of pores with a definitive size.

For any type of analytical separation resolution is a key parameter that is optimized to improve the performance of the separation. The resolution *R* for electrophoretic separations can be calculated from the simple relationship:

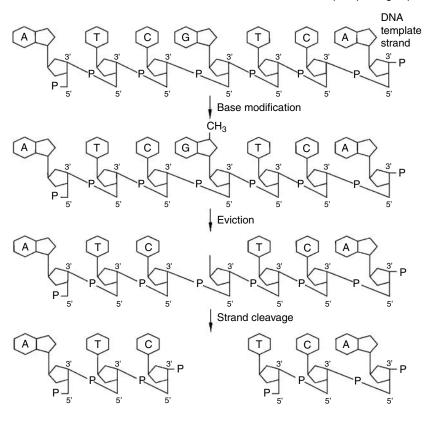

$$R = \frac{1}{4} \frac{\Delta \mu_{\text{app}}}{\mu_{\text{app,avg}}} N^{1/2}$$
 (53.2)

where $\Delta\mu_{app}$ is the difference in mobility between two neighboring bands, $\mu_{app,avg}$ is the average electrophoretic mobility for the same neighboring bands, and N is the plate number, which represents the efficiency (bandwidth) for the electrophoresis. This equation shows that the resolution can be improved by increasing the difference in the mobility of the two bands (increase selectivity, gel property) or increasing the plate numbers (narrower bands). As a matter of reference, when R=0.75, two bands are baseline resolved. For DNA sequencing, the accuracy in the base call depends intimately on the resolution obtained during gel fractionation.

A common polymer used for DNA sequencing is linear or crosslinked polyacrylamides or polyethylene oxides, both of which possess the appropriate pore size for sorting ssDNAs. Polyacrylamides are prepared from the acrylamide monomer ($-CH_2 = CHCONH_2$), which is copolymerized with a certain percentage of crosslinker, N,N'-methylene-bis-acrylamide ($-CH_2(CHCOCH = CH_2)_2^-$), in the presence of a catalyst accelerator-chain-initiator mixture. The porosity of the gel is determined by the relative proportion of acrylamide monomer to crosslinking agent. For reproducible fractionation of DNAs, they must be maintained in a single-strand conformation, which is accomplished by adding denaturants, such as urea or formamide, to the sieving gel.

The existence of a gel network contributes significantly to the electrophoretic migration pattern (i.e., electrophoretic mobility) observed in the sequencing process. Any DNA fragments to be fractionated will inevitably encounter the gel network of polymer threads. This encounter increases the effective

Dimethylsulfate is used to methylate guanine. After eviction of the modified base, the exposed sugar, deoxyribose, is then removed from the backbone. Thus the strand is cleaved in two.

В

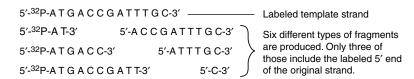

FIGURE 53.4 Maxam—Gilbert chemical degradation method for DNA sequencing. (A) Chemical cleavage method for a guanine residue using dimethylsulfate to methylate the G residue. (B) Fragments generated from chemical cleavage at only G.

friction and, consequently, lowers the velocity of movement of the molecules. It is obvious that the retardation will be most pronounced when the mean diameter of gel pores is comparable to the size of the DNA fragments. Size therefore plays a critical role in determining the relative electrophoresis mobility and the degree of separation of different DNA fragments. It is this sieving effect that partly determines the resolution obtained with polyacrylamide gels. The gel network also minimizes convection currents caused by small temperature gradients.

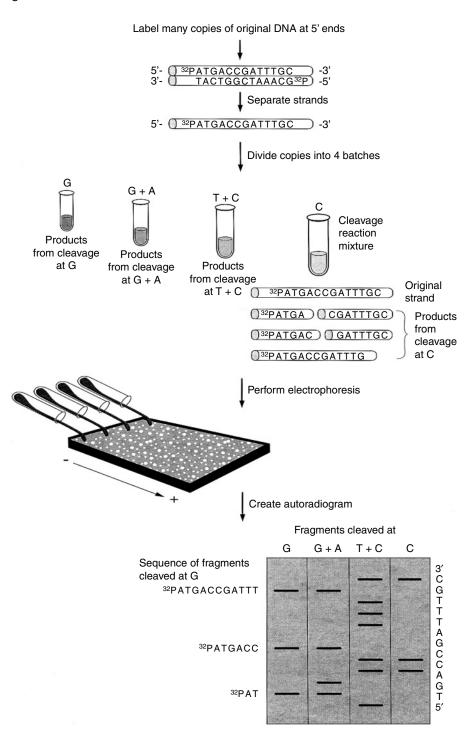

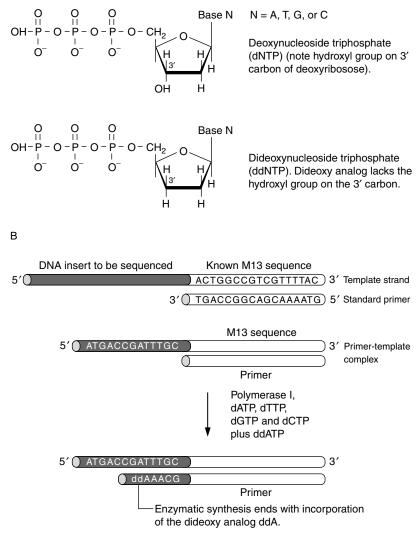

FIGURE 53.4 (continued) Maxam–Gilbert chemical degradation method for DNA sequencing. (C) Steps in Maxam–Gilbert sequencing.

Incorporation of ddATP rather than dATP is random so all possible strands ending at ddATP are synthesized in the reaction.

FIGURE 53.5 Sanger chain-termination DNA-sequencing method. (A) Chemical structures of a dNTP and also a ddNTP that lacks a hydroxyl group on the 3' site of the deoxyribose sugar. (B) Chain-termination reaction with ddATP. Also shown is primer annealing to the template, which is directed by Watson-Crick base-pairing rules.

The main characteristic property of DNA is that the value of the negative charge on the molecule is almost independent of the pH of the medium. Therefore, their electrophoretic mobility is due mainly to differences in molecular size, not in charge. For a particular gel, the electrophoretic mobility of a DNA fragment is inversely proportional to the logarithm of the number of bases — up to a certain limit. Since each DNA fragment is expected to possess a unique size, its electrophoretic mobility is unique, and it migrates to a unique position within the electric field in a given length of time. Therefore, if a mixture of DNA fragments is subjected to electrophoresis, each of the fragments would be expected to concentrate into a tight migrating band at unique positions in the electric field.

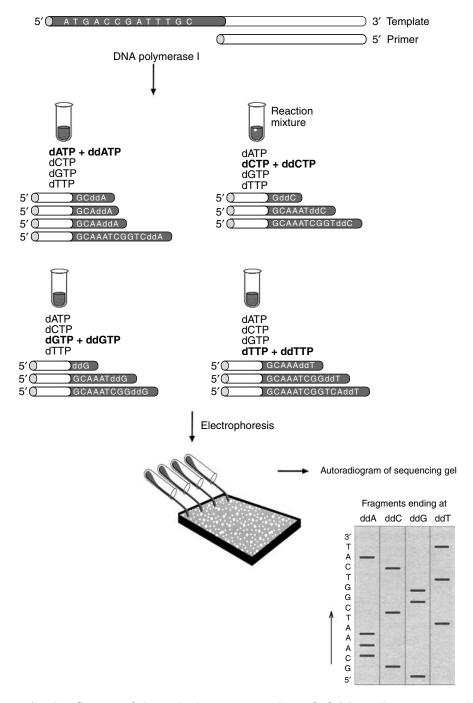

FIGURE 53.5 (continued) Sanger chain-termination DNA-sequencing method. (C) Steps in Sanger sequencing.

53.1.5.1 Slab-Gel Electrophoresis

DNA sequencing is usually performed with slab gels. In slab gel electrophoresis (SGE), polymerization of acrylamide as well as the electrophoresis are conducted in a mold formed by two glass plates with a thin spacer. When analytical electrophoresis is performed, several samples are usually run simultaneously in the same slab. Since all samples are present in the same gel, the conditions of electrophoresis are quite constant from sample to sample. In SGE the sample is loaded using a pipette into wells formed into the gel during polymerization. A loading volume of 1 to 10 μ l is typical for SGE. The field strength that can be applied to these types of gels ranges from 50 to 80 V/cm, with the upper limit determined by heating (Joule) caused by current flow through the gel. Due to the thick nature of the gel, this heat is not efficiently dissipated, causing convective mixing and thus zone broadening, which limits the upper level on the electric field strength that can be effectively used.

53.1.5.2 Capillary-Gel Electrophoresis

To reduce the development time in the electrophoresis, many sequencing applications now use capillarygel electrophoresis (CGE), in which a glass tube (i.d. = 50 to 100 μm; length = 30 to 50 cm) contains the gel-sieving matrix, and an electric field is applied to this capillary column. Due to the higher surfaceto-volume ratio afforded by the thin glass capillary, large electric fields can be applied (~300 V/cm), which results in shorter electrophoresis development times (2 to 3 h) and also enhanced plate numbers compared to SGE. The glass capillary contains silanol groups on its surface, which at high pH are deprotonated. As such, the glass capillary is negatively charged above pH = 7.0. Cations in the electrolyte solution buildup at the wall of the glass tube, producing an electrical double layer. When a voltage is applied across the capillary, the cations migrate to the wall and exert a force on the surrounding fluid, causing a bulk flow of solution toward the cathode (negative terminal). This electrically induced flow is called an electroosmotic flow and, unfortunately, can interfere with the electrophoresis of the DNAs. Therefore, in DNA separations using glass capillaries, the wall is coated with some type of polymer (e.g., a linear polyacrylamide) to suppress this electroosmostic flow. After the wall is coated, the capillary can then be filled with the sieving gel, which can be a linear polyacrylamide (no cross linking) or some other type of gel, such as a hydroxyl cellulose of poly (ethylene oxide).⁵ In addition, crosslinked gels may also be used in these small capillaries, but since crosslinked gels are not free flowing like their noncrosslinked counterparts, they must be polymerized directly within the capillary tube. Most capillary-based DNA sequencers use linear gels because they can be easily replaced using high-pressure pumping, which allows the capillary to be used for multiple sequencing runs. Once polymerized, the crosslinked gels cannot be removed from the capillary.

The electrophoresis is performed after the column is filled with the gel by inserting one end of the capillary into a sample containing the sequencing mix and applying an electric field to the capillary tube. The injection end is typically cathodic (negative), with the opposite end being anodic (positive). By applying a fixed voltage for a certain time period, a controlled amount of sample can be inserted into the column, with the injection volume ranging from 1 to 10 nl. Since the capillary is made of fused silica, fluorescence detection can be performed directly from within the capillary tube. In most cases, the capillary column is coated with a polyimide coating (nontransparent) to give it strength, and the optical detection window can be produced by simply burning off a section of the polymer using a low-temperature flame.

The higher plate numbers (i.e., better resolution) that are obtained in CGE vs. SGE are a direct consequence of the ability to use higher electric fields. Since development time is significantly shorter in CGE due to the ability to apply higher electric fields, band spreading due to longitudinal diffusion is reduced, resulting in higher plate numbers. The ability to use higher electric fields in CGE results from the fact that Joule heating is suppressed because the heat can be effectively dissipated by the high-surface-to-volume-ratio capillary.

53.1.6 Detection Methods for DNA Sequencing

53.1.6.1 Autoradiographic Detection

Following electrophoresis, the individual DNA bands separated on the gel must be detected and subsequently analyzed. One of the earlier methods implemented to detect DNA bands in gels was autoradiography. In this mode, one of the phosphates of an individual nucleotide is replaced with a radioisotope, typically 32 P ($\tau_{1/2} = 14$ d) or 35 S ($\tau_{1/2} = 87$ d), both of which are radioprobes that emit β -particles. When Sanger methods are used to prepare the sequencing reactions, either the primer or the dideoxynucleotide can contain the radiolabel. The labeling is done using an enzyme (T4 polynucleotide kinase), which catalyzes the transfer of a γ -phosphate group from ATP to the 5'-hydroxy terminus of a sequencing primer. After the electrophoresis is run, the gel is dried and then situated on an x-ray film. The film is developed (exposure to radiation from radioprobes), and dark bands are produced on the film where the DNA was resident. The sequence is then read manually from the gel.

The primary advantage of this approach is the inexpensive nature of the equipment required to perform the measurement — basically only a gel dryer, film holder, and film. The difficulties associated with this approach are numerous. One important issue is the fact that radioisotopes are used; therefore, waste disposal becomes a difficult problem. Throughput issues (data-production rates) are also a primary concern with autoradiographic detection. For example, radiography can sometimes require several days to expose the film to get strong signals to read the bases from the gel. In addition, the detection is done after electrophoresis, not during. Also, since there is no means of identifying the individual bases using radioprobes, each base must be analyzed in a different lane of the gel. And finally, the bases must be called manually, which often leads to frequent errors in the sequence reconstruction. Therefore, the inability to obtain data-production rates sufficient to accommodate large sequencing projects has made radiographic detection obsolete for high-throughput applications.

53.1.6.2 Fluorescence Detection

For most DNA-sequencing applications, irrespective of the separation platform used, fluorescence is the accepted detection protocol, for several important reasons. Fluorescence allows one to perform the base calling and detection in an automated fashion and alleviates the need for manual base calling. In addition, fluorescence can be carried out during the separation, eliminating long film-development times. More importantly, because multiple probes possessing unique spectral properties can be implemented, the four bases comprising the DNA molecule can be identified in a single gel lane, potentially increasing throughput by a factor of four vs. radiographic detection. All of these important advantages associated with fluorescence allow for higher throughputs in DNA-sequencing applications. As such, fluorescence can be considered one of the most important recent technical innovations in DNA sequencing and has made it feasible to consider tackling large genome-sequencing projects such as the human genome.

The first demonstrations on the use of fluorescence in DNA sequencing came with the work of Smith et al.,⁶ Prober et al.,⁷ and Ansorge et al.⁸ Slab gels or large gel tubes were used to fractionate the DNA ladders produced during enzymatic polymerization using Sanger sequencing strategies. The fluorescence detection was accomplished using four spectroscopically unique probes, which allowed the DNA-sequence reconstruction to be done in a single electrophoresis lane of the gel. The chemical structures of the dye labels used in the Smith et al.⁶ and Prober et al.⁷ experiments are shown in Figures 53.6 and 53.7, respectively. As shown in the figures, the dyes were attached (covalently) either to the sequencing primer or to the dideoxynucleotides. The advantage of using dye-labeled dideoxynucleotides is that the sequencing reactions can be performed in a single reaction tube, whereas the dye-labeled primer reactions must be performed in four separate tubes and pooled prior to electrophoresis. In the case of the dye-labeled terminators, succinylfluorescein analogs were used with slight structural modifications to alter the absorption/emission maxima. The dyes were attached either to the 5 position of the pyrimidine bases or the 7 position of the 7-deazapurines, both of which are nonhydrogen-bonding sites on the nucleotide

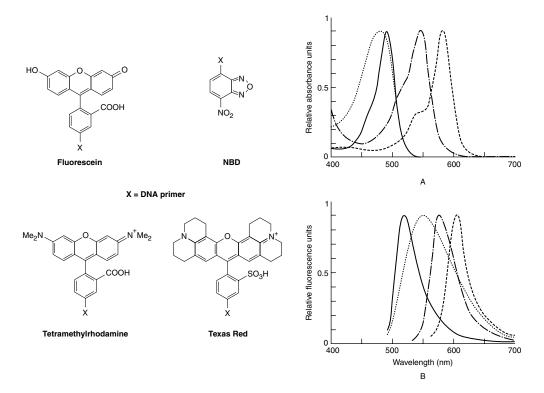

FIGURE 53.6 Chemical structures and absorbance (A) and emission spectra (B) of the dyes used for labeling primers. (Adapted from Smith, L.M. et al., *Nature*, 321, 674, 1986.)

base. The linker structure is also important, which in this case was a propargylamine, because the presence of the dye on the terminator radically affects its ability to be incorporated by the polymerase enzyme. For dye-labeled primers, the oligonucleotides possessing the appropriate sequence were prepared on a standard DNA synthesizer. For Smith et al.⁶ a thymidine derivative was prepared that contained a phosphoramidite at the 3' carbon and a protected alkyl amino group at the 5' carbon (typically a 6-carbon linker structure). During the final addition cycle of the oligonucleotide prepared via solid-phase synthesis using phosphoramidite chemistry, the thymidine residue was added, and, following deprotection of the alkyl amino group and cleavage from the support, a free primary amine group resulted, which can be reacted with any amino-reactive fluorescent dye to produce the oligonucleotide derivative.

Figures 53.6 and 53.7 also show the absorption and emission profiles for the dye sets used in these experiments. The major attributes of the dye sets are that they can be efficiently excited with either 488-or 514.5-nm lines of the argon ion laser. In addition, there is minimal separation between the emission maxima of the dyes, which allows processing of the fluorescence on as few detection channels as possible. However, there is significant overlap in the emission spectra of the four dyes, producing severe spectral leakage into other detection channels, which must be corrected by software.

The optical hardware used to process the four-color fluorescence for both systems is depicted in Figure 53.8. For the Smith et al. experiment,⁶ a single laser and a single detection channel were used; in this case, the detection channel consisted of a multiline argon ion laser and a conventional photomultiplier tube (PMT). Placed in front of the laser and PMT were filter wheels to select the appropriate excitation wavelength (488 or 514.5 nm) and emission color. The filter pairs used during fluorescence readout were 488/520 nm, 488/550 nm, 514/580 nm, and 514/610 nm. In the case of the Prober et al. experiment,⁷ due to the narrow distribution between the excitation maxima of the dyes only excitation using the 488-nm line from the argon ion laser was required as well as two PMT tubes to process the emission from the

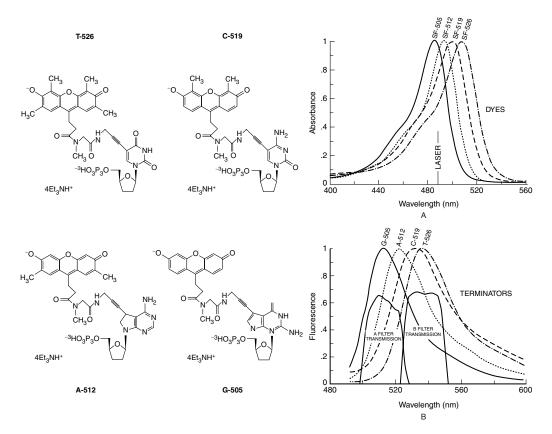

FIGURE 53.7 Chemical structures and the absorbance (A) and emission spectra (B) of dyes conjugated to ddNTPs. Also shown are the excitation laser wavelength (488 nm) and the filter set used to isolate the fluorescence onto the two detection channels. (Adapted from Prober, J.M. et al., *Science*, 238, 336, 1987.)

four colors. Discrimination of the four colors was accomplished by monitoring the intensity of each dye on both detectors simultaneously. By histograming the ratio of the fluorescence intensity of each dye (produced from an electrophoresis band) on the two detection channels, a discrete value was obtained that allowed facile discrimination of the four different fluorescent dyes (i.e., terminal base). To determine the limit of detection of these fluorescence systems, injections of known concentrations of dye-labeled sequencing primers were electrophoresed. In both cases, the mass detection limit was estimated to be 10^{-17} to 10^{-18} mol.

Figure 53.9 shows the data output from these systems. Unfortunately, reading the sequence directly from the raw gel data becomes problematic due to several nonidealities. These include signal from a single dye appearing on multiple detection channels due to the broad and closely spaced emission bands, dye-dependent electrophoretic mobility shifts, and nonuniformity in the intensity of the electrophoresis bands due to the enzymatic reaction used to construct the individual DNA size ladders. Thus, several post-electrophoresis-processing steps were required to augment sequence reconstruction of the test template. In the case of the Smith et al. example,6 these steps involved:

- 1. High-frequency noise removal using a low-pass Fourier filter.
- A time delay between measurements at different wavelengths corrected by linear interpolation between successive measurements.
- 3. A multicomponent analysis performed on each set of four data points, which produced the amount of the four dyes present in the detector as a function of time.

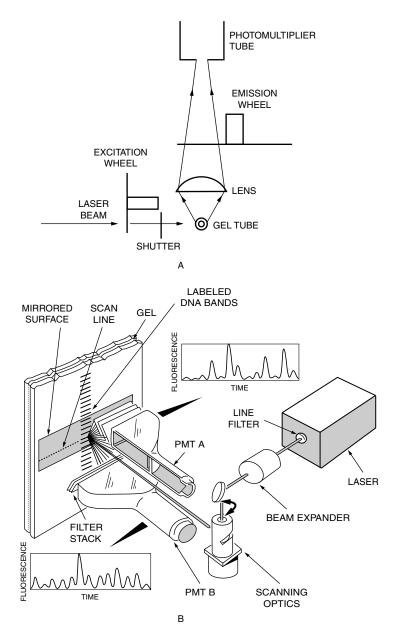

FIGURE 53.8 Fluorescence detector systems for DNA sequencing. (A) The laser consisted of an argon ion laser operating at 488 and 514 nm. The wavelength was selected using a rotating filter wheel. The emission was collected by a lens and sent through a filter wheel that contained four different filters, one for each of the multicolor dyes used to label the sequencing primers (see Figure 53.6 for their structures and fluorescence properties). (Adapted from Smith et al., *Nature*, 321, 674, 1986.) (B) The laser used for excitation is an argon ion laser operated at 488 nm only. The beam was rastered over the slab-gel plate using scanning optics. The emission was then processed on one of two elongated, stationary photomultiplier tubes (PMTs) (see Figure 53.7 for dye set used with this fluorescence detector). (Adapted from Prober, J.M. et al., *Science*, 238, 336, 1987.)

- 4. The peaks present in the located data stream.
- 5. The mobility corrected for the dye attached to each DNA fragment. In this case, it was empirically determined that fluorescein and rhodamine-labeled DNA fragments moved as if they were one base longer than the NBD-labeled fragments, and the Texas Red fragments moved as if they were 1.25 bases longer.

The important performance criteria in any type of automated DNA sequencer are its throughput, the number of bases it can process in a single gel read, and its accuracy in calling bases. In terms of base-calling accuracy, these early instruments demonstrated an error rate of approximately 1%, with a read length approaching 500 bases. The throughput of the instrument described by Prober et al.⁷ was estimated to give a raw throughput of 600 bases per hour (12 electrophoresis lanes). Interestingly, many present-day commercial automated sequencers still use similar technology in their machines, and the throughput can be as high as 16,000 bases per hour (96 electrophoresis lanes).

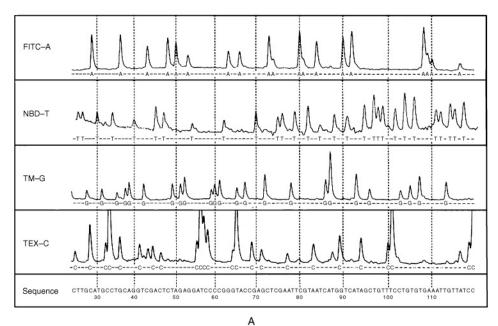

53.2 Fluorescent Dyes for DNA Labeling and Sequencing

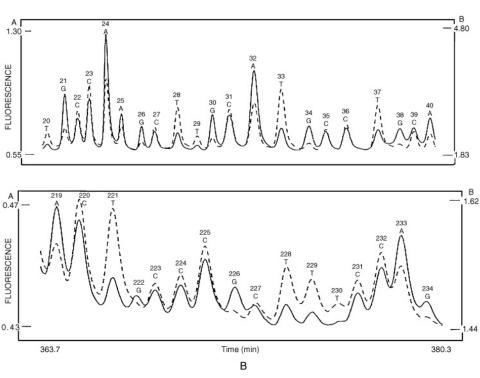

As stated above, fluorescence detection has had a tremendous impact on DNA sequencing because it possesses a high-speed readout process and has the ability to discriminate among the four nucleotide bases in a single gel lane due to the unique spectral properties of the target dye molecules. A variety of dye sets (typically four dyes per set, one for each nucleotide base) have been developed for DNA-sequencing applications, and regardless of the dye set under consideration certain properties associated with the dyes for DNA-sequencing applications are important. These properties are listed below:

- 1. Each dye in the set must be spectroscopically distinct. The ideal situation from a throughput point of view is to identify each base in a single gel lane instead of four gel lanes. In most cases, the discrimination is based on differences in the emission properties of each dye (distinct emission maxima); however, other fluorescence properties can be used as well such as fluorescence lifetimes.
- The dye set should preferably be excited by a single laser source. It becomes instrumentally difficult
 to implement multiple excitation sources because lasers are typically used as the source of excitation to improve the limit of detection in the measurement, and the upkeep on multiple lasers
 becomes problematic.
- 3. The dye set should possess high extinction at the excitation frequency and also large quantum yields in the gel matrix used to fractionate the DNAs. Good photophysical properties are necessary to improve detectability. In addition, the dye set should show reasonable quantum yields in denaturing gels, which consist of high concentrations of urea or formamide.
- 4. The dye set should show favorable chemical stability at high temperatures. A common procedure in most Sanger sequencing strategies is to implement a thermostable polymerase and then subject the sequencing reactions to multiple temperature cycles (55 to 95°C) to amplify the amount of product generated (cycle sequencing). Therefore, the dyes must be able to withstand high-temperature conditions for extended periods of time.
- 5. The dyes must induce minimal mobility shifts during the electrophoresis analysis of the sequencing ladders. Often, the mobility shifts induced by individual dyes cause misordering of the individual bases during sequence reconstruction. As such, post-electrophoresis corrections are often employed to rectify this perturbation in the DNA's mobility.
- 6. The dyes must not significantly perturb the activity of the polymerase enzyme. This is especially true in dye-terminator chemistry because the proximity of the dye to the polymerase enzyme can dramatically influence the enzyme's ability to incorporate that dye-ddNTP conjugate into the polymerized DNA molecule.

53.2.1 Visible Fluorescence Dyes for DNA Labeling

The dye set frequently used in many automated, fluorescence-based DNA sequencers is the FAM, JOE, TAMRA, and ROX series (see Figure 53.10), which consists of fluorescein and rhodamine analogs containing a succinimidyl ester for facile conjugation to amine-terminated sequencing primers or terminators. These dyes can be efficiently excited by the 488- and 514.5-nm lines from an argon ion laser; they also possess emission profiles that are fairly well resolved. Many of the Applied Biosystems (Foster City, CA) automated DNA sequencers use this particular dye set (for example, ABI 373 and 377 series, see www.perkin-elmer.com). Figure 53.10 shows emission spectra for this dye set as well as the filter set that

is used to isolate the emission from the dyes onto the appropriate detection channel. While this dye set is fairly robust and works well with typical DNA-cycle-sequencing conditions, this series present some difficulties, i.e., the broad emission profiles, dye-dependent mobility shifts, and inefficient excitation of TAMRA and ROX with the 514.5-nm line from the argon ion laser.

FIGURE 53.9

FIGURE 53.9 (Opposite) Fluorescence sequencing data obtained from the two fluorescence systems described in Figure 53.8. (A) The dyes (see Figure 53.6) were conjugated to a primer with a sequence, 5'-CCCAGTCACGACGTT-3', complementary to a site on the M13 phage vector. The reactions were run using Sanger chain-termination methods and run in four different vessels, one for each terminator. The polymerase enzyme was a T7 polymerase, and the reactions were pooled prior to electrophoresis. (Adapted from Smith, et al., *Nature*, 321, 674, 1986.) (B) Sequence of the M13mp8 template using the dye-labeled terminator set shown in Figure 53.7. The base assignment is given as a letter above each electrophoretic peak. The reactions were prepared using Sanger chain-termination methods and prepared in a two-stage fashion. In the first stage, the template (M13mp18) was added to a reaction tube along with the primer, heated to 95°C for 2 min and then cooled in ice water for 5 min. In the second stage, dNTPs and the dye-labeled ddNTPs were added along with an AMV reverse transcriptase enzyme. Following chain extension, the reactions were purified (removal of excess terminators) using gel filtration (Sephadex spin column) and loaded onto the gel. The gel was 8% polyacrylamide containing 7 M urea as the denaturant. In these traces, the solid line represents the fluorescence signal from PMT A, and the dashed line is from PMT B. (Adapted from Prober, J.M. et al., *Science*, 238, 336, 1987.)

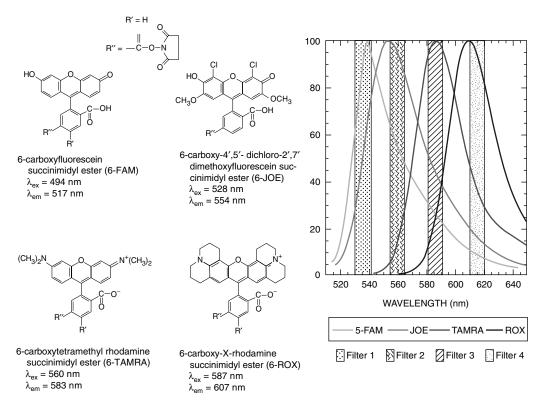

FIGURE 53.10 Common fluorescence-dye set used for labeling primers for DNA-sequencing applications. The functional group on each dye is a succinimidyl ester, which readily conjugates to primary amine groups. Also shown are the emission spectra of this dye set and the filters used to select the appropriate dye color-processed by each detection channel.

To eliminate dye-dependent mobility shifts and minimize crosstalk between detection channels using four-color processing, a bodipy dye set (4,4-difluoro-4-bora-3α, 4α-diaza-s-indacene-3-proprionic acid) has been used for DNA-sequencing applications. The structures of the dyes are presented in Figure 53.11. Inspection of the fluorescence-emission profiles for this particular dye set indicated that the bandwidths were less than those associated with the FAM/JOE/TAMRA/ROX dye set, which resulted in less spectral leakage between detection channels in the fluorescence readout hardware. Figure 53.11 reveals that all

FIGURE 53.11 Bodipy dye set used for DNA-sequencing applications. Below each structure is the absorption/ emission maxima (nm) of the particular dye. Also shown is the universal sequencing primer and the modification required to attach the dye to the primer. The linkers were either three or six carbon linkers with primary amine groups. The linkers are designated as R865 (C-6 linker, U-C₆), R930 (C-3 linker, U+C₃), or R931 (C-6 linker, U+C₆). (Adapted from Metzker, M.L. et al., *Science*, 271, 1420, 1996.)

these dyes are neutral and have very similar molecular structures, thereby minimizing dye-dependent mobility shifts. To fully compensate for any mobility-shift differences within the dye set, a modified linker structure was synthesized to account for this difference (see Figure 53.11).

A particular shortcoming associated with this dye set is the chemical instabilities the dyes display when subjected to extended heating at high temperatures. An example of this is shown in Figure 53.12, in which bodipy-labeled primers were used with cycle-sequencing conditions. In cycle sequencing, a linear amplification of the ddNTP-terminated fragments can be generated by subjecting the reaction cocktail to multiple temperature cycles consisting of 95°C (thermal denaturation of the double-stranded DNA molecule), 55°C (annealing the sequencing primer to the DNA template), and 72°C (chain extension using a thermostable polymerase enzyme, such as *Taq* polymerase). The difficulty arises during the 95°C

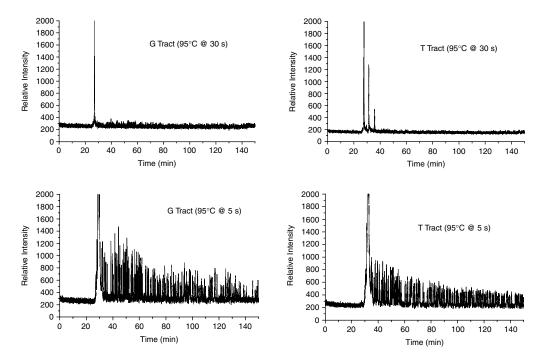

FIGURE 53.12 Cycle-sequencing effects on bodipy-labeled DNA-sequencing primers. The sequencing reactions were prepared using Sanger chain-termination methods and a *Taq* DNA polymerase. The cycling conditions consisted of 25 cycles with 95°C for 30 or 5 sec; 55°C for 10 sec, and 72°C for 60 sec. The reactions were run with a single terminator (ddGTP, ddTTP) and an M13mp18 template. The sequencing reactions were analyzed in a CGE DNA sequencer using laser excitation at 532 nm. The dyes were bodipy 564/570 (ddGTP) and bodipy 581/591 (ddTTP) (see Figure 53.11 for structures of dyes). The large peak at ~28 min is unextended dye-labeled primer.

step, where significant dye decomposition can result. Figure 53.12 shows fluorescence traces of sequencing ladders prepared using a 95°C step time of either 30 sec or 5 sec. As shown in the figure, there is a significant loss in signal when the cycling time (at 95°C) is 30 sec, but the signal is partially restored when the cycling time is reduced to 5 sec.

Many of the dyes discussed above have been employed in dye-primer sequencing applications, in which the primer used for selecting the DNA polymerization site on the unknown template is determined by Watson-Crick base pairing. An alternative is dye-terminator chemistry, where the fluorescent dyes are covalently attached to the ddNTP used in Sanger sequencing strategies. The advantages of this method are twofold. First, the sequencing reactions can be carried out in a single tube. In dye-primer chemistry, the sequencing reactions are carried out in four separate tubes and then pooled prior to the electrophoresis step. If four spectroscopically unique fluorescent probes attached to the ddNTP are implemented, the reactions can be carried out in a single tube, which reduces reagent consumption and also minimizes sample transfer steps. Second, primers of known sequence need not be synthesized. In primer sequencing, making oligonucleotides of 17 to 23 bases in length can be costly and time-consuming, especially if the dye must be chemically tethered to the primer. The use of dye-terminator chemistry eliminates the need for synthesizing dye-labeled primers. Unfortunately, dye terminators themselves can be quite expensive; in addition, many polymerase enzymes are very sensitive to the type of dye attached to the ddNTP. For example, fluorescein dyes are poor labels for terminators when using the Taq polymerase due to its incompatibility with the binding pocket of Taq, while the rhodamine dyes are more hydrophobic and are thus more suitable for use with Taq polymerase. The result is that the peak heights for the electrophoresis bands can vary tremendously due to differences in incorporation of the dye-modified ddNTPs by the particular polymerase enzyme. In dye-primer chemistry, this disparity is absent due to the large

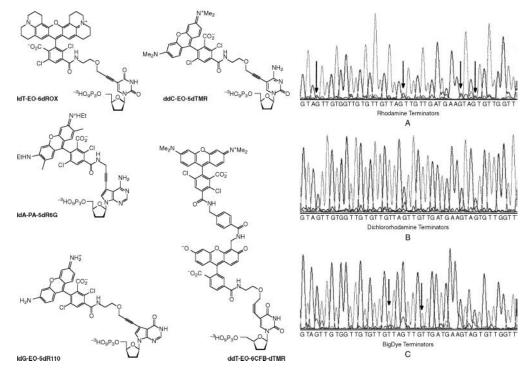

FIGURE 53.13 Chemical structures of the d-rhodamine dyes used for labeling terminators. Also shown is the structure of an energy transfer terminator (BigDye terminator). The accompanying panels show a comparison of sequencing data obtained using rhodamine- (A), d-rhodamine- (B), and Big Dye- (C) labeled terminators. The arrows in (A) are G-peaks with weak signal. In (C), the arrows indicate weaker T-peaks following G-peaks. The sequencing reactions were run with an AmpliTaq DNA polymerase and cycle-sequencing conditions (30 cycles with a temperature program of 95°C for 30 sec, 55°C for 20 sec, 60°C for 4 min). The DNA template was isolated from a bacterial artificial chromosome. Following chain extension, the reactions were purified using a Centri-Sep spin column to remove excess terminators and then dried in a vacuum and resuspended in 2 to 4 μl of formamide. The reactions were electrophoresed in a slab gel with laser-induced fluorescence detection. (Adapted from Rosenblum, B.B. et al., *Nucleic Acids Res.*, 25, 4500, 1997.)

displacement of the dye from the polymerization site. ¹⁰ It is interesting to note that several mutant forms of Taq polymerase have been prepared to allow more facile incorporation of dye-labeled terminators. ¹¹ For example, Taq Pol I (AmpliTaq FS®) has two modifications in it — a substitution that eliminates the Taq Pol I (AmpliTaq FS®) has two modifications in it—a substitution that eliminates the Taq Pol I (AmpliTaq FS®) has two modifications in it—a substitution that eliminates the Taq Pol I (AmpliTaq FS®) has two modifications in it—a substitution that eliminates the Taq Pol I (AmpliTaq FS®) has two modifications in it—a substitution that eliminates the Taq Pol I (AmpliTaq FS®) has two modifications in it—a substitution that eliminates the Taq Pol I (AmpliTaq FS®) has two modifications in it—a substitution that eliminates the Taq Pol I (AmpliTaq FS®) has two modifications in it—a substitution that eliminates the Taq Pol I (AmpliTaq FS®) has two modifications in it—a substitution that eliminates the Taq Pol I (AmpliTaq FS®) has two modifications in it—a substitution that eliminates the Taq Pol I (AmpliTaq FS®) has two modifications in it—a substitution that eliminates the Taq Pol I (AmpliTaq FS®) has two modifications in it—a substitution that eliminates the Taq Pol I (AmpliTaq FS®) has two modifications in it—a substitution that eliminates the Taq Pol I (AmpliTaq FS®) has two modifications in it—a substitution that eliminates the Taq Pol I (AmpliTaq FS®) has two modifications in it—a substitution that eliminates the Taq Pol I (AmpliTaq FS®) has two modifications in it—a substitution that eliminates the Taq Pol I (AmpliTaq FS®) has two modifications in it—a substitution that eliminates the Taq Pol I (AmpliTaq FS®) has two modifications in it—a substitution that eliminates the Taq Pol I (AmpliTaq FS®) has two modifications in it—a substitution that eliminates the Taq Pol I (AmpliTaq FS®) has two modifications in it—a substitution that eliminates the Taq Pol I

The nature of the dye on the terminator can also influence the mobility of the polymerized DNA fragment as well. For example, rhodamine dyes are typically zwitterionic and thus appear to stabilize hairpin (secondary) structures in the DNA fragment, causing compressions in the electrophoresis data, especially in GC-rich regions of the template. On the other hand, the fluorescein dyes, which are negatively charged, do not suffer from such anomalies.¹⁰

Slight structural modifications on the base chromophore can influence its incorporation during DNA polymerization. Also, the linker structure can influence the incorporation efficiency as well. Figure 53.13 shows a set of dye-labeled terminators that have been found to give fairly even peak heights in sequencing patterns and produce minimal mobility shifts; the figure also shows the sequencing patterns that were generated with both the rhodamine dyes and the dichlororhodamine (d-rhodamine) analogs. ¹² The linker structures chosen for this set were either the propargylamine linker developed by Prober et al. ⁷ or a propargyl ethoxyamino linker. The choice of linker was based on its ability to accommodate the polymerase enzyme and to minimize the mobility differences within the dye set. For the rhodamine terminators, very

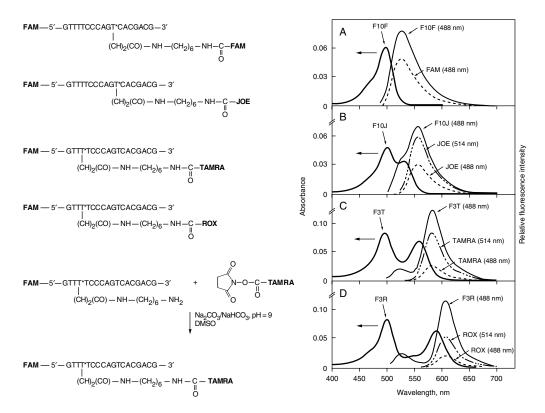

FIGURE 53.14 Chemical structures and absorbance and fluorescence-emission spectra of energy-transfer (ET)-labeled DNA-sequencing primers. The bottom panel shows the reaction of a dye-labeled FAM primer (5'-end with $-NH_2$ T modified residue) and a succinimidyl TAMRA dye (F3T). The absorption (dark line) and emission spectra for both the ET primers and the single-dye-labeled primers are also shown for comparison purposes. The number in parenthesis is the excitation wavelength used for collecting the emission profile. (Adapted from Ju, J. et al., *Proc. Natl. Acad. Sci. U.S.A.*, 92, 4347, 1995.)

weak G-peaks, which appeared after A-peaks, were observed. However, for the d-rhodamine terminators, this disparity in peak intensity was alleviated, with the peak heights in the pattern being much more uniform.

53.2.2 Energy Transfer Dyes for DNA Sequencing

One of the major problems associated with many of the single-dye sets mentioned previously is that their absorption spectra are dispersed over a relatively large spectral range, which provides poor excitation efficiency even for dual-laser (488 and 514 or 543) systems. As such, the red dyes are used at higher concentrations during DNA polymerization to circumvent poor excitation. To overcome this problem without sacrificing spectral dispersion in the emission profiles, the phenomenon of Förster energy transfer has been used to design sequencing primers that can be efficiently excited with a single laser line. ^{13–16} A brief introduction about these ET (energy transfer) primers in the context of DNA sequencing follows.

The chemical structures of the ET primers developed by Richard Mathies and his group¹⁵ are shown in Figure 53.14. The donor dye in this case was FAM, which could be excited with the 488-nm line of an argon ion laser. The acceptor dyes were FAM, JOE, TAMRA, or ROX. The donor (FAM) was attached to the sequencing primer on the 5' end during the solid-phase DNA synthetic preparation of the M13 (–40) sequencing primer using phosphoramidite chemistry. The sequencing primer also contained a modified base (T*) that possessed a linker structure with a primary amine. The appropriate acceptor

was conjugated to the primary amine group off the modified base following cleavage from the solid support via a succinimidyl ester functional group. The spacer distance between the donor and acceptor was selected by positioning T* within the M13 (-40) primer sequence during solid-phase synthesis. The naming of these ET primers followed the convention donor-spacer (bp)-acceptor. A ten-base spacer was used for the FAM and JOE ET primers, and a three-base spacer was selected for TAMRA and ROX. The choice of spacer size was primarily determined by producing ET primers, which showed uniform electrophoretic mobilities.

Figure 53.14 shows the absorbance and emission profiles of the ET primer series. While the absorption spectra show bands from both the acceptor and donor dyes, the emission profiles are dominated by fluorescence from the acceptor dyes. In fact, the ET efficiency has been determined to be 65% for F10J, 96% for F3R, and 97% for F3T.¹⁵ As shown in the emission profiles in Figure 53.14, the emission intensity was found to be significantly higher for the ET primers compared to their single-dye primer partners when excited with 488-nm laser light from the argon ion laser due to higher efficiency in excitation. This translates into improved fluorescence sensitivity of these ET primers during electrophoresis.

These ET primers do offer some advantages due to their improved detection sensitivities; those advantages include eliminating the need for adjusting the concentrations of the dye primers used during polymerization and also the need for smaller amounts of template in the sequence analysis. In fact, the use of ET primers required about one fourth the amount of template vs. the single-dye primers.

ET dye pairs can also be situated on terminators; an example is shown in Figure 53.13.¹² In this example, d-rhodamine and rhodamine dyes are used with a propargyl ethoxyamino linker. This dye set has been called BigDye terminators. Again, the dyes were selected so as to provide fairly uniform peak heights in the electrophoresis and also uniform mobility shifts within the series. A sample of a sequence run using these BigDye terminators is also shown in Figure 53.13.

53.2.3 Near-Infrared Dyes for DNA Sequencing

The attractive feature associated with fluorescence in the near-infrared (NIR) (λ_{ex} > 700 nm) includes smaller backgrounds observed during signal collection and the rather simple instrumentation required for carrying out ultrasensitive detection. In most cases, the limit of detection for fluorescence measurements is determined primarily by the magnitude of the background produced from scattering or impurity fluorescence. This is particularly true in DNA sequencing because detection occurs within the gel matrix, which can be a significant contributor of scattering photons. In addition, the use of denaturants in the gel matrix, such as urea (7 M) or formamide, can produce large amounts of background fluorescence. The lower background that is typically observed in the NIR can be attributed to the fact that few species fluoresce in the NIR. In addition, the $1/\lambda^4$ dependence of the Raman cross section also provides a lower scattering contribution at these longer excitation wavelengths.

An added advantage of NIR fluorescence is the fact that the instrumentation required for detection can be rather simple and easy to use. A typical NIR fluorescence-detection apparatus can consist of an inexpensive diode laser and single-photon avalanche diode (SPAD). These components are solid state, which allows the detector to be run for extended periods of time, requiring little maintenance or operator expertise.

NIR fluorescence can be a very attractive detection strategy in gel sequencing because of the highly scattering medium in which the separation must be performed. Due to the intrinsically lower backgrounds that are expected in the NIR vs. the visible, on-column detection can be performed without sacrificing detection sensitivity. To highlight the intrinsic advantages associated with the use of NIR fluorescence detection in capillary-gel DNA-sequencing applications, a direct comparison between laser-induced fluorescence detection at 488-nm excitation and 780-nm excitation has been reported.¹⁷ In this study, a sequencing primer labeled with FAM or a NIR dye were electrophoresed in a capillary-gel column and the detection limits calculated for both systems. The results indicated that the limits of detection for

TABLE 53.1. Chemical Structures of Some Typical NIR Fluorescent Dyes and Their Photophysical Properties

Note: In the top panel of this table, the dyes were modified with an intramolecular heavy atom to produce a set of dyes with four distinct lifetime values. In both cases, the dyes contained an isothiocyanate to allow conjugation to amine-containing molecules.

the NIR case were found to be 3.4×10^{-20} mol, while for 488-nm excitation the limit of detection was 1.5×10^{-18} mol. The improvement in the limit of detection for the NIR case was observed in spite of the fact that the fluorescence quantum yield associated with the NIR dye was only 0.07, while the quantum yield for the FAM dye was ~0.9. The improved detection limit resulted primarily from the significantly lower background observed in the NIR. NIR has also been demonstrated in sequencing applications using SGE, where the detection sensitivity has been reported to be ~2000 molecules. 18,19

The fluorophores that are typically used in the NIR include the tricarbocyanine (heptamethine) dyes, which consist of heteroaromatic fragments linked by a polymethine chain (see Table 53.1). The absorption maxima can be altered by changing the length of this polymethine chain or by changing the heteroatom within the heteroaromatic fragments. These NIR dyes typically possess large extinction coefficients and relatively low quantum yields in aqueous solvents.²⁰ The low-fluorescence quantum yields result primarily from high rates of internal conversion. An additional disadvantage associated with these dyes is their poor water solubility. These dyes show a high propensity toward aggregation, forming aggregates with poor fluorescence properties. This aggregation can be alleviated to a certain degree by inserting charged groups within the molecular framework of the fluorophore, e.g., alkyl-sulfonate groups. In addition, these dyes have short fluorescence lifetimes and are very susceptible to photobleaching vs. the visible dyes typically used in DNA-sequencing applications. In most cases, the NIR chromophore is covalently attached to either a sequencing primer or ddNTP via an isothiocyanate functional group. As shown in Table 53.1, this functional group can be placed on the heteroatom (N in this case) or in the para-position of the bridging phenyl ring. When the isothiocyanate group is situated on the heteroatom, the net charge on the dye becomes neutral and as such has limited water solubility. If the isothiocyanate group is placed

on the bridging phenyl ring, this gives a net -1 charge to the dye and improves its water solubility. Unfortunately, the ether linkage is susceptible to nucleophilic attack, especially by dithiothriotol (DTT), which can release the dye from the moiety (sequencing primer or ddNTP) to which it is attached. This can produce a large peak in the electropherogram, which can mask some of the sequencing fragments that comigrate with the free dye. This problem can be alleviated to a certain extent by using an ethanol-precipitation step following DNA polymerization.

53.3 Instrumental Formats for Fluorescence Detection in DNA Sequencing

The ability to read the fluorescence during the electrophoresis fractionation of the DNA ladders and also accurately identify the terminal base (Sanger sequencing) is a challenging task due to a number of technical issues. As such, a number of fluorescence-readout devices have been developed for reading such data. When considering the design of a fluorescence detector for sequencing applications, several instrumental constraints must be incorporated into the design including:

- 1. High sensitivity. As pointed out previously, the amount of material (fluorescently-labeled DNA) loaded onto the gel can be in the low attomole range (10⁻¹⁸ mol), and the detector must be able to read this fluorescence signature with a reasonably high signal-to-noise ratio (SNR) to accurately call the base. Therefore, in most cases, irrespective of the separation platform, the source of excitation is a laser that is well matched to the excitation maxima of the dye set used in the sequencing experiment.
- 2. Spectral-marker base identification. The instrument must be able to identify one of the four bases terminating the sequencing fragments by accurately processing the fluorescence via spectral discrimination (wavelength) or some other fluorescence property, such as the lifetime. For spectral discrimination, this would require sorting the fluorescence by wavelength using either filters or gratings. In addition, multiple detection channels would be required.
- 3. Fluorescence processing from many electrophoresis lanes. In most sequencing instruments, the fluorescence must be read from multiple gel lanes (SGE) or multiple capillaries (CGE). This can be done by either using a scanning system, in which the relay optic (collection optic) is rastered over the gel lanes or capillaries, or an imaging system, in which the fluorescence from the multiple gel lanes or capillaries are imaged onto some type of multichannel detector, such as a charge-coupled device (CCD) or image-intensified photodiode array.
- Robust instrumentation. Since many sequencing devices are run by novice operators and are also
 run for extended periods of time, the detector format must be dependable and turnkey in operation.

This short list of requirements for any type of fluorescence-readout device appropriate for sequencing presents itself with many challenges that are often noncomplementary with the sequencing requirements. For example, high sensitivity is particularly demanding because the separation platforms used to fractionate the DNA are becoming smaller; therefore, smaller amounts of material must be inserted into the device. In addition, detecting material directly within the gel matrix (typically a polyacrylamide gel) can be problematic due to the intense scattering photons that it produces. Also, the signal is transitory in that the DNA fragment resides within the probing volume (defined by the laser beam size) for a few seconds. Another issue is that many separation channels or lanes must be interrogated for high-throughput applications. On top of these considerations, a high SNR is required to obtain high accuracy in the base-calling phases of the readout process. As such, significant design considerations go into fabricating a fluorescence detector system for DNA-sequencing applications.

There are two general types of fluorescence detector formats — scanning and imaging-type devices. In most high-throughput sequencing devices, multiple lanes of the slab gel or multiple capillaries are

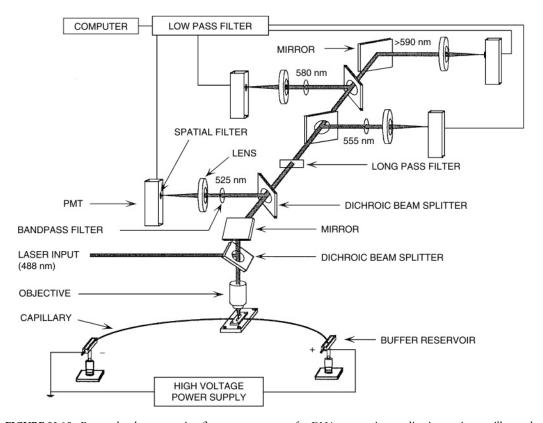

FIGURE 53.15 Four-color, laser scanning fluorescence system for DNA sequencing applications using capillary gel electrophoresis. The excitation source was an air-cooled Ar ion laser operating at 488 nm (1 mW average power). The collection and focusing optic consisted of a microscope objective ($20 \times$, NA = 0.5). The emission was directed onto one of four different PMTs using dichroic filters and further isolated from background photons using a bandpass filter. The fluorescence was sampled at 2 Hz with output filtered using a low-pass filter with a time-constant of 1 sec. (Adapted from Ju, J. et al., *Proc. Natl. Acad. Sci. U.S.A.*, 92, 4347, 1995.)

run in parallel to increase system throughput. For example, many machines run in a 96-lane format because microtiter plates, which are standard plates used to prepare sequencing reactions, come in a 96-well format. In the scanning systems, the excitation beam is tightly focused and irradiates only a single lane, while the relay optic is rastered over the lanes of the gel or the capillary array and the fluorescence from each lane processed sequentially on one set of detection channels. For the imaging systems, all of the electrophoresis lanes are irradiated by a laser or lasers simultaneously, with the fluorescence readout accomplished using a multichannel detector such as a CCD.

53.3.1 Fluorescence Scanning Instruments

Figure 53.15 shows a typical scanning system.^{21,22} This system uses a confocal geometry with epi-illumination in which the objective used to collect the emitted fluorescence also serves to focus the laser beam into individual capillaries (or lanes of the slab gel) used for the electrophoresis. Following collection the emission is focused onto a spatial filter at the secondary image plan of the collection objective. The laser light (488 nm, argon ion laser, 1 mW) is directed into the objective using a dichroic filter. The capillaries are held into a linear array, and in this particular example the capillary array is translated beneath the

microscope objective. As shown in the figure, the laser irradiates only one capillary at a time, but since the beam is tightly focused (diameter = 10 µm) the electronic transition can be saturated at relatively low laser powers, improving SNR in the fluorescence measurement.²³ In addition, the noise can be significantly suppressed in this system, since a pinhole is used in the secondary image plane of the collection microscope objective, preventing scattered out-of-focus light generated at the walls of the capillary from passing through the optical system. The capillary array is scanned at a rate of 20 mm/sec, with the fluorescence sampled at 1500 Hz/channel (color channel) resulting in a pixel image size of 13.3 μ m. The fluorescence is collected by a 32× microscope objective (numerical aperture = 0.4), resulting in a geometrical collection efficiency of approximately 12%. Once the fluorescence has been collected by the objective, it is passed through a series of dichroics to sort the color and then processed on one of four different PMTs, with each PMT sampling a different color (spectral discrimination). While the present system is configured with four color channels, the system could easily be configured to do twocolor processing as well by removing the last dichroic filter in the optical train and two of the PMTs. The concentration limit of detection of this system has been estimated to be 2×10^{-12} M (SNR = 3), which was determined by flowing a solution of fluorescein through an open capillary.²¹ The detection limit would be expected to degrade in a gel-filled capillary due to the higher background that would be generated by the gel matrix.

53.3.2 Fluorescence-Imaging Systems for DNA Sequencing

Figure 53.16A shows an imaging system for reading fluorescence from multichannel capillary systems for DNA sequencing.^{24,25} In this example, a sheath flow cell is used with the laser beam (or beams) traversing the sheath flow and the capillary output dumping into the sheath stream (see Figure 53.18C). This geometry allows simultaneous irradiation of all the material migrating from the capillaries without requiring the laser beam to travel through each capillary, which would cause significant scattering and reduce the intensity of the beam as it traveled through the array. The sheath flow cell also causes contraction of the fluid output of the capillary since the sheath flow runs at a greater linear velocity compared to the sample (capillary) stream. Figure 53.18B shows a fluorescence image of the output from the capillary array, indicating that the sample stream diameter at the probing point was ~0.18 mm and also demonstrating minimal crosstalk between individual capillaries in the array. The laser beams (488 nm from argon ion, 6 mW; 532 nm from frequency-doubled yttrium-aluminum-garnet [YAG], 6 mW) were positioned slightly below the exit end of the capillaries (see Figure 53.18A) with the beams brought colinear using a dichroic filter. The collection optic and focusing optic produced a total magnification of 1 and resulted in a geometrical collection efficiency of 1%. To achieve multicolor processing capabilities, the collected radiation was sent through an image-splitting prism to produce four separated (spectrally) line images on the array detector (one for each dye used to label the terminal bases). In addition, a series of narrow bandpass filters were placed in front of the image-splitting prism to assist in isolating the appropriate colors for data processing. The detector that was used for this system was a two-dimensional CCD camera with a cooled image intensifier. Interestingly, the detection limit reported for this system was found to be 2×10^{-12} M when operated in the four-color mode, comparable to that seen for the scanning system discussed above. However, the presence or absence of the gel matrix does not affect the sensitivity of the fluorescence measurement in this case, since the fluorescence interrogation is done off column in the sheath flow. In fact, researchers have reported that the implementation of the sheath flow geometry in gel electrophoresis can offer a significant improvement in limits of detection by minimizing scattering contributions to the background.26

When comparing these two fluorescence-readout systems, several issues should be highlighted. One is the duty cycle, which takes into account the loss in signal due to multiple-lane sampling. For any type of scanning system the sampling of the electrophoresis lanes is done in a sequential fashion. For a scanning system sampling 96 capillaries the duty cycle is approximately 1%. However, in the imaging system, all capillaries are sampled continuously and the duty cycle is nearly 100%. Therefore, comparisons of detection limits for any system must include a term for the duty cycle because lower duty cycles will degrade the limit of detection.

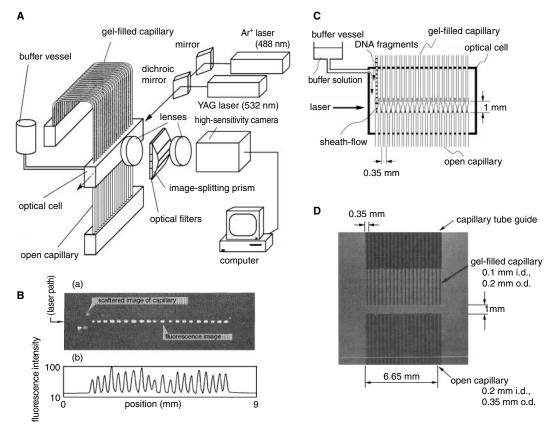

FIGURE 53.16 (A) Schematic of an imaging laser-induced fluorescence detector for reading four-color fluorescence from capillary-gel arrays. The lasers used for excitation were an argon ion (488 nm) and a YAG laser (532 nm). The lasers were allowed to traverse below the output of the gel columns and the fluorescence collected with a lens system. The fluorescence line image was split into four different color images using a polyhedral image-splitting prism coupled to optical filters. The filtered fluorescence was detected using a two-dimensional CCD. (B) Fluorescence image in the one-color mode across an array of 20 capillaries. The integrated fluorescence intensity is shown in the bottom panel. (C) Schematic view of the multiple sheath flow cell using gravity feed for the sheath flow. Twenty gel-filled capillaries were aligned at a 0.35-mm pitch in an optical cell (26 mm × 26 mm × 4 mm). (D) Photograph of the capillary array aligned in the sheath flow cell. (Adapted from Takahashi, S. et al., *Anal. Chem.*, 66, 1021, 1994.)

53.4 DYE Primer/Terminator Chemistry and Fluorescence Detection Formats

In most sequencing applications, dye-labeled primers are used for accumulating sequencing data using automated instruments. This stems from the fact that dye-labeled primers are typically less expensive to use vs. their dye-labeled terminator counterparts. Also, in most applications, small pieces of DNA (1 to 2 kbp in length) are cloned into bacterial vectors for propagation (to increase copy number), such as M13s, which have a known sequence and serve as ideal priming sites. However, dye-labeled primers do present problems; for example, the sequencing reactions must be run in four separate tubes during polymerization and then pooled prior to gel electrophoresis. In addition, unextended primer can result in a large electrophoretic peak (i.e., high intensity), which often masks the ability to call bases close to the primer-annealing site.

Dye-labeled terminators can be appealing to use in certain applications, for example, when high-quality sequencing data is required and in primer-walking strategies. In primer walking, the sequence of the DNA template is initiated at a common priming site using a primer that is complementary to that site. After reading the sequence at that site, the template is subjected to another round of sequencing, with the priming site occurring at the end of the first read. In this way, a long DNA can be sequenced by walking in a systematic fashion down the template. Dye terminators are particularly attractive because primers need to be synthesized frequently in primer-walking strategies, and the need for nonlabeled primers simplifies the synthetic preparation of these primers. Dye terminators improve the quality of sequencing data in many cases because the excess terminators are removed prior to electrophoresis (using size-exclusion chromatography) and as such give clean gel reads free from intense primer peaks. However, it should be noted that in most cases, terminators can produce uneven peak heights (broad distribution of fluorescence intensities) due to the poor incorporation efficiency of dye terminators by polymerase enzymes.

When dye-labeled primers are used, several different formats can be implemented to reconstruct the sequence of the template when fluorescence detection is being used. In the case of spectral discrimination, these formats may vary in terms of the number of dyes used, the number of detection channels required, or the need for running one to four parallel electrophoresis lanes. For example, if the sequencing instrument possesses no spectral-discrimination capabilities, the electrophoresis must be run in four different lanes, one for each base comprising the DNA molecule. However, if four different dyes are used, the electrophoresis can be reduced to one lane, and as a result the production rate of the instrument goes up by a factor of 4. The fluorescence-based formats discussed here include (number of dyes/number of electrophoresis lanes), single-dye/four-lane; single-dye/single-lane; two-color/single-lane, and, finally, four-color/single-lane strategies.

The most pressing issue in any type of DNA-sequencing format is the accuracy associated with the base call, which is intimately related to a number of experimental details, for example, the number of spectral channels used in the instrument as well as the SNR in the measurement. The information content of a signal, *I*, can be determined from the simple relation:²⁷

$$I = n\log_2(SNR) \tag{53.3}$$

where n is the number of spectral channels and SNR is the SNR associated with the measurement. The term I is expressed in bits, and typically two bits are necessary to distinguish between four different signals, but only if there is no spectral overlap between the dyes used for identifying the bases. Unfortunately, in most multicolor systems, the spectra of the dyes used in the sequencing device show significant overlap; thus, many more bits will be required to call bases during the sequencing run.

While the above equation can provide information on how to improve the accuracy of the base call, it does not provide the sequencer with information on the identity of the individual electrophoretic peaks (base call) or the quality of a base call within a single-gel read. For example, if four-color sequencing is used with dye-primer chemistry, how should the data be processed, and what is the confidence with which an electrophoretic peak is called an A, T, G, or C? To provide such information, an algorithm has been developed to not only correct for anomalies associated with fluorescence-based sequencing but also assign a quality score to each called base. The typical algorithm used is called the *Phred* scale, and it employs several steps to process the sequencing data obtained from fluorescence-based, automated DNA sequencers.²⁸

The data input into *Phred* consists of a trace, which is electrophoretic data processed into four spectral channels, one for each base. The algorithm consists of four basic steps:

1. *Idealized electrophoretic peak locations (predicted peaks) are determined.* This is based on the premise that most peaks are evenly spaced throughout the gel. In regions where this is not the case (typically during the early and late phases of the electrophoresis), predictions are made as to the number of correct bases and their idealized locations. This step is carried out using Fourier methods as well as the peak-spacing criterion and helps to discriminate noise peaks from true peaks.

- 2. Observed peaks are identified in the trace. Peaks are identified by summing trace values to estimate the area in regions that satisfy the criterion $2 \times v(i) \ge v(i+1) + v(i-1)$, where v(i) is the intensity value at point i. If the peak area exceeds 10% of the average area of the preceding ten accepted peaks and 5% of the area of the immediate preceding peak, it is accepted as a true peak.
- 3. Observed peaks are matched to the predicted peak locations, omitting some peaks and splitting others. In this phase of the algorithm, the observed peak arises from one of four spectral channels and thus can be associated with one of the four bases. It is this ordered list of matched observed peaks that determines a base sequence for the DNA template in question.
- 4. Observed peaks that are uncalled (unmatched to predicted peaks) are processed. In this step, an observed peak that did not have a complement in the predicted trace is called and assigned a base and finally inserted into the read sequence.

This algorithm deals mainly with sorting out difficulties associated with the electrophoresis by identifying peaks in the gel traces, especially in areas where the peaks are compressed (poor resolving power) or where multiple peaks are convolved due to significant band broadening produced by diffusional artifacts.

Often, preprocessing of the traces is carried out prior to *Phred* analysis to correct for dye-dependent mobility shifts. In most cases, these mobility shifts are empirically determined by running an electropherogram of a single dye-labeled DNA ladder (for example, T-terminated ladder) and comparing the mobilities to the same ladder labeled with another dye of the set. This type of analysis can be very complex and involved because the mobility shift depends both on the dye and linker structure and on the separation platform used. For example, dyes that show uniform mobility shifts in SGE may not show the same effect in CGE. In addition, these mobility shifts can be dependent on the length of the DNA to which the dye is attached.²⁹ An example of this phenomenon is shown in Figure 53.17. In this particular example, cyanine dyes were covalently anchored to an M13 (-40) sequencing primer and annealed to an M13 template followed by extension with a single terminator (ddT). The tracts were electrophoresed using CGE. In Figure 53.17A, comparison between a Cy5T7 (-2 charge) and Cy5.5T (-1 charge) tracts indicates that the Cy5T7-labeled fragments migrate faster in the beginning of the run (smaller DNA fragments), but after 300 bp, the two dye-labeled fragments comigrate. In Figure 53.17B, a mobility crossover occurs at ~125 bp for the dyes Sq5T4 (neutral charge) and Cy5.5T12 (-2 charge), with the shorter fragments migrating faster with the Cy5.5T12 label, and after this the Sq5T4-labeled fragments migrate faster. These types of mobility shifts have been ascribed to differences in the net charge of the dye label and to potential dye-DNA base interactions. These interactions, predominantly driven by hydrophobic interactions, may cause loops or hairpin structures on the 5' end of the dye-DNA complex. These structures would cause a faster migration rate compared to fully extended structures produced by most dye-DNA complexes.

53.4.1 Single-Color/Four-Lane

In this processing format, only a single fluorescence detection channel is required to analyze the signal from the labeling dye because only a single dye is used to detect the sequencing fragments produced following chain extension. However, since no color discrimination is implemented, the electrophoresis must be run in four lanes, one for each base, like the format used in traditional autoradiographic detection. While this is a reasonable approach for slab-gel separations, it is not a viable strategy in capillary-gel applications due to the poor run-to-run reproducibility in the migration rates of the fragments traveling through the different capillaries. This is due to differences in the gel from capillary to capillary as well as differences in the integrity of the wall coatings used to suppress the electroosmotic flow. In the slab-gel format, reproducibility in the migration times becomes less of a problem because all of the lanes are run in the same gel matrix.

Figure 53.18 shows the output of a typical single-color/four-lane sequencing device along with the called bases. In this example, each different color trace represents an electropherogram from an individual lane of the slab gel, which is overlaid to allow reconstruction of the sequence of the template. In this case, the device used a single microscope head containing the collection optics, a diode laser, filters, and avalanche photodiode to read the fluorescence from the gel. ¹⁸ The microscope scanner is rastered over

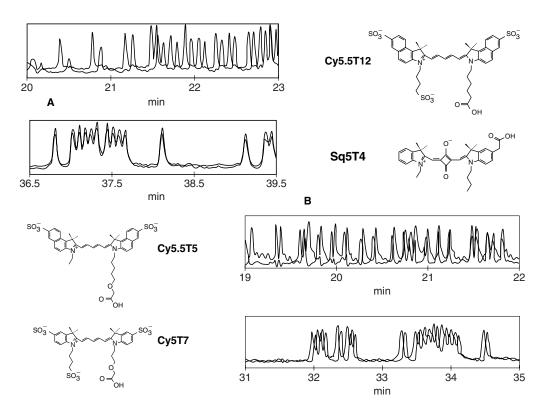

FIGURE 53.17 Electrophoresis traces and chemical structures of four different cyanine dyes used to end-label DNA sequencing primers. (A) Gel trace of Cy5.5T5 (red trace) and Cy5T7 (blue trace). (B) Gel trace of Cy5.5T12 (red trace) and Sq5T4 (blue trace). In all cases, the ladders were prepared using a single terminator (ddT) and an M13mp18 template. The electrophoresis was carried out in a capillary-gel column (field strength = 185 V/cm) using a hydroxyethyl cellulose sieving buffer. (Adapted from Tu, O. et al., *Nucleic Acids Res.*, 26, 2797, 1998.)

the gel at a rate of \sim 0.15 cm/sec and monitors fluorescence along a single axis of the gel. The gel is approximately 20 cm in width and 42 cm in length and can accommodate 48 separate lanes. The time required to secure this data was 6 h, with the extended time due primarily to the limited electric field that can be applied to the thick slab gel.

53.4.2 Single-Color/Single-Lane

In this sequencing approach, only a single fluorophore is used, and thus only a single laser is required to excite the fluorescence and only a single detection channel is needed to process the fluorescence. The advantage of this approach is that instrumentally it is very simple because the hardware required for detection is simple. In addition, because the sequence is reconstructed from a single electrophoresis lane and not four, the throughput can be substantially higher compared to a single-fluorophore/four-lane method.

The bases are identified by adjusting the concentration ratio of the terminators used during DNA enzymatic polymerization to alter the intensity of the resulting electrophoretic bands.^{17,27,30,31} Therefore, if the concentration of the terminators used during DNA polymerization was 4:2:1:0 (A:C:G:T), a series of fluorescence peaks would be generated following electrophoretic sizing with an intensity ratio of 4:2:1:0, and the identification of the terminal bases would be carried out by categorizing the peaks according to their heights. To accomplish this with some degree of accuracy in the base calling, the ability of the DNA polymerase enzyme to incorporate the terminators must be nearly uniform. This can be achieved using a special DNA polymerase, which in this case is a modified T7 DNA polymerase.^{32,33} This enzyme has

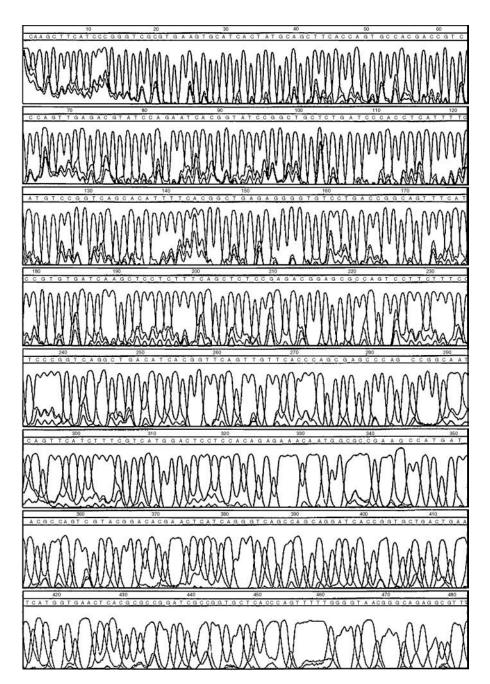

FIGURE 53.18 (Color figure follows p. 28-30.) Single-color/four-lane sequencing trace (called bases 1 to 480) of a PCR-amplified λ -bacteriophage template. The sequencing was performed using an IRD-800-labeled primer (21mer) and SGE instrument (Li-COR 4000). The gel consisted of 8% polyacrylamide with 7 M urea. The dimensions of the gel were 25 cm (width) by 41 cm (length). The traces from the four lanes were overlaid to reconstruct the sequence of the template.

been modified so as to remove its proofreading capabilities by eliminating its $3' \rightarrow 5'$ exonuclease activity. Since this method requires uniform incorporation of the terminators, it is restricted to the use of dyeprimer chemistry. In addition, since the T7 enzyme is not a thermostable enzyme, cycle sequencing cannot be used.

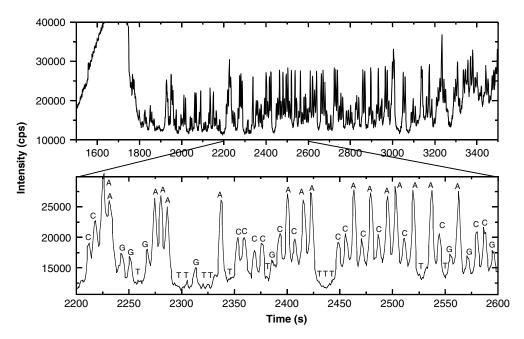

FIGURE 53.19 Single-color/single-lane capillary-gel sequencing data. The template was an M13mp18 phage, and the primer was labeled with a NIR fluorescent dye and detected using NIR, laser-induced fluorescence. The terminators were adjusted to a concentration ratio of 4:2:1:0 during extension to allow identification based on fluorescence intensities. The separation was performed at a field strength of 250 V/cm, and the gel column contained a 3% T/3% C crosslinked polyacrylamide gel. (Adapted from Williams, D.C. and Soper, S.A., *Anal. Chem.*, 67, 19, 3427, 1995.)

Figure 53.19 presents an example of sequencing data accumulated using this base-calling strategy. In this example, the terminator concentration was adjusted at a concentration ratio of 4:2:1:0 (A:C:G:T).⁵⁶ The accuracy in calling bases was estimated to be 84% up to 250 bases from the primer annealing site, with readable bases up to 400 but with the accuracy deteriorating to 60%. This is a common artifact in this approach — poor base-calling accuracy. The poor base calling results from variations in the activity of the T7 DNA polymerase and, in addition, the null signal used to identify Ts. Ambiguities are present when multiple null signals must be identified, which can lead to insertions or deletions.

53.4.3 Two-Color/Single-Lane

To improve on the base-calling accuracy associated with the single-color/single-lane strategy without having to increase the instrumental complexity of the fluorescence readout device associated with sequencing instruments, a two-color format may be used to identify the four terminal bases in sequencing applications. In this approach, one or two lasers are used to excite one of two spectrally distinct dyes used for labeling the sequencing primers, and the fluorescence is processed on one of two detection channels, consisting of bandpass filters and photon transducers.

Figure 53.15 shows a schematic of a two-color scanning instrument (last dichroic was not used, and two PMTs were removed). It was used to excite the fluorescence of the labeling dyes, FAM and JOE. Due to their similar absorption maxima, a single laser (488 nm) could efficiently excite the fluorophores. In addition, this dye pair was selected because they produced sequencing fragments that comigrated, and thus no mobility correction was required. The bases were identified using a binary coding scheme, which is shown in Table 53.2.²² During DNA polymerization, four separate reactions were run, with the A-reaction containing an equimolar mixture of the FAM- and JOE-labeled sequencing primers. In the case of G, only the JOE-labeled primer was present, while for T only the FAM-labeled primer was present, and for C no dye-labeled primer was used. By ratioing the signal in the red (JOE) to green (FAM) channel,

TABLE 53.2. Binary Coding Scheme for Two-Color DNA Sequencing

	FAM	JOE
A	1	1
C	0	1
G	1	0
T	0	0

Note: 1 = the presence of the dye-labeled primer during DNA polymerization, and 0 = represents the absence of the dye label.

a value was obtained that could be used to identify the terminal base. The attractive feature of this protocol is that while the absolute intensity of the bands present in the electropherogram may vary by a factor of 20 due to sequence-dependent termination, the ratio varies by a factor of only 1.7. The read length using this binary coding system was up to approximately 350 bases, with the number of errors \sim 15 (accuracy = 95.7%). The majority of the errors were attributed to C determinations, since a null signal was used to indicate the presence of this base.

To alleviate the errors in the base calling associated with identifying bases using a null signal, a two-dye, two-level approach can be implemented. Ad, In this method, the bases using a common dye label have the concentration of ddNTPs adjusted during chain extension to alter the intensity of the fluorescence peaks developed during the electrophoresis. Also required in this approach are uniform peak heights, requiring the use of the modified T7 DNA polymerase in the presence of manganese ions. For example, Chen et al. Used a FAM-labeled primer for marking Ts and Gs, with the concentration ratio of the ddNTPs adjusted to 2:1 (T:G). Likewise, the As and Cs were identified using a 2:1 concentration ratio of the terminators, with the labeling dye in this case being TAMRA. Sequencing data produced an effective read length of 350 bases, with an accuracy of 97.5%. When the concentration ratios of the terminators sharing a common labeling dye was increased to 3:1, the read length was extended to ~400 bases with a base-calling accuracy >97%. As is evident, the elimination of null signals to identify bases can improve the base-calling accuracy in these types of sequence determinations.

While most fluorescence-labeling strategies for DNA sequencing that depend on differences in intensities of the electrophoretic peaks to identify bases use dye-labeled primers, internal labeling, where the fluorescent dye is situated on the dNTP, can also be used.³⁶ The advantages associated with using dyelabeled dNTPs are (1) the ability to use a wide range of primers because no dye-labeled primer is required, (2) incorporation of the dye-labeled dNTP can be much more uniform than dye-labeled ddNTPs, and (3) dye-labeled dNTPs are much less expensive than dye-labeled primers and terminators. Using a tetramethylrhodamine-labeled dATP and a fluorescein-labeled dATP, a two-color/single-lane sequencing assay has been reported.³⁶ For internal labeling, a two-step polymerization reaction was used in which the template was annealed to the sequencing primer (unlabeled) along with the dye-dATP and the four unlabeled dNTPs as well as the polymerase enzyme. The extension reaction was incubated at 37°C for 10 min, after which the appropriate terminator was added and the reaction allowed to proceed for an additional 10 min. The initial extension reaction extended six to eight nucleotides to a quartet of As, with 80 to 90% of the fragments containing a single dye-labeled dATP. Since only two dyes were used in this particular example, the concentration ratio for a pair of terminators sharing a common dye was adjusted (3:1) to allow discrimination based on the intensity of the resulting electrophoretic peaks. Analysis of the sequencing data indicated that the read length was 500 bases with an accuracy of 97%.

53.4.4 Four-Color/Single-Lane

The commonly used approach in most commercial DNA-sequencing instruments using fluorescence detection is the four-color/single-lane strategy for identifying the terminal bases in sequencing applications. The primary reasons for using a four-color/single-lane approach are that it provides high accuracy in the base calling, especially for long reads, and the throughput can be high due to the fact that all bases comprising

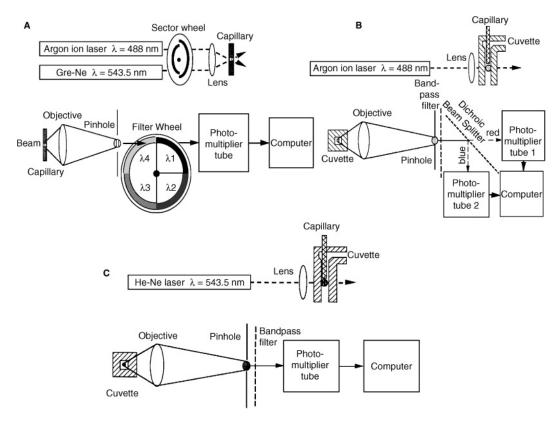

FIGURE 53.20 Laser-induced fluorescence-detection apparati for processing DNA-sequencing data obtained using CGE: four-color/single-lane (A), two-color/single-lane (B), and one-color/single-lane (C).

the template DNA can be called in a single-gel tract. Unfortunately, a four-color detector requires extensive optical components to sort the fluorescence, and in some cases multiple excitation sources are needed to efficiently excite the fluorophores used to label the individual sequencing ladders. In addition, post-electrophoresis software corrections may be required to account for spectral leakage into detection channels.

Most dye-terminator reads are used with this four-color strategy, since the data analysis (base calling) does not depend on uniform incorporation efficiencies, which are hard to achieve using dye-labeled teminators. The same type of instrumentation that is used for four-color/dye-primer reads can also be used for four-color/dye-terminator reads. The only difference is in terms of the sample preparation protocols and the software corrections in the sequencing data such as different mobility-correction factors. In most cases, a size-exclusion step is used following DNA polymerization to remove excess dye-labeled terminators because they are negatively charged and can mask the sequencing data due to the presence of a large dye-terminator band in the gel.

An example of a four-color detector for capillary-gel electrophoresis is shown in Figure 53.20A, in which two laser sources (argon ion laser, 488 nm, and green helium-neon laser, 543 nm) were used to excite the dye set FAM, JOE, TAMRA, and ROX. To process the emission on a single detection channel, a four-stage filter wheel was synchronized to a sector wheel situated in front of the two lasers. The synchronization was set to pass 488-nm excitation for FAM and JOE and simultaneously place the bandpass filters for FAM and JOE in the optical path. Following this, the 543-nm laser light was passed, and the filters for TAMRA and ROX were situated within the optical path. Figure 53.21 shows typical traces produced from this system in which the sequence of an M13mp18 phage test template was analyzed. A read length exceeding 550 bases was obtained at an accuracy of 97%.

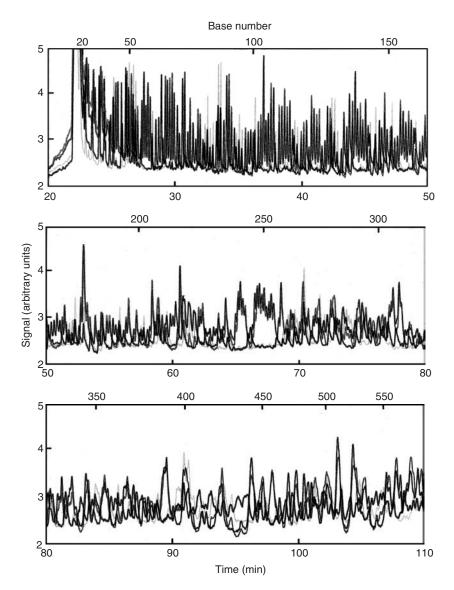

FIGURE 53.21 (Color figure follows p. 28-30.) Four-color/single-lane sequencing of an M13mp18 template with a histidine tRNA insert. The numbers along the top of the electropherogram represent cumulative bases from the primer-annealing site. The electrophoresis was performed in a capillary column with a length of 41 cm and an i.d. of 50 μ m. The sieving gel consisted of a cross-linked polyacrylamide (6% T/5% C) and was run at a field strength of 150 V/cm. The dyes used for the labeling of the sequencing primers were FAM, JOE, TAMRA, and ROX. Each color represents fluorescence from a different wavelength region (blue = 540 nm, green = 560 nm, yellow = 580 nm, red = 610 nm). (Adapted from Swerdlow, H. et al., *Anal. Chem.*, 63, 2835, 1991.)

53.4.5 Choosing the Right Sequencing Format

With a variety of different fluorescence-detection formats available, the question becomes which configuration is better in terms of base calling, both from a read-length and accuracy point of view. In addition, which detection format produces the best SNR in the measurement? Other issues require attention as well, e.g., the complexity of the instrumentation required for detection. A rigorous comparison between the various detector configurations for sequencing applications has been carried out.²⁷ In this study, three

TABLE 53.3 Comparison of Figures of Merit for Various Detector Formats for Fluorescence-Based DNA Sequencing

Detection	Noise	Detection Limit	Read	Base Calling	Information Content ^a	
Mode	(mass)b	(mol) ^b	Length ^c	Accuracy	10 amol	100 zmol
One color	700 ymol	2 zmol	400	85%	14	7
Two color	7 zmol	20 zmol	500	97%	21	8
Four color	70 zmol	200 zmol	550	97%	29	2

^a Calculated from Equation 53.3.

Note: The sequencing assays used capillary gel electrophoresis for fractionating the DNA ladders. The gel consisted of a crosslinked polyacrylamide gel with either formamide or urea as the denaturant. In all cases, the template was an M13mp18 phage with dye-primer chemistry used for fluorescence labeling. In the four-color experiment, FAM, JOE, TAMRA, and ROX were the labeling dyes, for the two-color experiment FAM and TAMRA were used, and for the one-color example only TAMRA was used. The sequencing primer was an M13 (–40) primer and the polymerase was a Sequenase enzyme.

different detector formats were used, and they are shown in Figure 53.20. These consisted of a four-color/single-lane format, a two-color/single-lane format, and a single-color/single-lane format.

Table 53.3 presents a summary of the data collected from this work. The single-color experiment, in which there is a single detection channel, provides the lowest limits of detection, followed by the twocolor system and the four-color system. The significant improvement in the detection limit for the twocolor and single-color systems was partly due to the use of the sheath flow detector that was used in these formats. However, in spite of the use of the sheath flow cell, the general trend is that the lower number of spectral channels typically results in a better SNR in the fluorescence measurement due to the fact that spectral sorting is not required. Spectral sorting causes emission losses due to reflection or inefficient filtering by the bandpass filters used in the optical train. If a filter wheel is used, as in this particular example, a reduced duty cycle will degrade the SNR in the measurement. However, this does not necessarily mean that the lower number of spectral channels will give better sequencing data. As shown by the results of Table 53.3, the four-color format produced better read lengths and favorable base-calling accuracies as compared with the other formats. This is a consequence of the fact that because four spectral channels are being used, the information content in the signal goes up, but only at reasonable loading levels of sample into the sequencing instrument. It is clear that at low loading levels of DNAsequencing ladders, the one-color or two-color approach may be better due to improved limits of detection.

53.4.6 Single-Color/Four-Lifetime Sequencing

While most sequencing applications using fluorescence require spectral discrimination to identify the terminal base during electrophoretic sizing, an alternative approach is to use the fluorescence lifetime of the labeling dye to identify the terminal base. In this method, either time-resolved or phase-resolved techniques can be used to measure the fluorescence lifetime of the labeling dye during the gel electrophoresis separation.

The monitoring and identification of multiple dyes by lifetime discrimination during a gel separation can allow for improved identification efficiency when compared to that of spectral wavelength discrimination. When the identity of the terminal nucleotide base is accomplished through differences in spectral emission wavelengths, errors in the base call can arise from broad, overlapping emission profiles, which results in crosstalk between detection channels. Lifetime discrimination eliminates the problem of

 $^{^{}b}$ ymol = 10^{-24} mol; zmol = 10^{-21} mol.

^c The read lengths were determined from sequencing data with high SNRs that were comparable across the series.

crosstalk between detection channels and can also potentially allow processing of the data on a single readout channel. Several other advantages are associated with fluorescence lifetime identification protocols, including:³⁷

- 1. The calculated lifetime is immune to concentration differences.
- 2. The fluorescence lifetime can be determined with higher precision than fluorescence intensities.
- 3. Only one excitation source is required to efficiently excite the fluorescent probes, and only one detection channel is needed to process the fluorescence for appropriately selected dye sets.

One potential difficulty associated with this approach is the poor photon statistics (limited number of photocounts) that can result when making such a measurement. This results from the need to make a dynamic measurement (the chromophore is resident in the excitation beam for only 1 to 5 sec) and the low-mass loading levels associated with many DNA electrophoresis formats. Basically, the low number of photocounts acquired to construct the decay profile from which the lifetime is extracted can produce low precision in the measurement, which affects the accuracy in the base call. In addition, the high scattering medium in which the fluorescence is measured (polyacrylamide gel) can produce large backgrounds, again lowering the precision in the measurement. An additional concern with lifetime measurements for calling bases in DNA-sequencing applications is the heavy demand on the instrumentation required for such a measurement. However, the increased availability of pulsed diode lasers and simple avalanche photodiode detectors has had a tremendous impact on the ability to assemble a time-resolved instrument appropriate for sequencing applications.

There are two different formats for measuring fluorescence lifetimes — time-resolved^{37–43} and frequency-resolved.^{44–48} Since the time-resolved mode is a digital (photon-counting) method, it typically shows a better SNR than a frequency-resolved measurement, making it more attractive for separation platforms that deal with minute amounts of sample. In addition, time-resolved methods allow for the use of time-gated detection in which background photons, which are coincident with the laser pulse (scattered photons), can be gated out electronically, improving the SNR in the measurement.

A typical time-correlated single-photon-counting (TCSPC) device consists of a pulsed excitation source, a fast detector, and timing electronics. A device that has been used for making time-resolved measurements during CGE is shown in Figure 53.22. 39 The light source consisted of an actively pulsed solid-state gallium aluminum arsenide (GaAlAs) diode laser with a repetition rate of 80 MHz and an average power of 5.0 mW at a lasing wavelength of 780 nm. The pulse width of the laser was determined to be ~50 psec (formal width half maximum [FWHM]). The detector selected for this instrument was a SPAD, which has an active area of 150 μ m and is actively cooled. In addition, the SPAD has a high single-photon-detection efficiency (>60% above 700 nm). The counting electronics (constant fraction discriminator [CFD], analog-to-digital converter [ADC], time-to-amplitude converter [TAC], and pulse-height analyzer) are situated on a single TCSPC board. The board plugs directly into a PC bus and exhibits a dead time of <260 nsec, allowing efficient processing of single-photon events at counting rates exceeding 2 × 106 counts/sec. This set of electronics allows for the collection of 128 sequential decay profiles with a timing resolution of 9.77 psec per channel. The instrument possesses a response function of approximately 275 psec (FWHM), adequate for measuring fluorescence lifetimes in the subnanosecond regime.

Probably the most important aspect of lifetime determinations in sequencing applications is the processing or calculation algorithms used to extract the lifetime value from the resulting decay. Since the photon statistics are poor and the accuracy in the base call depends directly on the lifetime differences between fluors in the dye set and the relative precision in the measurement, algorithms that deal with this situation are required as well as those that can be performed online during the electrophoresis. Two algorithms for on-the-fly fluorescence-lifetime determinations have been used — the maximum likelihood estimator (MLE) and the rapid lifetime determination method (RLD). MLE calculates the lifetime via the following relation:⁴⁹

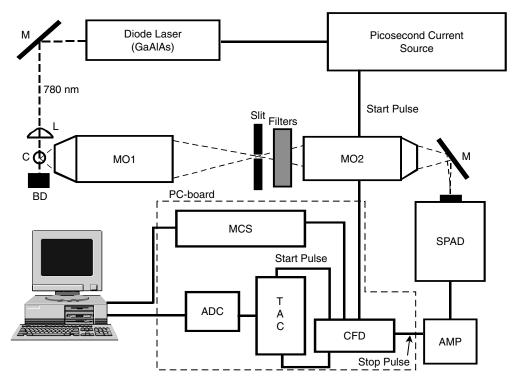

FIGURE 53.22 Time-correlated single-photon counting detector for CGE. The laser source was a pulsed diode laser that operated at a repetition rate of 80 MHz and lased at 780 nm (average power = 5 mW). The laser was focused onto a capillary-gel column with the emission collected using a 40× microscope objective (NA = 0.85). The fluorescence was imaged onto a slit and then spectrally filtered and finally focused onto the photoactive area of a single-photon-avalanche diode. The electronics for processing the time-resolved data was situated on a single PC board, which was resident on the PC bus. (Adapted from Legendre, B.L. et al., *Rev. Sci. Instrum.*, 67, 3984, 1996.)

$$1 + (e^{T/\tau_f} - 1)^{-1} - m(e^{mT/\tau_f} - 1)^{-1} = N_t^{-1} \sum_{i=1}^m iN_i$$
 (53.4)

where m is the number of time bins within the decay profile, N_i is the number of photocounts in the decay spectrum, N_i is the number of photocounts in time bin i, and T is the width of each time bin. A table of values using the left-hand side of the equation is calculated by setting m and T to experimental values and using lifetime values (τ_f) ranging over the anticipated values. The right-hand side of the equation is constructed from CE decay data over the appropriate time range. The fluorescence lifetime may then be determined by matching the value of the right-hand side obtained from the data with the table entry. The relative standard deviation in the MLE may be determined from $N^{-1/2}$.

Fluorescence lifetimes calculated using the RLD method is performed by integrating the number of counts within the decay profile over a specified time interval and using the following relationship:⁵⁰

$$\tau_f = -\Delta t / \ln(D_1/D_0) \tag{53.5}$$

where Δt is the time range over which the counts are integrated, D_0 is the integrated counts in the early time interval of the decay spectrum, and D_1 represents the integrated number of counts in the later time interval. Both the MLE and RLD methods can extract only a single lifetime value from the decay, which in the case of multiexponential profiles would represent a weighted average of the various components comprising the decay.

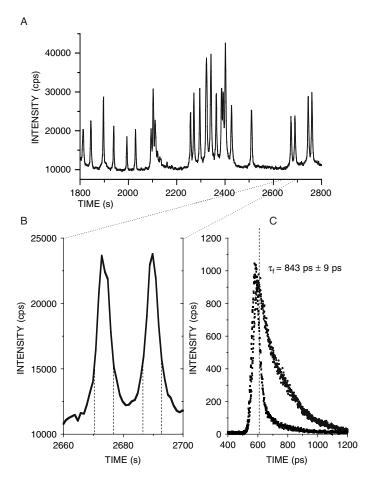

FIGURE 53.23 CGE of C-terminated fragments produced from an M13mp18 template with time-resolved fluorescence detection (A). The labeling dye (F-substituted, heavy-atom-modified NIR fluorescent label; see Table 53.1) was attached to the 5' end of a sequencing primer. (B) Expanded view of two peaks selected from the electropherogram showing the time area (dashed lines) over which photoelectrons were used to construct the decay profiles. The decay profiles shown in (C) consist of the gel blank and the dye-labeled DNA fragment. The dashed line shows the start channel in which the calculation was initiated. The lifetime was calculated using Equation 53.3. The electrophoresis was carried at a field strength of 200 V/cm using a cross-linked polyacrylamide gel. (Adapted from Soper, S.A. et al., Anal. Chem., 67, 4358, 1995.)

Wolfrum et al. have also implemented a special pattern recognition technique.³⁸ Basically, the method involves comparing a pattern to the measured decay and searches for a pattern that best fits the measurement. This algorithm is equivalent to the minimization of a log-likelihood ratio where fluorescent-decay profiles serve as the pattern. Since the pattern-recognition algorithm uses the full amount of information present in the data, it potentially has the lowest error or misclassification probability.

To demonstrate the feasibility of acquiring lifetimes on the fly during the CGE separation of sequencing ladders, C-terminated fragments produced from Sanger chain-terminating protocols and labeled with a NIR fluorophore on the 5' end of a sequencing primer were electrophoresed and the lifetimes of various components within the electropherogram determined.³⁷ An example of the data produced from this detection format is shown in Figure 53.23. The average lifetime determined using the MLE method was found to be 843 psec, with a standard deviation of ± 9 psec (RSD = 1.9%). The lifetime values calculated here compared favorably to a static measurement performed on the same dye.

Since the base calling is done with lifetime discrimination as opposed to wavelength discrimination, new types of dye sets can and need to be used that suit the identification method. For example, it is not necessary to use dyes with discrete emission maxima, and so structural variations in the dye set can be relaxed. A dye set developed for lifetime discrimination has been prepared and consists of a NIR chromophore that has unique fluorescence lifetimes with the lifetime altered via the addition of an intramolecular heavy atom.⁵¹ Each of these dyes possesses the same absorbance maximum and fluorescence-emission maximum but different fluorescence lifetimes (see Table 53.1). Since these were tricarbocyanine dyes, the lifetimes were found to be <1.0 nsec, with the lifetimes for the dye set ranging from 947 psec to 843 psec when measured in a polyacrylamide gel containing urea, with the observed lifetimes less than what was observed in methanol but still exhibiting single exponential behavior.

A dye set appropriate for lifetime-identification purposes has been prepared and used in four lifetime DNA-sequencing applications.⁴⁰ The dyes absorb radiation from 624 to 669 nm and possess lifetimes that range from 1.6 to 3.7 nsec (see Figure 53.24). Unfortunately, the dye set shows multiexponential behavior in sequencing gels containing denaturants (urea, 7 *M*). In addition, to correct for dye-dependent mobility shifts unique linker structures were used. Using this dye set (dye-primer chemistry) and a pulsed diode laser operating at 630 nm, the sequence of an M13mp18 phage was evaluated. The lifetimes were extracted from the decays using a pattern-recognition algorithm. The read length was found to be 660 bases with a calling accuracy of 90%.

53.5 Single-Molecule DNA Sequencing Using Fluorescence Detection

The sequencing strategies discussed to this point depend on a fractionation step (electrophoresis) to sort the DNA by size. While much progress has been made in reducing the time required to develop the electropherogram, resulting in increases in the throughput of acquiring sequencing data, many problems arise when using gel electrophoresis. These problems include the ability to sequence DNA pieces that are only 1000 to 2000 bp in length, the requirement of gels to fractionate the DNA, the relatively slow speed associated with the process, and the data-processing requirements. The most pervasive problem is the ability to work only with DNA pieces that are 1000 to 2000 bases in length. Since the chromosomes exceed 1×10^6 bases, the assembly of the sequence of the entire chromosome with extremely short pieces makes the task daunting. Directly sequencing larger strands of DNA would relieve some the technical challenges associated with assembly. In addition, since YAC clones are ~100,000 bp, this requires the shearing and then subcloning of these DNAs into M13s to produce templates for sequencing. The ability to work with longer DNAs would eliminate the need for this secondary cloning step.

A very attractive approach has been suggested to rapidly sequence DNA strands that are >40,000 bp in length. The process is based on the principle of single-molecule detection using fluorescence photon burst analysis.⁵² The process is depicted in Figure 53.25. Basically, the process involves immobilizing a long strand of DNA in a flow stream and then clipping the terminal base using an exonuclease enzyme, releasing the nucleotide from the original strand. The single nucleotide (either fluorescently labeled or nonlabeled) is then carried to a laser beam, which excites the fluorescence with the color used to identify the base clipped from the DNA strand. As shown in the figure, the single-molecule-sequencing approach does not involve a gel-fractionation step, potentially significantly speeding up the sequencing rate. In essence, the sequencing rate is determined by the rate at which the enzyme clips nucleotide bases from the strand, which for many exonuclease enzymes is on the order of 1000 bases per second. There are three key technical challenges associated with this technique: (1) tethering the DNA strand to a bead for holding it stationary within a flow stream, (2) creating a complement of the original DNA strand using dye-labeled dNTPs, and (3) detecting single-dye-labeled nucleotides using laser-induced fluorescence detection.

Since the premise of this sequencing protocol is to analyze single DNA molecules, a single DNA molecule must be selected and then trapped within a flow stream for processing. To accomplish this, a

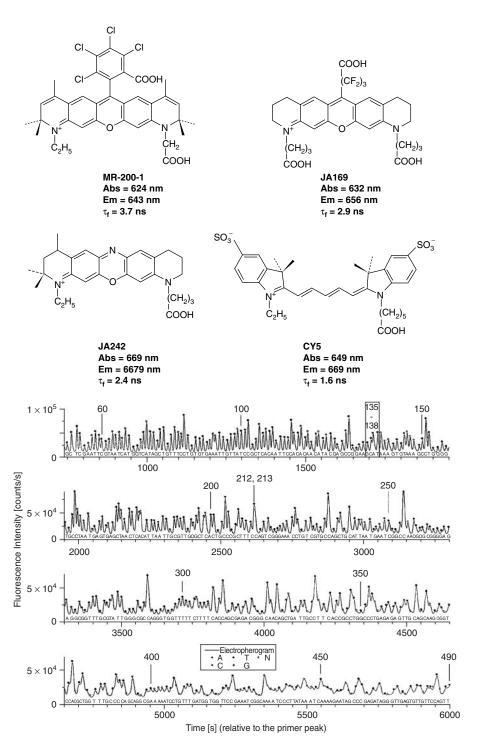

FIGURE 53.24 Chemical structures of dyes used for multiplex, time-resolved DNA sequencing as well as the fluorescence properties of this dye set. Also shown is the sequencing data obtained when using the dye set shown above conjugated to sequencing primers. The sequencing was performed in a 5% linear polyacrylamide gel containing 7 M urea at a field strength of 160 V/cm. The fluorescence detector consisted of a pulsed diode laser (630 nm) with the optics configured in a confocal geometry. (Adapted from Lieberwirth, U. et al., *Anal. Chem.*, 70, 4771, 1998.)

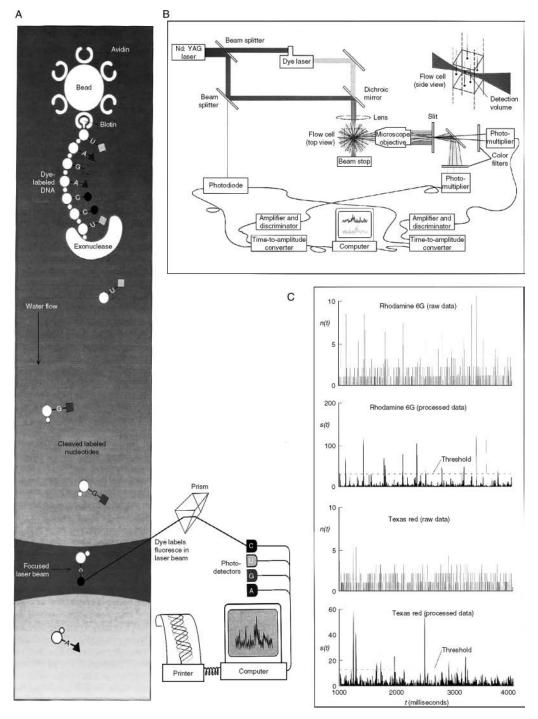

FIGURE 53.25 (A) Schematic diagram of single-molecule sequencing. (B) Block diagram of a dual-color single-molecule detection apparatus. (C) Single-molecule data of R6G and Texas Red using the apparatus described in (B). The dye concentration used in these experiments was set at 50 fM, which resulted in an arrival rate of ~1 molecule every 4 sec. The dashed line represents the threshold, which defined the detection of a single molecule when the observed signal (photon burst) exceeded this level. (Adapted from Soper, S.A. et al., *J. Opt. Soc. Am. B*, 9, 1761, 1992.)

DNA molecule can be prepared that contains a biotin molecule on its 5' end. The biotin-modified DNA molecule can then be attached to a microbead (i.d. = 1 to $10 \, \mu m$) coated with streptavidin. Streptavidin is a protein that contains binding sites for biotin. The association of biotin to streptavidin is very strong ($K_{assoc.} = 10^{15} \, M^{-1}$) and in addition is stable to both heat and the reagents used in most enzymatic reactions. In this case, a bead that has one DNA molecule attached to it must be selected, as a bead with multiple DNA strands would create a registry problem because the exonucleases work at different rates. Therefore, conditions that produce a sufficient population of beads containing a single DNA molecule must be selected. This can be done statistically by incubating the biotinylated DNA with a large excess of microbeads. This produces a large number of beads with no DNA molecule; therefore, the appropriate beads must be selected by staining the immobilized DNA with a fluorescent intercalating dye and using fluorescence to identify a bead with the appropriate number of DNA molecules attached.

The suspension of the bead containing the DNA molecule in the flow stream can be accomplished using an optical trapping technique. In this case, one or two tightly focused laser beams can be directed onto the bead. This generates an optical trap, which can hold the bead in the flow stream. The size of the trap is determined by the size of the focused laser beam (or beams) and is on the order of 5 μ m. Since the trap is generated by a momentum exchange between the photons and the trapped bead, it does not depend on any type of electronic or vibrational transition. As such, the trapping laser can be a farred or infrared laser that does not bleach the dyes incorporated into the target DNA molecule during polymerization.

The second technical challenge in this scheme is to produce a complement that contains dye-modified oligonucleotides. Since detection is accomplished using fluorescence (typically visible fluorescence) single-molecule detection, it is necessary to covalently label each dNTP with a probe and then, more importantly, build a fluorescent complement of the target DNA using a polymerase enzyme. As with dye-labeled ddNTPs, incorporation of dye-modified dNTPs is a challenge because the incorporation rate and fidelity of modified dNTPs by standard polymerase enzymes is not facile. Therefore, mutants will have to be prepared to accomplish this task. An alternative to using fluorescent dyes is to implement ultraviolet single-molecule detection, which requires unmodified dNTPs. While this strategy is much more forgiving in terms of molecular biology, it places severe challenges on the detection phases of the technique because the nucleotide bases have absorption maxima around 260 nm and the fluorescence quantum yields of the bases are low ($\sim 10^{-4}$) at room temperature in solution.

The final challenge in this approach is the ability to detect single-dye molecules (nucleotides) in solution and identify the single molecules via spectral discrimination. Since a DNA molecule is comprised of four different nucleotide bases, the bases as they are clipped by the exonuclease from the target DNA must be spectrally identified. While several researchers have demonstrated the ability to detect single molecules in flow streams,^{53–55} the ability to color-discriminate adds complexity to the instrumentation (multiple lasers, multiple detection channels) and requires careful selection of the dyes. Not only must the dyes be well resolved in terms of their emission maxima, but the photophysics of the dye must be conducive to single-molecule detection, i.e., must have a high quantum yield and favorable photochemical stability. Figure 53.25 shows an example of a dual-color single-molecule-detection apparatus.⁵⁶ It consists of a mode-locked neodymium:YAG laser operating at 532 nm (second harmonic) and also a synchronously pumped dye laser (λ_{em} = 585 nm). These wavelengths were chosen to match the absorption maxima of the two dyes selected for this experiment, R6G (λ_{ex} = 528 nm; λ_{em} = 555 nm) and Texas Red $(\lambda_{\rm ex} = 578 \text{ nm}; \lambda_{\rm em} = 605 \text{ nm})$. The fluorescence was processed on one of two photodetectors, which in this case consisted of microchannel plates (MCPs). The fluorescence from each dye was directed onto the appropriate MCP using a dichroic filter, with the emission further isolated from background photons and fluorescence from the other dye using a bandpass filter. The processing electronics consisted of conventional TCSPC electronics, which were used along with the pulsed lasers to allow for implementation of time-gated detection. Time-gated detection reduces the amount of background-scattered photons into the data stream, improving the SNR in the single-molecule measurement. An example of the data output from this dual-color single-molecule detector is shown in Figure 53.25 (raw data and processed data). The raw data were filtered using a weight quadratic sum filter [S(t)] given by the following expression:³⁷

$$S(t) = \sum_{\tau=0}^{k-1} w(\tau)d(t+\tau)^2$$
 (53.6)

where k represents the time range covered by the molecular transit through the laser beam, $w(\tau)$ is weighting factors selected to best distinguish the signal from noise, and d(t) represents the raw data point at time (t). These data make clear that large-amplitude bursts of photons occur with both dyes. The detection efficiency was estimated to be 78% for R6G and 90% for Texas Red. In both cases, the error rate (defined as identifying a molecule when one was not present, false positive) was estimated to be <0.01 per second.

54.1 Introduction: The Green Fluorescent Protein Breakthrough

Previous chapters in this handbook have extensively described new methods in the field of biophotonics and reviewed applications. The scope of this chapter is to present, from the biologist's point of view, a synthesis of the current and potential applications of the previously described techniques. The chapter focuses on techniques that have been or are supposed to be used for studying a type of biomolecular event occurring on a specific intracellular organelle. The advantages and, of course, limitations of each method, as they appear in the light of present knowledge, will be pointed out. An effort will be made to show how some techniques are able to give simultaneous but selective information on biochemical events occurring at different sites of the cell.

The recent breakthroughs in genomics and proteomics have completely changed the way we think about exploring intracellular dynamics. Previously, we would introduce inside the cell hexogenous fluorescent molecules that were selected to monitor some specific biomolecular pathways. We depended entirely on their ability to enter the cell and had few means of directing them to a specific intracellular target. As a consequence, the information obtained could often be biased in various ways. First, the fluorescence signal was often a mixture of signals resulting from different microenvironments due to the nonspecific location of the probe. Second, to be informative the hexogenous fluorescent molecules had to compete with the natural biomolecules, and thus they might induce some imbalance in the intramolecular processes.

The techniques of molecular biology have allowed for the generation of fluorescent chimera that mimic biological molecules and that can be vectorized to or expressed at specific targets (organelles or microcompartments). One can say that cells themselves have been reengineered to give us the requested information, even if potential under- or overexpression may yet undermine this information.

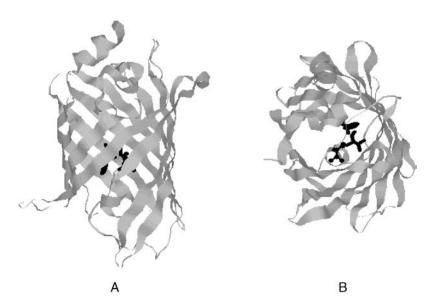

FIGURE 54.1 Side (A) and top (B) view of the 3D structure of enhanced yellow fluorescent protein (EYFP), showing the 11-stranded β -barrel as ribbon. The three amino-acid residues 64, 65, and 66, which form the chromophore after cyclization and oxygenation, are shown as balls and sticks.

Because these techniques have made it possible to get localized, real-time information on intracellular dynamics, it became necessary to modify and develop optical tools to get dynamic, three-dimensional (3D) microscopic maps of the living cell with nanometric resolution of individual molecules.

The green fluorescence protein (GFP) is a spontaneously fluorescent polypeptide of 27kD (238 aminoacid residues) from the jellyfish Aequorea victoria that absorbs ultraviolet (UV) blue light and emits in the green region of the spectrum.1 Its structure and potential uses for studying living cells have been recently reviewed in detail.²⁻⁷ The GFP chromophore results from a cyclization of three adjacent amino acids (S65, Y66, G67) and the subsequent 1,2dehydrogenation of the tyrosine.2-7 Although the chromophore by itself is able to absorb light, its fluorescence properties result from the presence of an 11stranded β-barrel. GFP has been expressed both in bacteria and in eukaryotic cells and has been produced by in vitro translation of the GFP messenger RNA (mRNA). Moreover, GFP retains its fluorescence when fused to heterologous proteins on the N- and C-terminals, and these bindings generally do not affect the functionality of the tagged protein.^{2,3,6} That leads to the use of GFP as an intracellular reporter. Unfortunately, the fluorescence intensity of the native GFP is not bright enough for most intracellular applications. Therefore, variants have been engineered with different excitation or emission spectra that better match available light sources.^{2,3,5–7} Brighter mutants were also found necessary in case of low expression levels in specific cellular microenvironments.^{3,5-7} Figure 54.1 shows the structure of a GFP-type variant molecule, the enhanced yellow fluorescent protein (EYFP). Moreover, the time lag between the protein synthesis and fluorescence development, as well as sensitivity for photobleaching, was also a limitation when changes in location or conformation of the protein were sought.⁶

The potential toxicity of GFP has been questioned.² The efficiency of all these new mutants has recently been extensively reviewed, as has the incidence of GFP mutations on mRNA transcription and translation rates.^{2,6} The only serious limitation to the use of GFP variants seems to be their size, which makes them unusable for tagging small biological molecules such as lipids or small proteins.

54.2 Exploring the Protein Factories

All recent studies have demonstrated that both tight control and coordination of gene expression require a high level of organization in the eukaryotic cell nucleus. Both fluorescence *in situ* hybridization (FISH)

and immunocytochemical studies have shown that chromosomes occupy distinct territories within the nucleus and that many of the factors involved in transcription and RNA processing are located in nuclear bodies. Active genes in transcription are located at the borders of the condensed chromatin regions, which give them access to the transcription, RNA processing, and transport machinery (see Reference 8 and references therein). Due to its importance for life conservation, it is not surprising that photonics techniques were used to visualize how this special organization is conserved during cell replication, how it is correlated to the cellular functional activities, and how endogenic or exogenic events might disturb it.

54.2.1 Information Storage and Conservation: Chromatin Structure and Cellular Division

Advances in the specific fluorescent labeling of chromatin in living cells, in combination with 3D fluorescence microscopy and image analysis, have led to detailed studies of the higher-order architecture of chromatin in the human cell nucleus. Techniques such as time-lapse confocal microscopy (TLCM), fluorescence-resonance energy transfer (FRET), and fluorescence redistribution after photobleaching (FRAP) have opened the way to space-time (4D) studies of the dynamics of this architecture and of its potential role in gene regulation.^{9–13} Several features of this architecture are well established; and even if many points remain in the speculative domain, models of the functioning of this super architecture have been proposed (see References 13 and 14 and references therein).

In parallel with the elucidation of the dynamics of chromatin architecture, many biophotonic studies have been devoted to nuclear transformation during mitosis and to the dynamics of postmitotic events. Multiwavelength fluorescence imaging (MWFI) has allowed the observation of the dynamic behavior of chromosomes and of some GFP fusion proteins linked to the nuclear envelope or the centromeres (see References 14 and 15 and references therein). The different pathways of assembly during nuclear-envelope formation of nuclear lamins A and B1 were also investigated by FRAP of lamins tagged with enhanced GFP (EGFP). Time-lapse fluorescence imaging (TLFI) was used for a detailed analysis of mitosis in fission yeast, revealing the consequence of the presence of lagging chromosomes on the rate of anaphase B. The expression of GFP-labeled centrin was used to study the respective contribution of mother and daughter centrioles to centrosome activity and behavior. The dynamics of nucleolar reassembly were monitored in living cells expressing fusions of the processing-related proteins fibrillarin, nucleolin, and B23 with GFP. Previously, the effects of mitotic inhibitors on cell-cycle progression were visualized by following the dynamics of chromosomes and microtubules stained with fluorescent chemicals.

54.2.2 Information Transmission to Endoplasmic Reticulum Factories

Although many problems still remain unclear, most modern pictures of the nucleus agree with the need for a high level of organization of the chromatin. It is accepted that chromosome territories contain regions in which the degree of chromatin condensation varies. To be transcriptionally active genes must be located at the border of the condensed chromatin, in what Cremer et al. named an "interchromatin domain compartment." This location contains ribonucleoprotein complexes involved in transcription and pre-mRNA splicing that can be detected through multiwavelength fluorescent microscopy. 8,12,14 The use of multifluorescent labeling protocols would make it possible to track gene transcripts in living cells. Figure 54.2 shows a schematic diagram of the main successive steps involved in the synthesis of proteins.

Several approaches based on fluorescence techniques have been developed to detect the different RNAs in living cells and to monitor their dynamic behavior. A discussion of the methods used for introducing fluorescent RNAs inside the nucleus (microinjection of fluorescent RNAs into the nucleus, *in vivo* hybridization of fluorescent oligonucleotides to endogenous RNAs, or expression in cells of fluorescent RNA-binding proteins) is beyond the scope of this chapter. From our point of view, most of these studies can be classified in two sets: those involving only one fluorescent tag and those that require the use of two fluorescent tags. In the first set, when short linear DNA nucleotides (20 to 40 bases) or short antisense fluorescent probes are involved, chemical fluorophores e.g., fluorescein and rhodamine, are used in

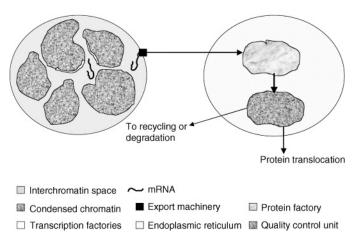

FIGURE 54.2 Schematic diagram of the main successive steps involved in the synthesis of proteins.

association with TLFl, FRAP, or fluorescence correlation spectroscopy (FCS) (see Reference 8 and references therein). mRNA was also visualized using GFP as a tag on the RNA-loop-binding protein MS2. In the second set, hairpin-shaped oligonucleotide probes named "molecular beacons" are synthesized with fluorescent donor and acceptor chromophores at their 5′ and 3′ ends (see Reference 8 and references therein; Figures 54.3A and B). In the absence of a complementary nucleic-acid strand, the stem–loop conformation induces a FRET signal that prevents the fluorescence emission of the donor fluorophore. On the other hand, hybridization with a complementary sequence opens the stem–loop conformation, increases the distance between the donor–acceptor pair, and decreases the efficacy of FRET, allowing the fluorescence emission of the donor to be detected with confocal laser microscopy. Although the use of such molecular beacons was supposed to increase the signal-to-noise ratio (SNR), this does not always seem to be the case, suggesting that other intracellular mechanisms might sometimes open the stem–loop conformation⁸ and included references. But detailed information reported in recent papers provides a model of the movement of mRNAs from transcription site to nuclear pores and of the role played by some nuclear proteins in facilitating or slowing down that complex process. ^{23,24} The development and applications of molecular beacons are further described in Chapter 57 of this handbook.

54.2.3 The "Quality-Control" System

When inserted into endoplasmic reticulum (ER) membranes, newly synthesized proteins encounter the lumenal environment of the ER that contains chaperone proteins. These proteins facilitate the folding reactions necessary for protein oligomerization, maturation, and export from the ER to the Golgi apparatus. Nevertheless, there are few studies that can actually visualize this complex process on living cells using fluorescence techniques.²⁵ In fact, visualization of this process involves a very impressive task. First, involved chaperones must be tagged to demonstrate their interaction with the target polypeptide. Second, the polypeptide itself must be labeled in a way that allows the properly folded protein to be distinguished from the polypeptide itself and from incompletely or improperly folded proteins. That task could be more demanding than having some GFP mutants at both ends of the target molecule. Nevertheless, interactions between different chaperones have been evidenced in solution.²⁶

In fact, it is not certain that such a complex process works properly for each polypeptide entering the ER. On the contrary, there are grounds for suspecting that alteration of the yield of this process may induce some diseases.²⁷ Details of the mechanisms by which properly folded proteins are sorted from improperly folded ones and from the resident proteins have yet to be clarified and visualized in living cells. Nevertheless, it has been shown that improperly folded proteins accumulate in a novel pre-Golgi compartment, sometimes called ERGIC (for ER-to-Golgi), where they aggregate or are targeted for ER-associated protein degradation.^{28,29}

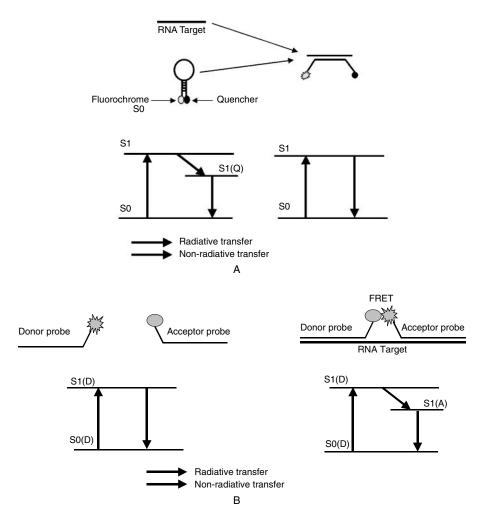

FIGURE 54.3 (A) General concept of molecular beacons: hybridization with the target-RNA sequence opens the stem-loop conformation that results in emission of fluorescence. (B) Use of double labeling for detecting an RNA sequence: the fluorescence of the acceptor probe is seen only when both the acceptor and donor are properly hybridized.

Recent studies have shown that membranes of some organelles have their own systems for transforming nuclear-encoded preproteins into proteins that can be internalized in these organelles. Although they have not yet been applied to living cells, some methods have been tested in solution, which would allow the study of the conformational changes of these preproteins during the process of internalization in mitochondria.³⁰

for visualizing cytoskeletal dynamics was the microinjection of purified and fluorescently labeled protein, a protocol of limited use due to technical difficulties. In contrast, the addition of fluorescent tags to cytoskeleton proteins allowed visualization of the reorganization of its spatial structure and the localization of individual cellular components such as proteins and organelles. Furthermore, activities directly associated with the cytoskeleton, such as intracellular transport, cell motility, and morphological plasticity, have been investigated.² The studied proteins span a wide range, from proteins incorporated in or bound to microtubules (α and β -tubulins, MAPs, Tau, Kinesin, etc.), ³¹ to some associated with microfilaments (actins, myosins, myomesin, titin, β 1-integrin, etc.), and finally to some incorporated in intermediate filaments (vimentin, lamin A) or septins.³² The dynamics of microtubules (stabilization, turnover, bending and breaking, 3D organization) have also been investigated in recent studies using time-lapse fluorescence or confocal laser scanning microscopy.^{33–39}

The functions of the motor proteins kinesin and dynein have also been studied using GFP tagging.^{40,41,42} Total internal reflection (TIR) has been successfully used to image the dynamics of individual GFP-kinesin.⁴³ Such a method could be used to characterize the dynamics of the rapidly increasing number of identified motor proteins because tagging with GFP is stoichiometric and allows the use of recombinant fusion protein directly from bacterial extracts.

Successful monitoring of microfilaments using GFP-actin has been reported.^{44–48} The actin cytoskeleton is an interesting target because it is involved in, and often drives a variety of, cellular processes such as morphogenesis,⁴⁹ endocytosis,⁵⁰ and cytokinesis, and links with the extracellular matrix.^{51,52}

54.3.1.2 Mapping Protein Distribution in Membranes

GFP exhibits fluorescence when it is used to create chimeric GFP proteins that can be easily visualized inside living cells. The main advantage of these GFP chimeras over chemical fluorescent tagging is the ease with which they may be assembled and introduced inside cells.^{3,7} Of course, the final steady-state levels of GFP are critical for further applications. As with any other protein, they depend on the kinetics of the transcription and degradation of the GFP–mRNA and on the rate of degradation of the protein.^{6,53} Furthermore, GFP chimeras can be used as *in vivo* markers for subcellular structures through the construction of systems that contain the appropriate targeting information.³ Thus GFP has been successfully used to visualize the localization of membrane proteins.^{5,6,54,55} Successful imaging of protein localization in the endoplasmic reticulum or the Golgi complex has also been reported.^{3,56,57}

Studying the colocalization of different kinds of proteins requires the use of GFPs that fluoresce at different wavelengths. Besides EGFP, EBFP (Enhanced Blue Fluorescent Protein), EYFP, and ECFP (Enhanced Cyan Fluorescent Protein) have been synthesized; they fluoresce at 440, 527, and 475 nm, respectively. Several investigators have demonstrated the potency of using these spectral variants of GFP to acquire image sets of two or more different organelles or proteins in living cells. 3,5–7,58 In a more sophisticated approach, the lifetimes of these markers can also be used for colocalization studies through fluorescence lifetime imaging (FLIM). Table 54.1 lists spectral properties and lifetimes of some commercially available GFP mutants.

53.3.1.3 Monitoring the Intracellular Trafficking of Proteins

Compared with the previous one, this goal is more demanding because it requires that the time necessary to record the fluorescent signal be short enough to allow a visualization of the protein translocation. Cellular expression or microinjection of brighter mutants of GFP allows for the construction of GFP chimeras usable for monitoring the translocation of proteins. However, the stability of the probes against photobleaching becomes a crucial factor for the successive illuminations of the same microscopic field that are necessary to detect any change in localization.

Expression, translocation, and turnover of proteins involve successive transient protein–membrane interactions that may be associated with changes in the membranar morphology. Optical methods used for monitoring the protein traffic have been found useful for monitoring morphological changes involved in the protein trafficking or resulting from the presence of viruses.⁶⁰

Direct observation of nucleocytoplasmic transport (combined with nuclear localization or nuclear export signal) of a GFP-tagged glutathione-S-transferase has been reported, ^{7,61} while visualization of the transport from reticulum to Golgi has been performed with a GFP-tagged temperature-sensitive mutant protein.³ Other studies have focused on expression and organellar targeting to test the ability to produce stable "green" transgenic parasites.⁶²

Secretion involves shuttling proteins between various intracellular compartments. The transport of secretory vesicles from the trans-Golgi network to the plasma membrane has been monitored using a GFP chimera of the protein chromogranin B and time-lapse imaging. The same imaging technique has been used to demonstrate the direct rapid translocation of MHC class II molecules from the lysosomal compartment to the plasma membrane in cells of the immune system.³

Several proteins involved in signal transduction have been tagged with GFP variants to visualize their transport between cytosolic and membrane-bound pools in response to stimulation. The protein kinase B (PKB) (a mitogen-regulated kinase that protects cells from apoptosis) binds to phosphatidylinositol 3,4,5 triphosphate (PIP3), generated and localized in the plasma membrane via its pleckstrin homology (PH) domain, and is subsequently activated. Its translocation upon growth-factor stimulation was monitored in transiently transfecting fibroblasts using a GFP-PKB chimera. Other signaling proteins, such as Bruton's tyrosine kinase, the Ras GTPase-activating protein GAP1(m), and the ARF guanine nucleotide exchange factor ARNO, have also been GFP-tagged and translocated to the plasma membrane via their PH domains upon cell stimulation.³

GFP variants with different spectral properties have been used to simultaneously monitor the intracellular movements of several distinct proteins to follow the dynamics of nuclear envelope disassembly and assembly.³ Fluorescent indicators have been developed to study in detail the cleavage of peptides in living cells as they are transported from the endoplasmic reticulum to the Golgi. When a peptide is labeled with these dyes at specific sites, a FRET is observed that disappears upon proteolytical process inside the cell.⁶³ Such a study leads the way to a new, elegant, and sophisticated approach to determining the precise mechanisms involved in immune surveillance.

GFP-tagged proteins have also been used to analyze the distribution of chemotactic receptors.³ Other applications included studies on inhibition of protein shuttling,⁶⁴ regulation of membrane diffusion of aquaporin water channels,⁶⁵ internal trafficking and surface mobility of a functionally intact 2-adrenergic receptor-GFP conjugate,^{5,7} and transient association of proteins with cell contact areas.⁶⁶ A quantitative study of fluorescent adenovirus entry has also been reported as a model system for cargo transport from the cell surface to the nucleus.⁶⁷

53.3.1.4 Monitoring "Proteins at Work" in Living Cells

Monitoring "proteins at work" is more challenging than protein mapping or trafficking because it requires techniques that allow dormant proteins to be distinguished from activated proteins. Because the physical characteristics of the fluorescence of a molecule strongly depend on its microchemical environment, fluorescence techniques can be used to probe the changes of conformation that occur when a tagged protein is activated. Of course, the labeling of the protein with a fluorescent molecule must obey rules

that are somewhat contradictory. The binding must occur at a definite location on the protein. This location must be far enough from the active site of the protein so that the binding does not change the activity of the protein but at the same time close enough to the active site so that it can be sensitive to the 3D conformational change occurring when the protein is activated.

Fluorescent molecules in which changes in chemical microenvironment induce spectral shifts of emission and excitation fluorescence spectra are numerous. Others experience changes in fluorescence intensity. Obtaining unambiguous information on potential changes in conformation for a given protein in living cells generally demands the use of two fluorophores: one of them must report only the total concentration of the protein, while the other must be sensitive to conformational changes. This could be troublesome when the tagged proteins must be microinjected inside the cells.

Another approach to monitoring conformational changes is to take advantage of change in the polarization of the fluorescence emission. Although anisotropy of fluorescence is practically independent of the concentration of the fluorescent dye, this technique has not been widely used in living cells until now, probably due to its relatively low sensitivity.⁷

The lifetime of the first excited state of a molecule is also very sensitive to changes in the chemical microenvironment of the dye while it is insensitive to the dye concentration. It was demonstrated 10 years ago that changes in fluorescence lifetime could in principle be used for FLIM. Until now, the use of this technique has been restricted to a few laboratories, due to technical difficulties.^{68–72} Nevertheless, it has recently been demonstrated that FLIM at a single modulation frequency can be used to image and follow the cellular distribution of two, and ultimately three, GFPs simultaneously. FLIM may become more commonly used in the near future due to several advantages over spectral discrimination. Simultaneous readout of data and the need for only one dichroic and long-pass emission filter result in the use of a lower light dose and reduce the risk of photochemical damage to the cells.⁵⁹

GFP chimeras were also found to be invaluable for time-lapse imaging to study the dynamics of proteins in cells of the immune system.³ The same technique was used to visualize transport of secretory vesicles from the trans-Golgi network to the plasma membrane.^{3,6} The dynamics of the distribution of chemotactic receptors on the surface of neutrophils were also monitored. More recently, the availability of GFP variants with different spectral characteristics has made it possible to compare the dynamics of two distinct proteins simultaneously.³

GFP chimeras have also demonstrated their potentialities in the field of functional studies. FRAP has been used to show the internalization of a β -adrenergic receptor chimera after stimulation. Its plasmamembrane-diffusion coefficient was also measured.⁷ An arrestin chimera was also used to visualize the arrestin-binding kinetics to different G-protein-linked receptor subtypes.⁷ GFP chimeras of galactosyltransferase, mannosidase II, and the KDEL receptor were found to have extremely high mobility in the Golgi of live HeLa cells; this implies that protein immobilization is not responsible for the retention of these proteins in the Golgi.⁶ FRAP was also used to monitor the mobility of a GFP fusion of E-cadherin at different stages of epithelial cell–cell adhesion.³

The intensity of signals obtained with the previously mentioned FRET technique is also independent of the dye concentration, but this technique requires the use of two fluorophores. FRET occurs only when two convenient fluorophores are close enough together, and it falls off with the sixth power of the distance between them. Consequently, this effect is well adapted to monitor 3D conformational changes experienced by a double-labeled macromolecule, but it can also be used for monitoring conformational changes occurring inside a cluster of proteins. This technique has been used recently for monitoring an interaction between a nuclear receptor and its specific activator that is required for transcription of transiently transfected and chromosomally integrated reporter genes. High-resolution FRET microscopy was used for studying the potential role of "lipid rafts" in the interaction between cholera toxin B-subunits and GPI-anchored proteins in the plasma membrane of HeLa cells. Receptor-mediated activation of heterotrimeric GTP-binding proteins was also visualized in living cells by monitoring FRET between α -and β -subunits fused to cyan and yellow fluorescent proteins.

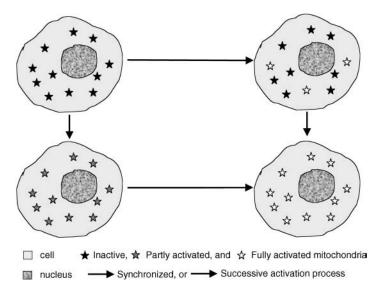

FIGURE 54.4 Schematic presentation of two potential activation pathways of the mitochondria network.

53.3.1.5 Looking at the Single Organelle/Protein Level for an Integrated Approach of Cellular Mechanisms

As discussed in the previous sections, FRET occurs only when the distance between the donor and the acceptor molecule is between 2 and 10 nm. FRET provides us with a way to light up interactions at the molecular level, far below the usual limitation of traditional optics. The interest in getting information at the single-molecule level is obvious. It would improve our basic knowledge of biological events such as signal transduction, gene transcription, and intracellular transport. Furthermore, it would provide invaluable information on the potential synchronization of the response to any stimulus of organelles belonging to the same network (e.g., mitochondriae, ionic channels). Figure 54.4 shows a schematic presentation of two potential activation pathways of the mitochondria network.

Fluorescence microscopy has demonstrated its capability in sensing single molecules in *in vitro* experiments. In particular, it has been shown that single-dye molecules and single-fluorescent proteins emit fluorescent photons in an intermittent on-and-off fashion, a kind of information that cannot be obtained from population-averaged measurements. Although single fluorophores have recently been detected in the membranes of living cells with good SNRs, it is still not clear whether single-molecule fluorescence microcopy can be achieved at the spatial and temporal resolution required for biological experiments. Even if stable and bright fluorophores existed that could be coupled *in vivo* to biological molecules, some crucial challenges would remain. One of them is the development of easy-to-use, affordable equipment that allows high-resolution localization of individual point-like sources in 3D at a rate compatible with that of biological events. Another challenge is quantitative recording of relatively weak signals that must be extracted from the fluorescence background resulting from normal fluorescent cellular components such as flavins or nicotine amine nucleotides. Nevertheless, single GFP molecules have been successfully imaged in living cells using a total internal reflection fluorescence microscope.⁷⁶

A new technique called fluorescence speckle spectroscopy (FSS) has recently been proposed for visualizing the movement, assembly, and turnover of macromolecular assemblies in living cells. A sensitivity of one to seven fluorophores per resolvable unit (270 nm) has been reported using a conventional wide-field epifluorescence light microscope and digital imaging with a low-noise, cooled CCD camera.⁷⁷

Both confocal microscopy and multiphoton microscopy allow the energy required for fluorescence excitation to be concentrated in a tiny volume (femtoliter). Both share the problems linked with the use of far-field optics (spherical aberrations and chromatic aberrations, both in the excitation and in the

detection arms) that are difficult to compensate for when deconvolution methods are used for image restoration. Nevertheless, fluorescently labeled lipid and receptor molecules have been monitored on the surface of living cells by single-molecule imaging techniques.^{78,79} Recently, the distribution of single molecules of transferrin-TMR in the nucleus or the cytoplasm was visualized in living HeLa cells by tightly focusing the beam of a continuous-wave argon ion laser.⁸⁰ Another study showed that ultrahigh resolution colocalization of fluorophores is possible in the FRET distance range if the different fluorophores can be excited at the same wavelength, are bright enough, and have emission properties that allow an unambiguous distinction between the different types.⁸¹ However, a closed-loop piezoscanner must be used that ensures a perfect alignment of each fluorophore on the optical axis to minimize the chromatic aberrations in the excitation path. Nothing is said about the rate of image recording.

The main advantage of multiphoton microscopy is that it allows the use of near-infrared (NIR) or infrared radiation instead of UV to excite fluorophores.^{82,83} Single-molecule detection with two-photon fluorescence-correlation spectroscopy has been demonstrated, although photobleaching-resistant fluorophores are required.^{82,84}

While limited to membranes, near-field scanning optical microscopy (NSOM) has been found useful for studying interactions between host and malarial skeletal proteins in erythocytes. ^{85,86} A protocol to extract the near-field fluorescence signal from the composite signal containing both near- and far-field fluorescence has been reported with improved image resolution. ⁸⁷ An elegant high-resolution, two-photon, near-field scanning spectroscopy has also been described. ⁸²

Besides these studies on improved methods for detecting single molecules, other studies have been focused on the dynamics of whole-organelle or ionic-channel networks using wide-field spectroscopy and different kinds of image processing.⁸⁸⁻⁹¹ Although they do not claim to have reached the single-molecule detection level, these studies contain valuable information on the dynamics of the mitochondrial- or ionic-channel network, strengthening the interest in single-molecule imaging in living cells.

53.3.2 Lipids and Small Proteins

As indicated earlier, the direct labeling of proteins with GFP is restricted to relatively large proteins due to the size of GFP. Nevertheless, many elegant methods have been developed to trace membrane lipids due to their importance in the cellular machinery (endocytosis, exocytosis, vesicular trafficking of proteins, transduction of extracellular signals, remodeling of the cytoskeleton, regulation of calcium flux, and apoptosis). In one approach, the membrane receptors of some lipids have been GFP-tagged to visualize their intracellular localization. However, these results are difficult to interpret in terms of lipid concentration when the effects of external stimuli are sought. Therefore, fluorescent analogs of these lipids have been synthesized and used to track their intracellular distribution or redistribution. He same approach has been used for smaller molecules such as cholesterol or cyclic AMP and GMP. S3,100,101

Theoretically, the same method can be used for small proteins. As stated previously, the problem consists in finding at least one amino-acid residue — and potentially two if one wants to use FRET techniques that match the following criteria. They must be reactive enough to allow a specific binding of the fluorescent tag and be conveniently located in the protein structure so that tagging does not change the properties of the protein (conformation, binding sites or potential receptors, etc.). Furthermore, tags must experience some changes in their chemical microenvironment upon protein binding (to substrates or receptors) if the intracellular protein activity is to be studied. So far only calmodulin intracellular activity has been studied using these methods.⁷

53.3.3 GFP Mutants as Ionic Sensors

Until now, the search for ion-specific, genetically engineered fluorescent probes has been limited mainly to Ca²⁺ and H⁺ due to their importance in the cell machinery, although a Cl⁻ probe has recently been reported.¹⁰² Several laboratories reported that some GFP mutants experience pH-sensitive spectral changes.^{3,6} Fluorescence intensity was found to decrease with pH, while the shape and position of the

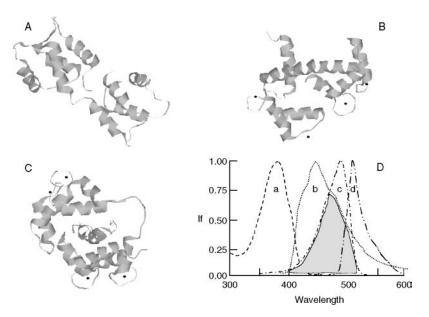

FIGURE 54.5 Changes in 3D structure of calmodulin upon binding to calcium ions and myosin chain M13. (A) Free calmodulin. (B) In the presence of calcium ions. (C) In the presence of calcium ions and myosin chain M13 (limited to the peptide involved in the interaction for sake of clarity). (D) Respective normalized excitation and emission spectra of GFP mutants Y66H and S65T: (a) excitation spectrum of Y66H, (b) emission spectrum of Y66H, (c) excitation spectrum of S65T, and (d) emission spectrum of S65T. The gray zone shows the wavelength range of overlapping between the emission spectrum of Y66H and the excitation spectrum of S65T.

spectrum were relatively insensitive to pH. Another type of pH-sensitive GFP mutant was developed that experiences a spectral shift upon pH change.^{3,6} Both these types of pH sensors have their advantages and limitations. The latter permits the measurement of pH from the ratio of intensity at two wavelengths, a method that is relatively independent of photobleaching and alteration in focal plane. The former allows easier use of confocal microscopy because only one excitation wavelength is required. Recent applications dealt with Golgi and secretory vesicle pH.^{101,103,104}

GFPs have also been used for Ca²⁺ measurements. Fluorescent intracellular calcium indicators called "chameleons" have been synthesized that are fusion proteins containing blue fluorescent protein or cyan fluorescent protein; calmodulin, the calmodulin-binding domain of skeletal-muscle myosin light chain kinase (M13); and either GFP or yellow fluorescence protein. In the absence of calcium, this long chain is extended; in the presence of calcium, calmodulin experiences a conformational change. This change favors its binding to M13, which results in a more compact conformation that increases the FRET between the flanking fluorescent proteins.^{2,3,5,7,105} Figure 54.5 schematically illustrates the changes in the 3D structure of calmodulin upon binding to calcium ions and myosin chain M13. Mutations inside calmodulin allowed the generation of chameleons with different calcium affinities from 10 nM to 10 mM. Furthermore, the inclusion of localization signals in the structure makes it possible to target these chameleons to specific intracellular locations for monitoring intraorganellar calcium dynamics. Measurements of rapid Ca²⁺ turnover in the endoplasmic reticulum during signaling have been reported, ¹⁰⁶ and the use of yellow fluorescent protein less sensitive to pH and chloride interference has allowed Ca²⁺ measurement in the Golgi. ¹⁰⁷ Furthermore, new fluorescent chimeras, dubbed "pericams," have recently been used to monitor free Ca²⁺ dynamics in the cytoplasm, the nucleus, and the mitochondria of HeLa cells. ¹⁰⁸

In another approach to calcium monitoring, a blue fluorescent protein was linked to GFP by a 26-residue spacer containing the calmodulin-binding domain from smooth-muscle myosin chain kinase. Due to the flexibility of that chimera, FRET occurred between the fluorescent proteins that were close

in the absence of calcium. This proximity did not exist in the presence of calcium, and FRET was no longer possible.⁴

Since all these probes rely on the interaction of calcium with calmodulin, a ubiquitous protein, they are expected to compete for Ca²⁺ with "normal" proteins. Perhaps this competition does not induce any perturbation in the cellular mechanisms, especially in nanocompartments where the probability of the presence of free Ca²⁺ is low.

53.4 Conclusion: Toward Nanosurgery and Nanomedicine

Future biological investigations are expected to focus on monitoring the interactions between the fundamental cellular building blocks that are currently under study. Once the 3D high-resolution structures and biological roles of proteins and RNAs have been elucidated, it will become necessary to determine their precise locations and translocations inside the cell to understand the cell machinery and circuitry. Many vital functions of the cell are performed by modular cellular machines self-assembled from a large number of interacting molecules and translocated from one cell compartment to another. Unraveling the organization and dynamics of these machines requires tools capable of providing *in vivo* 3D microscopic pictures of individual interacting molecules with nanometer resolution and at a time scale compatible with the speed of intracellular processes. The same kinds of tools are also necessary to monitor the cooperative behavior of networks such as the mitochondrial- or ionic-channel networks.

Significant advances in fluorescence techniques have recently improved their spatial resolution beyond the classical diffraction limit of light. Among them, the most promising appear to be wide-field image restoration by computational methods, ¹⁰⁹ wide-field single-molecule localization and tracking, ^{110–112} aperture-¹¹³ and apertureless-type near-field scanning spectroscopy, two-photon excitation microscopies, ^{114,115} and point-spread-function engineering by stimulated emission depletion. ¹¹⁶ Nevertheless, near-field scanning spectroscopy and total internal reflection fluorescence spectroscopy appear more appropriate for studying the cell surface than for monitoring intact cellular structures. ¹¹⁷ Recently, a new imaging and ultrahigh-resolution colocalization technique has been proposed that can pinpoint the locations of multiple distinguishable probes with nanometer accuracy and is said to better handle the limitations presented by other methods. ⁸¹ But to date this technique has not been used *in vivo* and requires probes relatively insensitive to fading.

Among the above-mentioned techniques, multiphoton technology seems to be the most appropriate for delivering a given dose of radiation into a predetermined nanovolume. Not surprisingly, it has been used for both noninvasive optical biopsy and nanosurgery.⁸² Due to the use of irradiation wavelengths in the 700- to 1100-nm spectral range, living tissues can be investigated at depths of up to 100 µm. The endogenous fluorophores that can potentially be excited are NADH, NADPH, flavins, and collagen, allowing for the imaging of intracellular structures, the location of the nucleus, and cell morphology in the different skin layers. Imaging of the accumulation of protoporphyrin in tumor cells of mice with solid carcinoma has also been reported, suggesting potential applications of two-photon technology to photodynamic therapy of tumors.

Femtosecond NIR laser pulses have numerous advantages over conventional nanosecond UV laser pulses: high penetration depth, absence of out-of-focus absorption, efficient induction of multiphoton excitation, and absence of plasma shielding and significant heat transfer. Convenient tuning of the laser power makes it possible to confine the energy necessary for material removal to the central part of the beam. Therefore, this technique may provide a noncontact nanoscalpel for surgery inside a cellular organelle that will not have unwanted effects on other cellular compartments.⁸² Optical tweezers that have been used for studying the strength of the interaction between fibronectin and its membrane receptor or the microrheology of biopolymer-membrane complexes have also been tested to facilitate *in vitro* fertilization.^{118–120}

Nanotechnology is opening up new possibilities for the development of fiber-optics-based nanosensors and nanoprobes of submicron-sized dimensions suitable for intracellular measurements. The ability to examine processes within living cells could provide great advances in our understanding of cellular

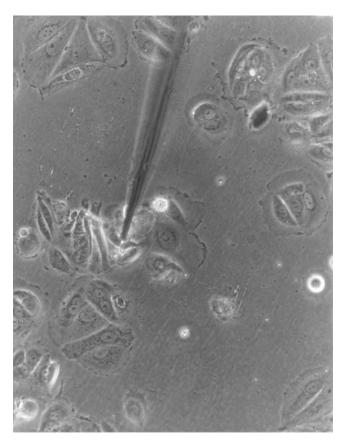

FIGURE 54.6 (Color figure follows p. 28-30.) Photograph of an antibody-based nanoprobe used to measure the presence of benzopyrene tetrol in a single cell. The small size of the fiber-optics probe allows manipulation of the nanoprobe at specific locations within the cell. (From Vo-Dinh, T. et al., *Nat. Biotechnol.*, 18, 76, 2000. With permission.)

function, thereby revolutionizing cell biology. Fiber-optic sensors offer important advantages for *in situ* monitoring applications due to the optical nature of the detection signal. These sensors are not subject to electromagnetic interferences from static electricity, strong magnetic fields, or surface potentials. Another advantage of fiber-optic sensors is the small size of optical fibers, which allows for sensing intracellular/intercellular physiological and biological parameters in microenvironments. Figure 54.6 shows a fiber-optic nanosensor with antibody probes for benzopyrene tetrol, a biomarker of human exposure to the carcinogen benzo[a]pyrene that has been recently developed and used for *in vivo* analysis of single cells. 121–125 Nanosensors could provide much needed tools to investigate important biological processes at the cellular level. For instance, the mode of entry of fluorescent proteins or exogenous chemicals into various cells is important, as are subsequent enzymatic processes inside cells. Tracking these species becomes feasible due to their natural fluorescence. Inspection of cells at submicron resolution by optical nanosensors that can interrogate at precise locations has the potential for significant advances in knowledge of cellular structure/function. The development and application of fiber-optic nanosensors are described in detail in Chapter 60 of this handbook.

The methods and techniques reviewed in this chapter have demonstrated that biophotonics may allow imaging of most of the different steps that result in the synthesis of proteins and monitoring of their activity. Thus, perhaps in the near future it will be possible to identify and image which specific steps in this complex process are responsible for any given disease. For instance, such a nanodiagnosis could show that a given disease results from an increase in the misfolding of a protein instead of a decrease in the

production of this protein. Will this mean that nanomedicine, involving the delivery of drugs especially designed to repair a dysfunction in a step of any biological pathway, can be expected in the near future and that it will be possible to visualize the benefits through biophotonic technology? The challenge for photonics to elucidate life processes will come from the complexity inherent in biological events, as demonstrated in a recent study. 126 The researchers reported that they have identified 997 messenger RNAs responding to 20 systematic perturbations of the yeast galactose-utilization pathway, providing evidence that approximately 15 to 289 detected proteins are regulated post-transcriptionally. 126

55.1 Introduction

This chapter presents a summary account of various amplification techniques for analysis of biological molecules (species) that use some form of optical detection as the endpoint. The analyte species possibly under consideration include lipids, carbohydrates, proteins, and nucleic acids (and combinations of the same such as glycolipids, glycoproteins, etc.), but this review is restricted to proteins and nucleic acids. Of course, there are many detection strategies for both proteins and nucleic acids, but for the purposes of this review, amplification must be involved. We therefore have limited our discussion to immunoassays and nucleic acid techniques employing amplification.

Immunoassays, which depend fundamentally on antibody recognition of antigens, have proved, over the course of many years, to be powerful analytical techniques for protein detection. They can also be used successfully for the detection of substances of lower molecular weight than the usual size of proteins (e.g., peptides, hormones, etc.), provided that antibodies specific against these molecular structures are developed and specially selected.

Detection of nucleic acids has been revolutionized by the development of the polymerase chain reaction (PCR) and other related techniques that produce large multiplications of specific nucleic acid segments. Even before the advent of these powerful amplification techniques, however, sensitive detection of nucleic acids was achieved using various procedures, some of which relied on the principles of immunoassays. Most nucleic acid detection strategies are based fundamentally on the base-pairing interaction that occurs between complementary strands of polynucleotides (even PCR, in which primers must recognize specific complementary sequences); thus, such complementary base pairing (i.e., hybridization) is a significant component of nucleic acid detection assays.

Finally, some detection strategies seem to wed elements of immunoassays and nucleic acid detection assays (e.g., immuno-PCR; PCR-enzyme-linked immunosorbent assay [ELISA]). In this review, we group such techniques into a third category, referred to as hybrid assays. These admittedly could be classified

as either immunoassays or nucleic acid amplification assays, but, in the hope that it will add clarity, they will be categorized separately.

This review makes no claim to comprehensiveness with regard to every possible assay technique that has been applied to a specific situation. Indeed, given the number of researchers in these fields and the time periods over which these techniques have been developed, it would be an enormous undertaking to be truly comprehensive in such a review. An attempt has been made to cover the more common and, in the authors' perception, more useful analytical techniques, with the further caveat that we have focused almost exclusively on the English language literature. The references given are not meant to be exhaustive with regard to any of the techniques discussed.

In addition, this chapter does not cover radiotracer techniques. In many cases, these procedures formed the basis for great advances in biological knowledge and still demonstrate remarkable sensitivity. However, safety issues and issues of waste disposal have somewhat diminished the attractiveness of radioisotopes for biological applications, hence the increasing reliance on other techniques including a heavy emphasis on optical-based analytical tools. Our goal is to provide a comprehensible introduction to various amplification techniques for optical detection that will allow for further investigation of those techniques that pique the reader's interest. If we have omitted significant analytical techniques, we apologize in advance to those dedicated researchers who have advanced the frontiers of science.

55.2 Immunoassays

Immunoassays make use of antibody/antigen recognition, a recognition that has great specificity and the potential for high affinity. Protein detection has been a major focus of immunoassay development, although low-molecular-weight substances (drugs, toxins, hormones, etc.) can also be conveniently detected. In the case of haptens of low molecular weight, these molecules can be conjugated to proteinaceous (or other) materials to form antigenic substances for which hapten-specific antibodies may be developed. It is possible to develop antibodies against specific epitopes (antigenic sites) on high-molecular-weight proteins and against high-molecular-weight carbohydrates. However, the adaptation of immunoassays to carbohydrates and lipids is considerably less rich in associated assay development than the protein/hapten systems, which have received the bulk of the efforts at innovation. Consequently, this review focuses essentially on protein detection by immunoassay. The interaction of biotin and avidin/streptavidin is a rather unique case of molecular recognition that has been extensively used in the development of detection schemes throughout biology. The relatively enormous affinity constant ($K_D = 10^{-15} \text{ M}^{-1}$) (see Reference 2) of biotin for avidin/streptavidin forms the basis of a recognition reaction of great specificity, and the small size and molecular structure of biotin allow for ready conjugation to a wide variety of molecules. Not surprisingly, this system has been exploited in the development of a wide variety of analytical techniques, which appear in this review.

Immunoassays have been performed in a wide variety of formats. The 96-well microplate-based assays are routinely performed throughout the world but are by no means the only feasible format. Immunoblotting, applied as detection for a wide variety of gel-based separation methods, is also widely used. Similarly, a rich literature has grown up regarding immunoassay techniques applied to histological/cytological specimens. Whether the samples are tissue sections, membrane blots, proteins in physiological fluids, or samples in microplate wells, the immunoassay techniques used for detection show similar basic principles. Thus, we do not, in general, divide the assay strategies according to their application (i.e., histological, immunoblot, etc.) but simply mention that some procedures fit certain applications well. In certain cases, we note an interesting and/or unusual format (such as the use of an unusual solid substrate for assay immobilization), but this is not intended to suggest an exhaustive review of all assay formats. After consideration of the various assay principles used, the reader will likely formulate original modifications suitable for specific applications.

Table 55.1 provides a summary of our review of immunoassays. Immunoassays are used routinely in many areas of biological science including basic research, pharmaceutical development, and clinical and forensic applications. Although the term "immunoassay" encompasses a wide variety of quite different techniques, this review will focus only on techniques involving amplification, many of which fall into

the category of enzyme-amplified immunoassays (EIA). This category is in and of itself daunting in the number of variants that have been developed. Thus, an attempt is made here to discuss general principles that govern development of immunoassays of this class, examples of general assay formats, and the suitability of various techniques.

53.2.1 Classification of Immunoassays

Immunoassays can basically be classified as heterogeneous or homogeneous, competitive or noncompetitive, and direct or indirect.^{3,4} Of course these terms may be used in various combinations (e.g., heterogeneous indirect noncompetitive immunoassay). Although the nomenclature for immunoassays can be quite variable and shortened forms of classification are very commonly used, definitions of the basic classifications are appended below.

Heterogeneous vs. homogeneous refers to whether a separation step is required in the immunoassay. In other words, heterogeneous assays require one or more separation steps, while homogeneous assays occur in solution phase without separation. Heterogeneous assays are commonly associated with a solid phase such as a microtiter plate. Immunoassays can be formatted as either competitive or noncompetitive. In the competitive mode, two pools of antigen, one pool labeled with a marker of some sort and the other consisting of the sample to be analyzed, compete for a limited number of antibody-binding sites. Competitive assays of this sort are, in general, homogeneous assays. In a noncompetitive assay, immobilized antibody binds (captures) antigen, and antigen is detected by a second antibody (detector) that has some label and binds to another epitope on the antigen. Perforce, these types of assays are heterogeneous. However, heterogeneous assays may also be formatted so that the immobilized antibodies capture a mixture of labeled and unlabeled antigen from two pools, i.e., a competitive heterogeneous assay. Alternatively, a limited amount of antigen may be immobilized and limited amounts of labeled antibody added to a mixture of sample antigen in solution. This format is also competitive, as increased antigen in solution produces fewer labeled antibodies binding to the immobilized antigen.

Direct immunoassays are assays in which only primary antibodies, with specificity against the antigen of interest, are used. The antibodies here may be labeled or unlabeled. Indirect assays, on the other hand, involve in some way an immune or other type of complex. For these types of assays, the final complex signals, through some indirect means, the formation of an immunospecific binding event. Examples include the interaction of an antispecies IgG antibody, with attached label, with the primary antigenspecific antibody; or the use of a labeled avidin/streptavidin to bind to a biotinylated antigen-specific antibody. Table 55.1 describes many of the immunoassays as homogeneous/heterogeneous, competitive/noncompetitive, etc. However, every immunoassay procedure is not labeled in this way because many assays have the potential to be applied in multiple fashions.

55.2.2 Amplification and Specificity

Table 55.1 presents a summary of various immunoassay techniques that employ amplification as a component of the assay. Amplification has multiple layers of meaning with respect to immunoassays. Fundamentally, in these assays, the desired goal is to detect the event of antibody-to-antigen binding. If the antibody has an attached enzyme, then the unique immunoreaction event is amplified by the processivity of the enzyme acting on the appropriate substrate. On the other hand, when immune complexes (e.g., PAP = peroxidase-antiperoxidase, APAAP = alkaline phosphatase-antialkaline phosphatase) are used, the number of enzyme molecules clustered at the site of a single antibody/antigen interaction can be multiplied.^{5,6} These are just two of many possible examples; many immunoassays have more than one multiplication strategy. As a final goal, all these amplifications serve to amplify the detection signal, hopefully lifting it above the noise of the system. Table 55.1 presents a distillation of a large compendium of techniques. For each technique, it presents a brief summary of the principle behind the assay, some comments considered germane to the discussion (including further explanation of amplification and comments about sensitivity), and pertinent references.

Of course, the fundamental question arises of why amplification is needed at all. The simplest answer is that the molecular interaction that one wishes to detect is undetectable without amplification. Of course, as the various immunoassay techniques developed over the years, the natural tendency was to push for greater and greater sensitivity, as the biological questions being asked demanded more powerful techniques. Hence a wide variety of amplification techniques have been developed, some of which admittedly have less applicability than others.

Some of the amplification techniques included in Table 55.1 seem to have minimal amplification associated with them, such as fluoroimmunoassay (FIA), where a fluorescent label is covalently attached to an antibody. In an attempt to be consistent, any technique that results in some amplification of a signal could be legitimately called amplification and will therefore be included. For example, in the simple direct FIA, where fluorophore is attached to antibody, if only one fluorophore is attached per antibody molecule, then the assay would not be considered amplified, since single-molecule antigen/antibody binding would only be detected by one fluorophore. In fact, there are multiple potential sites for fluorophore attachment per antibody molecule, and the usual fluorophore:antibody molar ratio following the labeling reaction is 2:1 to 4:1. Actually, controlling the reaction to insert only one fluorophore would be difficult, if not impossible. Nevertheless, the degree of amplification achieved by fluorophore labeling of antibody is certainly limited to relatively small numbers. Too many fluorophores attached can significantly alter the affinity/specificity of the antibody. In fact, the inherent extreme sensitivity of fluorescence is the major reason that simple FIA has become such a widespread technique. Even with only a few molecules of fluorescent label attached per antibody molecule, the antigen/antibody binding event is still amenable to detection.

In general, in Table 55.1, techniques that give high levels of amplification, as opposed to those that produce only small amounts of amplification, are emphasized. However, the extent of amplification is not necessarily synonymous with sensitivity. For instance, with respect to fluorescence, fluorescence polarization or time-resolved measurements can be highly sensitive detection schemes, even though only a few molecules of dye are attached to an antibody. In spite of the above comments, however, the more powerful amplification schemes, where the potential for manifold multiplication of signal exists, are inherently attractive, if for no other reason than the fact that they offer positive detection even under nonoptimum conditions of assay, instrumentation performance, etc.

The gold standard for amplification in immunoassay is probably the ELISA technique, which is used for protein detection as well as for numerous other biological molecules, notably nucleic acids. Here, the amplification occurs as the enzyme converts substrate to product, a process that generally involves many thousands of molecules per minute. This enzymatic process is potentially so powerful that, given the caveat of no denaturization of the enzyme protein and given enough time, it should be possible to detect *one* enzyme molecule bound to an immunoreagent. Seldom if ever is this most stringent detection limit necessary. Colorimetric detection of the ELISA reaction is a commonly used endpoint, and instrumentation for ELISA assays and detection based on this endpoint is readily available. Of course, if enzymatic conversion of a substrate to a colored product (either soluble or insoluble, depending on the endpoint of the amplification) is possible, the logical extension is to apply ELISA amplification to substrates that produce fluorescent or chemiluminescent products. This has been done — and sometimes with remarkable success in terms of sensitivity enhancement (see following discussion).

Simple ELISA, however, does not exhaust the ingenuity of amplification schemes, which have evolved. Numerous coupled-enzyme schemes can enhance enzymatic multiplication. Immune reaction coupled to lysis of liposomes produces release of large numbers of liposomally encapsulated indicator molecules. *In vitro* transcription/translation systems can be used to make multiple copies of a target DNA gene sequence attached to an immunoreagent. In some cases, such as surface-enhanced Raman spectroscopy, the optical detection method itself produces a large part of the signal amplification. Table 55.1 shows a variety of amplification schemes.

At its most fundamental level, the specificity inherent in immunoassays resides in the antibody/antigen interaction. No amount of assay ingenuity can improve an antibody reagent with poor specificity. Limit of detection (LOD) has to do with the specificity and affinity of the antibodies for the analyte and the

robustness of the amplification system, as well as with the amount of nonspecific interactions that take place in the assay system. As the LOD is pushed lower, at some point the "noise" due to nonspecific interactions becomes a significant limiting factor. Sensitivity, as opposed to limit of detection (which is the lower limit of analyte that can be detected above background "noise"), refers to the ability of the assay system to discriminate between analyte concentrations that do not vary much from one another. A nonsensitive assay system may have essentially the same LOD as a sensitive assay system, but the sensitive assay system can discriminate among analyte amounts, which the nonsensitive assay could not.

Some simple mathematical considerations demonstrate that the antibodies used in immunoassays constitute the limiting factor in developing highly sensitive, rapid, and powerful immunoassays. A brief demonstration taken from Avrameas¹⁰ illustrates this fact. The fundamental mass-action equation governing antigen/antibody intereactions is:

$$Ab + Ag \Leftrightarrow Ab - Ag \\ K_2$$
 (55.1)

where Ab = antibody, Ag = antigen, Ab-Ag = antigen – antibody complex, and K_1 and K_2 = rate of forward and reverse reactions, respectively. The association constant (K_a) at equilibrium is defined as:

$$K_a = K_1/K_2 = [Ab - Ag]/([Ab] [Ag])$$
 (55.2)

Generally, K_1 is larger than K_2 , so the [Ab-Ag] complex, once formed, only dissociates slowly (thus allowing the numerous washings common in EIA procedures). Avrameas cites several examples to illustrate the analytical limitations posed by this equilibrium. These examples serve to indicate that EIAs, like all other assays, have theoretical limitations beyond which they cannot go. Once the inherent limitations are understood, however, EIAs have the potential to detect analytes at extremely low concentrations and with notable precision and accuracy.

55.2.3 Comparisons of Immunoassays

Which immunoassays are the most sensitive with the lowest limits of detection? There are no simple answers to this question. Just as there are no simple answers to the question of which is the best immunoassay. The various immunoassays enumerated in Table 55.1 have apparently all been successfully implemented. The choice of a particular immunoassay must be defined by the individual researcher for a particular application. For example, sometimes the speed of analysis may be more important than the extreme sensitivity, or a very low limit of detection may be more valuable than the amount of time it takes to perform the analysis. The following discussion provides only some general comments about comparisons of various techniques; the ultimate choice rests with the reader.

Practically speaking, it is essentially impossible to make meaningful comparisons between one investigator's results and those of another. As mentioned above, a major factor in determining sensitivity is the affinity of the antibodies used for the analyte, and very seldom (if ever) do different investigators use exactly the same antibodies. However, a variety of experiments are described in the literature where investigators compare various immunoassay protocols using the same fundamental antibody reagents. Such studies provide a basis for more meaningful comparisons, although there are still many caveats including such questions as whether the various detection labels attached to the antibodies affect the affinity of the antibody to different extents and whether the composition of the immunoreagent "sandwich," if it becomes highly complex, produces steric hindrance to free access of, say, enzyme substrate.

Comparisons imply some standard to which other quantities are compared. Unfortunately, no universal standard exists for immunoassays. As indicated in Table 55.1, very often comparisons are made with ELISA-based colorimetric assays. In addition to direct comparisons using the same or very similar immunoreagents, one finds more nebulous statements in the literature such as that one technique is fourfold more sensitive than another.

One might argue that a comparison of the LODs observed for various immunoassays (of which there are numerous citations in Table 55.1) should provide a reasonable indication regarding which assays are the most sensitive. However, in addition to the fact that antibody reagents vary from investigator to investigator, the assay protocol itself, particularly where an enzyme step (or steps) is included, can significantly impact limits of detection. For example, usual times of incubation of enzyme-labeled immunoreagent with substrate are 30 min to 1 h. It is almost guaranteed that an overnight incubation of enzyme plus substrate would produce a lower LOD (if the enzyme did not lose activity completely).

Finally, and perhaps most perplexing, is the fact that there can be very large ranges over which sensitivity of one immunoassay is said to be increased compared to another immunoassay (for example, see under fluorescence EIA in Table 55.1, where the sensitivity is said to be 5- to 10⁵-fold increased over conventional EIA). Recall that immunoassays are, by their very nature, complex, and a variety of instrumentation can be used to detect the final endpoint. As more sensitive photon-counting detectors (e.g., charge-coupled device [CCD], avalanche photodiode [APD]) are brought into use, and as more intense excitation sources (lasers) are employed, it should be expected that LODs will continue to decrease. Whether single-molecule detection is needed (or even desirable) is another question altogether.

As mentioned previously, in terms of frequency of use, ELISAs are the gold standard of immunoassays. ELISA formats and techniques are well established, there are choices of multiple substrates, and much experience has been accumulated regarding effective coupling of enzyme to antibody. A good discussion of general ELISA principles and techniques can be found in work published by Tijssen in 1985.⁶ During much of the 1970s there was considerable debate as to whether enzyme labels in immunoassays would ever be as useful as radioactive labels in terms of sensitivity of detection.¹¹ Estimates of detection limits of 5 to 10 attomol for radioactive labels, e.g., ¹²⁵I, have been made based on the specific radioactivity of carrier-free ¹²⁵I of 4.8 dpm/attomol.¹² Aside from issues of safety, radioactive-waste disposal, and limited half-life, Ishikawa et al.¹² point out that the detection limit of some enzymes is < 1 attomol, and using other techniques still based on ELISA (i.e., immune complex transfer immunoassay) the detection limit has been pushed to milliattomoles.¹¹

However, Ishikawa et al.^{11,12} indicate that to achieve attomole sensitivity by ELISA certain formats and procedures must be used. These include use of a noncompetitive "sandwich" (two-antibody) ELISA format (competitive immunoassay with only one antibody is reportedly unable to achieve attomole sensitivity); the use of thiol groups in the hinge portion of the antibody Fab' fragment for enzyme coupling, providing better retention of the activities of both antibody and enzyme; and the use of a fluormetric substrate for the enzyme β -galactosidase, which change was said to improve the sensitivity 1000-fold over colorimetric substrates. As for this latter point, Ishikawa et al.¹² state that it is possible to measure 0.02 attomol of β -galactosidase and 0.5 attomol of HRP in a 100-min fluorimetric assay with an assay volume of 0.15 ml.

Shalev et al.¹³ also confirm that detection by fluorimetric ELISA could be demonstrated to be more sensitive than radioimmunoassay, and in fact detection levels of 3 to 10 attogram/ml, or 24,000 molecules, could be achieved. The authors discuss essentially three factors that enabled them to increase the total assay sensitivity ~10⁵ to 10⁶ times over a colorimetric ELISA. These factors were use of a fluorogenic substrate, prolongation of incubation time (15 h), and increase in surface area available for antigen binding. Interestingly, while Shalev et al.¹³ state that it is generally accepted that fluorometric methods are 10³ more sensitive than colorimetric methods, using a fluorogenic substrate instead of a colorimetric one enhanced sensitivity in their ELISA assay by only 16 to 30 times. Ruan et al.¹⁴ also note a 10²- to 10³-fold increase in sensitivity using a fluorogenic substrate vs. a colorimetric substrate in an ELISA assay for prostaglandin H synthetase.

Chemiluminescent ELISAs are also a useful route to increased assay sensitivity. For example, Brown et al.¹⁵ found that using an enzyme-cascade system and a chemiluminescent endpoint, alkaline phosphatase was detectable at concentrations down to 0.4 attomol. Lewkowich et al.¹⁶ found 12- to 29-fold increases in sensitivity in ELISA assays for interleukins when a chemiluminescent substrate was substituted for a colorimetric substrate. Porakishvili et al.¹⁷ observed increases of 10- to 100-fold in sensitivity when comparing chemiluminescent vs. colorimetric ELISAs. Direct comparison of radiolabel with chemiluminescent label

indicates that, on an attomole basis, chemiluminescent labels provide a better possibility for detection (i.e., 1 attomol of carrier-free $^{125}I = 5$ dpm, while 1 attomol of chemiluminescent label = 50 photon counts). 18

Other ELISA-based immunoassay methods indicated in Table 55.1 also provide the opportunity for great sensitivity. The cloned enzyme-donor immunoassay, for example, is stated to be the most sensitive of homogeneous enzyme immunoassays. Multienzyme cascade-based assays have demonstrated subattomole (e.g., 0.01 attomol for alkaline phosphatase) sensitivity, even when using a colorimetric substrate. He use of enzyme-mimetic catalysts is possibly a significant step forward, as these small (relative to enzymes) molecules offer higher labeling ratios for antibodies without adversely affecting their affinity and still offer catalytic activity comparable to actual enzymes. The catalyzed reporter deposition immunoassays also offer extremely high sensitivity, with the added potential advantage for certain applications of localization of signal. Finally, hybrid technologies combining elements of immunoassay with DNA-amplification technologies seem to offer the greatest sensitivity of all and approach that "Holy Grail" of detection limits — one molecule. These are discussed later in this chapter.

55.2.4 Other Techniques

Here we would like to mention some other techniques that involve some sort of amplification but that, in our opinion, do not fit with other optical detection techniques. This is not to imply that these techniques have no place in immunoassay procedures or that they are somehow inferior to other techniques (the immunogold–silver stain procedure seems exquisitely sensitive in comparison to other histochemical procedures). These techniques are either designed for histological use or in some other way do not lend themselves to rigorous quantitative analysis by optical detection such as with photomultiplier tubes (PMTs), CCDs, spectrometers, etc.

One such technique covers a whole series of assays involving agglutination reactions. Some of these procedures have been used for many decades.²² Amplification in these assays arises from multiple antigen or antibody molecules immobilized on red blood cells, latex spheres, etc. Reaction with antisera results in agglutination of the immuno-coated particles, which is visually observed. A recent application to substances-of-abuse screening using immunoreagent-coated colored latex spheres to distinguish the various metabolic products in urine by agglutination immunoassay has been reported.²³ Such assays can be very powerful screening tools but are usually read visually. The extent of quantification therefore depends on the judgment and visual acuity of the observer as well other factors such as serial dilutions of antisera used in the assay, extent of antigen labeling of the particles involved in agglutination, etc.

Another intriguing technique, originally developed for electron microscopy and subsequently applied to light microscopy of histological specimens, is the immunogold technique, which has been modified to an ultrasensitive procedure by employing a subsequent silver-precipitation step.²⁴ In this procedure, gold nanoparticles are used to label an antibody, and this labeled antibody then binds to tissue antigens (as part of a multiantibody "sandwich"). Then a silver precipitate is formed around the gold particles, and since multiple silver atoms precipitate around each gold particle, a large amplification results. This immunogold-silver staining procedure was found to be so sensitive (~200-fold more sensitive than immunoperoxidase staining method²⁴) that it was felt necessary to at least bring it to the reader's attention. Several not-so-attractive elements of this technique are the long (overnight) incubation with the immunogold reagent and the requirement for development of the silver stain in the dark. This procedure has been adapted for membrane staining, and we have included an entry toward the end of Table 55.1, as densitometry could be used to quantify the results of the silver stain.

55.3 Nucleic Acid Analyses

Although technologies for amplifying and detecting nucleic acids do not have as long a history as immunoassay techniques, they have nonetheless developed in the past few decades into an impressive armamentarium for biological investigations. Many of the caveats that have been mentioned in regard

to immunoassay techniques can also be applied to nucleic acid amplification technologies. As mentioned in the immunoassay section, nucleic acid amplification technologies that use radioisotopes for detection have been omitted because they do not strictly fall under the field of optical detection. We recognize that many of the key technologies for nucleic acid detection, such as PCR, reverse-transcription PCR, membrane blotting/hybridization, *in situ* hybridization, etc., as originally described, used radioisotopic detection. Often, in the earlier literature, autoradiographic methods were used to visualize the nucleic acids being detected; thus, strictly speaking, optical detection was used. Radioisotope techniques using such labels as ³²P have also been found to be very sensitive. Nevertheless, to remain consistent with the immunoassay section and to showcase such techniques as fluorescence and chemiluminescence, we have chosen to omit radioisotopic detection.

As in the immunoassay section, we have had to constrain ourselves somewhat with regard to the definition of amplification. As a number of reviews point out,25-27 amplification with respect to nucleic acids can refer to target amplification, probe amplification, and/or signal amplification. Thus, PCR, the extremely fertile technology devised in the mid-1980s, amplifies the target DNA (or RNA). Branched-DNA amplification techniques, on the other hand, do not amplify the nucleic acid target but rather amplify the signal of a hybridization event, allowing it to be detected. Probe amplification strategies involve techniques such as ligase chain reaction (LCR). All these techniques, and many others, are explained and referenced in Tables 55.2 and 55.3. In some of these technologies, amplification is more obvious than in others (such as when 106 copies of the target nucleic acid are made and detected, as in PCR). In in situ hybridization techniques, on the other hand, where a probe must hybridize to a target sequence on a chromosome, amplification is sometimes only achieved by the presence of multiple detection labels on the probe. Of course, it is experimentally possible to use only one label on the probe, followed by single-molecule detection, but this is very much the exception rather than the rule. The table below, taken from Schweitzer and Kingsmore, summarizes various mainstream technologies discussed in this section on nucleic acid amplification.²⁶ This is a very useful summary in that it provides in an easy-to-read format an idea of what kind of amplification is involved, the sensitivity, useful dynamic range, and other aspects of the assay systems. Not included in this table are various hybridization technologies that, strictly speaking, may not involve target amplification but that do involve some form of signal amplification to detect the hybridization event.

Properties of Various Nucleic Acid Amplification Technologies

Property	PCR	LCR	SDA	NASBA	bDNA	Invader	RCA
DNA-target amplification	/	/	/	×	×	×	/
RNA-target amplification	1	×	1	/	×	×	/
DNA-signal amplification	×	×	×	×	1	1	/
RNA-signal amplification	×	×	×	×	/	/	/
Protein-signal amplification	×	×	×	×	×	×	1
Multiplexing	Little	×	Little	Little	×	×	/
Mesothermal	×	×	1	1	1	1	1
Amplification with cells	✓	×	×	×	×	×	1
Amplification on microarrays	×	×	1	×	×	×	1
Sensitivity (copies)	<10	100	500	100	500	600	1
Range (logs)	5	3	4	5	3	4	7
Specificity (allele discrimination factor)	50	5000	50	50	10	3000	100,000

Data from Schwitzer, B. and Kingmore, S., Curr. Opinion Biotechnol., 12(1), 21, 2001.

The major focus of this section can be found in Tables 55.2 and 55.3, which provide brief summaries in the same format as Table 55.1 in the immunoassay section of various nucleic acid amplification techniques. Like Table 55.1, Tables 55.2 and 55.3 provide a brief description of the principles behind the assay, commentary, and appropriate references. Table 55.2 discusses PCR-based and non-PCR-based methods for nucleic acid amplification, signal amplification strategies like branched DNA, and various

hybridization technologies, *in situ* as well as others. Table 55.3 covers procedures that we call hybrid technologies. Here we include techniques like immuno-PCR and PCR-ELISA, which are in some sense a melding of immunoassay techniques and nucleic acid amplification techniques. For the most part, Tables 55.2 and 55.3 are self-explanatory, and no attempt will be made in this review to systematically discuss the information therein. Only a few comments regarding specific issues follow.

55.3.1 Target Amplification

The critical feature of nucleic acids that has allowed the powerful amplification/detection technologies to develop is the complementarity of the nucleotide bases (i.e., base pairing) and the resultant ability to form double-stranded molecular hybrids. From these fundamental chemical properties flow all the varied and ingenious experimental systems that exploit these properties. Due to the base-pairing phenomenon, relatively short primers can be annealed to single strands of DNA, and the succeeding DNA sequence (on the 3' side) can be replicated (in a complementary sense), giving rise to PCR. Of course, this property of nucleic acids, which has proved to be such a powerful analytical tool, also has the potential to introduce errors because mismatches in base pairing can occur and go undetected, giving rise to spurious amplicons, hybridizations, etc. Issues of specificity, fidelity, and efficiency of PCR have been discussed by various authors and the effects of various reaction conditions on the overall process explained (see, for example, Cha and Thilly²⁸). This propensity for incorrect hybridization of probes and primers becomes an even greater problem when various detection labels (fluorophore, biotin, enzymes) appear as decorations on the probe/primer strands.¹ Indeed, one of the powerful advantages of using ³²P radioactively-labeled nucleic acids is the fact that incorporation of the label has minimal effect on overall hybridization of probe/primer to target.

Even if no overt mispairing occurs, as a result of these decorations, the net effect may be a decrease in thermodynamic stability, which would reduce the effectiveness of hybridization under conditions where some degree of stringency is needed. Therefore, considerable effort has been expended to develop analytical techniques to incorporate detector decorations into probes and primers without affecting (to any significant degree) the part of the probe/primer that must effect recognition of the target nucleic acid.

PCR is, without question, the premier target-amplification technique for nucleic acids, with applications that span the gamut of biological investigations. It has been applied to target nucleic acid amplification in microtubes as well as to tissue/cell sections; in the latter case it is known as *in situ* PCR. Very often when PCR is carried out in microtubes, the amplified product is analyzed by agarose-gel electrophoresis. Commonly ethidium bromide, an intercalating dye, is included in the gel, so that location of the amplified sequence can be visualized by ultraviolet-excited fluorescence. We have included this technique as part of the optical detection technologies because it is certainly optical in nature and comprises the analytical endpoint in many applications of PCR technology. On the other hand, this fluorescence-based analysis of gels is usually not done for quantitative purposes because the information desired from PCR is often in regard to the molecular size of the PCR product, not quantitative information regarding the amplification achieved by PCR.

As stated above, PCR products can be detected by direct staining in gel matrices. However, it is also common to use labeled probes (such as molecular beacons, "scorpions," or "Taq Man,")²⁶ that bind by hybridization to PCR amplicons and by this binding produce a detection signal (i.e., fluorescence). Another strategy is to use PCR primers with attached labels, so that as the amplification proceeds the amplified products are all labeled. In this type of assay, some separation of labeled amplicons from labeled but unincorporated primers must be carried out.

The enormous amplification power of PCR, coupled with the development of highly efficient instrumentation for the obligatory thermal cycling, has overshadowed all other target-amplification technologies. Table 55.2 also includes such techniques as LCR, strand-displacement amplification, nucleic acid sequence—based amplification, and rolling-circle amplification (RCA). Some of these techniques have real advantages over PCR, such as no requirement for thermal cycling, but none has yet succeeded in unseating PCR from its commanding position.

RCA, a relatively new technology, has the potential for either linear or exponential target amplification and has the additional advantage of isothermal amplification. In this procedure, a primer hybridizes to a circular DNA, and the circular DNA is amplified by polymerase extension. Up to 10⁵ copies of the DNA circle are generated on a concatemerized chain from one primer.²⁶ The amplification potential of this technique is obviously tremendous. RCA can also be used as a signal amplification technology. In this application, a defined circular DNA segment is amplified, and the concatemerized product is labeled either during the polymerase amplification or subsequently. Again, the larger degree of amplification produced by the rolling-circle technique results in enhanced ability to detect signal.

Of course, PCR and other target amplification techniques not only are useful for detecting DNA but can be applied to RNA as well, since RNA can be converted into a DNA copy using reverse transcriptase. In addition, PCR has been applied to *in situ* hybridization studies, where the detection of a nucleic acid sequence in a tissue sample proves a difficult analytical challenge.²⁹ In such a case, PCR can be used to make many copies of a primer that is complementary to the target strand of interest. This primer may itself be labeled, or labels may be incorporated during amplification. In the strictest sense, this is not target amplification but probe amplification; however, the net effect remains the same. Oddly, while one might expect diffusion of the amplicons away from the site of the PCR reaction, this does not occur to such an extent as to render the technique unusable.

55.3.2 Signal Amplification

Target amplification of nucleic acids is not the only way in which nucleic acid sequences may be detected. Signal amplification technologies can be used in which the signal from a hybridization event where probe binds to target is somehow amplified. Branched-DNA amplification, in which a dendrimer structure is formed upon a probe hybridizing to target and in which the branches of the dendrimer can carry multiple labels, is one example of such a signal amplification technique.^{25,26} A powerful advantage of the branched-DNA technique is the fact that the amplification of the signal, rather than the target, permits direct quantification of the amount of target DNA being detected based on the signal. Table 55.2 also includes a variety of other techniques that involve signal amplification. For example, a variety of hybridization techniques involve binding of antibody molecules to haptenylated nucleic acid probes. In these instances, signal amplification can take place in a variety of ways. There can be multiple antibody molecules bound to each probe, each antibody can have multiple fluorophores (for example), or the antibodies can be conjugated with enzymes, thereby allowing the tremendous amplification potential of enzyme processivity to contribute to overall amplification.

For membrane hybridization detection, nucleic acid recognition is quite commonly coupled with enzyme-associated signal amplification to produce highly sensitive analyses. For example, biotinylated probes can be hybridized to nucleic acid targets on membranes, and subsequently avidin/streptavidin conjugated with an enzyme such as alkaline phosphatase can be added. The biotin/avidin linkage immobilizes the enzyme at the specific site on the membrane, and addition of substrate results in signal amplification due to enzyme activity. Either fluorogenic or chemiluminescent substrates may be used, and the resulting assays are quite sensitive.

Assays of this nature are a blend of immunoassay techniques and nucleic acid assay techniques and could thus readily be put into the category of "hybrid assays." Perforce, our division into separate categories is somewhat artificial but may serve a useful purpose in delineating key characteristics of various assay schemes. Another hybridization assay that bears a strong similarity to immunoassay techniques is the use of tyramide signal amplification for *in situ* hybridization studies.²⁵ This technique, also known as CARD (catalyzed reporter deposition), begins with the specific recognition event of a probe hybridizing to its target *in situ*. Either directly or indirectly, horseradish peroxidase is linked to the hybridization probe, and the hybridization event thus localizes the enzyme at the target site. Addition of a tyramide conjugate results in activation of the tyramide by peroxidase, depositing large numbers of

tyramide molecules at the reaction site by binding to electron-rich targets near the site. If the tyramide is conjugated to a fluorophore, the net effect is to deposit many fluorophore molecules at the site of reaction. Further signal amplification can be achieved by using immunochemical techniques, such as adding antifluorophore antibodies conjugated with an enzyme (e.g., horseradish peroxidase), and thereby going through another round of tyramide deposition before detection occurs.

These are just a few examples of signal amplification. A more extensive list of examples can be found in Table 55.2. We end this section by simply mentioning the interesting category of detection molecules termed molecular beacons.³⁰ These molecules derive their powerful detection capabilities from the fundamental chemical properties of nucleic acids. In their simplest form, beacons consist of a stem–loop structure in which the nucleotides in the loop are complementary to a target sequence, while the nucleotides in the stem portion have a fluorophore and quencher held in close apposition on the two terminal nucleotides of the stem. Hybridization of the loop to its target destabilizes the stem, freeing the fluorophore from the quenching effect of the quencher molecule, thereby resulting in fluorescence. Obviously, the beacon must be carefully designed to accomplish the intended purpose. The molecular-beacon concept can also be easily adapted to FRET-based assays.

55.4 Hybrid Technologies

Table 55.3 lists the nucleic acid amplification techniques referred to as "hybrid technologies," i.e., a blending of immunological and nucleic acid detection strategies. We have included basically two technologies in this category — immuno-PCR and PCR-ELISA. Each of these techniques is a mirror image of the other in terms of recognition and amplification technologies employed. In immuno-PCR, recognition/specificity is achieved by antigen/antibody interaction. A nucleic-acid fragment attached (directly or indirectly) to the antibody supplies the target for PCR amplification. Thus, in this case, the nucleic acid serves in place of an enzyme attached to the antibody (e.g., standard ELISA immunoassay) as the amplification vehicle. Obviously, both the specificity of the antibody for the antigen and lack of nonspecific binding must be maximized because otherwise the tremendous amplification power of PCR will serve to amplify not only the immuno-specific reaction but spurious reactions as well.

In contrast, with PCR-ELISA assays the hybridization of primers to target nucleic acid sequences serves to provide specificity, while enzymes conjugated to immunoreagents boost the amplification potential of PCR. In this case, the same pitfalls applicable to PCR analysis again hold, as amplicons arising from spurious hybridizations will be amplified by the ELISA process, thereby contributing to the overall nonspecific background. Of course, the immunological reaction, in and of itself, can also contribute to analytical "noise," since binding of enzyme-conjugated antibody nonspecifically to sites other than antigenic sites (commonly digoxigenin) on the target amplicons will lead to increases in nonspecific background.

Both of these techniques have the potential for large signal amplification. Both also have the potential for high specificity. The PCR-ELISA technology has the advantage of building on many years of experience in both PCR and ELISA development. The immuno-PCR procedure, while seemingly straightforward, has a shorter lifespan of development behind it and thus is in its early stages. Even so, some of the results achieved by immuno-PCR have been impressive. For example, Hendrickson et al.³¹ were able to develop a multianalyte immuno-PCR assay for three separate analytes in which sensitivities were found to be three orders of magnitude better than conventional ELISA assays. Table 55.3 explains and lists some examples of these powerful analytical tools.

 TABLE 55.1
 Immunoassay Amplification Schemes

Assay	Principle	Comments	Ref.
	Enzyme-Linked Immunoassays [Solid-Phase	e Heterogeneous]	
	In all enzyme immunoassays (EIA) the final signal detected is produced by the activity of an enzyme, while specificity is obtained by antigen/antibody (Ag/Ab) interaction; addition of enzyme substrate to final immune complex results in accumulation of colored product	Large signal amplification because of high rate of processivity of enzymes for substrate molecules	
Direct EIA (ELISA)	Enzyme-labeled Ab recognizes Ag	If capture-Ab system used, enzyme-labeled Ab must recognize different Ag epitope then capture Ab; can be formatted as competitive or noncompetitive assay	1, 2
Indirect "Sandwich" EIA (Immune Complex) (ELISA)	Antispecies IgG enzyme-labeled Ab binds directly to Ag-recognizing Ab or is bound indirectly via an unlabeled antispecies IgG Ab that recognizes both Ag-specific Ab and enzyme-labeled Ab; both direct and indirect immune complex assays termed ELISA	Enzyme numbers multiplied through multiple epitope sites on IgG Ab	3–7
	ELISA carried out on cloth [usually plastic surfaces (e.g., microwells)]	Cloth assay described as instantaneous; no incubation time with Ab steps; 5-min incubation with substrate ³	3
Bispecific/Chimera Ab Molecules			8–14
Ab Molecules	Abs constructed to possess dual specificity for Ag and for enzyme; or chimeric Ab constructed to recognize a hapten (covalently linked to an immunoreagent) and an enzyme; in either case enzyme is indirectly linked to immunocomplex, as opposed to directly linked, as in the case of enzymes covalently coupled to Ab	Bispecific Ab constructed so that it binds to both FITC (used as a label for Ag or Ab) and to reporter (HRP) enzyme; thus, hybrid antibody serves as bridge between FITC-labeled immunoreagent and enzyme molecule; this procedure avoids possible deleterious effect on Ab affinity by covalent binding of enzyme directly to Ab, amplification both in number of FITC on primary Ab, and by enzyme indirectly linked to each FITC molecule ¹⁰	10
		or: Bispecific Ab constructed so that it recognizes both specific Ag and HRP; again, advantage in indirect linking of reporter enzyme and specific Ab ¹¹	11
	also: Chimeric fusion protein constructed having single-chain variable region of Ab fused to enzyme (alkaline phosphatase); bifunctional immunoreagent thus constructed; other constructs allow expression of enzyme-labeled Fab' fragments ^{8,9}		8, 9, 12, 13

	Fusion protein constructed between protein A and enzyme; as immunoreagent sandwich is formed, protein A portion of fusion protein binds to Fc region of Ag-specific Ab, forming, in effect, an enzyme-linked immunoassay	Fusion protein construct of enzyme-protein A avoids random nature of chemically labeling Ab with enzymes; since Ab itself is not labeled in this technique, more likely to have less adverse effect on Ab affinity than if Ab were directly labeled	14
Enzyme/Antienzyme Immune Complexes	Multiple enzyme molecules localized by antienzyme Ab, the whole complex held at Ag site as above (that is, Ag-specific Ab binds to Ag; antispecies IgG Ab binds to Ag-specific Ab, as well as antienzyme Ab made in same species as Ag-specific Ab; antienzyme Ab binds enzyme molecules; excess enzyme washed away); commonly used complexes include: PAP = horseradish peroxidase complex AP-AAP = alkaline phosphatase complex	Enzyme numbers multiplied; often used in immunohistochemistry; 2- to 50-fold increased sensitivity ¹⁵	15–21
Antihapten Ab "Sandwich"	Haptens (e.g., FITC, DNP) bound to Ag-specific primary antibody, recognized by enzyme-labeled antihapten Ab; can use bridge antibody (i.e., IgM anti-DNP) and DNP-labeled enzyme for increased sensitivity; can also use DNP-labeled glucose oxidase in addition to primary enzyme (peroxidase) for increased sensitivity	Enzyme numbers multiplied – multiple hapten molecules bound to primary Ab – bridging Ab gives more multiplication; used in immunohistochemistry; fourfold more sensitive than PAP ²²	22, 23
Cell–ELISA (Enzyme- Linked Immunofilter Assay)	Detect cell surface molecules on cells, using Ag-specific Ab and enzyme-labeled anti-species IgG Ab	Usually applied to cells in microwells; Limitations: may be necessary to use different enzymes (e.g., bacterial β -galactosidase) if endogenous cellular enzyme interferes; if cells are fixed, surface antigens may be destroyed; good correlation with flow cytometric analysis ²⁴	2, 24–27
ELISPOT (Spot–ELISA)	Ags secreted by individual cells are captured by Ag-specific capture Ab immobilized on solid surface; cells are removed and Ag-specific reporter Ab is added; either reporter Ab has enzyme label or enzyme-labeled antispecies IgG Ab is added; substrate is added to give insoluble product	Need relatively high Ag density on solid-phase surface; nitrocellulose better than plastic; biotin/avidin systems can be used to advantage in this technique; technique developed to reveal secretion by single cell; does not measure Ag concentration	26–30
ELIFA (Enzyme-Linked Immunofilter Assay)	Ag (e.g., bacteria) captured on membrane detected by Ag-specific Ab and additional immune complex; antispecies IgG Ab + enzyme-labeled Ab	Detect ~50 to 60 bacterial cells using chemiluminescent or colormetric assay, carried out in ~1 h; very rapid (17 min) EIA reported for airborne antibiotic trapped on cellulose nitrate filter; ³¹ colorimetric detection	31–35

TABLE 55.1 Immunoassay Amplification Schemes (continued)

Assay	Principle	Comments	Ref.
EIA (Enzyme-Labeled Ag)	Ag conjugated with marker enzyme; free Ag in sample competes with enzyme-labeled Ag for binding to immobilized Ab	Heterogeneous, competitive assay format; assay stated not to be as sensitive as radioimmunoassay ³⁶	36–38
	Fusion protein made between protein A and enzyme; binding to immobilized Ag-specific Ab results in some of enzyme–Ag fusion protein being immobilized in immune complex	Competitive, heterogeneous assay; Ag in analyte solution competes with enzyme–Ag fusion protein for binding to Ab; amplification due to enzyme; such chimeric constructs for use as Ags require a protein Ag	37
	or: Enzymes covalently attached to different hapten Ags; incubation with Agspecific Abs and free Ag in solution results in some enzyme-labeled Ag forming immunocomplex with Ab; addition of second Ab (antispecies IgG) results in precipitation of immune complex; following washing, addition of enzyme substrates results in enzymatic activity and optical signal proportional to amount of labeled Ag bound in original immune complex	Heterogeneous assay format; enzyme-labeled Ag competes with free Ag for binding to limited amount of Ab; use of two different enzymes can allow use of two different enzyme substrates whose products can be distinguished by optical properties; ³⁷ applied to simultaneous assay of two Ags – triiodothyronine and thyroxin	38
Immune Complex Transfer Immunoassay	Ag is complexed between Ag-specific Ab (Fab') labeled with enzyme, and Ag-specific Ab labeled with both biotin and DNP; resulting immune complex is trapped on solid phase by anti-DNP Ab bound to solid phase; immune complex eluted from solid phase by DNP-lysine wash; immune complex again trapped on streptavidin-linked solid phase; enzyme substrate is added and product is measured; similar principles applied to noncompetitive heterogeneous assays of small MW haptens	Important step is transfer of immune complex to different solid phases, as this removes nonspecifically bound Ab; lends itself to various assay formats; extreme sensitivity, subattomole, down to 1 zeptomol (600 molecules) in assay of human ferritin ³⁹	39–41
Enzyme-Amplified Cascade (RELIA) = Releasable Linker Immunoassay	Ag captured by immobilized capture Ab; second biotin-labeled detector Ab binds to immune complex; addition of alkaline phosphatase-conjugated streptavidin followed by addition of release (i.e., biotin-containing) reagent results in release of enzyme–streptavidin conjugate; enzyme activity detected indirectly by enzyme cascade as follows: alkaline phosphatase converts FADP to FAD, which binds to inactive apoenzyme amino-acid oxidase, resulting in active holoenzyme, which oxidizes proline to produce H ₂ O ₂ , which further reacts with horseradish peroxidase and other chemicals to form a colored product	Heterogeneous assay format; large multiplication due to involvement of multiple enzymes; sensitivity found to be comparable to fluorometric assays	42

Fusion Protein-Based EIA	Genetically fused protein is prepared that has both immunoreactivity and enzymatic activity; this protein can take part in immunoreactions and also serve as detection system by generating enzymatic product that is detected; IA carried out in usual manner; fusion protein is part of immunoreactant complex; (example: firefly luciferase:protein A fusion protein–protein A binds to F_c region of Ig, while luciferase reacts with luciferin to produce luminescence) ⁴³	Potential for sensitive, specific IA; fusion products may not have same degree of binding affinity/enzyme activity as native proteins	43
	or: Fusion protein prepared that is Ag-fused to enzyme (i.e., proinsulinalkalinephosphatase); competitive immunoassay carried out in which fusion protein Ag competes with Ag in sample for binding to Ab ⁴⁴		44
Nonenzymatic Catalytic Amplification Immunoassay (Mimetic Enzyme EIA)	Immunoreactant "sandwich" set up in usual way (i.e., capture Ab, Ag and detector Ab); detector Ab has conjugated to it a chemical which can serve as a catalyst for a reaction which produces an optically detectable product (e.g., p-hydroxyphenyl acetic acid + $\rm H_2O_2$ in the presence of the catalyst hemin generates a fluorescent product)	Amplification occurs by catalytic activity of reagent conjugated to Ab; also, multiple catalytic reagents can be conjugated to single Ab; small size of catalytic reagent compared to usual size of enzyme should result in less steric inhibition of Ab:Ag binding events; catalytic reagent likely to be more stable than enzyme	45–48
	Enzyme-Linked Immuno Assays [Solution-	·Homogeneous]	
	Enzyme-Linked Immuno Assays [Solution- Same general principle as for Heterogeneous EIA	·Homogeneous]	
EMIT = Enzyme-Multiplied Immunoassay Technique	, , , , , ,	Competitive assay; usually limited to low MW Ags – direct proportionality between free analyte concentration and enzyme activity (i.e., the more free Ag present, the less enzyme-labeled Ag is complexed with Ab, and the more enzyme activity is expressed)	49–51
Enzyme-Multiplied	Same general principle as for Heterogeneous EIA Free Ag in sample competes with enzyme-labeled Ag for binding to Ab; enzyme-labeled Ag bound to Ab results in inhibition of enzyme activity; the more Ag in the sample, the more uninhibited enzyme results, and the larger	Competitive assay; usually limited to low MW Ags – direct proportionality between free analyte concentration and enzyme activity (i.e., the more free Ag present, the less enzyme-labeled Ag is complexed with Ab, and the more	49–51 52, 53

TABLE 55.1 Immunoassay Amplification Schemes (continued)

Assay	Principle	Comments	Ref.
Enzyme Inhibitory Immunoassay	Ab (Fab' fragments) bound to enzyme (Dextranase); binding of Ag to enzyme-bound Ab results in inhibition of enzyme's ability to bind to insoluble substrate; enzyme substrate is in suspension along with other components; inhibition of enzyme activity produces less product	Designed to allow assay of high MW Ag; signal inversely proportional to analyte Ag concentration	55, 56
Cofactor-Labeled Immunoassay	Essential enzyme cofactors bound to Ag; free (sample) Ag competes with labeled Ag; when Ab binds to cofactor-labeled Ag, cofactor unable to activate apoenzyme, so enzyme activity is not expressed	Competitive assay; very low background; signal (enzyme activity) directly proportional to free analyte concentration	57
Cloned Enzyme Donor Immunoassay (CEDIA)	<i>E. coli</i> β-galactosidase genetically engineered, so that two inactive subunits, a large polypeptide called enzyme acceptor (EA) and a small polypeptide designated enzyme donor (ED), are present in the assay; EA and ED can spontaneously associate to produce active enzyme; in assay Ag is attached to ED; Ag-specific Ab binds to Ag:ED complex and inhibits reassembly of active enzyme; Ag in solution competes with Ag:ED complex for limited amount of Ab; more free analyte in sample, more active β -galactosidase formed; substrate in solution converted to colored product	Homogeneous, competitive assay format; colored product directly related to amount of analyte in sample; assay simple to perform and rapid; minimal background; high sensitivity	58–60
Enzyme–Channeling Immunoassay	Coupled enzyme reaction wherein activity is accelerated when two enzymes are brought into close contact; hapten + enzyme 1 co-immobilized on bead; Ab labeled with enzyme 2 binding to immobilized hapten on bead produces coupled reaction; if Ab is complexed to analyte in solution, coupled enzyme reaction does not occur	Inverse proportionality; low background	61
	Biotin: Avidin/Streptavidin Proce	edures	62–67
	Biotin and avidin/streptavidin form integral part of immune complex; due to extremely high association constant of biotin avidin/streptavidin, stable complexes with favorable rates of formation are produced	Same general detection methodologies as other immunoassays; biotin:avidin complexes contribute to immune "sandwich"	
Simple Complex	Biotinylated Ab recognizes Ag, and binds to enzyme-labeled avidin/ streptavidin	Enzyme number multiplied – multiple biotinylation sites on Ab since biotin is a small molecule; small size of biotin also produces only minimal effects on Ab activity; multiple enzyme molecules on each avidin/streptavidin molecule	62, 63

"Sandwich" Complex	Biotinylated Ag-specific Ab reacts with avidin/streptavidin which also binds biotinylated enzyme – can preform avidin/biotinylated complexes (ABC = avidin-biotin complex)	Enzyme number multiplied (see above) also, avidin has four combining sites for biotin; 2- to 100-fold more sensitive than conventional EIA techniques; 64 ABC likely forms a lattice complex containing several (>3) enzyme molecules	62–67
	also: Multiple "layers" can be built up to form large immunoreagent—biotin—avidin complexes; example: detector Ab is biotinylated; avidin binds to biotinylated detector Ab; avidin-specific biotinylated Ab binds to avidin; last two steps can be repeated; finally add avidin—enzyme complex followed by enzyme substrate	Amplification results from multiple enzyme molecules; amplification increases with number of "immunolayers" added; enhancement of 10- to 20-fold over standard ELISA for cytokine detection reported ⁶⁵	65
	also: Avidin can be conjugated to either Ag-specific or antispecies IgG Ab; subsequent reaction with biotinylated enzymes results in enzyme-labeled antibody–avidin complexes	Multiplication of enzyme molecules in each immunoreactant complex; five- to eightfold enhancement of sensitivity compared to directly enzyme-labeled Ab and fivefold more sensitive than ABC technique ⁶⁶	66
	Coupled Enzyme Procedures	s	
	Same general idea as for EIA; enzyme linked to immunoreagent produces product that is then indirectly detected	Potential for large increase in amplification since secondary enzymes contribute to overall multiplication of molecules responsible for final signal	
Multi-Enzyme Cascades	Product of one enzymatic reaction becomes substrate for another enzyme; also enzyme product (e.g., NAD+) can be recycled many times; example: alkaline phosphatase converts NADP+ to NAD+; alcohol dehydrogenase + ethanol converts NAD+ to NADH; diaphorase oxidizes NADH to NAD+ and reduces a tetrazolium salt to a colored formazan dye	Amplified enzymatic signals; 100-fold increase in sensitivity compared to conventional EIA; ⁶⁸ 0.01 attomol of alkaline phosphatase was detectable using multi-enzyme cascade ⁶⁴	64, 68
Catalyzed Reporter Deposition (CARD) Immunoassay	Form standard ELISA "sandwich"; enzyme linked to Ab in ELISA sandwich reacts with enzyme substrate and biotinyl tyramide (phenolic structure) to form free radical intermediate of tyramide which binds to receptor on solid surface (i.e., tyrosine residues in close proximity to site of enzyme reaction); addition of enzyme-labeled streptavidin results in binding of streptavidin at biotin sites; addition of enzyme substrate results in final product, which is measured; usually applied to procedures where final product is a precipitate; also feasible to use fluorescein tyramide as substrate for production of "activated" intermediate that is deposited; in this case, fluorescein serves as Ag for subsequent addition of antifluorescein Ab conjugated to enzyme; addition of enzyme substrate follows	Potential for many-fold multiplication of enzyme linked to streptavidin, since many biotinylated tyramides can be deposited; final enzyme does not need to be same as ELISA enzyme; other substrates than biotinyl tyramide can be used; HRP, AP, and β -Gal enzymes can be used; HRP used as the first enzyme to generate the "activated" tyramide; other enzymes may be used for secondary amplification (e.g., AP and β -Gal)	69–73

TABLE 55.1 Immunoassay Amplification Schemes (continued)

Assay	Principle	Comments	Ref.
	also: Can use multiple amplification cycles, where sequential additions of tyramide derivative plus ligand which binds to deposited tyramide results in many more deposition sites and deposited secondary enzyme	Can be readily applied to membrane-based immunoassays; CARD procedure improved detection limits 8- to 200-fold over standard ELISA format, depending on cycles of tyramide amplification and enzyme substrate used ⁶⁹	
	So-called "super" CARD assay; a modified protein with many sites for tyramine immobilization is used in the assay microwells instead of the usual blocking agent; essential point is that more reactive sites are provided for biotinylated tyramide immobilization, thus providing more sites for subsequent enzyme immobilization when avidin-HRP is added	Many more molecules of HRP are eventually immobilized around site of each primary HRP-conjugated antibody than in "standard" CARD; incubation time very significantly reduced from standard CARD assay; "super" CARD assay had limit of detection tenfold lower than ELISA and fivefold lower than regular CARD assay	70
	Principle is same as "super" CARD; synthetic proteins with many binding sites for tyramide deposition are used as blocking agents around sites of immunoreagents	Applied to immuno-dot type assay; "super" CARD assay found to be $\sim 1 \times 10^4$ -fold more sensitive than standard CARD, using casein as blocking agent in standard CARD vs. modified casein in "super" CARD ⁷⁰ all other immunoreagents being the same; visual detection of as little as 800 molecules of rabbit IgG reported ⁷⁰	
Dual Enzyme Cascade	Action of enzyme 1 converts inactive inhibitor into an active inhibitor of enzyme 2; residual activity of enzyme 2 provides measure of amount of enzyme 1 present	Inverse relation between concentration of first enzyme and strength of signal; increase in sensitivity of 125-fold over using single enzyme (i.e., enzyme 1 alone) system observed	74
Bioluminescence Enhanced Enzyme Immunoassay	Standard immunoassay "sandwich" set up with enzyme attached either to Ab or Ag (competitive format); following this, luciferin derivatives susceptible to hydrolysis (to make free luciferin) by the enzyme in the immune "sandwich" are added; after incubation, some of the product solution transferred to luciferase-containing solution; extent of bioluminescence produced used to quantify immune reaction	Can be formatted for competitive or noncompetitive assay; many assay steps, which contributes to longer assay time; maximal LODs stated to be 10^{-19} mol for antigen detection ⁷⁵	75, 76
	Fluorescence Immunoassays	,	
	Two approaches: (1) fluorophores attached to immunoreagent (Ab or Ag); when immunocomplex forms, extent of complex formation can be quantified by fluorescence; (2) EIA carried out, but enzyme produces fluorescent product from substrate	Fluorescence inherently more sensitive than absorption spectroscopy; other properties of fluorescence (fluorescence polarization, fluorescence lifetimes) can serve as basis for detection	

Fluoroimmunoassay (FIA) Direct	Fluorophore-labeled Ab binds to immobilized Ag (Ag can be immobilized by capture Ab); immobilized Ab binds free or fluorophore-labeled Ag	Heterogeneous assay; can be competitive or noncompetitive format; minimal amplification; amplification depends on number of fluorophores bound to either Ab or Ag; requirement that Ag be protein or larger peptide; small hapten that is conjugated to one fluorophore, by definition, does not involve amplification; limitations on fluorophore labeling of Ab, because of loss of affinity for Ag, and for Ag, because of potential loss of antigenic epitopes, self-quenching between adjacent fluorophores on same Ag molecule, etc.; immobilized Ab configuration can be used for competitive assay in which fluorophore-labeled Ag competes with free Ag in analyte for binding to limited number of immobilized Ab sites	77–91
	also:		
	Can measure either the fluorescence of the immobilized labeled fraction or the fluorescence of the labeled immunoreagent remaining in solution when immobilized Ab concentration is limited	Competitive assay in which fluorophore-labeled Ab binds to Ag in analyte solution; any remaining free labeled Ab is reacted with Ag immobilized on beads; thus, fluorescence is inversely proportional to analyte Ag concentration	
FIA (Indirect "Sandwich")	"Sandwich" formed with Ag-specific Ab and fluorescently-labeled antispecies IgG Ab, which binds to Ag-specific Ab	Some amplification, due to multiple fluorophore-labeled Abs bound to primary Ab; heterogeneous assay	80, 89, 92–95
	also: For better detection sensitivity, immunoreactant "sandwich" can be extended: i.e., after primary Ag-specific Ab binds, fluorophore-labeled antispecies IgG Ab made in another animal species binds to primary Ab; third fluorophore-labeled antispecies IgG (specific for animal species of second Ab) binds to secondary Ab; can be extended further	Multiplication of fluorophore labels with each additional Ab added to "sandwich"; used in histochemistry, cytochemistry	73
Fluorescent CARD Immunoassay	Same principle as CARD assay (see under Coupled Enzyme Procedures); fluorophore-labeled tyramide is converted by action of enzyme to "activated" tyramide, which binds close to site of activation; thus, a cluster of fluorophores is deposited at the site of immunoreagent localization	Multiplication of fluorophore labels deposited at specific locus due to enzyme activity; used in histochemistry, cytochemistry, and immunoblotting; increase in sensitivity over usual fluorescent Ab techniques in histochemistry stated to be 10- to 100-fold ⁷³	73, 96, 97
	also: Applied to detection of Ags on cells and membranes	Enhancements of 4- to 15-fold over standard indirect immunofluorescent staining were observed using CARD ⁹⁶	96

TABLE 55.1 Immunoassay Amplification Schemes (continued)

Assay	Principle	Comments	Ref.
Fluorescence Immunoassay: Avidin/Streptavidin	Fluorophore-labeled avidin/streptavidin binds to biotinylated Ab	Multiple biotin sites on Ab, multiple fluorophores on avidin; heterogeneous assay	98
Fluorescence EIA (Enzyme Amplification)	Weakly or nonfluorescent substrate generates fluorescent product upon enzyme action; immune "sandwich" same as for ELISA	Heterogeneous assay; fluorescence inherently more sensitive than absorption (colorimetric); 5- to 10^5 -fold more sensitive than conventional EIA 64	64, 100–105
		Extreme sensitivity with certain fluorogenic substrate/ enzyme pairs reported (i.e., single enzyme-molecule detection) ⁹⁹ and detection of activity in single bacterial cells ¹⁰⁰	99, 100, 104, 105
FIA/Fluorescence EIA (Magnetic Bead Separation)	Ab bound to magnetic beads captures free Ag in sample; separation of bound from free fractions done by magnet; fluorophore-labeled Ag added to beads; extent of fluorescence inversely related to free Ag	Unique solid-phase separation employed; heterogeneous assay; rapid assay times; ready removal of interferent substances	106
	or: Immobilized Ab captures Ag to which enzyme-labeled second Ag-specific Ab also binds; after separation, incubation with fluorescence-generating substrate (also variant in which Ag is bound to beads and Ag-specific Ab is assayed by antispecies, enzyme-labeled Ab)		107
Microsphere-Based Immunoassay/Flow Cytometry	Microspheres of different sizes are used to provide discrimination for different immunoassays; each size microsphere can be labeled with different immunoreagent and appears as a distinct population by flow cytometry; in particular assay, different Ags immobilized on microspheres react with analyte Abs in sera; addition of fluorophore-labeled antispecies Ab results in fluorescently labeled microspheres if Ab is present in analyte serum; fluorescence detected by flow cytometry	Amplification is minimal since only amplification results from multiple fluorophores on detector Ab; detection can be quite sensitive since laser-induced fluorescence is used; possibility of multiple analyte analysis; flow cytometric assay reported to be fivefold more sensitive than microplate-based EIA ¹⁰⁸	108

Total Internal Reflection Spectroscopy with Fluorescence Detection	Immunological reaction between Ag and Ab monitored at interface between optical waveguide and sample solution; detected by fluorescence excited by evanescent wave resulting from total internal reflection; results in detection of Ag-Ab binding events only very near surface at which internal reflection occurs	Capture Ab immobilized on waveguide binds Ag in sample; second Ab with fluorescent label binds to Ag; fluorescence detection close to waveguide (evanescent wave) monitors Ag-fluorophore-labeled Ab binding event; no washing necessary; requires rather elaborate optical setup; free fluorophore-labeled Ab contributes to fluorescence seen at waveguide/solution interface; thus Ag-Ab binding event seen as incremental increase in fluorescence	109
		Ag (hapten) immobilized on waveguide surface; fluorophore-labeled Ab binds to immobilized Ag and is detected by evanescent-wave excitation; free Ag in solution competes with immobilized Ag for limited amount of Ab; signal decreases as amount of free Ag in solution increases	110
		or: Fluorophore-labeled Ag binds to immobilized Ag on waveguide surface and is detected by evanescent-wave excitation	111
Fluorescence Polarization Immunoassay (FPIA)	A change (increase) in fluorescence polarization occurs when fluorophore-labeled Ag binds to Ab due to changes in rotary motion attendant upon large increase in size of immune complex compared to Ag alone; competitive assay may be used with free Ag and fluorophore-labeled Ag; can also determine specific Ab levels using fluorophore-labeled Ag; FPIA using fluorophore-labeled Ab to detect Ag does not appear to work due to flexibility of Ab or relatively free rotation of attached fluorophore	Amplification minimal — fluorescent labeling of Ag limited to low MW Ags if fluorophores with nanosecond lifetimes used; competitive, homogeneous assay possible; extent of change in fluorescence polarization inversely proportional to free Ag concentration; no separation of bound vs. free Ag required for assay; sensitivity of assay strongly dependent on Ab affinity; potentially very short assay time; low background; potential for high sensitivity; other proteins in Ag sample may interfere with assay if they bind to fluorophore-labeled Ag; sensitivity sub-ng/ml ¹¹²	112–115
FPIA with Metal–Ligand Complexes	Same principle as FPIA above, but use of transition-metal (e.g., Re, Ru) ligand complexes allows fluorescence polarization assays for high MW antigens; these complexes display high polarization in absence of rotational diffusion and long lifetimes	Competitive, homogeneous assay; metal—ligand complexes do not show probe—probe interactions, and so higher metal—ligand complex/Ag protein ratios can be used; amplification in terms of fluorophore groups is small; metal—ligand complexes have low extinction coefficients and low quantum yields; long lifetimes allow off-gating of fluorescence interferences.	116–118

fluorescence interferences

TABLE 55.1 Immunoassay Amplification Schemes (continued)

Assay	Principle	Comments	Ref.
Time-Resolved FIA	Immune "sandwich" formed in usual way, with one of components being biotinylated Ab; the biotinylated Ab serves as recognition sites for streptavidin-containing macromolecular complex that also contains multiple chelator molecules saturated with Eu³+; after reaction with immune reagents, unbound macromolecular complex is washed away, and Eu-chelate associated with solid phase is measured by time-resolved fluorescence; homogeneous assay not feasible because of instability of Eu chelate/macromolecular complex; particular chelator used forms highly fluorescent, stable complex with Eu³+ and can be covalently linked to proteins	Heterogeneous assay; capture Ab immobilized on solid surface captures Ag; biotinylated Ag-specific Ab also binds to Ag; addition of streptavidin-thyroglobulin-chelator-Eu³+ macromolecular complex results in some complex being immobilized at immunoreagent sites, if biotinylated Ab is bound; excess macromolecular complex is washed away, wells are dried, and Eu³+ fluorescence determined by time-resolved techniques; large amplification due to hundreds of Eu³+ bound in macromolecular complex; use of the macromolecular complex resulted in improved detector limits for a number of antigens, in comparison with smaller streptavidin-thyroglobulin-chelator-Eu³+ complexes; laser excitation used; detection limit for α-fetoprotein was 60 attomoles/well; ¹¹⁹ enhancement of Eu fluorescence when multiple chelator-Eu complexes bound to protein, thus, when 160 chelator molecules are bound to thyroglobulin in presence of excess Eu³+, fluorescence equivalent to 900 molecules of unconjugated chelator-Eu³+ is obtained ¹¹⁹	119, 120
	also: Immune complex formed in usual way; same chelator as above is used, but Ab directly labeled with chelator + $\rm Eu^{3+}$; chelator binds to $\rm NH_2$ groups on proteins; after washing and drying, fluorescence of $\rm Eu^{3+}$ measured	Too much labeling of proteins with chelator interferes with biological activity of proteins (e.g., Ab/Ag interaction); extent of labeling tolerated before biological activity decreases depends on particular protein; for one Ab, 18 chelator–Eu ³⁺ complexes could be attached per Ab molecule without adverse effect; competitive heterogeneous immunoassay for cortisol demonstrated	
Dissociation-Based Time- Resolved Fluoroimmunoassay (DELFIA)	Either Ab or Ag is labeled with stable hydrophilic lanthanide (Eu, Tb) chelate, which is nonfluorescent in aqueous solution; immunoassay takes place in standard way (i.e., immune complex "sandwich"); after all immunoreactions are finished, the lanthanide chelate is dissociated with an enhancement reagent, which contains a diketone that chelates the lanthanide in a micellar environment, resulting in a highly fluorescent solution; separation step required to eliminate labeled reagent not bound in immune complex; new chelate with lipophilic reagent is formed, enhancing lanthanide fluorescence; time-resolved fluorescence (delay time between excitation and emission signal) determined	Can be heterogeneous or homogeneous format; time-resolved fluorescence virtually eliminates background and interferents; generally requires laser excitation; only amplification is in the number of metal-chelates per Ag or Ab; narrow emission bands suggest use of multiple labels (more than one lanthanide chelate) for dual analyte assays	121–125

EIA with Time-Resolved

Immunoassay carried out like regular EIA; enzyme substrate consists of a chemical that does not form a chelate with lanthanide ion (Tb³+, Eu³+), but after enzyme activity a product is formed that chelates to lanthanide ion to form highly fluorescent complex; fluorescence measured by time-resolved methods or second derivative synchronous fluorescence; luminescence (fluorescence) increase directly related to enzyme activity; mainly uses Tb³+

Heterogeneous assay format; time-resolved fluorescence advantages (see above); attomole sensitivity observed for one Ag species;¹²⁶ possibility for rapid assay; lanthanide chelates have high quantum yields, large Stokes shifts, narrow emission peaks; potential for several orders of magnitude increase in sensitivity over conventional fluorescence;¹²⁷ Tb³⁺ has advantages over Eu³⁺ for this type of assay; observed to be ~30-fold more sensitive than assay where no enzyme amplification was used, but where Euchelate served as label for immunoreagent (thus, also time-resolved fluorescence detection);¹²⁸ 300-fold more sensitive than colorimetric EIA; ~20 attomole of Ag detected¹²⁸

126-132

Fluorescence Resonance Energy Transfer (FRET) Fluorophore donor/Ag conjugate (β-phycoerythrin/thyroxine) competes with free Ag in sample for binding to Ab-fluorophore acceptor conjugate (antithyroxine Ab/Cy5); when labeled Ag binds to labeled Ab, FRET occurs; this transfer is detected by measuring changes in fluorescence lifetime, performed by phase-modulation methodology

Homogeneous, competitive assay; particular pair of dyes chosen allow FRET to occur over greater distances than for most acceptor-donor pairs; ¹³³ eliminates many sources of fluorescent interference; instrumentation rather complex; laser required

133-137

or:

Two fluorophore-labeled Abs bind to different epitopes on analyte Ag; when immune complex forms, excitation of one fluorophore (donor) results in transfer of energy to second fluorophore (acceptor) because of close apposition; emission from second fluorophore signals formation of immune complex

One Ab labeled with europium (III) cryptate binds to Ag; second Ab labeled with allophycocyanine (acceptor) also binds to other epitope on Ag; excitation by laser of donor results in transfer of excitation energy to donor, if both are bound to the same Ag molecule; signal detected by time-resolved technique

137

or:

134

Two fluorophore-labeled Abs used that recognize same Ag; one fluorophore is a Eu³+-labeled cryptate; the other fluorophore (on different Ab) is allophycocyanine; formation of immune (Ab/Ag/Ab) complex results in nonradiative energy transfer; excitation of Eu³ label, coupled with appropriate filtering and time-resolved detection, results in the detection of fluorescent signal arising from allophycocyanine due to energy transfer in immune complex; fluorescence from Eu³+-labeled Ab free in solution or allophycocyanine-labeled Ab free in solution not detected due to elimination by optical filtration or time-resolved measurement

Laser excitation; homogeneous assay format; theoretically, only fluorescence from immune complex detected; amplification arises because of high value of quantum yield from allophycocanine and the high efficiency of the energy transfer; therefore, overall fluorescence yield from immune complex higher than would arise from Eu³+ alone; detection limit for prolactin found to be as good as for radioactive assay for this same Ag¹³4

 TABLE 55.1
 Immunoassay Amplification Schemes (continued)

Assay	Principle	Comments	Ref.
	or: Fluorescamine-labeled Ag reacts with fluorescein-labeled Ab in solution; two fluorophores matched so that excitation of fluorescamine on Ag results in energy transfer so that fluorescin on Ab is excited and fluoresces; addition of unlabeled Ag results in decrease in fluorescence, since fewer labeled Ags are bound in immune complex and participate in FRET	Competitive, homogeneous assay format; amplification due to multiple fluorophores on Ab; approximately equivalent limit of detection compared to ELISA observed, when same Ab reagents used ¹³⁵	135
	or: Ag labeled with chemiluminescent (isoluminol) derivative; binding to fluorescein-labeled Ab sets up conditions for nonradiative energy transfer; addition of microperoxidase and $\rm H_2O_2$ after formation of immune complex results in emission of light due to chemiluminescent reaction and energy transfer to fluorophore-labeled Ab, resulting in fluorescence emission from the Ab-associated fluorophore, since donor/acceptor species are designed to allow FRET	Homogeneous, competitive assay format; amplification due to multiple fluorophores on Ab (4-12 fluoresceins/Ab molecule); since both chemiluminescence and fluorescence occur, ratio of light intensity at two wavelengths used to evaluate extent of energy transfer (and, thus, indirectly to evaluate extent of Ag and Ab binding); assay applied to a variety of Ags, e.g., cAMP, progesterone, IgG; rather complicated experimental apparatus, as chemiluminescence/fluorescence monitored simultaneously; assay for camp found to be comparable in sensitivity to radioimmunoassay for cAMP ¹³⁶	136
Fluorescence Excitation Transfer Immunoassay (FETI)	Fluorophore-labeled Ag binds to Ab labeled with a different fluorophore; immunospecific binding event results in fluorescence excitation transfer, where donor fluorophore emits in same spectral region as acceptor fluorophore absorbs; fluorescence (at donor excitation energies) is quenched when immune complex forms; can also be used for multiepitope Ag, with two different Ag-specific Abs, labeled with donor and acceptor fluorophores	Competitive-type assay; homogeneous; amplification only due to multiple fluorophores on Ag and Ab; requirement for dual labeling	138
	or: Unlabeled Ag in sample competes with fluorophore-labeled Ag (i.e., "fluorescer" Ag) for binding to Ab that is labeled with a "quencher" (i.e., a fluorophore whose absorption wavelength is closely matched to the fluorescence emission of the "fluorescer" Ag); binding of fluorophore-labeled Ag to quencher-labeled Ab, followed by excitation of the "fluorescer" fluorophore with light of the appropriate wavelength results in energy transfer to quencher, due to short distance between "fluorescer" and quencher in immune complex, and decrease in fluorescence; the more Ag in sample, the less "fluorescer" Ag binds to Ab and therefore the more intense the resulting fluorescence	Homogeneous, competitive assay format; increasing fluorescence obtained with increased concentration of Ag in sample, i.e., signal directly proportional to concentration of Ag in sample; amplification due to multiple fluorophores on "fluorescer" Ag; various pairs of "fluorescer" and quencher pairs may be used; for example, fluorescein as "fluorescer" can be coupled with β -phycoerythrin as quencher or β -phycoerythrin as "fluorescer" may be coupled with Texas Red as quencher98	98

Fluorescence Modulation Immunoassay Homogeneous assay; Ag-specific Ab and hydrolytic enzyme are in solution; fluorogenic-labeled hapten Ag is prepared by synthesis; fluorogenic label is a substrate for enzyme listed above, such that action of the enzyme on the fluorogenic-labeled hapten releases a fluorescent product upon enzymatic hydrolysis; when fluorogenic-labeled Ag and unlabeled Ag in solution are added to Ab and enzyme solution, fluorogenic-labeled Ag bound by Ab is unavailable for enzymatic hydrolysis; any free labeled Ag is acted upon by enzyme to produce fluorescent product; only applied to hapten Ag

Competitive assay format; fluorescence, produced by enzymatic action, directly proportional to amount of Ag in analyte solution; amplification by enzyme activity; results obtained with this assay correlated well with EMIT assay; 139 potentially very rapid assay, i.e., 20 min, 140 and simple to perform

139, 140

Substate-Labeled Fluorescent Immunoassay (SLFIA) Like substrate-labeled immunoassays where Ab binding to an analyte-substrate conjugate inhibits action of enzyme on substrate; addition of analyte (Ag) in sample results in more sample analyte being bound to Ab, consequently freeing more of analyte-substrate conjugate for breakdown by enzyme; however, analyte (Ag)-substrate conjugate is constructed to contain a fluorophore linked to a quencher via an enzyme-hydrolyzable linkage, while the analyte (Ag) is conjugated to the fluorophore; free analyte-substrate conjugate (not Ab-bound) can be hydrolyzed by enzyme, thereby releasing inhibition of fluorescence due to energy transfer to quencher and resulting in full fluorescence of fluorophore

Homogeneous, competitive assay format; amplification due to enzyme action; fluorescence increases as amount of free Ag (analyte) in sample increases, so signal is directly proportional to free Ag; Li and Burd¹⁴¹ use AMP bound to FMN as quencher/fluorophore pair, respectively; Ag (theophylline) is bound to AMP; if antitheophylline Ab is unavailable for binding due to amount of theophylline in sample, then nucleotide pyrophosphatase in solution hydrolyzes AMP-FMN linkage, restoring FMN fluorescence

141

Chemiluminescence Procedures

Same concept as fluorescence IA; either an immunoreactant is labeled with a chemiluminescent compound or an enzyme substrate is used that produces a chemiluminescent product upon enzyme action

Potentially very sensitive; additional advantage in that background should be very low since no exciting light source is needed (as is the case with fluorescence)

Chemiluminescence Immunoassay (CIA) Capture Ab used to immobilize Ag on solid surface as per standard assay; second Ag-specific Ab with chemiluminescent label (acridinium ester) binds to immunocomplex; after washing, addition of appropriate reagents produces chemiluminescence (flash)

142-149

Multiple chemiluminescent labels per Ab produce some amplification (see entry under FIA); heterogeneous noncompetitive assay; sensitivity should theoretically increase with increase in specific activity of label (i.e., increased moles of label per mole Ab); calculated detection limit <1 attomol; ¹⁴² CIA observed to be more sensitive and with wider working range than radioimmunoassay; chemiluminescent immunoassay using luminol-labeled Abs found to be as sensitive as radioimmunoassay, ~22 luminols per Ab molecule; ¹⁴³ losses in quantum yield after conjugation of luminol to Ab; sensitivity of chemiluminescence immunoassay for thyrotrophin described as far more sensitive than other immunoassays

 TABLE 55.1
 Immunoassay Amplification Schemes (continued)

Assay	Principle	Comments	Ref.
	or: Ag labeled with chemiluminescent derivative (isoluminol); Ag-specific Ab immobilized on solid surface; unlabeled Ag in sample competes with labeled Ag for binding to Ab; following binding and washing, addition of appropriate reagents produces chemiluminescence (flash);	Heterogeneous competitive assay; light yield inversely proportional to concentration of analyte; rate of light production not constant, so timing of addition of reagents very important; chemiluminescent materials not usually present in biological samples, so no additional background from this source	
	or: Chemiluminescent label chemically attached to Ag; addition of free (unlabeled) Ag in sample sets up competitive assay; Ab binding to chemiluminescent- labeled Ag enhances chemiluminescence significantly; free Ag competes for Ab binding sites — the more Ag in the sample, the less enhanced chemiluminescence is seen	Homogeneous, competitive assay format; Ab concentration has to be carefully adjusted; "burst" of light requires specialized measurement apparatus	
Chemiluminescence Enzyme Immunoassay (CLEIA)	Immunoassay done in same way as EIA; enzyme label on one of immunoreagents; enzyme activity on substrate results in product that is chemiluminescent, usually a "glow" chemiluminescence; or action of enzyme on substrate (i.e., hydrogen peroxide) generates product that reacts with other chemicals (luminol) in reaction mixture to produce chemiluminescence; enzymes used include alkaline phosphatase, horseradish peroxidase, and β -galactosidase	Very low background; inherently highly sensitive; enhancers produce stronger, more stable light signal; proportionality over large ranges of analyte concentration; using a derivative of adamantly 1,2-dioxetane phosphate as substrate, <10-20 mol of alkaline phosphatase were detected on membrane or in solution; 150 light emission persists for many minutes; more sensitive than colorimetric EIA or radioimmunoassay; sensitivity for CLEIA using alkaline phosphatase as enzyme label 67-fold improved over colorimetric endpoint and ~3-fold improved over timeresolved fluorimetric assay; 151 possibility for very rapid total assay time; photographic film can be used as detector; very rapid response to reach peak light emission (3 min or less); 152 integration of chemiluminescent signal for longer periods of time can be done to increase sensitivity for "glow"-type chemiluminescent reactions 153	150–162
	Establishment of sensitivity study; enzyme (alkaline phosphatase) dilutions added to substrate + enhancer; reaction results in chemiluminescence	1.6 zeptomol of enzyme could be detected with a signal-to- noise ratio of >6; luminescence increases with time and reaches plateau by 40 min; proportionality of response over five orders of magnitude concentration of enzyme; enhancer provides 400-fold increase in chemiluminescence efficiency ¹⁵⁴	

Enzyme-labeled (peroxidase) Ab or Ag used in either noncompetitive or Heterogeneous assay format; direct comparison of competitive (enzyme-labeled Ag) format in standard immunoassays; in the colorimetric, fluorimetric, and chemiluminescent assays case of enzyme-labeled Ag assays, labeled and unlabeled (sample) Ag compete using same immunoreagents in same assay format for limited number of immobilized Ab molecules; substrate + luminol + demonstrated that the chemiluminescent assay was 10-fold enhancer added and chemiluminescence (glow) read 30 to 60 sec later more sensitive than the colorimetric and ~2.5-fold more sensitive than the fluorimetric assay155 Ag (bacterial) immobilized on membrane; enzyme-conjugated Ab added, Single-cell luminescence detected using a CCD camera and followed by addition of substrate, enhancer, and luminescent chemical: image processor156 chemiluminescence detected Following electrophoresis, immunoblot analysis on membranes is carried out Chemiluminescent substrates offer advantages over 163 using immunoreagents in standard way (Ag-specific pimary Ab; antispecies colorimetric substrates including higher sensitivity, shorter IgG secondary Ab conjugated to enzyme); chemiluminescent substrate added incubation times, potential for blot reuse, and ease of and chemiluminescence measured; can modify immunoreagent "sandwich" imaging; amplification by enzyme turnover and by by using biotinylated secondary Ab and enzyme-conjugated streptavidin localization of multiple enzyme molecules in immunoreagent "sandwich" Electrochemiluminescent-active species bound to Ab, Ag, or hapten Ag; Cycling of active species through electrochemical oxidation-164-166 chemiluminescence is produced by electrochemical generation of chemical reduction cycles at electrode produces many photons species at an electrode; example of active species reaction: ruthenium (II) (multiplication); each electrochemiluminescent label on tris(bipyridyl)++, with tripropylamine; as the electrochemistry occurs, an immunoreactant can therefore emit many photons during excited state of the ruthenium complex arises, and this excited state decays this cycling; also, can label Ab or protein Ag with many with emission of a photon, i.e., chemiluminescence electrochemiluminescent labels; assay restricted to certain formats (e.g., microbeads, solution) due to requirement for close approach of labeled molecules to electrode; somewhat complicated experimental setup; very large dynamic range (six orders of magnitude); assay can be set up with competitive or noncompetitive, heterogeneous or homogeneous format or: Ag-specific Ab immobilized on electrode surface; Ag is captured by Homogeneous (no wash) or heterogeneous assay format; 167 amplification occurs only by multiple labels on Ab; low immobilized Ab, but second detector Ab labeled with terbium chelate also binds to immune complex of Ag:Ab; either excess labeled Ab is washed away background or not eliminated; since electrochemiluminescence occurs only very near electrode, removal of labeled Ab not in immune complex may not be necessary; application of voltage produces luminescence, which is measured

by time-resolved techniques

Electrochemiluminescent

Labels

TABLE 55.1 Immunoassay Amplification Schemes (continued)

Assay	Principle	Comments	Ref.
CLEIA with Coupled Enzyme Partners	Immunoreactions carried out in usual way; enzyme label detected indirectly as follows; primary enzyme (β -galactosidase) bound to detector Ab reacts with substrate to generate product (galactose), which becomes substrate for second enzyme (galactose dehydrogenase); product (NADH) of activity of second enzyme reacts with chemical + O_2 + isoluminol and microperoxidase to produce chemiluminescence	Overall procedure is rather complicated and assay time is long; detection limits for β -galactosidase reported to be $\sim\!10^{-20}$ mol for 2-h incubation and 10^{-21} mol for 1000-min incubation; immunoassay using this procedure for 17α -hydroxyprogesterone reported to be 43-fold more sensitive than colorimetric ELISA; 168 immunoassays formatted as heterogeneous competitive	168–172
	also: Detector Ab conjugated to alkaline phosphatase; addition of FADP results in generation of FAD; FAD reacts with glucose oxidase (apoenzyme) to form active holoenzyme; addition of glucose results in production of H_2O_2 , which reacts with another chemical to produce chemiluminescence	Heterogeneous noncompetitive assay for thyrotrophin demonstrated; LOD of 4×10^{-19} mol for alkaline phosphatase; "glow" luminescence	
	or: $\beta\mbox{-}Galactosidase activity indirectly coupled to bacterial luciferase activity, using NADH generated from coupled-enzyme system to feed into two enzyme-catalyzed reactions, the final one involving luciferase, to generate light$	Complicated procedure with many steps; long assay time; detection limit of β -galactosidase for 2-h incubation is $\sim 10^{-21}$ mol and $\sim 10^{-22}$ mol for 1000-min incubation ¹⁷⁰	
	Liposome Immunoassays		
	Liposome, either directly or indirectly, becomes part of immune complex; release of liposome contents produces signal for detection	Potential for large amplification because liposomes can encapsulate many molecules	
Liposome Immune Lysis Assay (LILA)	Liposomes constructed with Ag-specific Ab in liposomal membrane and fluorescent dye encapsulated within; addition of Ag followed by second Agspecific Ab + complement results in lysis, releasing dye	Homogeneous assay as described; assay time <1 h; some nonspecific lysis observed	173–176
	or: Ag immobilized indirectly on liposome surface through streptavidin–biotin bridges; addition of complement + Ag-specific Ab results in lysis	Competitive homogeneous assay as described; unique method for immobilizing protein through streptavidin–biotin bridge	177
	or: Ag immobilized directly on liposome surface reacts with Ag-specific Ab; addition of complement lyses liposome, releasing its contents	Homogeneous, competitive assay; competition for liposome-immobilized Ag and Ag in sample	178

Immunoliposome-Based Immunoassay	Liposomes with Ag-specific Ab incorporated in membrane and encapsulating fluorescent dye are formed; incubation with immobilized Ag results in Abliposome immobilization; lysis of liposomes with ethanol/detergent releases fluorescent dye; fluorescence proportional to Ag concentration	Competitive, heterogeneous assay, where free Ag concentration decreases number of liposomes subsequently trapped on Ag-treated surface; total assay time somewhat long	179
	Liposomes formed with encapsulated fluorescent dye and biotin in the liposomal membrane; immobilized Ab captures Ag; second biotinylated Agspecific Ab binds to immobilized Ag; streptavidin forms bridge between immune complex and liposome; after washing to remove interferents, immobilized liposomes lysed, releasing fluorophore; can also be formatted with streptavidin incorporated in liposomal membrane	Heterogeneous, noncompetitive assay; fluorescence directly proportional to concentration of Ag captured; multiplication due to multiple fluorophores per liposome; stated to be as sensitive as best colorimetric ELISAs for Ag tested ¹⁷⁹	180, 181
Liposome Lysis- (Substrate)-Linked Immunoassay	Liposomes with Ag in membrane and encapsulating an enzyme substrate are constructed; presence of Ag-specific Ab and complement lyses liposomes, releasing substrate; addition of substrate-specific enzyme results in optically detected product	Could be used to detect specific Ab; potential for homogeneous assay	182
Liposome Lysis- (Reporter)-Linked Immunoassay	Immunoreaction of Ag-enzyme conjugate with Ab in solution inhibits enzymatic activity (e.g., phospholipase C), which can lyse liposome, thereby releasing liposomal contents, i.e., fluorescent dye molecules; free (sample) Ag competes with enzyme-labeled Ag; increasing free Ag results in increased liposome lysis	Multiplication due to many reporter molecules encapsulated within each liposome; homogeneous competitive assay as described; said to be as sensitive as heterogeneous EIA ¹⁸³	183
	Liposomes formed with encapsulated reporter enzyme; free Ag in sample competes for binding to Ag-specific Ab with Ag conjugated to melittin (a cytolysin); Ab binding to Ag-melittin conjugate inactivates cytolytic activity of melittin; Ag-melittin conjugate not bound by Ab lyses liposomes, releasing enzyme which reacts with substrate in solution	Multiplication due to many reporter enzymes per liposome plus enzyme activity; as described, homogeneous, competitive assay; Ag must be low MW for effective inhibition of melittin by Ab binding	184, 185
Immunoliposome Assay (Dye-Sensitive Photobleaching)	Immune "sandwich" (Ab-Ag-Ab attached to liposome) formed; 1 Ab has attached erythrosine; liposome has fluorescent compound embedded in membrane; when formed "sandwich" is illuminated by Hg lamp, erythrosine generates singlet $^1\mathrm{O}_2$, which photooxidizes fluorescent dye in membrane, decreasing fluorescence; singlet O_2 able to oxidize membrane-embedded dye only if site of generation is very close to the liposome surface; can also be set up as competitive Ag assay with erythrosine-labeled Ag competing with unlabeled Ag	Competitive and sandwich-type formats both possible; homogeneous assay; detection limit about the same as, or better than, conventional solid-phase assays ¹⁸⁶	186

TABLE 55.1 Immunoassay Amplification Schemes (continued)

Assay	Principle	Comments	Ref.
Immunoliposome Assay (Fluorescence Energy Transfer)	Liposome contains Eu-chelate embedded in liposomal membrane and membrane-attached Ab; free Ag competes with allophycocyanine-labeled Ag; when dye-labeled Ag binds to Ab and long-lived fluorescence measured, excitation of Eu results in energy transfer to allophycocyanine which is detected; energy transfer efficient only when two dyes close together	Competitive, homogeneous assay as described; potential for very low background; only demonstrated with biotin as Ag	187
	Expression Immunoassay		
	Immunoreactant complex formed as usual; DNA attached to immune complex codes for protein that, when expressed, produces signal for detection	Potentially large amplification, both because of number of protein molecules synthesized, and the fact that the synthesized protein is an enzyme	
	Immobilized Ag reacted with biotinylated Ag-specific Ab; streptavidin bridge couples biotinylated Ab to biotinylated DNA segment, which codes for α -peptide of β -galactosidase; addition of transcription/translation system, produces α -peptide, which then reacts with inactive M15 protein to reconstitute active enzyme; addition of substrate results in a signal, e.g., chemiluminescence	Assay carried out as solid-phase, heterogeneous assay; transcription/translation system potentially multiplies final active enzyme many-fold over other methodologies; theoretically, background should be zero, since active enzyme should not be present unless immune complex generates component needed for activity; assay procedure more complex (more steps) than usual ELISA and of longer duration; potential for very high sensitivity, depending on chemical (chemiluminescent, fluorescent) or enzyme chosen ¹⁸⁸	188
	Same general design as above, but DNA codes for firefly luciferase; assay endpoint is bioluminescence	Estimated 12 to 14 molecules of luciferase protein produced from each DNA template; comparison with enzyme amplified, time-resolved fluoroimmunoassay showed expression immunoassay to be considerably more sensitive ¹⁸⁹	189
	Immunoassays/Chromatograp	ohy	
Immunoaffinity Chromatography	Ag-specific Ab immobilized on columns; analytes in sample labeled <i>in toto</i> with fluorescent dye; analytes bound on Ag-specific immunoaffinity columns, and eluted sequentially; detection by laser-induced fluorescence	Potentially rapid and sensitive; may be nonuniform labeling of analytes in sample; multiple fluorophores may be attached to single analyte molecules; detection levels at pg/ml for various cytokines	190
	Surface-Enhanced Raman Spectroscopy (SER	RS) Immunoassays	
	Same principle as usual IA, but SERS-active chemicals are used as labels or substrates; SERS effect produces large signal amplification		

Heterogeneous Indirect Immunoassay	Capture Ab adsorbed on rough silver surface captures Ag analyte; Ab labeled with SERS-active molecules binds to Ag; SERS signal or surface-enhanced resonance Raman scattering signal is detected	Multiple SERS labels on each Ab; 10 ³ to 10 ⁶ (or higher for resonance Raman) enhancement in Raman signal from SERS effect; requires close apposition of SERS label to silver surface; potential for minimal assay steps (e.g., no washes) since only SERS label bound immunologically to silver surface produces signal; marked reduction in fluorescence background; special equipment needed to generate surfaces; laser required for measurements	191
	As above, but capture Ab adsorbed on gold surface; Ag captured and detected by Ab attached to gold nanoparticles, which in turn are labeled with SERS-active molecules	Simultaneous detection of multiple Ags using different SERS active labels; very narrow Raman bands provide potential for sensitive multianalyte detection; Ab bound to nanoparticles noncovalently; possible problem with Ab dissociation/reassociation leading to "cross talk"	192
EIA with SERS detection of Enzyme Product	Enzyme immunoassay carried out in standard way on microplates; after enzyme reaction (peroxidase), reaction product (azoaniline) is transferred to silver substrate and the surface-enhanced resonance Raman signal is determined; intensity of signal correlates directly with Ag concentration	See above; advantages over other techniques include low background, high selectivity, amplification from enzyme, as well as SERS effect; disadvantages are the elaborate equipment and the extra detection step at the end of the assay; detection limit stated to be 10 ⁻¹⁵ mol/l (for IgG) ¹⁹³	193
	Imprinted Polymer-Based Immuno	passays	
	Polymer with imprinted molecular sites is the immunorecognition element rather than Ab; otherwise IA is the same		
Chemiluminescent ELISA	Imprinted polymer serves as recognition element instead of Ab; polymer immobilized in tubes or wells; antigen (hapten) labeled with enzyme competes with Ag in analyte solution for imprinted sites in the polymer; following washing, enzyme activity associated with polymer determined by chemiluminescent assay	Heterogeneous, competitive assay format; signal inversely proportional to concentration of Ag in analyte; detection limit not as low as when usual ELISA assay with AB was used; useful range extends over four orders of magnitude; rapid and potentially robust assay; whether molecularly imprinted polymers can serve as Ab substitutes in the wide range of Ags currently detected by immunoassay still an open question	194, 195
	Miscellaneous Heterogeneous Immu	noassays	
	These procedures involve standard immunoreagents but also entail the use of beads, particles, crystals, etc., which serve as solid substrates for immunoreactions		

TABLE 55.1 Immunoassay Amplification Schemes (continued)

Assay	Principle	Comments	Ref.
Bacterial Magnetic Particle-Based Immunoassay	Magnetic particles (with lipid membranes) produced by bacteria are used as solid phase; Ag-specific Ab covalently immobilized on particles captures Ag; second (detection) Ab has enzyme label; detection by chemiluminescence (for enzyme-labeled Ab)	"Natural" magnetic particles disperse better than artificial; small size (50 to 100 nm) gives very rapid reaction kinetics; chemiluminescence using enzyme amplification was found to be very sensitive with detection limit of 6.7 zeptomol; detection range extended over 1 to 10 ⁵ fg/ml; a rapid chemiluminescence assay (~10 min) was also devised, but with detection limits of ~10 ng of IgG/ml	196
	or: Magnetic particles from bacteria are labeled with fluorescently labeled Ab; addition of Ag results in particle aggregation, which produces decrease in fluorescence due to self quenching by fluorophore	Amplification results from numerous fluorescently labeled Ab molecules bound to each magnetic particle; inverse relationship between Ag concentration and fluorescence; bacterial magnetic-particle assay found to be more sensitive than assay using artificial magnetic particles; ¹⁹⁷ applied to detection of bacterial cells (<i>E. coli</i>) with limit of detection ~10 ² cells/ml ¹⁹⁸	197, 198
Phosphor Crystals	Immunoreagents (Ab, avidin, protein A) directly linked to phosphor particles; assays carried out on membranes or cells; Ag immobilized on membrane or on cell surface detected by immunoreagent sandwich incorporating phosphor conjugates in one or more layers of the immune "sandwich"; fluorescent detection	Amplification based on formation of immune sandwich (i.e., biotinylated Ab, avidin); fluorescence not affected by environmental factors and does not fade; sensitivity found to be as good as ELISA with colorimetric endpoint ¹⁹⁹ Also applications to immunocytochemical analyses using immunoreagents linked to phosphor particles	199
Microspheres with CARD Amplification	Microspheres with encoding dye (to permit performance of multiple assays simultaneously) were derivatized with Ag on their surface; enzyme-labeled Ab was added to mixture of microspheres + Ag-containing analyte solution; any enzyme-labeled Ab bound to bead-immobilized Ag is detected using CARD technology; fluorescent tyramide is deposited on microspheres and fluorescence read	Competitive, heterogeneous assay format; fluorescent signal decreases as Ag concentration in analyte solution increases; encoding dye on microspheres allows multiplex assays; choice of fluorescent dyes has to be carefully made to allow discrimination between fluorescence of microsphere and tyramide derivative; preparation of Ag-derivatized, dyeencoded microspheres somewhat complex	201

Immunomagnetic Separation + Immunoassay	Immunoreagents (e.g., capture Abs) immobilized on magnetic beads, so that analyte can be extracted/isolated from bulk sample; rest of immunoassay can take place in usual manner (i.e., formation of immuno-"sandwich" with or without enzyme conjugate, incubation with substrate and detection)	Total assay time $<$ 1 h; 202 fluorescence ELISA using immunomagnetic separation was tenfold more sensitive than standard ELISA 202	202, 203
		Electrochemiluminescence-based assay (see under Chemiluminescence) compared with immunomagnetic separation/fluorescence ELISA; electrochemiluminescence-based assay found to be more sensitive in general, perhaps tenfold; ²⁰³ both assays could be completed in <1 h	
	Immunogold-Based Immunoass	says	
	Gold nanoparticles serve as label on immunoreagents and as nuclei for deposition of silver atoms		
Immunogold/silver Assay	Ag immobilized on membrane or in histological specimen; Ag-specific Ab binds to Ag; secondary antispecies IgG Ab labeled with gold nanoparticles binds to primary Ab; silver subsequently precipitated on gold particles	Addition of silver strongly amplifies gold immunostaining; used for immunoblots/dot blotting; 2-h incubation period; found to be more sensitive than PAP or ABC method (with same time of incubation with detector Ab) ²⁰⁴	204, 205
	Immunoassays Incorporating Aeq	uorin	
	Immune "sandwich" with primary Ab and Ag formed in usual way; secondary (antispecies IgG Ab) Ab, which is biotinylated, is then incorporated into complex; subsequent sequential additions of streptavidin and biotinylated aequorin are made, resulting in immobilization of aequorin at site of immune complex; addition of Ca²+ results in luminescent flash, which can be detected	Applied to both microwell and membrane blot assays; heterogeneous format; amplification because of multiple binding sites on streptavidin for biotin; detection may be challenging since light flash decays very significantly by 1 sec; immunoassay for Forsman antigen using aequorin was demonstrated as detecting less than 40 fmol	206

 TABLE 55.2
 Nucleic-Acid Amplification Schemes

Assay	Principle	Comments	Ref.
	PCR-Based Nucleic Acid Amplification	r	
	Target DNA is exponentially amplified by using a thermostable polymerase to copy complementary strands of DNA using one primer for each strand; RNA can enter PCR cycle via initial reaction with reverse transcriptase; various strategies can be used to incorporate a label or other moieties to which a label can be attached during the course of PCR so that amplicons can be detected		
Polymerase Chain Reaction (PCR)	Two primers are used in interactive process to amplify specific segment of DNA; first DNA target is denatured by heating, followed by hybridization of both primers to complementary strands of target at about 10°C below melting temperature of primers; next step involves raising temperature to 70–73°C, optimizing temperature for extension of primers by thermostable DNA polymerase; this extension may extend beyond region of interesting target in both directions, but is limited in its total length; denaturation, annealing, and primer extension steps are repeated; in presence of excess primers, after a few cycles copies of region of interest in target sequence begin to dominate product formed; each cycle results in doubling of DNA target sequence (exponential amplification); can also be applied to amplifying RNA if RNA is transcribed into cDNA by reverse transcriptase	PCR originally carried out with Klenow fragment of <i>E. coli</i> DNA Polymerase I; thermal instability required addition of fresh enzyme at each denaturation step; use of thermostable enzyme is now essentially universal; 25–30 cycles can produce 10 ⁶ -fold amplification; further amplification can be achieved by diluting PCR product and subjecting it to a second round of PCR using fresh enzyme (producing 10 ⁹ - to 10 ¹⁰ -fold amplification); usually a different set of primers (nested) are used that hybridize downstream from the first set of primers; nonspecificity can arise from primers hybridizing to similar DNA sequences elsewhere in target; fragments as long as 2 Kb can be generated; PCR product can be visualized by ethidium bromide staining on agarose gels; a single target can be amplified and detected, but 10–250 DNA copies are the more usual starting material; efficiency of reaction can vary depending on concentration of polymerase, primers, Mg ²⁺ , etc.; due to exponential nature of PCR, small changes in efficiency can have large effects on final quantity of PCR product	1–5
Reverse Transcription (RT) PCR	For amplification of target RNA species (e.g. mRNA), RNA target is first reverse transcribed by one of a variety of reverse transcriptase enzymes, forming DNA copy (cDNA) of the RNA; then, PCR can take place using two primers as in conventional PCR; during first round of PCR, one primer binds to cDNA, and complementary strand to cDNA is formed; during second cycle other primer binds to newly formed strand and forms complement; eventually exponential amplification occurs	Amplification of target RNA by PCR	6–10

PCR (Fluorescence Detection)	One or both PCR oligonucleotide primers are labeled on the 5' end with fluorescent dyes; PCR carried out in usual manner; PCR product can be analyzed in numerous ways, but separation of product from unreacted fluorophore-labeled primers must be carried out	Possibility for simultaneous determination of multiple PCR products if different fluorophores are used for labeling; PCR products analyzed by gel electrophoresis or after separation from unreacted primers by microfiltration; technique can be used to detect point mutations and small deletions, chromosome translocations, infectious agents; demonstrated detection of five different PCR products simultaneously, using different fluorescent dyes	11
Quantitative PCR with Fluorescence Detection	To assess starting quantity of target DNA in PCR reaction an internal DNA standard was used that was same length as target sequence, but with different central sequence; PCR is carried out in usual manner, but constant amount of internal standard is included in each PCR reaction; central sequence of internal standard allows discrimination between internal standard and target-DNA sequence; PCR products analyzed by hybridization reactions with specific probes; in one analysis, PCR products labeled with digoxigenin were captured in microwells by hybridization to a probe; in other analysis, PCR products were captured in microwells by hybridization probe, denatured, and subsequently hybridized to probes with tails of digoxigenin-dUTP; in both cases, addition of antidigoxigenin Ab conjugated to AP, followed by addition of AP substrate 5′-fluorosalicylphosphate results in release of 5′-fluorosalicylic acid, which forms a highly fluorescent complex with Tb³+-EDTA; fluorescence is measured by time-resolved techniques		12
	also: mRNA detected and quantified using a synthetic RNA as an internal standard in PCR reactions; in this case internal standard is of different size than mRNA target, so both target and standard can be distinguished; RNAs transcribed into cDNAs by reverse transcriptase before PCR	Products analyzed by ethidium bromide-stained agarose gels	13
PCR (Liquid Chromatography Detection)	PCR products are separated from other reactants and analyzed by liquid chromatography (LC)	PCR product detected by UV absorption after LC; PCR product is also purified during LC process; detection by LC reported to be more sensitive than staining of PCR product by Hoechst dye 33258 or analysis on ethidium bromide stained agarose gels	14
PCR (Colorimetric Detection)	PCR performed in usual way; following PCR, 3 to 10 subsequent cycles are performed using a pair of nested primers internal to the PCR product to incorporate biotin and a site for a dsDNA-binding protein; DNA-binding protein immobilized in microwell captures smaller nested-primer-generated PCR product; biotin tag on other end of this product reacts with peroxidase-conjugated avidin; addition of peroxidase substrate produces color that provides detection confirmation (indirect) for original PCR product produced	Nested primers achieve specificity because their PCR products will form only if they hybridize to correct sequence generated by first PCR target amplification; use of these labeled primers allows rest of assay to proceed	15

TABLE 55.2 Nucleic-Acid Amplification Schemes (continued)

Assay	Principle	Comments	Ref.
PCR (Modified)	PCR carried out as usual, but one primer has a T7 phage promoter sequence attached to it; after PCR, addition of T7 RNA polymerase generates RNA transcripts; an oligonucleotide primer for reverse transcriptase is then added with a sequence complementary to a sequence within region of interest being amplified; addition of reverse transcriptase generates a cDNA product; this final step improves specificity of PCR, since extraneous DNA sequences amplified during PCR will not be targets for hybridization to the reverse-transcriptase primer	Additive amplification from both DNA and RNA types of amplification; products detected on ethidium bromidestained agarose gels; in application to sequencing, amount of DNA in 150 diploid cells was sufficient for a readable sequence (using radioactive labeling)	16
PCR (Oligonucleotide Ligation Assay [OLA])	PCR carried out in usual manner on sequence of interest, followed by ligation reaction using two labeled ligation probes, one labeled with biotin and the other with digoxigenin; following ligation, ligated product is captured on streptavidin-coated microwell; treatment with AP-conjugated antidigoxigenin Ab results in immobilization of AP in microwell; colorimetric detection accomplished by addition of enzyme substrate	Applied to detection of allelic sequence variants; amplification by PCR, ligation and ELISA enzyme; ligation reaction enhances specificity; colorimetric assay found capable of detecting 3 fmol of ligated product	17
Scorpion Probes	One of the primers for PCR has attached to it the following probe structure; this probe consists of specific sequence complementary to a sequence internal to the PCR amplicons; the whole probe is held in a hairpin loop structure (loop portion is PCR-specific internal sequence) by complementary stem sequences; at 5′ and 3′ side of stems are attached a fluorophore and quencher molecule, respectively; at lower (subdenaturing) temperature, probe stays in hairpin loop structure and fluorescence is quenched; during PCR, hairpin loop is denatured during heating step, primer binds to target during annealing step and is extended; during the next heat denaturation cycle, double-strand amplicon product is denatured as is hairpin-loop probe structure; now loop sequence can hybridize to internal sequence on same amplicon strand to which it is attached, thus fixing the separation of fluorophore and quencher, and producing fluorescence	Amplification by PCR; can detect PCR amplicons in homogeneous solution without separation step; comparisons between Scorpions, Molecular Beacons, and <i>Taq</i> Man indicated Scorpions performed better than the other two; ¹⁸ Scorpion probes act almost exclusively by unimolecular mechanism	18, 19
<i>Taq</i> Man	PCR reaction carried out in usual manner, but advantage is taken of $5' \rightarrow 3'$ exonuclease activity of Taq DNA polymerase; oligonucleotide probe labeled on $5'$ end with quencher and $3'$ end with fluorophore is added at start of PCR; fluorescence is quenched until probe binds to internal sequence of amplicons being generated; then exonuclease activity of Taq polymerase cleaves probe, releasing fluorophore and producing fluorescence; increasing PCR cycles result in increased fluorescence	Amplification by PCR; detection in homogeneous solution possible, without separation step; quencher and fluorophore must be close to each other for efficient energy transfer but cannot be too close	20

FRET-Based Detection	One or both PCR primers have a stem-loop structure attached to their 5' end; stem-loop sequence does not have to match PCR amplicon sequence; on 5' end of stem is fluorophore and on 3' end of stem is quencher; FRET occurs and no fluorescence is detected; PCR reaction carried out in usual manner; modified primer is incorporated into PCR product; during next round of PCR, polymerase synthesizes complementary strand of stem-loop sequence; as double strands of DNA form, stem-loop sequence is linearized and fluorophore and quencher are separated; fluorescence increases	Taq DNA polymerase must be free of $5' \rightarrow 3'$ exonuclease activity; amplification by PCR; technique similar to molecular beacon approach; fluorescence correlates to amount of incorporated primers; ten molecules of starting target can be detected	21
	Post-PCR Product Detection		
	Amplicons from PCR process are labeled subsequent to PCR, allowing detection of PCR product		
	DNA is amplified by PCR, using a biotinylated primer; following PCR, product is denatured and hybridized to detector oligonucleotide, which is labeled with electrochemiluminescent label; subsequently, biotinylated DNA strand with hybridized detector oligonucleotide attached is captured by reaction with streptavidin-coated beads and subject to electrochemical analysis	Amplification by PCR; electrochemiluminescent label is tris (2,2'-bipyridine) ruthenium (II) chelate (see Table 55.1, Immunoassays); detection limit found to be ~2 attomol, for direct detection on beads using electrochemiluminescence	22
	or: DNA can be amplified by PCR, using one biotinylated primer, while the other primer is labeled with the electrochemiluminescent label; in this case, PCR product (double stranded) is <u>not</u> denatured, but is captured directly by streptavidin-coated beads		
Bioluminescence Detection	Reverse transcription (RT) PCR carried out as usual; one primer is biotinylated, so PCR product can be captured on streptavidin-treated surface; digoxigenin-labeled probes are hybridized to immobilized PCR product; reaction with antidigoxigenin Ab conjugated to aequorin immobilizes Ab and aequorin at hybridization site; addition of Ca ²⁺ triggers flash of light	This technique found to be 30- to 60-fold more sensitive than radioimaging for detecting cytokine mRNA; ²³ also permits detection of amplicons at lower PCR cycle numbers; amplification due to PCR	23, 24
Electrochemiluminescence Detection	One PCR primer biotin-labeled, while other primer labeled (via amino group linker) with ruthenium (II) tris (bipyridy) label; after PCR takes place, double-stranded product is captured on streptavidin-coated beads and then subjected to		25, 26

electrochemiluminescence analysis (see Table 55.1)

of assay as above

Alternatively, PCR carried out as usual but with one biotinylated primer; biotinlabeled amplicon captured on streptavidin-treated beads, and hybridized to complementary probe labeled with electrochemiluminescent label (see above); rest

 TABLE 55.2
 Nucleic-Acid Amplification Schemes (continued)

Assay	Principle	Comments	Ref.
Molecular Beacons	DNA is amplified by PCR, and subsequently detected by a molecular beacon which is immobilized on a solid surface by a biotin-modified nucleotide linked to avidin bound to surface; molecular beacon is a stem-loop structure in which the loop is complementary to target nucleic-acid sequence and stem has a fluorophore on its 5′ end and a quencher on its 3′ end; as long as the stem-loop structure remains intact, fluorescence is quenched; when target DNA binds to loop, however, stem structure is disrupted, and resulting fluorescence indicates hybridization has occurred	Amplification by PCR; either DNA or RNA can be detected; limit of detection was found to be attomole to subattomole ²⁷	27
	or: Molecular beacon used as a probe to hybridize internally to PCR amplicons; beacons included in PCR reaction, and as amplicons accumulate, fluorescence from hybridization of beacons increases	Amplification by PCR; significant fluorescence signal can be detected in early cycles of PCR if target is at fairly high concentration initially	28
	Non-PCR-Based Nucleic Acid Amplificati	ion	
Nucleic Acid Sequence–Based Amplification (NASBA)	A variety of techniques are used to achieve amplification of target nucleic acids; all involve enzymes; most use a polymerase to generate complementary copies of target molecule A target RNA is hybridized to a primer oligonucleotide (primer 1) that has on its 5' end a promoter sequence for T7 RNA polymerase; a mixture of T7 RNA polymerase, RNase H, and reverse transcriptase are in reaction solution; following hybridization, reverse transcriptase replicates RNA sequence, making a complementary cDNA strand, resulting in RNA/DNA hybrid; RNase H hydrolyses the RNA strand, leaving single cDNA strand (denatured DNA as a template could enter the process at this point); second primer (primer 2) included in the reaction mix hybridizes to the cDNA strand, and reverse transcriptase replicates cDNA, producing a dsDNA with a double-stranded promoter region for T7 RNA polymerase; this enzyme	Process is continuous, homogeneous, and isothermal; described as robust, even though multiple enzymes involved; incubation at one temperature for 1.5 to 2 h sufficient to achieve amplification of about 10°; NASBA requires fewer cycles than PCR to achieve similar levels of amplification; samples with as little as ten molecules of target found to produce positive results; ²⁹ can be used to detect mRNA	29
	transcribes RNA copies from double-stranded cDNA template; the RNA copies produced can serve as templates for reverse transcriptase; thus, primer 2 binds to newly generated RNA template and reverse transcriptase extends, producing RNA/DNA hybrid hydrolyzed to a single cDNA strand; primer 1 binds to this strand and a double-stranded cDNA is produced by reverse transcriptase, which again can serve as a template for RNA polymerase, etc.		

NA if 31	amplicons; addition of peroxidase substrate pro proportional to amplicon concentration ³⁰
	NASBA can directly, and selectively, amplify ssR denaturation carried out at 65°C, which avoids DNA; ten copies of interferon gene detected us chemiluminescence detection on membrane ³¹
of NASBA	RNA polymerase can produce 10 to 10^3 copies of copy of DNA template; 32 thus four to six cycles produces 2×10^6 amplification; total time ~ 3 to
synthesis of ng 3SR o no SBA; DNA n carried out	Within first 15 min, each of the input RNA targ increased 10 ⁵ -fold; each cDNA template directs minimum of 90 copies of detectable RNA duri reaction; 3SR reaction operates only at 37°C, so denaturation step for dsDNA, as is used in NA template can be amplified by 3SR if denaturation prior to start; much more rapid kinetics than E
	Rolling-Circle Small circular single-stranded oligonucleotides serve as the template for DNA Isothermal amplification; replication can proceed synthesis by several DNA polymerases; progressive copying produces a long linear DNA strand consisting of complementary repeats of circular template itimes round circle; most efficient DNA polymerases; progressive copying produces a long linear activity with time
35	RCA with Condensation of Amplified Circles after Hybridization of Encoding Tags (CACHET-RCA) RCA with CACHET; fluorescently labeled oligonucleotides also having dinitrophenyl (DNP) label are hybridized at multiple sites on tandem repeats generated by RCA; addition of anti-DNP IgM antibody causes condensation into small object more readily visualized by CCD or: BUDR can be incorporated into RCA product and detected by (1) reaction with biotinylated anti-BUDR Ab and (2) reaction with fluorescently labeled avidin
f RNA/single f of NASBA o 4 h ets was synthesis of ng 3SR o no SBA; DNA n carried out PCR hundreds of crases lose	denaturation carried out at 65°C, which avoids DNA; ten copies of interferon gene detected us chemiluminescence detection on membrane³¹ RNA polymerase can produce 10 to 10³ copies of copy of DNA template;¹² thus four to six cycles produces 2 × 10° amplification; total time -3 to with first 15 min, each of the input RNA targ increased 10°-fold; each cDNA template directs minimum of 90 copies of detectable RNA duri reaction; 35R reaction operates only at 37°C, st denaturation step for dsDNA, as is used in NA template can be amplified by 35R if denaturation prior to start; much more rapid kinetics than I soften (RCA) Rolling-Circle Amplification (RCA) Small circular single-stranded oligonucleotides serve as the template for DNA synthesis by several DNA polymerases; progressive copying produces a long linear DNA strand consisting of complementary repeats of circular template RCA with Condensation of Amplified Circles after Hybridization of Encoding Tags (CACHET-RCA) RNA polymerase can produce 10 to 10³ copies of copy of DNA template carbon to six cycles produces 2 × 10° amplification; total time -3 to with time 10°-fold; each cDNA template directs minimum of 90 copies of detectable RNA duri reaction; 35R reaction operates only at 37°C, st denaturation step for dsDNA, as is used in NA template can be amplified by 35R if denaturation template or to start; much more rapid kinetics than I sothermal amplification; replication can proceed times round circle; most efficient DNA polyme activity with time Single-molecule (DNA) detection reported (DNP) label are hybridized at multiple sites on tandem repeats generated by RCA; addition of anti-DNP 1gM antibody causes condensation into small object more readily visualized by CCD or: BUDR can be incorporated into RCA product and detected by (1) reaction with

TABLE 55.2 Nucleic-Acid Amplification Schemes (continued)

Assay	Principle	Comments	Ref.
Padlock Probes with RCA	A linear single-stranded probe with two target-DNA-complementary sequences joined by linker region is hybridized to target DNA; complementary sequences on probe are designed to complement contiguous sequence on target; following ligation by a ligase, probe forms circular strand wrapped around target; labels on padlock probe allow detection; once padlock probe is circularized, it can be amplified by RCA before detection, using suitable primer plus enzymes	High specificity; not as likely to have nonspecific reactions as PCR; reduction in nonspecific background; RCA reaction rate stated to be 53 nucleotides/sec for phage 029 DNA polymerase ³⁵	35, 36
	or: Using second primer (binding to a distinct site on padlock probe from first primer) in addition to first primer, a continuous pattern of DNA branches can be formed, connected to the first circle; ³⁵ called Hyperbranched RCA	Possible to initiate hyperbranched RCA with as few as 20 molecules of closed circles; each circle estimated to produce 5×10^9 copies after 90-min reaction ³⁵	
Ligation Amplification Reaction (LAR); also called Ligase Detection Reaction (LDR)/Ligase Chain Reaction (LCR)	In linear amplification, two oligonucleotide probes used; immediately adjacent to each other on DNA target strand, so action of DNA ligase covalently links two oligonucleotides, if nucleotides at junction are perfectly base-paired to target; in exponential amplification both strands of target DNA are used as templates for ligation of oligonucleotide probes (i.e., four oligonucleotide probes), so exponential amplification can occur, because ligation of one set of probes generates a target for complementary probe set; in both cases multiple rounds of denaturation, annealing, and ligation with thermostable ligase result in amplification	Thermostable ligase allows multiple repetitions of ligation reaction, thus linearly increasing product (termed ligase detection reaction); specificity arises from sequence of two oligonucleotides, requirement for perfect base pairing at ligated junction and performing of ligation at elevated temperatures; powerful technique for discriminating singlebase substitution; time required for 20 to 30 cycles \cong 100 to 150 min; sensitivity of LCR: 200 molecules of target DNA amplified $\sim 2 \times 10^5$ -fold after 30 cycles ³⁷	37, 38
	also: Oligonucleotide can be fluorophore labeled on 5' end; upon ligation with downstream oligonucleotide, ligated probe can be detected by fluorescence, following suitable separation methods (i.e., gel electrophoresis) to separate ligated product from unreacted labeled probe; alternatively, one oligonucleotide can be labeled on appropriate end by biotin and ligation product detected after immobilization on streptavidin/solid support ¹¹	Generation of target-independent products due to blunt-end ligation can limit sensitivity	39
GAP-LCR	Four oligonucleotide probes are used as in LCR, but two of the probes have 3' overhangs (extensions) when hybridized to their DNA targets; after hybridization, a gap of 1 to 3 bases exists between adjacent oligonucleotides, which is filled by a thermostable DNA polymerase; resultant "filled-in" probes joined by DNA ligase	Use of probes with noncomplementary 3' extensions prevents generation of target-independent ligation products; exponential amplification; amplification detected by fluorescence ELISA assay; specificity found to be better than allele-specific PCR	40

Strand Displacement Amplification (SDA) Target amplification technology in which sequence-specific exponential amplification occurs under isothermal conditions; target amplification occurs by process in which two primers bind to opposite ends of target sequence, as in PCR; with SFA, 3' ends of the primers recognize the target sequence, while 5' ends have restriction-enzyme-recognition site; DNA replication by exonuclease-deficient form of DNA polymerase produces double-stranded amplicons with a restriction enzyme recognition site; one of strands is protected from enzyme cleavage because modified nucleotide (dATPαS) incorporated during amplification; restriction enzyme nicks unprotected strand; DNA polymerase extends complementary strand starting at the 3' end, thus displacing nicked strand; polymerization/displacement step regenerates nickable recognition; nicking and polymerization cycle continuously; a fluorogenic probe is also designed to hybridize to target strand (different probe for each target strand) but downstream from primer site; probe acts as primer to generate extended probe; extended probe displaced as above; extended, displaced probe now has 3' end complementary to second SDA primer; hybridization occurs, and DNA polymerase extends in both directions; probe can be designed with a loop-stem structure, although not necessary; if loop-stem structure, polymerase activity unfolds this structure during polymerization; in any case, conversion of probe to double-strand structure creates restriction endonuclease site; probe constructed with fluorophore and quencher on opposite sides of restriction site; action of endonuclease releases fluorophore from quenching activity

1010-fold amplification occurs in 15 min; detection of 10 target copies within 30 min using fluorogenic assay reported; fluorogenic assay relies essentially on FRET-like process; process is complicated conceptually, but appears to work experimentally

Hybridization

A probe (oligonucleotide or nucleic-acid segment) with either a label or labeling potential is hybridized to target DNA, and hybridized complex is detected; alternatively, probe can be amplified by PCR process; hybridization commonly applied to membranes, tissue sections, microarrays, beads

42 - 77

Membrane Detection

DNA transferred to membrane detected with oligonucleotide probes either labeled with alkaline phosphatase (AP) directly or biotin; if biotin-labeled probes are used, membranes subsequently reacted with avidin-AP conjugate; final detection by use of substrate that produces chemiluminescence by AP activity

Subfemtomole detection reported by Tizard et al.;43 membranes could be successfully stripped and reprobed;

DNA on membrane hybridized to biotinylated probe, followed by reaction with streptavidin/biotinylated AP complex; incubation with luciferin-o-phosphate releases luciferin which now acts as substrate for luciferase

Bioluminescent detection technique; two enzymes theoretically provide large amplification

enzyme activity provides amplification

44

43

TABLE 55.2 Nucleic-Acid Amplification Schemes (continued)

Assay	Principle	Comments	Ref.
	DNA on membrane hybridized to biotinylated probe, followed by reaction with streptavidin-AP conjugate; incubation with either colorimetric or fluorogenic substrate produces visible color or fluorescence	Colorimetric reaction carried out using 5-bromo-4-chloro-3-indolyl phosphate + nitroblue tetrazolium; fluorometric assay used ATTOPHOSTM; fluorescence assay carried out in solution using membrane strips in cuvette; amplification by enzyme activity; fluorescent assay ~100-fold more sensitive than colorimetric assay; ~ 2×10^6 molecules of DNA detected by colorimetric assay and 2×10^4 molecules by fluorescent assay	45
		also:	
		Use of salicylphosphate esters in conjunction with alkaline phosphatase produces well-localized fluorescent products	46
	DNA on membrane detected by hybridization to digoxigenin-labeled probes; immunochemical techniques (anti-digoxigenin Ab labeled with AP) plus incubation with chemiluminescent sustrate gives chemiluminescence	10 to 50 fg of target DNA could be detected ⁴²	42
Fluorescence <i>in Situ</i> Hybridization (FISH) CARD-Based	Same principle as CARD-based immunoassay; hapten-labeled DNA probe hybridizes to DNA target; then either antihapten Ab labeled with peroxidase or streptavidin labeled with peroxidase (if DNA probe is labeled with biotin) is bound to DNA/DNA probe complex; addition of either biotin tyramide or fluorophore tyramide results in deposition of fluorophore or biotin at site of peroxidase action; in the case of biotin deposition, addition of fluorophore-labeled streptavidin completes the detection "sandwich"	Raap et al. ⁴⁸ indicate much higher signal intensities (at least tenfold) than with conventional FISH; large amplification due to enzyme activity and multiple layers of detection reagents	48
	or: As above, but after hybridization avidin/biotin/peroxidase complex (ABC) added, followed by biotinylated tyramine; deposition of biotin tyramine at site is detected by addition of fluorescein-avidin conjugate	CARD-FISH technique provided visual detection, when conventional FISH failed	49
	by addition of intorescent aviain conjugate	A variety of fluorophores were conjugated to tyramine; sensitivity found to be better than conventional FISH ⁴⁷	47, 50
In Situ Hybridization (Colorimetric) CARD- Based	After initial hybridization as above, ABC is added, followed by biotinylated tyramine and $\rm H_2O_2$; this is followed by application of ABC followed by addition of colorimetric substrate for detection	Amplification by enzyme activity — both for tyramide deposition and for processive turnover of colorimetric substrate; Kerstens et al. ⁴⁹ found strong amplification in comparison to conventional <i>in situ</i> hybridization	49, 51

In Situ Hybridization with Probe Extension or Amplification, i.e., in Situ PCR Probe for hybridization to target DNA consists of a single oligonucleotide primer; *Taq* DNA polymerase used to extend primer based on target sequence; various reporter or haptenated nucleotides in the reaction mix are incorporated into extended probe; these serve to provide direct or indirect (immunochemical) detection signals; technique called primed *in situ* DNA synthesis (PRINS); also cycling PRINS, where 2 oligonucleotide primers are used, and essentially a PCR amplification takes place; reporter/haptenated nucleotides in reaction mix incorporated into PCR product

Amplification due to multiple reporter/hapten nucleotides incorporated during probe DNA synthesis; also, for cycling PRINS, multiple copies of probe DNA made

52-55

RT *in situ* PCR, for RNA amplification; as above, but cDNA generated by reverse transcriptase; this serves as target for standard PCR

56

57 - 63

In Situ Hybridization without Probe Amplification; if fluorescent labels used, termed FISH (Fluorescence in Situ Hybridization) DNA probes are developed for hybridization to specific DNA or RNA targets; these probes are either directly labeled with reporter molecules (e.g., fluorophores) or with hapten moieties, which can participate in immunochemical reactions; positive hybridization events are recorded by presence of reporter molecules or by product of the immunochemical reaction (e.g., conversion of an enzyme substrate to a fluorescent product)

Amplification by multiple reporter/hapten sites in DNA probe; also by immunochemical reactions; probes labeled with biotin-, digoxigenin-, or directly with fluorescein-dUTP by nick translation; in case of fluorescein-labeled DNA, results visualized directly, or indirectly, using an antifluorescein AB and antifirst species IgG Ab conjugated to fluorescein; for biotin-labeled probes, fluorescently labeled avidin was used for visualization; for digoxigenin-labeled probes, fluorescentlabeled Ab to digoxigenin was used; immunochemical "sandwiches" of greater complexity also used; direct labeling technique was found to yield lower backgrounds; sensitivity of detection found to be 50 to 100 Kb for directly labeled probes by visual observation; for immunochemical detection, visual detection sensitivity found to be 1 to 5 Kb

64

Biotinylated DNA probe hybridized to target DNA and subsequently reacted with avidin/biotinylated peroxidase; substrate for peroxidase was diaminobenzidine, providing colorimetric detection

TABLE 55.2 Nucleic-Acid Amplification Schemes (continued)

Assay	Principle	Comments	Ref.
		also: Chemiluminescent detection after using biotin-labeled DNA probe for hybridization to target, followed by immunochemical sandwich (antibiotin Ab; antispecies IgG Ab labeled with peroxidase); addition of enhanced luminol reagent gave chemiluminescence; found to be same order of sensitivity as ³⁵ S-labeled probes detected by autoradiography; ⁵⁷ other applications where chemiluminescent substrates were used in immunochemical reactions after hybridization of a biotinylated probe to detect two different viral DNAs in same specimen ⁵⁸	57, 58
		also: Hybridizations on glass microarray detected by enzyme- catalyzed chemiluminescent reactions; 250 attomol target DNA detection limit; enzyme amplification	59
<i>In Situ</i> Hybridization (Colorimetric)	Biotinylated probe hybridized to DNA, followed by antibiotin Ab, biotinylated Ab specific to species IgG of first Ab, followed by avidin and biotin peroxidase complex (ABC); colorimetric substrate for peroxidase added for final detection	Amplification by enzyme activity; diaminobenzidine used as precipitable peroxidase substrate; this was further amplified by treatment with CuSO ₄	49
FISH (Not CARD)	After hybridization of biotinylated probe to DNA, fluoresceinated avidin was added, followed by biotinylated antiavidin Ab, followed by avidin–fluorescein conjugate for fluorescence detection		49
Chemical Modification of Probe	Guanine residues in nucleic acids are modified chemically by incorporation of N-2-acetylaminofluorene (AAF) (or 7-iodo derivative) at C-8 position of guanine; following hybridization of modified probe to target, Ab specific to AAF can be used to bind to modified probe, allowing detection by immunochemical methods; also such modified nucleic acids can be immuno-precipitated	Attachment of Ab to nucleic acids allows amplification of detection signal by immunoassay techniques (e.g., ELISA); sensitivity comparable to autoradiographic methods	65

Probes Linked to Gold Nanoparticles Small oligonucleotides are linked through mercaptoalkyl linkage to gold nanoparticles; part of the oligonucleotide sequence is complementary to the target sequence being detected; two different probe oligonucleotides, which recognize adjacent sites on the target, are linked to nanoparticles (more than one pair of oligonucleotide probes are bound per nanoparticle); upon hybridization to the target, an extended polymeric network is formed in which nanoparticles are interlocked by multiple short duplex segments arising from hybridization of probe with target; this close juxaposition of nanoparticles changes the optical properties of color changes from red to blue, upon hybridization

Amplification due to numerous nanoparticles entrapped in polymeric network; specificity of this two probe system seems extremely good; one mismatched base detected; sensitivity of unoptimized system showed detection of ~10 fmol of target oligonucleotide; technique seems to be more sensitive than detection by means of fluorescein-labeled probe as reported in the literature

Bead Capture; Enzyme Amplification Five different oligonucleotides used for this assay to detect analyte DNA; two oligonucleotides (A and B) have sequences complementary to analyte DNA as well as single-strand overhangs, which act as recognition sites for other oligonucleotide probes; oligoprobe C is biotinylated at one end and has sequence complementary to probe A; it is bound to avidin-coated beads and serves to capture analyte DNA; oligoprobe D is a chemically cross-linked oligonucleotide complex (multimer), which has a complementary sequence to the single-strand overhang of probe B; probe D binds (via probe B) to the analyte DNA and offers a number of sites (due to multimer nature) for attachment of probe E, which is an oligonucleotide complementary to probe D and which also has peroxidase attached to it; addition of substrates results in detection signal, indicating analyte DNA is present

Amplification occurs by using multiple probes for binding to target DNA, the use of multimer oligonucleotide probes that provide multiple sites for attachment of peroxidase, and the enzyme itself; Urdea et al. report that this technique was as sensitive as most sensitive radiolabeled dot-blots; chemiluminescent substrate used in this assay; applied to detection of sub-pg quantities of viral DNA

Hybridization on Microarrays with Optical Detection Essentially same strategies as used for other hybridization formats; "capture" oligonucleotides attached to solid surface (glass, gel pad, etc.); labeled (often by incorporation of biotin-labeled primers or fluorescently labeled primers in PCR) "target" nucleic acid is hybridized to microarray and detected by various means; for example, biotin-labeled targets can be detected by standard procedures, such as reaction with streptavidin-alkaline phosphatase, and subsequent development of color, fluorescence, or chemiluminescence by addition of appropriate enzyme substrate

68-72

PCR/LDR Mutation Detection on Microarray 73

Multiplex PCR is used to amplify the regions of interest (for mutation analysis); addition of two oligonucleotides which are complementary to sequences on both sides of mutation sets the stage for ligase-dependent ligation, only if sequence at junction of two oligonucleotides is exact match for mutation; one oligonucleotide is fluorescently labeled and the other has overhanging sequence coded for a specific complementary capture oligonucleotide at specific site on microarray; fluorescence detection at this site indicates presence of mutation

TABLE 55.2 Nucleic-Acid Amplification Schemes (continued)

Assay	Principle	Comments	Ref.
Invader Assay	Assay depends on use of thermostable flap endonucleases; two overlapping probes are constructed to target sequence; upon hybridization to target, downstream oligonucleotide is cleaved at site of overlap; cleaved portion of oligonucleotide hybridizes to biotin-labeled template, which has a number of A residues at 5' overhang; use of DNA polymerase and digoxigenin-labeled dU results in incorporation of digoxigenin-dU into probe fragment; double-stranded template + probe (extended by digoxigenin-dU) captured on streptavidin-coated microwell; probe fragment detected by binding of alkaline phosphate-conjugated antidigoxigenin Ab, followed by addition of fluorogenic substrate for alkaline phosphatase	Amplification by thermostable endonuclease (3000 cleavage events per target molecule) and by alkaline phosphatase enzyme bound to Ab; found detection of DNA targets at subattomole levels	74
	also: First round of invader assay as described above; cleaved probe fragment binds to a biotin-labeled, streptavidin-immobilized probe that also has bound to it another small oligonucleotide with a fluorophore and quencher in close apposition; hybridization of cleaved probe fragment from first round produces another single-nucleotide overlap, also susceptible to endonuclease cleavage; cleavage releases fluorophore, abolishing FRET quenching	Serial version of invader assay can generate more than 10^7 reporter molecules for each target molecule in 4-h reaction; sensitivity for detection of less than 1000 target molecules reported	75
Chromosome Painting	Biotinylated oligonucleotide probes specific for some chromosome or chromosomal site hybridized to target chromosome; alternating layers of fluorophore-labeled avidin and biotinylated anti-avidin Ab added to give amplification for detection	Detection of unique intrachromosomal sequences required multiple (3) layers of fluorophore-labeled avidin	8
Intensification	Biotinylated probes were reacted with target DNA <i>in situ</i> , followed by standard immunocytochemical techniques resulting in immobilization of peroxidase at hybridization sites; following incubation with diaminobenzidine and $\rm H_2O_2$, further staining intensification was achieved by silver staining, using a series of silver and gold solutions	More sensitive than colorimetric stain alone	76
Eu-Labeled Probes	DNA hybridization probes are labeled with a Eu-chelate by introducing aliphatic amino groups on cytosine residues; following hybridization, positive hybridization events detected by time-resolved fluorometry	Amplification by numerous fluorophores on DNA probe — 4 to 8% of total nucleotides labeled; 77 detection limit was 0.15 attomol of target DNA 77	77
	Branched DNA Technology		
	Target DNA is not amplified, but a series of oligonucleotides complementary to portions of target are used to hybridize to target and form dendrimer structure with many labels that can be used for detection		

Branched DNA Amplification

- (a) Target DNA is immobilized to solid surface by series of oligonucleotides (called capture probes and capture extenders [CE]) complementary to segments of target DNA; subsequently, other oligonucleotides (label extenders [LE]) complementary to other segments of target DNA hybridize to target, the LE also bind (by complementarity) to a branched DNA segment (amplifier), which then binds many alkaline phosphatase molecules; alkaline phosphatase is bound to a short oligonucleotide with sequence complementary to repeated triplicate sequence on branched DNA;
- (b) in other developed assays, LE probes bind preamplifier oligonucleotide probes, which then bind many amplifier segments;

Incorporation of nonnatural bases, isocytidine and isoguanosine, into amplifier molecules can reduce nonspecific hybridization, thus improving sensitivity; final detection step involves adding chemiluminescent substrate for alkaline phosphatase and detecting luminescence; branched DNA technology amplifies reporter signal, not the target

Amplification of signal is linear, so signal directly related to number of target molecules present in original sample; first generation assay quantifies targets between 10⁴ and 10⁷ molecules; second generation assay quantifies down to ~500 molecules; detection limit of ~50 molecules//ml reported⁷⁸

78, 79

Detection and quantification of mRNA directly from cells; CE and LE probes about 30 bases long and between them provide complete coverage of the mRNA sequence; branched DNA amplifiers have 15 branches, each of which is labeled subsequently with alkaline phosphatase; thus great amplification; solid surface has synthetic DNA designed to hybridize to CE

80

Kern et al.⁸¹ used branched DNA technique for detection of HIV RNA; use of preamplifier intermediate resulted in binding of eight amplifier molecules; each amplifier molecule had 15 branches and each branch could bind three alkaline phosphatase-labeled probes; thus theoretically each HIV RNA could be decorated with as many as 10,080 alkaline phosphatase probes; result detected by chemiluminescent assay; detection limit was 390 HIV RNA copies/ml

81

TABLE 55.2 Nucleic-Acid Amplification Schemes (continued)

Assay	Principle	Comments	Ref.
Signal Amplification Cassettes (SAC)	Signal amplification cassettes (SACs) are attached to DNA dendrimers; SACs are oligonucleotides (hairpin or double strand) with 15 adenine overhangs at one or both ends; polymerase activity of T7 DNA polymerase extends strand to fill in overhang with TTP (thymidine triphosphate); for each TTP incorporated, a PP _i is liberated; this reaction continues to recycle because 3′–5′ exonuclease activity regenerates original SAC, which again becomes substrate for DNA polymerase; PP _i generated is converted enzymatically to ATP and luciferase reacts with luciferin + ATP to produce light; many SACs are attached to each DNA dendrimer; potential for tremendous amplification; hybridization of dendrimer to target produces specificity of reaction	Multiple amplification steps involved; many enzymes (DNA polymerase, ATP sulfurylase, luciferase) involved, all contributing to amplification; also amplification by multiple dendrimer sites; detection of 5 zeptomol of DNA dendrimer demonstrated; SAC consisting of just two polymerase reaction sites sufficient to detect low attomole levels of DNA	82

TABLE 55.3 Hybrid Technologies

Assay	Principle	Comments	Ref.
	Immuno-PCR		
	Technique combining antibody (Ab) specificity for molecular recognition with amplification potential of PCR		
Immuno-PCR	Immobilized antigen (Ag) is recognized by Ag-specific Ab, which is linked to specific segment of DNA through some linker molecule (<i>vide infra</i>); following immune recognition, PCR reaction is carried out on segment of attached DNA; PCR products are detected as final step in analysis: (a) linker molecule is a streptavidin-protein A chimera; protein A component binds to Ab and streptavidin binds to biotinylated DNA (linear plasmid pUC19) forming a bridge between DNA and Ab;¹ (b) linker molecule is avidin; biotinylated Ab and biotinylated DNA bind to avidin and form complete complex,² and (c) primary Ab recognizes Ag; secondary biotinylated Ab recognizes primary Ab; modified avidin (to lessen nonspecific binding) forms bridge between biotinylated Ab and biotinylated DNA	Specificity resides in Ag/Ab recognition and in specificity of PCR for target sequence defined by primers; possibility for quantification of Ag concentrations below level at which PCR reaction saturates; tremendous amplification because of exponential nature of PCR; universal usefulness of single immuno-PCR protocol for detection of variety of Ags Because of extreme amplification of PCR, any nonspecific binding of DNA or Ab to other immobilized reagents or solid substrate contributes to background; avidin-/biotin-based linker systems must be carefully titrated to form usable complexes (i.e., Ab linker-DNA) that actually contribute to PCR; may be necessary to preform Ab-linker-DNA complexes; scrupulous washing required during assay steps to eliminate nonspecific binding; standard microtiter plates used for immunoassay are suitable for PCR thermal cycling; DNA target used for PCR amplification should, ideally, be very different from any DNA present in sample to avoid possible interferences in PCR amplification arising from exogenous DNA; total assay time likely to be longer than ELISA-type assays; increasing PCR cycle number increases sensitivity, but also increases nonspecific amplifications; amplification also occurs because more than one copy of biotinylated target DNA can be immobilized at each avidin/streptavidin site, if the stoichiometric ratios are titered carefully	1–10

or:

Immuno-PCR carried out in usual manner, but during PCR amplification a hapten-labeled (digoxigenin) nucleotide is incorporated into PCR products; one PCR primer also has a biotin label to permit capture of the PCR products; subsequently, the biotinylated, hapten-labeled PCR products are captured on a streptavidin-coated solid surface, enzyme-labeled antihapten Ab is added, and the addition of enzyme substrate results in accumulation of detected product

Amplification also from multiple biotinylation sites on primary detection Ab and multiple hapten sites on each individual PCR product molecule; plus enzyme amplification

or:

Immuno-PCR procedure carried out, and DNA product produced by amplification is detected by staining with a dsDNA selective intercalating fluorescent dye (Pico Green)

or:

Usual immuno-PCR protocol, but capture Ab used to immobilize Ag of interest, followed by reaction with another Ag-specific biotinylated Ab; streptavidin serves as bridge to biotinylated target DNA; PCR primers each have one fluorescein/primer; after PCR, amplified product hybridized to capture oligonucleotide immobilized to solid surface; addition of antifluorescein Ab conjugated to enzyme allows standard ELISA endpoint

Total assay is time-consuming; very extensive washing required for certain steps; more than one biotin bound per detection Ab, resulting in more than one target DNA bound/detection Ab

Sensitivity:

Enhancement of 10⁵ vs. colorimetric ELISA using same immunoreagents and linker; 580 molecules of Ag detected, ¹ estimated to be several orders of magnitude greater sensitivity than radioimmunoassay¹

Enhancement of 10^8 vs. colorimetric ELISA; 41 molecules/ml (or 2 molecules per microwell) of Ag detected, with signal:noise \cong 4 (Reference 3)

Detection limits on the order of 10 to 10⁷ molecules for various antigens, if primary Ag-specific Abs used at higher concentrations; up to 10⁹ enhancement of sensitivity compared to colorimetric ELISA⁴

Enhancement of 16-fold compared to colorimetric ELISA in terms of sensitivity, using the same immunoreagents for both assays⁵

Sensitivity enhancement of $\sim \! 10^4$ compared to colorimetric ELISA⁶

Enhancement of 10^5 compared to colorimetric ELISA; lower limit of Ag detection $\cong 6000$ molecules⁸

TABLE 55.3 Hybrid Technologies (continued)

Assay	Principle	Comments	Ref.
		Detection limits for mouse IgG as Ab were 10 attornol for direct detection using an intercalating dye; 1 attornol for colorimetric ELISA detection and 0.1 attornol for fluorescent enzyme substrate; fluorescence-based assay allowed quantitative detection over six orders of magnitude; compared to standard ELISA using fluorescent substrate, immuno-PCR was 1000-fold more sensitive ⁹	
Immuno-PCR with DNA- Streptavidin Nanostructures	Essential principle same as immuno-PCR but an oligomeric biotinylated DNA-streptavidin network is used as attachment to biotinylated Ab, rather than single streptavidin bridge between Ab and DNA; rest of analysis identical	Oligomeric DNA-streptavidin complexes provide superior immuno-PCR performance; better signal intensities than standard immuno-PCR; approx. tenfold increase in sensitivity over standard immuno-PCR, and 100- to 1000-fold increase in sensitivity over ELISA immunoassay	11
In Situ Immuno-PCR	Immuno-PCR carried out as usual, but on tissue sections; after binding DNA-labeled Ab to specific Ag, <i>in situ</i> PCR carried out, followed by hybridization to digoxigenin-labeled DNA probe and subsequent immunostaining	Amplification by PCR and immunoenzyme step; sensitivity of <i>in situ</i> immuno-PCR compared to immunohistochemical analysis using: (1) avidin-biotin-peroxidase complex, (2) alkaline phosphatase, antialkaline phosphatase complex, (3) tyramide signal amplification (i.e., CARD, see Table 55.1), (4) <i>in situ</i> PCR; <i>in situ</i> immuno-PCR found to be most sensitive of all amplification systems	12
Immuno-RCA (Rolling-Circle Amplification)	Oligonucleotide that is primer for RCA is attached to an Ab (either primary Agspecific Ab or secondary Ab); following formation of immunoreactant complex, RCA is initiated by addition of circular template; hundreds of tandemly linked copies of template generated in a few minutes; amplified DNA detected in a variety of ways, e.g., direct incorporation of hapten- or fluorophore-labeled nucleotides into template copies; hybridization with fluorophore or enzymelabeled oligonucleotides	RCA can be carried out with linear or geometric kinetics; amplification not only by RCA, but each Ab can have more than one oligonucleotide primer attached per Ab molecule; even in linear kinetic mode, immuno-RCA could detect IgE with 100-fold sensitivity increase over conventional ELISA	13
	also: Incorporate fluoresceinated nucleotides into RCA product; use alkaline phosphatase-conjugated anti-fluorescein + fluorescent substrate to detect signal		
		Signal amplification by immuno-RCA applied to protein analysis on glass microarrays; 75 cytokines measured simultaneously with femtomole sensitivity	14

Immune Capture + PCR	Ag-specific Ab used to capture analyte Ag, thereby concentrating it; PCR subsequently applied to amplify diagnostic DNA target sequence, followed by detection of PCR product	Applied to detection of bacteria in various samples	15
Immuno-Detection Amplified by T7 RNA Polymerase (IDAT)	Very similar to immuno-PCR with following differences; double-stranded "reporter" DNA still attached to Ab via a linker, but this DNA contains the T7 promoter sequence; Ab binding to Ag target also immobilizes "reporter" DNA; action of T7 RNA polymerase produces multiple copies of RNA, this multiplication being linear and directly related to number of "reporter" templates; RNA is subsequently detected	Very large amplification from T7 RNA polymerase; authors state that fluorescence-detection technique was developed, but no data are shown (all data based on radiometric technique); authors state that detection of only a few copies of an Ag in a mixture should be possible using IDAT	16
	PCR-ELISA		
	PCR process used to amplify target DNA; incorporation of various haptens or other reagents allows immunological detection using ELISA technique		
PCR-ELISA	Hybrid technique where specificity and amplification of PCR are coupled to detection by ELISA; different formats, but one example is as follows; target-DNA sequence is amplified by standard PCR techniques; digoxigenin-modified nucleotide incorporated into amplicons during PCR; after denaturation, single-stranded amplicons hybridized to biotinylated capture probe and hybridized product captured on streptavidin-coated surface (solid-phase process necessary for ELISA assay); subsequently, antidigoxigenin Ab conjugated to enzyme (i.e., horseradish peroxidase) added and binds to digoxigenin sites on PCR product; after washing away excess Ab, substrate for enzyme added, and color/fluorescence/chemiluminescence detected as in standard ELISA; technique can be applied to detection of mRNA with reverse transcription step before PCR	Amplification potential is great, since PCR and enzyme amplification both used in different parts of assay; specificity for target DNA only as good as PCR specificity and the specificity of the Abs used in the ELISA assay; blend of established immunoassay technique and PCR; demonstrated detection sensitivity of <10 spores of <i>B. anthracis</i> in 100 g soil sample, using a colorimetric assay; ¹⁷ Hall et al. ¹⁸ measured mRNA expression using biotinylated primers in PCR to enable capture of PCR products on avidin-coated plates; PCR amplicons were labeled with digoxigenin; antidigoxigenin Ab conjugated to alkaline phosphatase; colorimetric assay used for detection	17–22
	DNA amplified by PCR, using biotinylated primers; PCR product immobilized in microwells by hybridization to internal capture probe; streptavidin–AP conjugate or strepavidin-peroxidase conjugate subsequently added and allowed to react; either colorimetric or fluorogenic substrate added for detection	Amplification by both PCR and enzymatic (AP or peroxidase) means; colorimetric and fluorometric assays compared to detection using ethidium bromide-stained agarose gels; colorimetric assay found to have about the same sensitivity as analysis by gels, while chemiluminescent assay was tenfold more sensitive; colorimetric substrates were tetramethylbenzidine for peroxidase and pnitrophenylphosphate for AP; chemiluminescent substrate (for AP) was Lumi-Phos 530; approximately five cells of Salmonella could be detected using PCR + chemiluminescent method; colorimetric detection limits were 50 cells	23

56.1 Introduction

Optical imaging techniques for the assessment of tissue anatomy, physiology, and metabolic and molecular function have emerged as an essential tool for both the basic researcher and the clinical practitioner. One concern of clinical practitioners is that too much harmful radiation is used to detect diseased tissue. The attractiveness of optical imaging techniques arises from the fact that fluorescent dyes can be detected at low concentrations and nonionizing, harmless radiation can be applied repeatedly to the patient. Furthermore, the remarkable progress in the development of optical instrumentation in the last two decades (laser excitation and detection systems) has decisively contributed to the growing applicability of optical imaging techniques, which have the advantage of being cheap, small in size, and, therefore, readily at hand to solve clinical problems. The design of contrast agents for optical *in vivo* imaging of diseased tissues has also emerged and is reflected by an increasing number of publications in this area.^{1,2} Novel probes have been synthesized and characterized for their ability to monitor disease-specific anatomical, physiological, and molecular parameters through their optical signals. The multifarious world of chromophores and fluorophores provides various parameters that can be exploited for diagnostic measurement and detection.

This chapter describes the essential principles of optical imaging and current medical opportunities that are related to the use of fluorescent probes as exogenously applied agents; this is followed by a review of recent progress in the design of these probes for biomedical imaging purposes. The agents discussed in this chapter are categorized by their structural families, covering the class of cyanine dyes, tetrapyrrole compounds, lanthanide chelates, and other entities. For selected examples, the physicochemical, biochemical, and pharmacological features constituting the diagnostic efficacy of the compounds are illustrated.

56.2 Principles of Optical Imaging

56.2.1 Tissue Optics and Function of Dyes as Contrast Agents

The term optical imaging encompasses a large variety of different disciplines. In general, the method uses light within the ultraviolet (UV) and the near-infrared (NIR) spectral region to obtain information on the optical characteristics of tissue. Generally, the interaction of photons with tissue is based on absorption of light, scattering of light, and emission of fluorescence. These three parameters can be used separately to characterize tissue optical properties.

A fundamental observation for optical diagnostic procedures relates to the fact that the penetration depth of light in living tissue strongly depends on the wavelength used³ because the number of absorption and scattering events in tissue is a function of wavelength.⁴

For wavelengths below approximately 600 nm the penetration of light into tissue is limited to a depth of hundredths of micrometers up to a few millimeters due to strong absorption of the photons, so that only superficial assessment of tissues in this spectral region is possible. The absorption of light in tissue originates from oxy- and deoxyhemoglobin and several tissue components such as porphyrins, melanin, NADH and flavins, collagen, elastin, and lipopigments. Most of these chromophores that contribute to tissue absorption exhibit characteristic fluorescence spectra throughout the visible (VIS) spectral region up to approximately 700 nm. Fluorescence of these intrinsic fluorescent markers (autofluorescence) has been studied as a source of specific spectral information on tissue structure and pathophysiological states^{5,6} and was thoroughly exploited to identify diseased tissue areas, e.g., in endoscopy^{7,8} or cardiovascular diagnosis.⁹ Direct visual inspection or characterization using microscopic techniques is established practice in medicine. Hence, the modality is capable of generating images of tissue structures with high spatial resolution, as does microscopy.

A primary field of application of optical imaging technology is the examination of tissue surfaces via optical fibers incorporated in endoscopes or laparoscopes, as well as of ocular diseases through ophthalmoscopes and direct assessment of skin diseases or during surgical procedures. The only modality found in daily and widespread clinical use so far is the imaging of ocular diseases in ophthalmology. Fluorescein and indocyanine green (ICG) are established as fluorescent agents to enhance fluorescence angiography. Currently under clinical evaluation is the fluorescence-guided identification of tumor margins during surgery as a tool to improve the accuracy and safety of tumor resection. For this purpose, ICG, Il fluorescein-based conjugates, I2,13 and 5-ALA¹⁴ have been studied.

Imaging of larger tissue volume requires light within the NIR spectral range (700 to 900 nm) because the absorption coefficient of tissue is relatively small, resulting in penetration depths of up to a few centimeters (Figure 56.1).¹⁵ Thus, the identification of inhomogeneities exhibiting a difference in absorption or fluorescence compared to the bulk tissue is possible. However, due to scattering, photons do not follow straight paths when propagating through tissue limiting the spatial resolution of images obtained (diffuse imaging). Nevertheless, tissue absorption is mainly determined by oxyhemoglobin, deoxyhemoglobin, and water. These exhibit a well-defined minimum in absorption in the NIR spectral region (see Figure 56.1) and provide information that can be used to quantitatively calculate important physiological parameters such as blood concentration (total hemoglobin) and oxygenation (ratio oxy-/deoxyhemoglobin). These absorption data, together with tissue-dependent scattering properties, can be fitted by mathematical models to reconstruct the most probable photon propagation through tissue and generate a spatial map of tissue optical properties for a given illumination and detection geometry. This method has been applied primarily to detect breast tumors and image brain function (see Chapter 57 of this handbook). It is beyond the scope of this review to elucidate the underlying basics in more detail. The interested reader is referred to References 4, 16, and 17.

The exogenously introduced optical contrast agents principally provide the opportunity of engendering disease-specific signals within the tissue. This enables the display of physiological and molecular conditions that are characteristic of certain disease states and progression. The detection of fluorescent contrast agents is comparable to nuclear imaging methods; in both modalities the photon sources (fluorescent

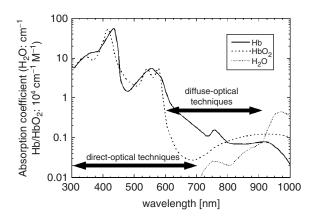

FIGURE 56.1 Contributions of oxyhemoglobin, deoxyhemoglobin, and water to tissue absorption depending on wavelength. Diffuse optical imaging techniques require NIR light between 700 and 900 nm to achieve maximal penetration into tissue, while for direct optical imaging VIS light of 300 to 700 nm is usually used.

dye or radionuclide) are distributed within the tissue. Generally, the choice of the spectral range of absorption and fluorescence for the dye dictates whether it is detectable on tissue surfaces (UV-VIS dyes) or from deeper tissue areas (NIR dyes). A prerequisite for sensitive detection of an absorbing dye is a high extinction coefficient at the desired excitation wavelength. If fluorescence photons are acquired, the compounds should exhibit large Stokes' shifts (spectral distance between absorption and fluorescence maximum) and high fluorescence quantum yields in physiological media. If fluorescence is recorded within the UV/VIS spectral region, both autofluorescence and the administered contrast agent will contribute to the observed signal, while in the NIR spectral region tissue autofluorescence is negligible due to the absence of endogenous NIR fluorophores. In the latter case, the distribution of the contrast agent is nearly exclusively revealed by the detected signal. The disadvantage of fluorophores over radionuclides is that excitation light must be brought to the dye, so that this factor additionally contributes to penetration-depth limitations. An important advantage, however, is related to the fact that fluorescence can be excited continuously and is not limited to inherent properties as is radioactive decay. A set of photophysical properties is accessible, ranking from changes in fluorescence quantum yield and fluorescence lifetime to alterations of spectral signatures. Moreover, for many dves these parameters are influenced by local physiological or molecular conditions, such as pH, ions, or oxygen, and have therefore been used for their monitoring and quantification. Most importantly, light applied to fluorescence imaging is nonionizing radiation, rendering it harmless and nontoxic.

56.2.2 Imaging Techniques and Medical Applications

Optical imaging techniques and applications may be divided into two groups. On the one hand, imaging of superficial objects acquires directly reflected or scattered photons, while for diffuse imaging techniques photons are recorded after they have passed through relatively thick tissue and optical properties of the tissue are spatially reconstructed using mathematical models. Different technical solutions and instrumental geometries are required for each of these applications. Illumination with light of a desired wavelength and detection with suitable devices (e.g., charge-coupled device, or CCD cameras) generally yields images from superficial structures in reflection geometry. This process is similar to conventional photography. A primary field of application is the examination of tissue surfaces via optical fibers embedded in endoscopes or laparoscopes, as well as of ocular diseases through ophthalmoscopes and direct assessment of skin diseases or during surgical procedures. Several types of superficial diseases in hollow organs have been monitored using fluorescence-guided endoscopy. Tetrapyrrol-based agents have been examined for this purpose, 18 but the most promising results have been obtained with ALA. Clinical studies included the diagnosis of urinary bladder cancer, 19 bronchial cancer, 20 and gastrointestinal diseases. 7 An essential task was

TABLE 56.1 Medical Applications of Optical Diagnostics

Modality/Discipline	Signal	Clinical Indication
Direct-Optical		
Ophthalmology Intraoperative diagnostics Dermatology	Reflected-light fluorescence	Ocular diseases Detection of tumor boundaries Skin tumors
Via Endoscopic or Catheter Devices		
Endoscopy Cardiovascular imaging	Reflected-light fluorescence	Tumors of the GI tract, lung, bladder, cervix, oral cavity Atherosclerotic plaques
Diffuse Imaging and Mathematical Reconstruction		
Optical mammography Brain imaging	Reflected- or transmitted light fluorescence	Breast tumors Brain perfusion, stroke

to improve the detection of dysplastic changes and carcinoma *in situ*, which escape the endoscopist's eye and require more reliable techniques. Besides ALA, other fluorescent agents such as those presented in Chapter 57 were suggested for these purposes.^{21–24}

The assessment of larger tissue volumes has been realized for different transillumination geometries in which tissue areas are illuminated with light, and the transmitted, scattered light is detected at defined positions (e.g., 180° projection geometry or 0°C reflection geometry). Diffuse optical tomography (DOT) is based on the detection of photons at multiple positions and the mathematical reconstruction of three-dimensional (3D) optical images. 4,16,17

The application of DOT for breast-cancer detection and characterization has stimulated a great deal of research in the past few years. Several approaches for the detection of breast cancer using NIR light and utilizing intrinsic tissue optical properties have been followed. The first attempts at detecting breast tissue by means of tissue transilluimnation were reported as far back as 1929,²⁷ and the development of more powerful light sources and monitoring systems led to a revival of this technique in the 1980s and 1990s. Several clinical studies revealed the limitations of this modality — low spatial resolution and an inability to differentiate between malignant and benign tissue — which limit its clinical usefulness, especially in relation to x-ray mammography. ^{15,26,28,29} DOT using continuous-wave (CW), modulated, or pulsed light demonstrated advances in the quantification and 2D or 3D display of tissue absorption, scattering, vascularization, and oxygenation. However, only limited patient data have been acquired and published so far with respect to oxygenation. ^{4,15,30,31} The application of contrast agents was proposed repeatedly and will be the subject of subsequent chapters. The first contrast-enhanced imaging in a clinical setting was reported by Ntziachristos et al., who have demonstrated uptake and localization of ICG in breast lesions using DOT. ³²

Table 56.1 summarizes the various experimental and clinically established modalities and clinical applications that employ exogenously administered optical contrast agents.

56.3 Dyes as Contrast Agents for Optical Imaging

56.3.1 Cyanine Dyes

56.3.1.1 Nonspecific Cyanine Dyes of Classical Contrast-Agent Format

The structural class of cyanine dyes comprises chromophoric structures of more or less arbitrary absorption and fluorescence from the VIS to NIR spectral range (approximately 450 to 900 nm). Cyanine dyes generally exhibit very high molar-extinction coefficients (>150,000 M⁻¹ cm⁻¹) and good fluorescence quantum yields (up to 50%). They have been originally prepared for the photography industry and were

FIGURE 56.2 Chemical structure of (A) indocyanine green (ICG) and (B) the hydrophilic derivative SIDAG.

adapted to many applications in analytical chemistry, bioanalytics, and biomedicine. (See References 33 and 34 for a comprehensive discussion.)

The first attempts at designing such probes for *in vivo* applications date back to the 1950s, when ICG, a prominent representative of a NIR-absorbing cyanine dye, was first synthesized (see Figure 56.2 for its chemical structure). ICG was clinically applied as a drug for the assessment of hepatic function and cardiac output, for which this compound exhibits favorable pharmacokinetic properties.³⁵ It has recently been discovered as an imaging agent for ocular diseases to visualize vascular disorders of the retina and choroidea. In a few studies, ICG has been reported as a potential NIR contrast agent for the detection of tumors in animal research^{36,37} and at the clinical level.³²

For tumor-imaging purposes it has been recognized that the high plasma-protein-binding, intravasal distribution and resulting rapid plasma clearance of ICG by the liver leads to a quickly disappearing signal loss, which limits its potential as contrast agent.³⁷ One possible way to improve tissue retention and differentiation is through the use of nonspecific contrast agents similar to contrast agents for magnetic resonance imaging and computed tomography (CT), which usually are highly hydrophilic structures and achieve contrast enhancement based on morphological and physiological properties of tumor tissue such as increased tumor vasculature, endothelial leakiness, and enlarged extracellular volume. Thus, attempts were made to design structurally related agents of improved properties. The literature describes the synthesis and comparative pharmacokinetic characterization of ICG-related indotricarbocyanine derivatives with carboxy, hydroxyalkyl, and monosaccharide residues.^{37,38} Figure 56.2 shows the chemical structures of ICG and the derivative SIDAG, a hydrophilic glucamide-derivatized indotricarbocyanine. Probes such as SIDAG are characterized by a highly increased hydrophilicity and reduced plasma-protein binding. It was assumed that after systemic administration the compounds would be capable of leaving the intravascular space and extravasate into the extracellular compartment, with a certain degree of preference for tumor tissues.

In animal studies, SIDAG showed improved efficacy as an optical contrast agent vs. ICG based on a higher tumor concentration and tumor-to-normal tissue contrast shortly after injection and, in addition, an unexpectedly elevated fluorescence contrast at 24 h after injection (Figure 56.3).^{37–39}

Although contrast enhancement with the agents covered in this chapter mainly relies on a more distinct perfusion of tumors compared to normal tissue (as is achieved with ICG) and does not employ target-specific moieties, the value of contrast-enhanced tumor imaging was successfully demonstrated. These agents represent the classical format of a contrast agent.

56.3.1.2 Targeted Cyanine-Dye Conjugates

One way to improve the selectivity of fluorescent dyes for diseased tissues is based on the high instrumental detection sensitivity for optical signals, which makes it possible to monitor signals derived from

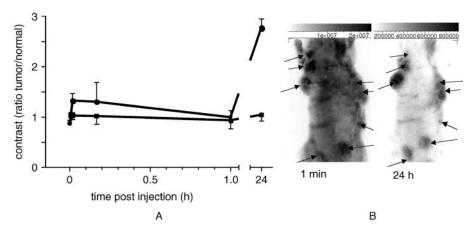

FIGURE 56.3 Fluorescence-imaging performance of hydrophilic dye SIDAG in rats with chemically induced multiple mammary carcinoma (dose: $2 \mu mol/kg$) in comparison to rats after injection of the same dose of ICG. (A) Time course of SIDAG (squares) and ICG (triangles) and (B) corresponding fluorescence images with SIDAG obtained at 1 min and 24 h after injection. Arrows indicate multiple tumor sites. (From Licha, K. et al., *Acad. Radiol.*, 9(Suppl. 2), 320, 2002. With permission.)

molecular states and events. Optical molecular imaging can therefore be considered the nonradiative counterpart to radionuclide-based methods, of course always limited by the penetration of light into tissue. Hence, novel probes consisting of an efficiently fluorescing dye label and a biological targeting unit (e.g., an antibody, peptide, oligonucleotide, or small molecule) have been reported in recent publications and will be discussed below.

A primary synthetic goal of chemical and physicochemical research in the area of fluorescent probes has been to provide novel fluorescent markers for application in immunoassays, screening assays, or genetic analysis. Many of the structures developed for these purposes contain reactive or activatable groups, e.g., carboxylic acids,^{40–42} *N*-hydroxysuccinimidyl esters,^{43–45} isothiocyanates,⁴⁵ or maleimido⁴⁶ functionalities. Figure 56.4 depicts selection of chemical structures. Well established is the commercially available CyDyeTM-series (e.g., Cy3, Cy5, Cy5.5, Cy7; Amersham-Pharmacia Biotechnology, Piscataway, NJ). Those and other cyanine-dye derivatives were employed for the preparation of various targeted cyanine-dye conjugates.

The strategy of coupling cyanine-dye labels to antibodies for *in vivo* diagnostic purposes was first reported by Folli et al. and Ballou et al.^{47–50} The authors demonstrated target-specific uptake in experimental tumor models by planar-reflection imaging of superficial fluorescence patterns and fluorescence-microscopy methods.

Generally, imaging contrast is improved when the probe localizes in the target area with high binding affinity and maintains its concentration level while the circulating fraction is cleared from the blood to the greatest possible extent. Therefore, from the standpoint of background signal, contrast improves when going from full-size antibodies to targeting vehicles of reduced molecular weight such as antibody fragments and peptides.

The use of engineered antibody fragments of reduced molecular weight but still high binding affinities as target-specific carrier molecules for fluorescent dyes^{51–54} was reported recently. Neri et al. described antibody single-chain fragments that were identified by phage-display library technology⁵¹ and that exhibited high binding affinities against an extracellular angiogenesis marker, the fibronectin isoform ED-B-FN. This matrix protein is present exclusively in neoplastic blood vessels during angiogenesis and is therefore a promising target for specific fluorescent ligands. After labeling with fluorophores the antibody fragments were successfully applied to the *in vivo* fluorescence imaging of tumor angiogenesis in animal models.^{51–53}

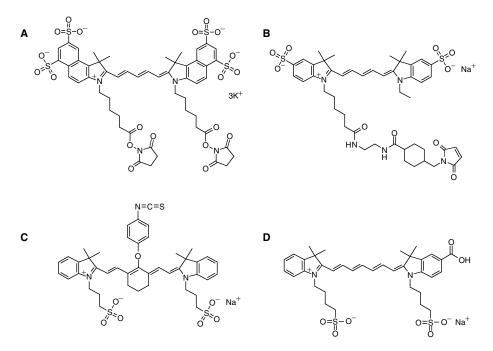

FIGURE 56.4 Carbocyanine-dye labels with different reactive groups for fluorescence labeling purposes. (A) Commercially available Cy5.5-bis-NHS-ester, (B) maleimido-derivative of Cy5,⁴⁶ (C) indotricarbocyanine with isothiocyanate functionality,⁴⁵ and (D) derivative with carboxy group at exterior ring position.⁴⁰

Synthetic peptides as vehicles for diagnostic molecules offer a promising strategy for the further reduction of molecular weight. Many tumors are known to overexpress receptors for specific peptide ligands, e.g., somatostatin (SST), bombesin, or vasoactive intestinal peptide (VIP).⁵⁶ Pharmacologically optimized derivatives of these natural ligands in radiolabeled form are already clinically established as radiolabeled probes for the receptor scintigraphy of tumors, e.g., OcteoScan,* an ¹¹¹In-DTPA-conjugated SST analog.⁵⁷ The literature reports some examples in which these principles were successfully adapted to optical receptor imaging by replacing the radiolabel by fluorescent cyanine dyes.^{21,22,40,41,58} The synthesis and *in vivo* characterization of different conjugates between cyanine dyes and peptides, such as the SST analog octreotate,^{21,22,40} the bombesin-derived analog bombesate,^{41,58} and structurally optimized VIP,^{59,60} were the subject of studies by various investigators. Figure 56.5 illustrates the structures of selected cyanine dye–peptide conjugates. The authors demonstrated that the conjugates were accessible by standard solid-phase peptide synthesis, which led to structurally well-defined and pure products. The fluorescence properties of the conjugated dyes were less affected only by the peptide, typically leading to fluorescence quantum yields for indotricarbocyanine conjugates in the range of 10%.⁴⁰

Fluorescence-imaging experiments using SST-receptor positive animal-tumor models revealed receptor-mediated uptake resulting in elevated fluorescence at the tumor site compared to surrounding normal tissue areas. Unlike *in vivo* imaging features of nonspecific extracellular dyes or fluorescent single-chain-fragment conjugates, the highest contrast was achieved already within 1 to 2 h after intravenous injection and lasted up to 24 h^{22,58} (Figure 56.6). This behavior is based on receptor-mediated accumulation of the peptide conjugates into tumor cells, while nonbound molecules undergo rapid body clearance via the renal pathway.²²

As an interesting alternative to vehicles of biological origin, the targeting of the LDL (low-density lipoprotein) receptor was demonstrated with "small-molecule" conjugates between different indotricar-bocyanines and cholesteryl laurate, which can bind to LDLs and thus mediates internalization of the entire conjugate into LDL-receptor-expressing tumor cells.⁶¹

FIGURE 56.5 Chemical structures of cyanine dye–peptide conjugates designed for receptor-targeted fluorescence imaging of tumors. (A, B) cyanine dye conjugated to the SST-receptor-binding peptide octreotate^{21,22,40,41,58} and (C) a bombesin-receptor-avid peptide sequence.^{41,58}

(A) Time course of indotricarbocyanine octreotate (squares) vs. a control conjugate where two cysteins in the octreotate sequence are replaced by methionine (circles). Corresponding fluorescence images obtained at 6 h p.i. for the indotricarbocyanine octreotate (B) and the control conjugate (C). (From Licha, K. et al., *Acad. Radiol.*, 9 (Suppl. 2), 320, 2002. With permission.)

FIGURE 56.7 Structures of of Cy5.5-labeled poly(ethylene glycol) poly-(L-lysine) graft polymers with a peptide sequence cleavable by the proteolytic enzyme MMP-2. Arrows indicate the enzyme cleavage sites.⁶⁵

56.3.1.3 Activatable Cyanine Dye Conjugates ("Smart Probes")

A number of groups have demonstrated enzyme-activatable conjugate complexes where the quenched signal (fluorescence, for example) is turned on by tumor-associated lysosomal protease activity *in vivo*.^{23,62–67} These probes carry Cy5.5 molecules (excitation 670 nm, emission 700 nm) that are bound to long circulating graft copolymers consisting of poly-L-lysine and poly(ethylene)glycol. An intratumoral NIR fluorescence signal is generated when tumor-associated proteases cleave the macromolecule, thereby liberating Cy5.5 fragments and affording previously quenched fluorescence.

This approach utilizes the unique opportunity of modulating optical signals through intramolecular fluorescence-quenching effects. Thus, the agents can report information on protein function and molecular conversion (enzymatic activity) and, furthermore, circumvent the necessity of target-specific accumulation, as the circulating fraction, which needs to be cleared for targeted agents, avoids fluorescence detection.

The contrast agent is composed of a poly(ethylene glycol) poly-(L-lysine) graft polymer, which is labeled with Cy5.5 (see Figure 56.4) at the ϵ -amino groups of free lysines. This drug exhibits increased fluorescence signals in the presence of the proteolytic enzymes cathepsin B and H by cleavage of the polylysine backbone and leads to a substantial signal increase both in cell culture and animal tumors. 23,63,64

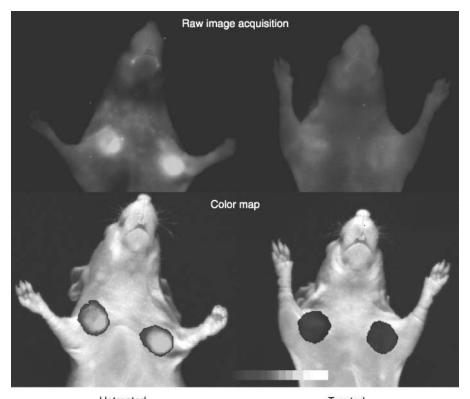

To broaden the specificity of the probe as a substrate for any other desired enzyme, a cleavable peptide sequence was incorporated in the polymeric backbone. As illustrated in Figure 56.6, the graft polymer was modified in such a way that a desired peptide sequence could be linked to the graft polymer. Fluorophores were conjugated at the N-terminal amino group of the peptide, again being subject to fluorescence quenching (Figure 56.7). These peptide spacers can be easily modified to act as a substrate for tumor- or angiogenesis-specific enzymes with proteolytic activity, e.g., matrix metalloproteinases (MMPs)⁶⁵ or the serine protease thrombin.⁶⁷

The particular promise of applying probes for the visualization of protein function relates to the contrast-enhanced imaging of diseased tissues and is expected to have significant impact as a tool for the monitoring of drug response and efficacy at the molecular level. Figure 56.8 shows the results of an experiment in which a probe activatable by MMP-2 was used to monitor treatment response in a mouse model.^{65,68}

56.3.2 Tetrapyrrole-Based Dyes

56.3.2.1 Synthetic Porphyrins, Chlorins, and Related Structures

The main area of application of tetrapyrrole-based compounds, such as porphyrins, chlorins, benzochlorins, phthalocyanines, and expanded porphyrins, has been for photodynamic therapy (PDT).^{69–71} While PDT is treated elsewhere in this book (see Chapter 38), it is noteworthy, given the focus of this review,

Untreated Treated

FIGURE 56.8 (Color figure follows p. 28-30.) Fluorescence imaging of HT1080 tumor-bearing mice 48 h after injection of Cy5.5-labeled poly(ethylene glycol) poly-(L-lysine) graft polymer (see Figure 56.6) into animals treated with the MMP-inhibitor primomastat vs. untreated animals. The top row shows raw fluorescence images, and the bottom row shows color-coded intensity profiles superimposed onto white-light images. The results show a significantly less fluorescence signal in treated animals relative to the untreated group. (From Bremer, C. et. al., *Nat. Med.*, 7(6), 743, 2001. With permission.)

that many agents originally designed for PDT have shown to be applicable for diagnostic purposes, as these structures exhibit strong fluorescence in the VIS-to-NIR spectral region. The main rationale behind this type of application has been to use the fluorescence emission for real-time assessment of therapy progress and effectiveness during photodynamic treatment.

A variety of PDT compounds have been studied for their diagnostic capabilities, e.g., hematoporphyrin (HpD),⁷² meso-tetra-*m*-hydroxyphenylchlorin (*m*-THPC),⁷³ benzoporphyrin derivatives (BPD),⁷⁴ sulfonated phthalocyanines,⁷⁵ pheophorbides,⁷⁶ derivatives of chlorin e6,⁷⁷ and, finally, the expanded porphyrin derivative lutetium texaphyrin (Lu-Tex).⁷⁸ Figure 56.9 illustrates selected chemical structures.

Attempts to enhance the selectivity of photosensitizers by conjugating them to target-specific vehicles have been described.⁷⁹ Like the approaches based on cyanine dyes, conjugates with antibodies,^{80,81} antibody fragments,^{53,82} peptides,⁸³ and the serum proteins albumin and transferrin,^{84,85} as well as estradiol⁸⁶ and cholesteryl laurate,⁸⁷ have been prepared and studied in animals.

56.3.2.2 5-Aminolevulinic Acid (ALA) and Protoporphyrin IX (PpIX)

The underlying mechanism of fluorescence enhancement using ALA differs fundamentally from other approaches where exogenous agents are applied. ALA is not fluorescent per se but represents an essential precursor in the heme biosynthetic pathway. In the last step of the biosynthesis of heme, iron is incorporated into PpIX. After administration of ALA the intracellular synthesis of heme is stimulated with a certain degree of selectivity for tumor cells and engenders a temporarily increased intracellular PpIX

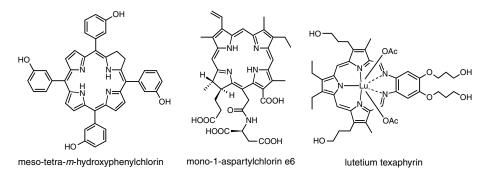

FIGURE 56.9 Chemical structures of photosensitizers applied as diagnostic agents for the fluorescence detection of tumors.

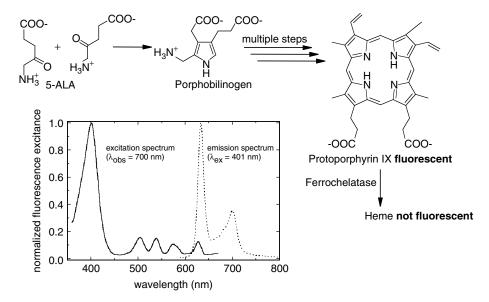

FIGURE 56.10 Synthetic pathway of heme biosynthesis leading to intracellular formation of fluorescent protoporphyrin IX (PpIX). Fluorescence excitation spectrum and fluorescence emission spectrum of PpIX in methanol. (Figure courtesy of B. Ebert, Physikalisch-Technische Bundesanstalt, Berlin.)

concentration in tumor cells relative to healthy tissue. This phenomenon is based on the finding that the incorporation of iron is catalyzed by the enzyme ferrochelatase, which was suggested to have lower activity in many tumors, thereby leading to a "bottleneck effect" at the level of PpIX formation. Figure 56.10 illustrates the essential steps. Upon irradiation with light, a cell-destructive, photodynamic effect is induced that is of much higher selectivity for malignant cells and accompanied with fewer side effects than is usually achieved with exogenously applied photosensitizers. The principles of PDT using ALA were reviewed, for example, by Peng et al.⁸⁸

While heme is not fluorescent, PpIX exhibits a fluorescence-emission spectrum typical of porphyrins of this structural class (Figure 56.10). Thus, PpIX fluorescence has been used to detect and visualize tumors and other tissue abnormalities in a large variety of clinical applications^{7,19,20,89,90} (see also Chapter 2).

Successful attempts to improve ALA delivery to cells were followed by synthesizing ester derivatives of ALA, particularly alkyl esters of different alkyl chain length, 19,91,92 which are converted into free ALA through ester cleavage by esterases. Many of these compounds have proven to penetrate more effectively into tissues and lead to enhanced amounts of accumulated PpIX, 19,91–94 with the highest efficacy described for the *n*-hexyl ester. 91,93,94

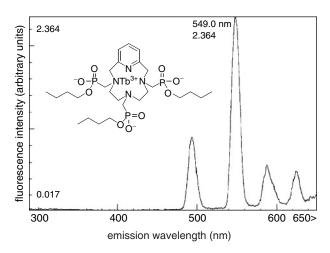

FIGURE 56.11 Chemical structure and fluorescence emission spectrum of Tb-[*N*-2-pyridylmethyl)-*N'*,*N'''*,*N'''*-*tris*(methylenephosphonic acid butyl ester)-1,4,7,10-tetraazacyclododecane] (Tb-PCTMB).

56.3.3 Other Dyes and Reporter Systems

56.3.3.1 Fluorescent Lanthanide Chelates

Many of the lanthanides, e.g., La³⁺, Eu³⁺, Tb³⁺, Nd³⁺, and Yb³⁺, form stable organometallic complexes with unique optical properties.⁹⁵ When an aromatic structure is located close to the complexing moiety, the metal ion exhibits a characteristic emission spectrum upon light absorption through the aromatic system and intramolecular energy transfer of the absorbed energy to the metal ion. This "sensitized luminescence emission" is of long lifetime — up to milliseconds — and typically consists of several emission bands throughout the VIS up to NIR spectral range depending on the metal used. In particular, Tb³⁺ and Eu³⁺ complexes have been synthesized in large structural diversity,^{96,97} applied in biotechnology, and used for the development of screening assays based on time-resolved detection techniques.^{34,98,99} Terbium yields a bright green fluorescence (major peak at 550 nm), and europium fluoresces in red color (major peak at 600 nm). Another focus for the chemical design of fluorescent rare-earth complexes was driven by the fact that the optical properties of these compounds are sensitive to environmental conditions, such as pH, pO₂, glucose, halide ions, and alkali metals, permitting their use as chemical and biological sensors.^{100,101}

The application of such compounds for the *in vivo* fluorescence detection of cancer has been proposed by several researchers. $^{24,102-104}$ More specifically, a pyclen-based macrocyclic complex with Terbium, Tb-[N-2-pyridylmethyl)-N', N'', N-tris (methylenephosphonic acid butyl ester)-1,4,7,10-tetraazacyclododecane] or Tb-PCTMB (Figure 56.11) is extremely luminescent, water soluble at millimolar levels, thermodynamically stable, and nontoxic. $^{24,102-105}$ This compound has been detected at the picomolar level in rat intestinal-tissue endoscopies, facilitating an enhanced visual detection of chemically induced colon cancers in the rats. 24,103,105

Bioconjugatable chelating derivatives of similar structure, consisting of a 1,4,7,10-tetraazacyclodode-cane system bearing a light-harvesting quinaldine structure, two phosphonic acids, and a single carboxylic acid moiety for fluorescence labeling of target-specific biomolecules, have been described. 106,107

56.3.3.2 Fluorescein, Oxazine, and Thiazine Dyes

Dyes based on the fluorescein chromophore are probably the most frequently applied fluorescent dyes in bioanalytics and biomedical diagnostics. A broad spectrum of reactive derivatives, such as 5-amino-fluorescein or fluorescein-isothiocyanate (FITC) and many further differently derivatized analogs, ¹⁰⁸ are commercially available. Fluorescein is a drug routinely used for optical diagnosis in ophthalmology in medical imaging. ¹⁰⁹

A recent *in vivo* imaging approach has been the application of fluorescent serum albumin conjugates with 5-aminofluorescein for the intraoperative detection of tumor margins.¹² The synthesis of fluorescent cobalamin derivatives employing FITC and other fluorescein-related fluorophors (Oregon Green, naphthofluorescein) was reported, and the use of these conjugates for the intraoperative visualization of cobalamin receptors was suggested.¹¹⁰ An oxazin-type dye, ethyl Nile blue A, was used as a marker for the fluorescence-guided identification of premalignant lesions in animal models.¹¹¹ Finally mentioned is the phenothiazine dye, toluidine blue, which is established as histological staining dye both in the laboratoty and for clinical examinations.¹¹²

The Haugland group (see www.MolecularProbes.com) has successfully implemented a host of fluorescein- and oxazine-based dyes into molecular-imaging regimes. Currently, many probes are commercially available for visual signal amplification, organelle probes, fluorescent tracers, and viability kits that extend across many diverse cell lines.

56.3.3.3 Zinc Sensing

Intracellular zinc is thought to be available in a cytosolic pool of free bound Zn(II) ions in the micromolecular to picomolar range. ¹¹³ Several Zn(II)-responsive transcription factors are known to mediate zinc homeostasis *in vivo* and are thought to do so by monitoring changes in this hypothetical pool of free Zn(II). ^{113–119} In research conducted by O'Halloran et al., the response of the mechanism of zinc sensors that control metal uptake or export was calibrated against thermodynamically defined free Zn(II) concentration, and it was shown that whereas the cellular zinc quota is millimolar, free Zn(II) concentrations that trigger zinc uptake or export are femtomolar, thereby suggesting extraordinary intracellular zinc-capacity binding. The cells would then exercise tight control over cytosolic metal concentrations. ¹¹³

56.3.3.4 Connexin Trafficking

Recombinant proteins containing tetracysteine tags have been shown to be successfully labeled in living cells via multicolor and electron-microscopic imaging of connexin trafficking. ¹²⁰ Tsien et al. have shown that this approach makes discrimination between older and younger protein molecules possible. FlAsH and ReAsH, two fluorescent labeling ligands, label temporally separated pools of Cx43-TC to facilitate the recording of junctional-plaque renewal over time. This approach describes a method for studying the life cycle of proteins including assembly and internalization. ¹²⁰

56.3.3.5 PEBBLES

PEBBLES stands for sol-gel probes encapsulated by biologically localized embedding. Kopelman et al. have reported sol-gel-based optical nanosensors that are ratiometrically referenced and can provide real-time measurements of subcellular molecular oxygen¹²¹ and intracellular pH and calcium.¹²² The polymer sensors easily incorporate multiple signaling dyes, such as oxygen sensitive [Ru-(dpp)₃]²⁺ and oxygen-insensitive Oregon green 488-dextran, and are on the order of 50 to 300 nm (radius) in size.

56.3.3.6 Smart DNA Detection

Tan et al. have developed sensitive fluorescent DNA probes that can be used for real-time biomolecular recognition of target DNA sequences. 123 These probes, called "molecular beacons," consist of a hairpin-shaped oligonucleotide that contains both a fluorophore and a quenching moiety. Molecular beacons act like on–off switches that are normally off (no fluorescence). The dye is activated upon hybridization of the stem to complementary DNA. As a result, the stem hybrid unwinds, thereby increasing the distance between the quencher and the fluorescent molecule and selectively generating a quantifiable signal. Two forms of energy transfer that exist in molecular beacons are direct energy transfer and fluorescence resonance energy transfer (FRET). While both forms of energy transfer are distance-dependent, FRET has the added complication of requiring spectral overlap between the donor's (fluorescent dye) emission and the acceptor's (nonfluorescent quencher) absorption spectra. This effect has been further used for the detection of thrombin through specially designed molecular aptamer beacons, employing a fluorescein/ Dabcyl quenching system and a thrombin-binding DANN oligonucleotide. 124

56.4 Conclusions

Remarkable optical techniques for the imaging and detection of diseases have emerged in the past few years. The current literature in this area outlines the broad applicability of light-based instrumental solutions for many clinical disciplines. The strength of optical imaging is that it allows for the combination of conventional display of tissues with the promise of highly sensitive detection of molecular signals. Thus, remarkable progress in the design of novel fluorescent probes has been made. In that respect, the chemistry of fluorescent dyes offers various opportunities to the acquisition of optical signals. Several parameters, such as the absorption coefficients, fluorescence quantum yields, fluorescence decay times, and fluorescence quenching/recovery processes, are accessible for reporting physiological states, molecular conditions, and molecular function. Unlike radioactive decay, fluorescence is sensitive to its chemical environment, thereby broadening the applicability to the sensing of chemical analytes.

Progress in biotechnology, from which new biological targets and designated biological vehicles will arise, is credited with having a tremendous impact on the design of specific fluorescent probes. Optical techniques will likely be of increasing importance for sophisticated clinical diagnostic methods, for both laboratory purposes and clinical applications. Yet it remains to be identified which combination of fluorescent probe, biological principle, and instrumental solution will be able to solve the most urgent clinical questions and provide practical assets for the clinician.

Acknowledgment

Ms. Gretchen Cohenour is acknowledged for her assistance in preparing this chapter.

57.1 Introduction

Fluorescent probes for biomolecular recognition are of great importance in the fields of chemistry, biology, and medical sciences, as well as in biotechnology. These probes have been used for mechanism studies of biological functions and in ultrasensitive detection of biological species responsible for many diseases.¹ In the post-genome era, quantitative studies of genomic information for disease diagnosis and prevention and drug discovery will be fast growing areas of research and development. This has led to a continued demand for advanced biomolecular recognition probes with high sensitivity and high specificity. The molecular beacon (MB), a recently developed single-stranded DNA (ssDNA) molecule,² appears to be a very promising probe for quantitative genomic studies. MBs are hairpin-shaped oligonucleotides that contain both fluorophore and quencher moieties and act like switches that are normally closed to bring the fluorophore/quencher pair together to turn fluorescence "off." When prompted to undergo conformational changes that open the hairpin structure, the fluorophore and the quencher are separated, and fluorescence is turned "on." MBs were first developed in 1996. Since then, they have

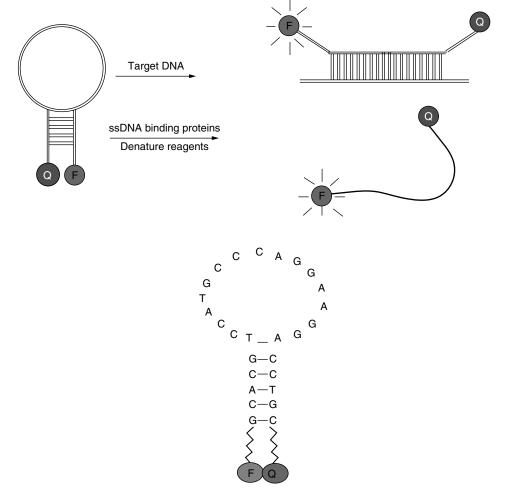

FIGURE 57.1 Mechanism of operation of molecular beacon DNA probes. On their own these molecules are non-fluorescent because the stem hybrids keep the fluorophores close to the quenchers. Molecular beacons emit intense fluorescence only when the stems are apart through hybridization of DNA molecules with sequences complementary to their loop sequences, unwinding the stem hybrids upon interaction with ssDNA binding protein, if denaturing reagents are used, or under other denaturing conditions.

provided a variety of exciting opportunities in DNA/RNA/protein studies both inside living-cell specimens and in solution.

57.2 The MB Principle

57.2.1 Molecular Recognition and Fluorescence-Energy Transfer

The hybridization of a nucleic-acid strand to its complement target is one of the most specific well-known molecular recognition events. A MB makes use of this unique feature for DNA/RNA/protein studies. MBs are synthetic short oligonucleotides that possess a loop and stem structure, as schematically shown in Figure 57.1.

Its signal-transduction mechanism for molecular recognition is based on fluorescence-resonance energy transfer (FRET). The loop portion of a MB is a probe sequence complementary to a target nucleic-acid molecule. The arm sequences flanking either side of the probe are complementary to each other but are unrelated to the target sequence. These arm sequences, which have five to seven base pairs,

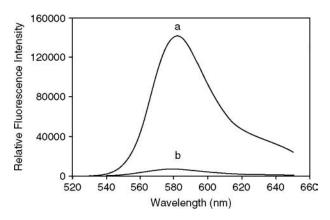

FIGURE 57.2 Fluorescence spectra of MBs obtained at room temperature. Spectra were taken for MB hybridization with cDNA molecules (a) and with non-cDNA molecules (b).

anneal to form the MB's stem. A fluorescent moiety is covalently attached to the end of one arm, and a quenching moiety is covalently attached to the other end. The fluorescent dye serves as an energy donor, and the nonfluorescent quencher plays the role of an acceptor. The stem keeps these two moieties in close proximity to each other, causing the fluorescence of the fluorophore to be quenched by energy transfer. Thus, the probe is unable to fluoresce. When the probe encounters a target molecule, the loop forms a hybrid that is longer and more stable than the stem. The molecular beacon undergoes a spontaneous conformational change that forces the stem apart. The fluorophore and the quencher are moved away from each other, leading to the restoration of fluorescence. Unhybridized MBs do not fluoresce; thus, it is not necessary to remove them to observe hybridized probes.

Two forms of energy transfer may exist in MBs: direct energy transfer and FRET.³ Direct energy transfer requires contact between the two moieties in a MB. The collision between the fluorophore and the quencher can distort the energy level of the excited fluorophore, causing the fluorescence of the fluorophore to be quenched by energy transfer. In brief, the quenching moiety dissipates the energy that it receives from the fluorophore as heat, rather than emitting it as light. The other mechanism, FRET, can occur between the two moieties in a MB with a relatively long distance (20 to 100 Å). It requires a spectral overlap between the donor's emission spectrum and the acceptor's absorption spectrum. The rate of FRET is directly proportional to the inverse sixth power of the separation distance of the donor and the acceptor or the quencher.¹ Both forms of the energy transfer are strongly dependent on the distance between the dye moieties. Therefore, the spatial separation of the fluorophore and the quencher in a MB determines the energy-transfer efficiency. When a target DNA hybridizes to a MB, a substantial increase of the fluorescence signal is observed (Figure 57.2) due to larger separation distance between the two moieties in a MB. As DABCYL (dimethylaminophenylazobenzoic acid) has been found to efficiently quench a large variety of fluorophores independent of the spectral overlap, direct energy transfer may be dominant in MBs.⁴

57.2.2 Advantages of MB Probes

The hybridization of a nucleic-acid strand to its complement has been widely used in many areas of research and development. Various types of DNA fluorescent probes have been designed for these applications. For example, nucleic-acid blotting techniques have been used to make great strides in our understanding of gene organization and function. In these techniques, a solid support is used to immobilize DNA fragments.⁵ A labeled oligonucleotide probe containing the sequence of interest is then used to hybridize with its counterpart. In today's laboratories, nucleic-acid techniques are increasingly being harnessed for use in practical applications such as the molecular diagnosis of disease. But what if one needs to monitor the real-time synthesis of nucleic acids as it is happening? Or what if your research calls for the labeling of nucleic acids within living cells? Methods based on immobilization of hybridized

nucleic acids, probes requiring intercalation reagents, or other means requiring the isolation of probe—target complexes cannot be used for these applications. MBs can overcome these difficulties.

The inherent fluorescent-signal-transduction mechanism enables a MB to function as a sensitive probe with high signal-to-background ratio for real-time monitoring. Its fluorescence intensity can increase more than 200 times when it meets the target under optimal conditions.⁴ This provides the MBs with a significant advantage over other fluorescent probes in ultrasensitive analysis. With this inherent sensitivity, individual MB DNA molecules have been imaged, and their hybridization process has been monitored on a single-molecule basis.⁶ MBs can be used in situations where it is either impossible or undesirable to isolate the probe–target hybrids from an excess of the unhybridized probes, such as in real-time monitoring of polymerase chain reactions (PCRs) in sealed tubes or in detection of messenger RNAs (mRNAs) within living cells. The usefulness of "detection without separation" for these applications cannot be overemphasized. This feature enables the synthesis of nucleic acids to be monitored as it is occurring, in either sealed tubes or in living specimen, without additional manipulations.

Another major advantage of MBs is their molecular-recognition specificity. They are extraordinarily target-specific, ignoring nucleic-acid target sequences that differ by as little as a single nucleotide. While current techniques for routine detection of single-base-pair DNA mutations are often labor-intensive and time-consuming,⁷ MBs provide a simple and promising tool for the diagnosis of genetic disease and for gene-therapy study. This specificity of MBs comes from its loop-and-stem structure. The stem hybrid acts as a counterweight for the loop hybrid. Experiments have shown that the range of temperatures in which perfect complementary DNA (cDNA) targets form hybrids but mismatched DNA targets do not is significantly wider for MBs than the corresponding range observed for conventional linear probes.⁸ Therefore, MBs can easily discriminate DNA targets that differ from one another by a single nucleotide. Thermodynamic studies revealed that the enhanced specificity is a general feature of structurally constrained DNA probes.

57.3 MB Synthesis and Characterization

The synthesis of a MB is similar to that of dual labeling a short oligomer with two dyes. The length of the loop sequence (15 to 40 nucleotides) is chosen so that the probe-target hybrid is stable at the temperature of probing. The stem sequences (five to seven nucleotides) should be strong enough to form the hairpin structure for efficient fluorescence quenching while still weak enough to be dissociated when a cDNA hybridizes with the loop of the MB. Also, the stem sequence must be designed so as not to interfere with the probe sequences. Since DABCYL can serve as a universal quencher for many fluorophores,4 MBs are generally synthesized using DABCYL-CPG (controlled-pore glass) as starting material. Various fluorescent-dye molecules can be covalently linked to the 5' end to report fluorescence at various wavelengths. There are carbon chain linkers between the bases and the labeled-dye molecules. The stem and the linker keep the fluorophore and the quencher in close proximity and increase the probability for their direct contact. There are four important steps in this synthesis.² First, a CPG solid support is derivatized with DABCYL and used to start the synthesis at the 3' end of the oligonucleotide. The rest of the nucleotides are added sequentially using standard cyanoethylphosphoramidite chemistry. Second, a primary amine group at the 5' end is linked to the phosphodiester bond by a six-carbon spacer arm. A trityl protecting group at the ultimate 5' end protects the amine group. Third, the oligonucleotide is hydrolyzed and removed from the CPG and then purified by reversed-phase HPLC. Fourth, the purified oligonucleotide is removed from the trityl group and labeled with a fluorophore. After labeling, the excess dye is removed by gel-filtration chromatography on Sephadex G-25. The oligonucleotide is then purified again by reversed-phase HPLC. The product peak from the HPLC is collected. The synthesized MB is characterized by ultraviolet (UV) and by mass spectroscopy. The purification of the MB after synthesis is critically important to ensure a high signal-to-noise ratio and to achieve ultrahigh sensitivity. A detailed protocol for MB synthesis can be found on the Internet at http:\\www.molecular-beacons.org. There are also approximately ten commercial companies specializing in custom synthesis of MBs. Today, molecular

beacons with specific sequences are readily available at affordable prices and without tedious synthesis by individual investigators.

57.3.1 Synthesis and Purification of MBs

MB synthesis is now commercially available. Even though there are many companies involved in MB synthesis, the techniques are similar. Here we give a description of a typical method for MB synthesis (from http://www.molecular-beacons.org). The starting material for the synthesis of MBs is an oligonucleotide that contains a sulfhydryl group at its 5′ end and a primary amino group at its 3′ end. DABCYL is coupled to the primary amino group using an amine-reactive derivative of DABCYL. The oligonucleotides that are coupled to DABCYL are then purified. The protective trityl moiety is then removed from the 5′-sulfhydryl group, and a fluorophore is introduced in its place using an iodoacetamide derivative. Recently, a CPG column that introduces a DABCYL moiety at the 3′ end of an oligonucleotide has become available that enables the synthesis of a molecular beacon completely on a DNA synthesizer. The whole sequence of the molecular beacon used throughout this protocol is shown as the following: fluorescein-5′-GCGAGCTAGGAAACACCA AAGATGATAT TTGCTCGC-3′-dabcyl, where the underlines identify the arm sequences.

57.3.1.1 Coupling of DABCYL

- 1. Dissolve 50 to 250 nmol dry oligonucleotide in 500 μl of 0.1 *M* sodium bicarbonate, pH 8.5. Dissolve about 20 mg of DABCYL (4-(4'-dimethylaminophenylazo)benzoic acid) succinimidyl ester (molecular probes) in 100 μl *N*,*N*-dimethylformamide and add to a stirring solution of the oligonucleotide in 10-μl aliquots at 20-min intervals. Continue stirring for at least 12 h.
- 2. Remove particulate material by spinning the mixture in a microcentrifuge for 1 min at 10,000 rpm. To remove unreacted DABCYL, pass the supernatant through a gel-exclusion column. Equilibrate a Sephadex G-25 column (NAP-5, Pharmacia, Peapack, NJ) with buffer A, load the supernatant, and elute with 1 ml buffer A. Filter the elute through a 0.2-μm filter (Centrex MF-0.4, Schleicher & Schuell, Keene, NH) before loading on the HPLC column.
- 3. Purify the oligonucleotides on a C-18 reverse-phase column (Waters), using a linear elution gradient of 20 to 70% buffer B in buffer A, and run for 25 min at a flow rate of 1 ml/min. Monitor the absorption of the elution stream at 260 nm and 491 nm. A typical chromatogram is shown in Figure 57.3. Collect the peak that absorbs in both wavelengths, which contain oligonucleotides with a protected sulfhydryl group at their 5′ end and DABCYL at their 3′ end (peak D).
- 4. Precipitate the collected material with ethanol and salt and spin in a centrifuge for 10 min at 10,000 rpm; discard the supernatant, dry the pellet, and dissolve it in 250 μl buffer A. As explained in Figure 57.3, we can collect the desired portion of the synthesized DNA probes.

57.3.1.2 Coupling of Fluorophore

- 1. To remove the trityl moiety, add 10 μ l of 0.15 M silver nitrate and incubate for 30 min. Add 15 μ l of 0.15 M dithiothreitol to this mixture and shake for 5 min. Spin for 2 min at 10,000 rpm and transfer the supernatant to a new tube. Dissolve about 40 mg 5-iodoactamidofluorescein (Molecular Probes, Eugene, OR) in 250 μ l of 0.2 M sodium bicarbonate, pH 9.0, and add it to the supernatant. Incubate the mixture for 90 min. Each of these solutions should be prepared just before use.
- 2. Remove excess fluorescein from the reaction mixture by gel-exclusion chromatography and purify the oligonucleotides coupled to fluorescein by HPLC, following the instructions in steps 2 and 3 of the previous section. A sample chromatogram is shown in Figure 57.3. Collect the fractions corresponding to peak D, which absorb at wavelengths 260 and 491 nm and are fluorescent when observed with a UV lamp in a dark room. If a different fluorophore is coupled in place of fluorescein, its maximum absorption wavelength should be used instead of 491 nm.
- 3. Precipitate the collected material and dissolve the pellet in 100 μ l TE buffer. Determine the absorbance at 260 nm and estimate the yield (1 OD260 = 33 μ g/ml).

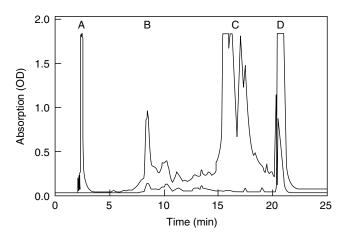

FIGURE 57.3 Chromatographic separation of oligonucleotides coupled to DABCYL. The top line represents absorption at 260 nm, and the bottom line represents absorption at 491 nm. The oligonucleotides in peaks A and B do not contain trityl moieties, whereas the oligonucleotides in peaks C and D are protected by trityl moieties. The oligonucleotides in peaks B and D are coupled to DABCYL, whereas the oligonucleotides in peaks A and C are not coupled to DABCYL. Peak D should be collected.

57.3.1.3 Automated Synthesis

- 1. Use a CPG column to introduce DABCYL (Glen Research, Sterling, VA) at the 3′ end of the oligonucleotide during automated synthesis. At the 5′ end of the oligonucleotide either a thiol or an amino modifier can be introduced for a subsequent coupling to a fluorophore, or a fluorophore can be directly introduced during automated synthesis using a phosphoramidite. The 5′ modifiers and fluorophores should remain protected with a trityl moiety during the synthesis. Perform post-synthetic steps as recommended by the manufacturer of the DNA synthesizer. Dissolve the oligonucleotide in 600 μl buffer A.
- When the fluorophore is to be introduced manually, purify the oligonucleotide protected with atrityl moiety. Remove the trityl moiety from the purified oligonucleotide and continue with the coupling of the fluorophore, as described above.
- 3. When a 5' fluorophore is introduced via automated synthesis, purify the oligonucleotide protected with the trityl moiety and then remove the trityl moiety from the purified oligonucleotide. Precipitate the molecular beacon with ethanol and salt and dissolve the pellet in $100~\mu l$ TE buffer. Determine the absorbance at 260~nm and estimate the yield.

57.3.2 MB Characterization

57.3.2.1 Characterization of MB by Mass Spectrometry

Once the MBs are synthesized, various methods will be used to evaluate the quality of the product. One of the effective ways of doing this is to run a mass spectrometry and determine the molecular weight. Usually, an aliquot of the MB product collected from HPLC was taken out for analysis by mass spectrometry. Matrix-assisted laser desorption/ionization time-of-flight mass spectrometer was used to confirm the molecular weight of the MB. For example, the calculated molecular weight of a MB used in biosensor development is 10076. As shown in Figure 57.4, the main peak in the mass spectrum was 10085.7 Da. The difference between the measured value and the calculated one is only about 0.1%, which is less than the typical error, 0.2%, in mass-spectrum measurement. Another small peak appeared near a position corresponding to half of the MW of the MB. This was due to the molecules that had lost two electrons in the desorption process during the measurement. The mass-spectrum results support the synthesis of the designed MB.

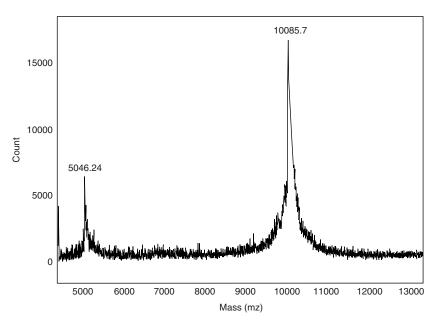

FIGURE 57.4 Mass spectrum of the synthesized biotinylated molecular beacon.

57.3.2.2 MB Hybridization Activity

MBs can be tested by hybridization to evaluate their activity in DNA/RNA reaction. For example, a newly synthesized MB has been used for DNA hybridization in solution. The MB's hybridization properties were tested using fluorescence measurements performed on a SPEX Industries F-112A spectrophotometer. A submicro quartz cell was used for the hybridization experiment. Two 200-µl sample solutions were prepared: the MB and a fivefold molar excess of its cDNA, and the MB and a fivefold molar excess of a non-cDNA. The concentrations of MB in the two solutions were 50 nM. They were incubated for 20 min in the hybridization buffer (20 mM Tris-HCl, 50 mM KCl, and 5 mM MgCl₂, pH = 8.0). Emission spectra were recorded at room temperature with excitation at 515 nm for the MB labeled with fluorescein. Hybridization of the MB inside the solution has shown strong fluorescence signal when ssDNA molecules reacted with their cDNA molecules. Theoretically, the enhancement could be as high as more than 200-fold with optimal design of the sequence and under optimal hybridization and optical-detection conditions. The solution with the non-cDNA has no enhancement under the same conditions. Hybridization dynamics of the MB has also been investigated. These experiments clearly show that the MB synthesized is what we have designed and can be used for DNA/RNA studies.

57.3.3 MB Lifetime Measurements

Many studies have been undertaken to effectively design and understand the structure of MBs. In addition, many studies have begun to probe how the MB binds to its target. The biggest question in MB research is the opening/closing mechanism of the probe as well as its specificity toward its DNA/RNA targets. Out of many potentially useful techniques, lifetime measurement is ideal for probing the state of the fluorophore in MBs either in closed or open forms. It helps in understanding the opening/closing mechanism of the molecular beacon. This technique is being used to study MBs and their cDNA interaction as well as MB at high pH and different temperatures in expectation of overall comprehension of MBs.

The frequency-domain lifetime instrument was first studied with rhodamine 6G (R6G). The average lifetime on this instrument was found to be 4.06 nsec. Lifetime measurements were taken on the MB at a pH of 12.5. At this pH, the MB exhibited two lifetimes, with average lifetimes of 4.17 and 1.61 nsec. It

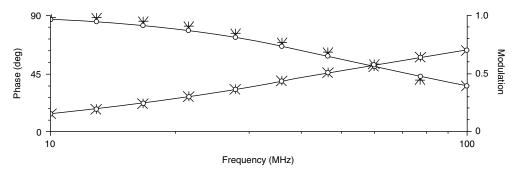

FIGURE 57.5 Lifetime scan of molecular beacon at high pH.

is a well-known fact that DNA can be affected by a change in pH. At high pH, the bases undergo alkaline hydrolysis, causing denaturation, and a low pH would cause the cleavage of bases. In addition, a high pH causes the stem to unwind, opening the MB and restoring fluorescence. The two lifetime values obtained suggest two conformations for the MB at high pH (shown in Figure 57.5) — the open state (unquenched R6G) and the closed state (quenched R6G). Lifetime measurements are difficult to obtained directly for MBs due to the quenching of DABCYL on R6G. Specific measurements must be taken to enhance the signal.

The effects of temperature on lifetime measurements were studied with the MB. The lifetimes at the melting point T_m of the MB were found to be 3.89 and 0.67 nsec. At a high temperature of 85°C, the lifetime of the MB was found to be 4.01 nsec. Studies were also conducted involving MB targets such as cDNA and single-stranded binding protein (SSB) at varying concentration ratios. At a MB-to-cDNA concentration ratio of 1:1, lifetime values of 4.23 and 0.75 nsec were obtained. For the following concentration ratios of 1:4 and 1:8 of MB and cDNA, lifetime values of 3.91 and 3.97 nsec were found, respectively. A lifetime of 3.87 nsec was found for MB binding to SSB in a 1:2 concentration ratio. It is seen that the open and closed forms can be studied using lifetime measurements due to the distance separating the quencher and the fluorophore. Future detailed experiments to obtain precise lifetime values of MB will help determine the overall mechanism of molecular beacons.

57.4 MBs as Fluorescent Probes for DNA/RNA Monitoring

57.4.1 DNA/RNA PCR Detection

57.4.1.1 Real-Time Monitoring of PCR

MB probes are suitable tools for real-time monitoring of DNA/RNA amplification during PCRs.^{2,4} They can be simply added to a sealed PCR tube. The fluorescence signal is monitored at the annealing step of every cycle. At the annealing temperature, the target amplicons' products bind to the MB to generate fluorescence, while the unbound MB remains in the closed form without fluorescence. The MB–amplicon hybrids dissociate at elevated temperatures, where MBs do not interfere with polymerization. The fluorescence signal increases with the increased cycling, and it directly indicates the concentration of the amplicons in the PCR process. The MB assay is fast, sensitive, and nonradioactive. The PCR tubes are sealed during the entire measurement, thereby avoiding carryover contamination. Compared to TaqMan probes, which are another type of fluorescent probe used in PCR monitoring, MBs give more reliable genotyping results, especially in a GC-rich region. Moreover, MBs allow for sensitive and quantitative detection of low-abundance sequence variants over a wider range. For example, *Chlamdophila felis* infection of cats was detected by a MB to identify the major outer-membrane protein gene. The detection limit was fewer than ten genomic copies.¹¹

57.4.1.2 Gene Typing and Mutation Detection for Disease Study and Diagnosis

For the detection of genetic mutations, a method called spectral genotyping has been developed.⁷ The principle involves two different MB probes with different loop sequences: one specific for a wild-type allele and the other for a mutant allele. These two MBs also have two different fluorophores. The fluorescence measured at the two emission wavelengths during amplification indicates whether the samples are homozygous wild type, homozygous mutants, or heterozygote. The MB-based PCR mutation-detection method has been used for the study of many diseases,^{12–19} for example, acquired immunodeficiency syndrome (AIDS). The polymorphisms in the gene for human CC-chemokine receptors CCR5 and CCR2, which are associates of human immunodeficiency virus type 1 (HIV-1), have also been studied.^{12–15} Using MBs researchers are able to investigate the HIV disease mechanism, progression process, and therapeutic effects.

MB-based PCR is also a promising tool for rapid and reliable clinical diagnosis. An example is the method developed to assay four pathogenic retroviruses: HIV-1, HIV-2, and human T-lymphotrophic virus types I and II. The retroviral DNA sequences were amplified by simultaneous PCR reaction, which contained four sets of primers and four MBs, each one being specific for one of the four amplicons and labeled with a different colored fluorophore. The color of the fluorescence generated in the course of amplification identified which retroviruses were present. The number of thermal cycles required for the generation of each color was used to measure the number of copies of each retroviral sequence originally present in the sample. Fewer than ten retroviral genomes were detected. Moreover, ten copies of a rare retrovirus were detected in the presence of 100,000 copies of an abundant retrovirus. There were no false positives for 96 clinical samples. This method will be useful in screening donated blood and transplantable tissue.

It is known that MBs have excellent characteristics for mutation detection. Therefore, sequence analysis of HIV-1 from 74 persons with acute infections identified eight strains with mutations in the reverse transcriptase (RT) gene by real-time nucleic-acid sequence-based amplification assay with molecular beacons.²⁰ The results illustrate that infection with nucleoside-analog-resistant HIV leads to newly infected individuals with mutants that are sensitive to nucleoside analogs, but it is only a single mutation removed from drug-resistant HIV.

MB-based, real-time PCR allele discrimination has been used to detect all three chemokine receptor mutations that are associated with HIV-1 disease.²¹ These spectral genotyping assays were used to genotype 3923 individuals from a globally distributed set of 53 populations. The results showed that CCR2–641 and CCR5–59653T genetic variants were found in almost all populations studied, and their allele frequencies were greatest (similar to 35%) in Africa and Asia but decreased in Northern Europe.

The fast one-tube assay that identifies and distinguishes among all subtypes — A, B, C, and CRFs, AE, and AG — of HIV-1 has been developed by using subtype-specific MBs with multiple fluorophores. The lower detection level of the assay was approximately 10³ copies of HIV-1 RNA per reaction. However, the assay in this format would be unsuitable for clinical use but could possibly be used for epidemiological monitoring as well as vaccine-research studies.²² Meanwhile, all HIV-1 groups, subtypes, and CRFs were detected and quantified with equal efficiency by the addition of molecular beacons to the amplification reaction. The lower level of quantification was 100 copies of HIV-1 RNA with a dynamic range of linear quantification between 10² and 10⁷ RNA molecules.²³

In conclusion, the real-time monitored HIV-I assay is a fast and sensitive assay with a large dynamic range of quantification and is suitable for quantification of most if not all subtypes and groups of HIV-1.

57.4.1.3 Bacteria Detection

Bacteria exist almost everywhere in the world. Scientists have found bacteria in many different environments. The simplest detection method for bacteria is through observation by microscopy. To identify different kinds of bacteria, a fluorescence-strain method associated with PCR has been developed. Last year, MB PCR was demonstrated to show positive results more rapidly than traditional agarose-gel

electrophoresis analysis of PCR products. Use of MBs allows real-time monitoring of PCR reactions, and the closed-tube format allows simultaneous detection and confirmation of target amplicons without the need for agarose-gel electrophoresis or Southern blotting. Therefore, MBs have become a powerful tool for bacteria detection. To accomplish this, the MB that is to hybridize with a target sequence of the bacteria is incorporated into PCRs containing DNA extract from *Escherichia coli* in an artificially contaminated skim milk.²⁴ The bacteria can then be sensitively analyzed.

Based on the molecular beacon, a rapid and simple homogeneous fluorescence-PCR assay was developed for the clinical diagnosis of infectious diseases. This method could reproducibly detect Mycobacterium tuberculosis at the 10 bacteria/mL level with a higher sensitivity than traditional methods. The feasibility of this method was further supported by successful detection of Neisseria gonorrhoeae and Chlamydia trachomatis.25 Another bacteria-analysis method based on MBs was also demonstrated by a real-time PCR assay to detect the presence of E. coli O157:H7.24 MBs were designed to recognize a 26base-pair region of the rfbE gene, encoding for an enzyme necessary for O-antigen biosynthesis. The specificity of the MB-based PCR assay was very high. All E. coli serotype O157 tested were positively identified, while all other species, including the closely related O55, were not detected by the assay. Positive detection of E. coli O157:H7 was demonstrated when >102 colony-forming units (CFU)/ml were present in the samples. The ability of the assay to detect E. coli O157:H7 in raw milk and apple juice was demonstrated. The sensitivity was as few as 1 CFU/ml after 6 h of enrichment. These assays could be carried out entirely in sealed PCR tubes, enabling rapid and semiautomated detection of E. coli O157:H7 in food and environmental samples.²⁶ Further development was proposed on a real-time PCR assay to detect the presence of Salmonella species using MB, which was designed to recognize a 16-base-pair region on the amplicon of a 122-base-pair section of the himA. As few as two colony-forming units per PCR were detected. The high selectivity of MBs made it feasible to detect similar species such as E. coli and Citrobacter freundii in real-time PCR assays.27

57.4.2 mRNA Monitoring inside Living Cells

Obtaining knowledge about subcellular localization and cellular transport pathway of RNAs is of crucial importance for our understanding of basic cell biological and developmental processes. It is also of great interest for the study of functional genomics in the post-genome era. Up till now little has been known about the rate at which RNAs are synthesized and processed as well as their pathways in the cell. *In situ* hybridization (ISH) techniques have been successfully used in the past few decades for the microscopic detection of specific mRNA molecules in fixed and pretreated cells and tissues. However, the fixed cell may not really reflect the situation in living cells. Fixation and cell pretreatment also prevent us from studying the dynamics of RNA synthesis and the transport process when they are actually occurring in the cell. MB-based fluorescence *in vivo* hybridization (FIVH) offers a new way to overcome the limitations of traditional ISH for RNA monitoring.²⁸

MBs have been reported to visualize the bFGF (basic fibroblast growth factor) mRNA in human trabecular cells, 29 β -actin mRNA in K562 human leukemia cells, 30 and PTK2 kangaroo rat kidney cells. 31 Successful application of MB in mRNA detection and localization depends mainly on the following three factors: rational design of a MB probe for the specific mRNA, efficient introduction of the MB probe into the cell, and optimization of the experimental conditions for fluorescence imaging and detection. Choosing an appropriate sequence on the target mRNA that will be most accessible to the MB probe hybridization and choosing a corresponding MB loop and stem that will avoid the secondary structure of the loop sequence are the major concerns in the MB probe design. A computer analysis of the RNA and MB folding structure can be of help for the optimal design. Microinjection and liposome delivery have been used as effective tools for the transfer of the MB probes into living cells while maintaining the physiological and structural integrity of the cells. However, special care must be taken to introduce an appropriate amount of MB to minimize the disturbance of the cell during the delivery process. Another approach is the use of a biosensor format in which MB probes are immobilized on a solid carrier surface

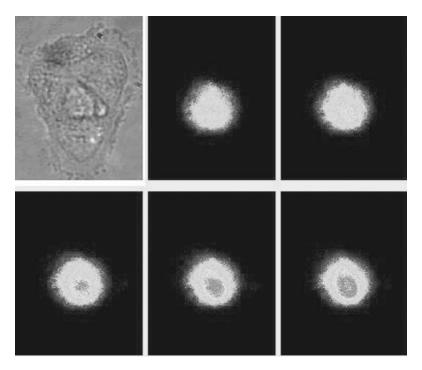

FIGURE 57.6 (Color figure follows p. 28-30.) Hybridization of the MB to mRNA in living cells. Clockwise, from top left: An optical image of the kangaroo rat kidney cell and the fluorescence images of the cell at 3, 6, 9, 12, and 15 min after injection of MB to the PtK2 cell.

(see below). A highly sensitive fluorescence-imaging system is usually used to visualize the MB's hybridization with the target mRNA. Control experiments should also be carried out to preclude any signal originating from the opening of the MB by other possible proteins or nuclease cleavage enzymes in cells.

Coupled with the advanced imaging system, MBs have been used for real-time monitoring of the steady-state levels of specific mRNA molecules in the cytoplasm of cultured PtK2 cells. 31 A series of MBs having variable stem—loop sequences with tetramethylrhodamine (TMR) as a fluorophore and DABCYL as a quencher has been designed to serve as hybridization probes and control probes for the PtK2 cell β -actin mRNA detection. Picoliter amounts of MB solution were directly delivered into the cytoplasm of the cells using an Eppendorf microinjection system. Optical images and fluorescence images before and after the MB injection were taken by fluorescence microscopy equipped with an intensified charged-couple device (ICCD) and an argon ion laser excitation system.

Figure 57.6 shows a set of typical images collected for a MB probe hybridized with the β -actin mRNA in one cell. The fluorescence intensity of the cell continuously increased with the hybridization time for the first 15 min and then remained relatively constant for the next 25 min. To determine if the fluorescence-intensity increase represented hybridization of the MB to the target β -actin mRNA, control experiments were conducted as follows. First, control MBs were injected into different PtK2 cells, and all the cells consistently showed no increase in signal intensity over a period of 15 min. Second, the cDNAs of the control MBs were injected into the same respective cells with their corresponding control MBs, and all the cells showed immediate fluorescence enhancement. This clearly shows that the control MBs remained closed after the first injection due to the lack of their specific targets in the cytoplasm of the PtK2 cells. It is also interesting to note that there was a variation in the MBs' relative fluorescence intensity during the same period of hybridization among different cells. The most likely explanation for this difference between cells is different concentrations of β -actin mRNA presented in the cytoplasm of these individual cells.

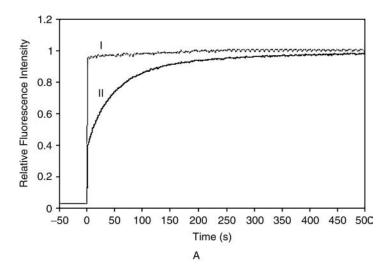

The results presented in cell mRNA monitoring clearly show that at the single-cell level (1) MBs can be used to successfully monitor, in real time, the hybridization to specific mRNA molecules in the cellular environment and (2) the optical imaging system can differentiate between background fluorescence due to incomplete quenching of control MBs and true signal resulting from MBs designed to hybridize to specific targets.

Using fluorescently labeled DNA probes, researchers are able to investigate the expression of human c-fos mRNA in a living transfected Cos7 cell.³² Human c-fos mRNA was observed by detecting a hybrid formed with two fluorescently labeled oligodeoxynucleotides and c-fos mRNA in the cytoplasm. Two fluorescent DNAs were prepared, each labeled with a fluorescence molecule different from the other. The FRET occurred when two DNA strands hybridized to an adjacent sequence on the target mRNA. To find sequences of high accessibility of c-fos RNA to the DNAs, several sites that included loop structures on the simulated secondary structure were selected. Each site was examined for the efficiency of hybridization to c-fos RNA by measuring changes in fluorescence spectra when c-fos RNA was added to the pair of the DNAs in solution. A 40mer-specific site was found, and the pair of DNAs for the site was microinjected into Cos7 cells that expressed c-fos mRNA. Hybridization of the pair of the DNAs to c-fos mRNA in the cytoplasm was detected in fluorescence images, indicating FRET. To block the DNAs from accumulating in the nucleus, the DNA probes were bound to a macromolecule (such as streptavidin) to prevent passage to the nuclear pores.

57.4.3 MBs for Protein Recognition and Protein/DNA Interaction Study 57.4.3.1 Nonspecific Protein-Binding Study

While MB probes were originally designed for nucleic-acid studies, their hairpin structure can also be disturbed to restore fluorescence upon binding to some proteins. The introduction of MBs for protein–DNA interaction studies will be of great interest in understanding many important biological processes and in ultrasensitive protein detection, as proteins play critical roles in many biological processes. This protein-recognition ability was first realized using an *E. coli* SSB.³³ The fluorescence enhancement caused by SSB and by a cDNA target is very comparable (Figure 57.7A). Using MB–SSB binding, it was possible to detect SSB at a concentration as low as 2×10^{-10} mol/l using a conventional spectrometer with a mercury lamp. The interaction between the SSB and MB was found to be much faster than that between the cDNA and MB (Figure 57.7B). The fast speed of the protein–DNA binding reaction will provide the basis for rapid protein assays. In addition, there are significant differences in MB binding affinity with different proteins such as albumin, histone, etc. This will lead to the exploration of the potential for selective binding studies of a variety of proteins using designer MBs.

A MB DNA probe has also been used for detailed binding studies of an enzyme, lactate dehydrogenase (LDH). The fluorescence signal of the MB was increased upon interaction with LDH, which was then used for the elucidation of the binding properties and the study of the binding process. Different LDH isoenzymes were found to have different ssDNA binding affinities. The results showed that the stoichiometry of LDH-5/MB binding was 1:1, and the binding constant was 1.9×10^{-7} mol/l. Detailed studies of LDH/MB binding, such as salt effects, temperature effects, pH effects, binding sites, binding specificity for different isoenzymes, and competitive binding with different substrates were carried out by a simple fluorescent method using the MB probe. The possibility of using MB probes for quantitative protein detection with ultrasensitivity shows great promise in understanding many important biological processes involving two key biomolecules: nucleic acids and proteins. Although only nonspecific DNA-binding proteins have been investigated so far, 33-35 the method opens the possibility for further development of easily obtainable, modified DNA molecules for real-time specific-protein detection. On the other hand, the study of the nonspecific DNA-binding proteins is also very important. One example is the development of an easy and efficient DNA cleavage enzyme assay using MBs³⁵ (see below).

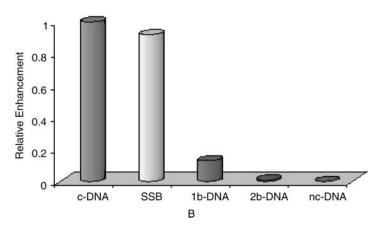

FIGURE 57.7 (A) The relative fluorescence-intensity time scan of the MB binding reaction with cDNA (I) and SSB (II). The molecular mole ratio is cDNA:MB = 1:1, and SSB:MB is also 1:1. cDNA: cDNA; 1b-DNA: one-base mismatched DNA; 2b-DNA: two-base mismatched DNA; nc-DNA: non-cDNA; SSB: single-stranded binding protein. (B) The relative fluorescence enhancement of the molecular beacon DNA probe when hybridized with different DNA molecules and interaction with SSB. The MB used here is 5'-6FAM-GCTCG TCC ATA CCC AAG AAG GAA G CGAGC-DABCYL-3'.

57.4.3.2 Real-Time Enzymatic Cleavage Assay

Traditional methods to assay enzymatic cleavage of ssDNA are discontinuous and time-consuming. The lack of suitable fluorescent probes is an obstacle in the development of fluorescence methods that are continuous and convenient. Based on MB probes, a novel method has been proposed to assay the ssDNA cleavage reaction by single-stranded specific nuclease.³⁵ The single-stranded nuclease binds to and cleaves the single-stranded loop portion of the MB. The cleavage results in the dissociation of the stem because the five to seven base pairs in the stem are unstable at the cleavage temperature (37°C) when the loop is broken. Consequently, the fluorophore and quencher are completely separated from each other, giving rise to an irreversible fluorescence enhancement that is higher than that caused by the MB's cDNA. Figure 57.8 shows that there is good agreement in the nuclease assay between traditional gel electrophoresis and the fluorescence assay based on MBs. The fluorescence method permits real-time monitoring

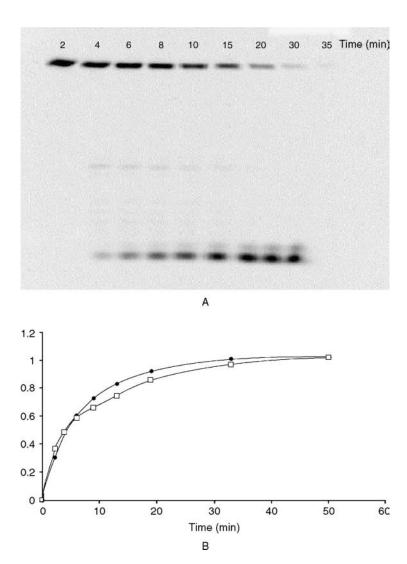

FIGURE 57.8 The comparison between fluorescence assay and gel electrophoresis assay for the cleavage reaction of the molecular beacon by S1 nuclease. In the fluorescence assay, the time course was recorded for the cleavage reaction. In each scheduled time point, a fixed amount of reaction solution was taken out for gel electrophoresis assay. (A) Polyacrylamide-gel electrophoresis assay. The samples were run on denaturing polyacrylamide gel. The upper bands represent the intact MB, and reaction time points (minutes) are labeled above the bands. (B) Comparing the results on MB cleavage percentage obtained by the two assays. The data for fluorescence assay curve (●) was extracted from the reaction time-course curve; the cleavage percentage in electrophoresis assay (□) at each time point was determined by quantifying the fluorescence decrease of the substrate relative to the total fluorescence.

of the enzymatic cleavage-reaction process, easy characterization of the activity of DNA nucleases, and the study of steady-state cleavage-reaction kinetics. Due to their high sensitivity, reproducibility, and convenience, MBs have been used to observe the study of ssDNA cleavage reactions.

Other cleavage experiments were done as well. For example, efforts have focused on developing imaging probes that can be activated to measure specific enzyme activities *in vivo*. Using cathepsin D as a model target protease, Tung et al. synthesized a long-circulating, synthetic graft copolymer bearing near-infrared (NIR) fluorochromes positioned on cleavable substrate sequences.³⁶ In its native state, the reporter probe was essentially nonfluorescent at 700 nm due to energy-resonance transfer among the bound fluorochromes (quenching) but became brightly fluorescent when the latter was released by cathepsin D. Using

matched rodent tumor models implanted into nude mice expressing or lacking the targeted protease, it could be shown that the former generated sufficient NIR signal to be directly detectable and that the signal was significantly different compared with negative control tumors.

Because MBs carry an appropriate cleavage site within the stem, it has been applied to develop the continuous assay for cleavage of DNA by enediynes. The generality of this approach is demonstrated by using the described assay to directly compare the DNA cleavage by naturally occurring enediynes, nonenediyne small-molecule agents, as well as the restriction endonuclease BamHI.³⁷ Meanwhile, MBs were used to quantify low levels of type I endonuclease activity.³⁸ Given the simplicity, speed, and sensitivity of this approach, the described methodology could easily be extended to a high-throughput format and become a new method of choice in modern drug discovery to screen for novel protein-based or small-molecule-derived DNA-cleavage agents.

57.4.3.3 Protein Detection with Specificity

The above nonspecific DNA-binding-protein study opens the possibility for the further development of easily obtainable, modified DNA molecules for real-time specific-protein detection. We have recently developed a new molecular-recognition mechanism by combining the molecular beacon's excellent signal-transduction mechanism with an aptamer's specificity in protein binding for a novel approach to real-time protein detection.³⁹

In most biomedical applications, high-affinity recognition and specific-protein recognition are accomplished by using antibodies. Dye-labeled antibodies are often used to detect specific proteins *in vitro*. Although antibodies are highly specific in molecular recognition, they have limitations. Aptamers are a new class of designer DNA/RNA molecules that compete with the antibody in protein recognition. Aptamers have many advantages over antibodies: easier synthesis, easier labeling, better reproducibility, easier storage, faster tissue penetration, and shorter blood residence. However, an aptamer itself cannot be used as a fluorescent probe because it lacks the signal-transduction capability to report the binding to a target. The new protein probe, which combines the binding specificity and generality of aptamers with the excellent signal-transduction capability of MBs, has great potential in monitoring protein production in living cells.

The feasibility of this approach has been demonstrated by the successful development of a MB aptamer (MBA) probe for a model protein, thrombin. A MBA probe is constructed by engineering a 17mer thrombin-binding aptamer with a fluorophore and a quencher attached at its two ends. Upon binding to the thrombin, the MBA experiences a significant conformational change, from a loose random coil to a compact unimolecular quadruplex in a solution with low salt concentration. The conformational change brought about by the specific binding is converted to a significant fluorescence signal change of the MBA. This signal change is large enough for sensitive thrombin detection with a detection limit in the sub-nM range.

The MBA-thrombin binding is highly specific, both in target specificity and aptamer-sequence specificity. The aptamer's inherent specificity has been retained in the MBA for the thrombin. To achieve better protein quantitation in living cells, a two-fluorophore MBA based on FRET has been developed for ratiometric imaging. Labeled with two fluorophores, such as coumarin and fluorescein, the MBA "lights up" upon thrombin binding. Comparing this to the direct intensity imaging, the ratio imaging gives a much-improved signal-to-background ratio and hence higher sensitivity and better reliability for precise determination of the proteins desired.

The aptamer beacon has become a sensitive tool for detecting proteins and other chemical compounds. For example, Stanton et al. have designed aptamer beacons⁴³ for detecting a wide range of ligands. A fluorescence-quenching pair was used to report changes in conformation induced by ligand binding. An antithrombin aptamer was engineered into an aptamer beacon by adding nucleotides to the 5' end that were complementary to nucleotides at the 3' end of the aptamer. In the absence of thrombin, the added nucleotides formed a duplex with the 3' end, forcing the aptamer beacon into a stem–loop structure. In the presence of thrombin, the aptamer beacon forms the ligand-binding structure. This conformational change causes a change in the distance between the fluorophore attached to the 5' end and a quencher attached to the 3' end.

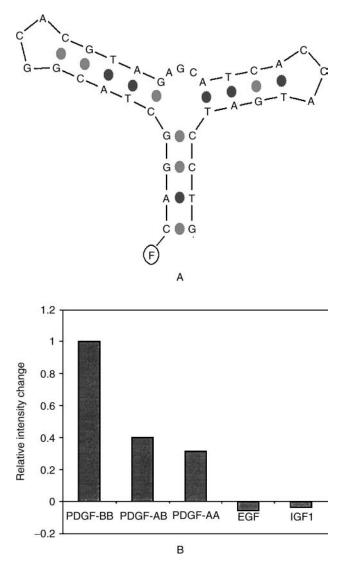

FIGURE 57.9 (A) The structure of the fluorescein (F)-labeled aptamer probe. (B) Binding specificity of the aptamer, comparing the binding capability of the PDGF-B chain (PDGF-B) to other growth factors such as PDGF isomers PDGF-AA and PDGF-AB, epidermal growth factor (EGF), insulin-like growth factor-I (IGF1). The molar ratio of the protein to the aptamer is 1:1.

Aptamer-derived molecular beacons can also be used to analyze the Tat of HIV and the possible applications of such constructs in the field of biosensors.⁴⁴ To make a new MB, two RNA oligomers derived from RNA (Tat) were constructed. In the presence of Tat or its peptides, but not in the presence of other RNA binding proteins, the two oligomers underwent a conformational change to form a duplex that led to the release of fluorophore from the quencher, and thus a significant enhancement of the fluorescence of fluorescein was observed.

Oncoproteins, coded by prooncogene to regulate cell growth and differentiation, play an important role in cancer growth and are often found overexpressed or mutated in malignant tumors. We have designed a new fluorescent probe based on a high-affinity platelet-derived growth factor (PDGF) aptamer (shown in Figure 57.9) for the ultrasensitive detection of oncoprotein PDGF in homogeneous solutions.⁴⁵

The aptamer is labeled with a fluorophore/quencher pair to specifically bind with PDGF. Upon binding, the conformational change of the aptamer results in a FRET-based fluorescence-signal-intensity change of the probe. The aptamer probes are highly sensitive and highly selective. They can detect PDGF in the sub-nM range. Neither the tested extracellular proteins nor other PDGF-related peptide growth factors interfere in the probe binding to PDGF, as shown in Figure 57.9. The new oncoprotein-detection methods are simple and inherit all the advantages of molecular aptamers. They are expected to find wide applications in protein-detection, cancer-diagnosis, and other disease-diagnosis and mechanism studies.

57.5 Combining MB and Biosensor Technology

57.5.1 Surface-Immobilizable MBs

As the common MB can only be used in homogeneous solution, surface-immobilizable MBs are critical for the development of highly sensitive biosensors for *in vivo* detection and for the study of biomolecular recognition processes at an interface. A biotinylated ssDNA MB has thus been designed.⁴⁶ Biotin–avidin binding is one of the most common ways for biomolecule immobilization onto a solid surface and is suitable for DNA hybridization. There are several important considerations regarding the design of biotinylated MB synthesis.⁵ Of them, the position of the biotin is very important and should be carefully chosen to minimize the effect of the avidin–biotin bridge on the MB hybridization. It is desirable to add the biotin functional group at the quencher side in the stem of a MB. A spacer between the biotin and the sequence should be added to provide adequate separation to minimize potential interactions between avidin and the DNA sequence. A photostable dye, such as TMR, should be chosen to minimize photobleaching as only a small amount of fluorophores are immobilized on a surface. To immobilize biotinylated MBs, a silica surface is first physically or covalently coated with avidin.^{46–49} The biotinylated ssDNA MB then binds to avidin. The binding process is fast and stable. The hybridization properties of MBs on the surface are similar to those in solution.

A method was developed for rapid detection of PCR amplicons based on surface-immobilized PNA–DNA hybrid probes that undergo a fluorescent-linked conformational change in the presence of a cDNA target.⁵⁰ Amplicons can be detected by simply adding a PCR to a microtiter-well containing the previously immobilized probe and reading the generated fluorescence. No further transfers or washing steps are involved. The specificity of the method for the detection of ribosomal DNA from *Entamoeba histolytica* was excellent.

57.5.2 Optical-Fiber DNA Biosensors Using Surface-Immobilizable MBs

Immobilized MBs have been used for the preparation of optical-fiber DNA biosensors such as submicrometer biosensors and fiber-optic evanescent-wave biosensors.^{47,48} The evanescent-wave biosensor was prepared by exposing the core surface of an optical fiber to chemical etching. An evanescent wave generated on the core surface was used for fluorescence excitation in the longitudinal surface of the fiber where the MBs were immobilized (Figure 57.10A).

The microscopic optical-fiber probe was fabricated using either pulling or etching technologies. 51–56 MBs were immobilized only at the small tip (submicromenter in diameter) of the probe. A highly sensitive optical imaging and detection system with an avalanche photon diode or an ICCD⁶ was used for the detection of the fluorescence signal from the optical-fiber biosensor. The biosensors were used for the detection of nonlabeled DNA targets in real time and with high sensitivity and one-base-mismatch selectivity. As shown in Figure 57.10B, there was a linear relationship between the initial hybridization reaction rate and the concentration of the cDNA for the submicrometer DNA biosensor. The concentration-detection limit of the target cDNA was 0.3 nM for the ultrasmall DNA biosensor. The sensors are stable and reproducible and have remote detection capability. They can be easily regenerated by a 1-min rinse with a 90% formamide solution. 47 They have been applied to the quantitative detection of

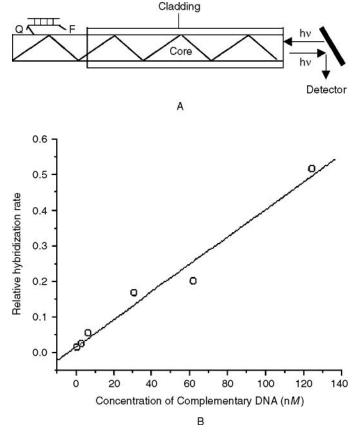

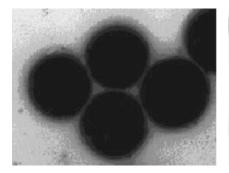

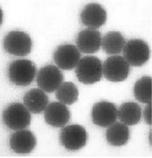

FIGURE 57.10 (A) Configuration of the evanescent-wave fiber-optical DNA biosensor based on MBs. The MBs are excited by the evanescent wave generated at the core surface of the fiber. The returning fluorescence then travels through the same fiber for detection. (B) Application of the DNA biosensor: linear relationship between the hybridization rate and the concentration of the target DNA.

mRNA sequences and to the study of DNA-hybridization kinetics.^{47,48} They hold the potential of direct detection of DNA/RNA targets in living cells without DNA/RNA amplification.

The immobilization method for biotinylated MBs has also enabled the exploration of MB probe arrays for simultaneous multiple-analyte detection.^{49,57} MBs with various loop sequences can be immobilized onto the tips of different microscopic-fiber probes.⁴⁷ Those biosensors are individually addressable with a spatially resolved imaging system based on the ICCD camera.⁶

We have proposed a bridge structure to immobilize the biotinylated MB.⁵⁸ The MB was biotinylated at the quencher side of the stem and linked on a biotinylated glass cover slip through streptavidin, which acted as a bridge between the MB and the glass matrix. An efficient fluorescence-microscope system was constructed to detect the fluorescence change caused by the conformation change of MB in the presence of cDNA target. The proposed biosensor was used to directly detect, in real-time, the target-DNA molecules. The bridge-immobilization method caused the proposed DNA biosensor to have a faster and more stable response. Many efforts were made to develop a more sensitive and stable DNA biosensor. The sol-gel method was shown to be a very efficient approach to immobilize biotinylated MBs.⁵⁹ The sol-gel matrix provided a solid support for the immobilized MB, which can be doped on the surface of many materials. This will widen the application of MB in clinical detection and biotechnology. The potential application of DNA biosensors includes the fabrication of submicrometer optic-fiber probes to detect mRNA inside living cells.⁶⁰

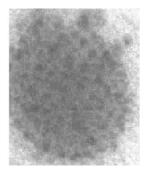

FIGURE 57.11 TEM images of dye-doped silica-coated nanoparticles: (left) 400 ± 10 nm; (center) 63 ± 4 nm; (right) 2 nm. The particles are uniform and have a silica surface for MB immobilization.

57.5.3 Nanoparticle MB Biosensor

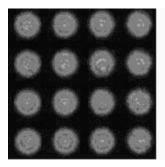

We have prepared MB sensors based on silica nanoparticles.^{61,62} Tens of thousands of uniform nanoparticles have been successfully immobilized with MB. These particles can be attached to the tips of optical fibers for the preparation of a large quantity of fiber probes or introduced into cells as individual sensors. Recently, a gene array has been developed based on the MB using particles and an imaging fiber bundle.⁵⁷ Different MB-coated microspheres are randomly distributed in an array of wells etched in a 500-µm diameter optical imaging fiber bundle. To recognize different DNA targets, an optical encoding scheme and an imaging fluorescence-microscope system were used for positional registration and fluorescence-response monitoring. We have also used nanoparticles for MB biosensor development as shown in Figure 57.11. These nanoparticle-based MB biosensors are highly efficient in hybridization as they have a large surface-to-volume ratio.

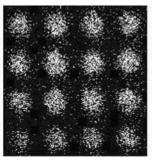

57.5.4 MB Microarray Sensor and Biochip

The multianalyte DNA sensors are expected to provide an easy and fast way for high-throughput gene analysis and disease diagnosis.⁵⁷ A methodology for the implementation of multiplexed nucleic-acid hybridization fluorescence assays on microchannel glass substrates. Fluorescence detection was achieved using conventional low-magnification-microscope objective lenses as imaging optics whose depth-of-field characteristics matched the thickness of the microchannel glass chip. The optical properties of microchannel glass were shown, through experimental results and simulations, to be compatible with the quantitative detection of heterogeneous hybridization events taking place along the microchannel sidewalls, with detection limits for oligonucleotide targets in the low-attomole range.⁶³ A nanoscopic well system for MB biosensors and biochips has also been developed, as shown in Figure 57.12. The system is being used for multiple gene analysis. Overall, a variety of biosensor formats based on MBs have been developed, and their application is just on the horizon.

57.6 Prospects

As the human-genome-sequencing project comes to fruition, there will be a resulting change in the focus of quantitative studies of genomic information from the collecting and archiving of genomic data to their analysis and use in prediction and discovery. The key to this new era is research across many disciplinary interfaces and the development and use of new quantitative tools. MBs are ideally suited for and hold great promise in genomics and proteomics. While there are many possibilities and great potentials, we believe that the following three areas are of greatest interest to the bioanalytical sciences and are feasible in the near future. First, more research is expected for MB application in mutation detection for a variety of disease diagnostics and disease-mechanism studies. Efforts will also be made

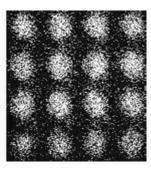

FIGURE 57.12 The microwell array was made by photolithography. A group of consecutive images was taken as the MB hybridization proceeded. A fixed 1-min interval between two images was used. The figure shows that from the beginning to the end of the hybridization experiment more and more MBs hybridize spontaneously to their targets and undergo a conformational change that results in the generation of fluorescence.

in finding suitable mRNA sequences and real-time studies of RNA processing in living cells and other living specimens without using amplification techniques. This will be expedited with the development of MB biosensors and highly sensitive optical-detection methods.^{6,64} Gene expression under different conditions will be studied with precise quantitation. Second, the extraordinarily target-specific capability and the availability of different fluorophore-quencher pairs make MB probes extremely useful for multiple-analyte applications. The detection of many different targets in the same solution can be achieved by the simultaneous use of several MBs, each of which emits light of a different wavelength or which can be excited by light of a different wavelength. These excellent properties also make molecular beacons exquisitely suited for use in the identification of genetic alleles or particular strains of infectious agents. The multiple-MB-probe approach will also be highly useful in combinatorial chemistry for high-throughput-methodology development for drug design and for molecular diagnosis of a variety of genetic diseases, especially with the abundance of genetic information available in the post-genome era. Third, the MB's application as a novel biomolecular recognition agent for proteins will be further explored. With further development, MBs are expected to be useful as intracellular protein-recognition agents to probe proteins in different environments and to monitor protein-DNA/RNA interactions. Preliminary results show significant differences in MB binding affinities by different proteins, which will constitute the basis for highly selective bioassays of a variety of proteins. Approaches to this goal include using designer DNA molecules or aptamer-based⁴⁰ MBs for better specificity and using a large array of MB biosensors for pattern recognition. Better understanding of the conformational kinetics of MBs⁸ and their fluorescence-energy-transfer mechanism^{4,56} will result in optimally designed MB probes for biomolecular recognition with high sensitivity and excellent specificity. All of these developments will open the possibility of using easily obtainable and designer DNA molecules for genomics and proteomics studies, for molecular diagnosis of diseases, and for new drug development.

58.1 Introduction

The development of optical-detection labels has substantially impacted many areas of biomedical research such as high-throughput drug screening, clinical diagnostics, and *in vivo* monitoring of gene expression and enzyme activity.^{1,2} These probes are traditionally based on organic dyes conjugated to biomolecules.³ Because of their complex molecular structures, however, organic fluorophores often exhibit unfavorable absorption and emission properties such as photobleaching, environmental quenching, broad and asymmetric emission spectra, and the inability to excite more than two to three colors at a single wavelength. These problems can be overcome by exploiting the unique optical properties of metal and semiconductor nanoparticles. In fact, recent research by several groups has linked such nanoparticles to peptides,⁴ proteins,^{5–7} and DNA^{8–13} and has demonstrated their applications in assembling new materials,¹⁴ in homogeneous bioassays,^{12–15} and in multicolor fluorescence imaging and detection.^{5–10}

Semiconductor nanocrystals, also known as quantum dots, are composed of atoms from group I-VII, II-VI, or III-V elements and are defined as particles with physical dimensions smaller than the exciton Bohr radius. ^{16,17} For spherical CdSe particles, this occurs when the particle diameter is less than ~10 nm. This quantum-confinement effect gives rise to unique optical and electronic properties that are unavailable in either discrete atoms or in bulk solids. In the last 20 years, significant progress has led to the synthesis of high-quality nanocrystals in large quantities. Prior to 1993, attempts to synthesize quantum dots were conducted in aqueous buffers with added stabilizing agents (e.g., thioglycerol or polyphosphate) or in micelles. ^{18–22} These procedures yielded quantum dots with low quantum yields (< 20%) and broad size distributions (relative standard deviation or RSD > 15%). In 1993, Bawendi et al. synthesized highly luminescent quantum dots by using a high-temperature organometallic procedure. ²³ This method was later improved by three independent research groups. ^{24–26} These nanocrystals have nearly perfect crystal structures, 30 to 50% quantum yields, and a narrow size range (RSD < 5%). In 1998, Nie, Alivisatos, and their co-workers pioneered the use of these quantum dots as biological labels. ^{5,6}

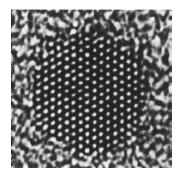

FIGURE 58.1 High-resolution transmission-electron micrograph of a hexagonally shaped CdSe quantum dot. Note the highly crystalline, ordered layers (rows) of alternating Cd and Se atoms. (Adapted from Alivisatos, A.P., *Science*, 271, 933, 1996.)

This chapter discusses the biological applications of semiconductor nanocrystals. The main sections deal with quantum-dot synthesis, quantum-confinement and optical properties, surface chemistry, and bioconjugation. We conclude with a brief discussion of future challenges and prospects.

58.2 Synthesis

Both group II-VI (e.g., CdSe, CdTe, CdS, and ZnSe) and group III-V (e.g., InP and InAs) nanocrystals have been synthesized and characterized.²⁷⁻³⁵ In particular, CdSe quantum dots are highly luminescent and have been extensively studied.^{23–26} Figure 58.1 shows a high-resolution transmission electron microscopy (TEM) image of a single CdSe quantum dot. Group II-VI nanocrystals can be prepared in either aqueous or organic media. Two aqueous methods have been developed. In the first method, stock solutions consisting of cadmium and sulfur precursors are directly injected into a hot aqueous solution (containing stabilizing agents and micelles).¹⁸⁻²² Nucleation of nanocrystals occurs within 5 min, as observed by a change in the solution color. Solvent additives (e.g., stabilizing agents and ions) and environmental factors (e.g., pH and temperature) are used to control the nanocrystal size. This method is simple and does not require specialized equipment, but the resulting nanocrystals have broad emission spectra (~50 nm full width at half maximum [FWHM]) and low quantum yields (<10%). In the second method, nanocrystals are grown in yeast cells such as Candida glabrata or Schizosaccharomyces pombe.36-38 When cultured in the presence of cadmium or zinc ions, yeasts express proteins with the general structure of (γ-Glu-Cys)_n-Gly. Thiol and carboxylic groups from amino-acid residuals bind to the metal ions and induce nucleation. Further addition of cadmium or zinc ions results in the growth of nanoparticles. These nanocrystals have optical properties similar to those synthesized by the first method.

Improved schemes to synthesize nanocrystals have been developed by several groups. ^{23–26} In one approach, organometallic and chalcogenide compounds are dissolved in tri-*n*-butyl phosphine or tri-*n*-octyl phosphine (TOP), which are injected into a hot coordinating solvent (e.g., tri-*n*-octylphosphine oxide or TOPO) at 340 to 360°C. Rapid nucleation is observed by changes in the reaction mixture's color. A (4,4)-coordination crystal lattice is formed, and the nanoparticles have a Wurtzite-type structure. With this procedure, technical-grade (90 to 92% purity) TOPO is preferred, but the role of impurities such as alkyl phosphonics and alkylphosphonic acids is still unclear. Peng et al. recently used phosphonic or fatty-acid additives in pure TOPO to synthesize high-quality CdS, CdSe, and CdTe nanocrystals. ^{39,40} The results indicate that CdO and Cd(CH₃COO)₂ can be used to replace dimethylcadmium, an expensive organometallic compound. By using organic solvents to synthesize quantum dots, the surfactant molecules TOPO and TOP reside on the particle's surface and act to stabilize the nanocrystals against aggregation. Due to the nonpolar nature of TOPO and TOP, the resulting nanocrystals are soluble in organic solvents such as chloroform and hexane.

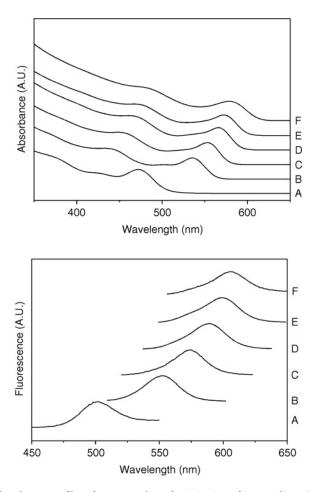

FIGURE 58.2 (Top) Absorbance profiles of quantum dots after injection of 3 mL Cd(CH₃)₂/Se stock solution (time = 0 min) (A), grown for 5 min (B), and after successive injection of Cd(CH₃)₂/Se stock solution (C–F). (Bottom) Fluorescence profiles of quantum dots after injection of Cd(CH₃)₂/Se stock solution (time = 0 min) (A), grown for 5 min (B), and after successive injection of Cd(CH₃)₂/Se stock solution (C–F). (From W.C.W. Chan and S.M. Nie, unpublished data.)

Both the nanocrystal size and shape can be changed by manipulating the kinetics of particle growth. Recently, Peng et al. developed a novel method to control the shape of CdSe nanoclusters.^{41,42} Wurtzite-type particles grow in an anisotropic fashion in which growth is favored along the *c*-axis. Manipulation of solvent conditions (e.g., addition of hexyl-phosphonic acid and tetradecylphosphonic acid in pure TOPO) alters the growth rates, leading to the formation and isolation of nanoparticles with discrete aspect ratios (1:1 to 1:30). The size of nanocrystals can be controlled by several procedures. For example, nucleated CdSe quantum dots can be grown at high temperatures (300°C or higher) for an extended period of time (ranging from 2 min to 2 weeks, depending on the desired particle size).⁴³ In this process (also known as Ostwald ripening), smaller nanocrystals are broken down, and the dissolved atoms are transferred to larger crystals. The rate of this "ripening" process depends on both the temperature and the amount of the limiting reagent.^{44,45}

Continuous injection of precursor solutions into the CdSe reaction mixture (in TOPO) at 300°C also produces larger nanocrystals. Figure 58.2 shows the absorption and fluorescence spectra of CdSe quantum dots after successive injections. As the size of nanocrystals increases, there is a shift in the absorbance and fluorescence emission to the red. The fluorescence shift from 500 to 550 nm shows crystal growth

FIGURE 58.3 (Color figure follows p. 28-30.) Ten distinguishable emission colors of ZnS-capped CdSe quantum dots excited with a near-UV lamp. From left to right (blue to red), the emission maxima are located at 443, 473, 481, 500, 518, 543, 565, 587, 610, and 655 nm. (Adapted from Han, M.Y. et al., *Nat. Biotechnol.*, 19, 631, 2001. With permission.)

at 300°C for 5 min before the addition of excess precursors. After repeated injections of 1 ml $Cd(CH_3)_2/2$ Se stock solution, the fluorescence-emission peak shifts from 550 to 575, 590, 600, and 610 nm.⁴⁶ Smaller nanocrystals, with fluorescence-emission peaks at 530 nm or less, can be synthesized by slowing the Ostwald ripening process. This is achieved by rapidly decreasing the temperature after initial injection of the $Cd(CH_3)_3/Se$ stock solution to prevent formation of large nanocrystals.

The quantum yields of these CdSe nanocrystals are usually 2 to 15% but can be dramatically increased by capping the dots with an inorganic layer such as ZnS or CdS. Zinc sulfide has a wider bandgap than that of CdSe (0.9 eV greater),⁴⁷ but the Zn–S bond length is similar to that of Cd–Se (~12% larger).²⁶ These conditions allow the deposition of a thin ZnS layer on the CdSe core by epitaxial growth.^{24–26} In practice, the Zn(CH₃)₂/S solution is added slowly in small aliquots to the CdSe/TOPO solution to prevent ZnS nucleation. The quantum yields of the capped CdSe nanocrystals are typically about 30 to 50% and have been reported to be as high as 85% at room temperature.²⁵ Figure 58.3 depicts a set of different-sized ZnS-capped CdSe quantum dots excited with a hand-held ultraviolet (UV) lamp.

The observed increase in quantum yields can be attributed to the removal of shallow trap states on the surface of quantum dots. These states are defined as discrete electronic energy levels arising from structural defects. For CdSe nanocrystals these defects are mainly located on the surface, where the bonding geometries of chalcogenide atoms are different than those in the interior. These shallow traps lead to a broad emission peak at 700 to 800 nm. At the ZnS layer becomes thicker, the quantum efficiency increases to \sim 50% and then levels off. Several groups have determined that the optimal capping thickness is about one to two monolayers of ZnS. At the ZnS layer becomes thicker, the quantum thickness is about one to two monolayers of ZnS.

Group III-V nanocrystals can also be prepared by using the TOPO/TOP solvent system. To synthesize InP, a dehalosilylation reaction occurs when $InCl_3$ and $P(Si(CH_3)_3)$ are injected into a TOPO/TOP solution at 240 to 265°C. The size distribution of the InP nanoparticles is narrowed by size-selective precipitation. InP nanocrystals in the size range of 2.5 to 6.0 nm are isolated with a relative standard deviation of 10 to 15%. ^{28–30} Similar procedures have been used to prepare InAs nanocrystals. ⁵⁰

58.3 Optical Properties

The optical properties of semicondutor nanoclusters stem from interactions between electrons, holes, and their local environments. Semiconductor quantum dots absorb photons when the energy of excitation exceeds the bandgap energy. During this process, electrons are promoted from the valence band to the conduction band. Measurements of UV–visible spectra reveal a large number of energy states in quantum dots. The lowest excited energy state is shown by the first observable peak (also known as the quantum-confinement

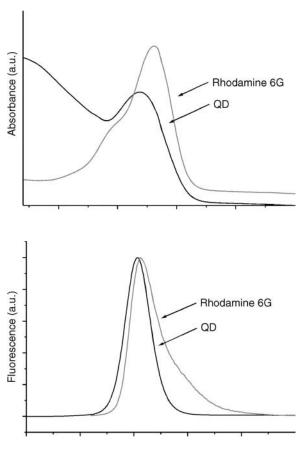

FIGURE 58.4 Comparison of the excitation (top) and emission (bottom) profiles between rhodamine 6G and CdSe quantum dots. (From Chan, W.C.W., Ph.D. thesis, Department of Chemistry, Indiana University, Bloomington, 2001. With permission.)

peak) at a shorter wavelength than the fluorescence-emission peak. Excitation at shorter wavelengths is possible because multiple electronic states are present at higher energy levels. In fact, the molar-extinction coefficient gradually increases toward shorter wavelengths (Figure 58.4).^{24–26} This is an important feature for biological applications because it allows simultaneous excitation of multicolor quantum dots with a single light source.^{5,6}

Light emission arises from the recombination of mobile or trapped charge carriers. The emission from mobile carriers is called excitonic fluorescence and is observed as a sharp peak. The emission spectra of single ZnS-capped CdSe quantum dots are as narrow as 13 nm (FWHM) at room temperature. Defect states in the crystal interior or on its surface can trap the mobile charge carriers (electrons or holes), leading to a broad emission peak that is red-shifted from the excitonic peak. Nanocrystals with a large number of trap states generally have low quantum yields, but surface capping or passivation can remove these defect sites and improve the fluorescence quantum yields (as discussed in the previous section).

The excited-state lifetimes of nanocrystals have three exponential components. In bulk measurements, the lifetimes are 5 nsec, 20 to 30 nsec, and 80 to 200 nsec, with the 20- to 30-nsec lifetime dominating. 51,52 These excited-state decay rates are slightly slower than those of organic dyes (1 to 5 nsec) but much faster than those of lanthanide probes (1 μ sec to 1 μ sec). Single-dot measurement further reveals that the excited-state lifetimes depend on the emission intensity, but the exact origins of this multiexponential behavior remain unclear. 51

The excitonic fluorescence depends on the nanocrystal size. Research by several groups has demonstrated a linear relationship between the particle size and the bandgap energy.^{24,43} This quantum-size

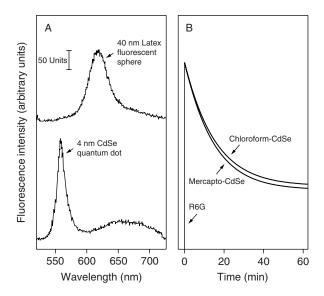

FIGURE 58.5 Comparison of photophysical properties between luminescent quantum dots and organic dyes. (A) Wavelength-resolved spectra obtained from a single 40-nm fluorescent latex sphere and a single mercapto-quantum dot. The broad emission peak around 660 nm is believed to arise from surface defects on the quantum dot. (B) Time-resolved photobleaching curves for the original quantum dots, the solubilized quantum dots, and the dye rhodamine 6G. (From Chan, W.C.W. and Nie, S.M., Science, 281, 2016, 1998. With permission.)

effect is similar to that observed for a "particle in a box." Outside of the box, the potential energy is considered to be infinitely high. Thus, mobile carriers (similar to the particle) are confined within the dimensions of the nanocrystal (similar to the box) with discrete wave functions and energy levels. As the physical dimensions of the box become smaller, the bandgap energy becomes higher. For CdSe nanocrystals, the sizes of 2.5 and 5.5 nm correspond to fluorescence emission at 500 and 620 nm, respectively. In addition to size, the emission wavelength can be varied by changing the semiconductor material. For example, InP and InAs quantum dots usually emit in the far-red and near-infrared, while CdS and ZnSe dots often emit in the blue or near-UV. It is also interesting to note that elongated quantum dots (called quantum rods) show linearly polarized emission, whereas the fluorescence emission from spherical CdSe dots is circularly polarized or not polarized.

In comparison with organic dyes such as rhodamine 6G and fluorescein, CdSe nanocrystals show similar or slightly lower quantum yields at room temperature. The lower quantum yields of nanocrystals are compensated by their larger absorption cross sections and much-reduced photobleaching rates. Bawendi et al.^{23,24} estimated that the molar-extinction coefficients of CdSe quantum dots are about 10⁵ to 10⁶ M⁻¹ cm⁻¹, depending on the particle size and the excitation wavelength. These values are 10 to 100 times larger than those of organic dyes but similar to the absorption cross sections of phycoerytherin, a multichromophore fluorescent protein. Chan and Nie⁶ estimated that single ZnS-capped CdSe quantum dots are ~20 times brighter than single rhodamine 6G molecules. Similarly, phycoerytherin is estimated to be 20 times brighter than fluorescein.⁵⁷

Another attractive feature of using quantum dots as biological labels is their high photostability. Gerion et al. examined the photobleaching rate of silica-coated ZnS-capped CdSe quantum dots against that of rhodamine 6G.⁵⁸ The quantum-dot emission stayed constant for 4 h, while rhodamine 6G was photobleached after only 10 min. It has been suggested that capped CdSe nanocrystals are 100 to 200 times more stable than organic dyes and fluorescent proteins (Figure 58.5).⁶ Under intense UV excitation, single phycoerytherin molecules were found to photobleach after 70 sec, while the fluorescence emission of quantum dots remained unchanged after 600 sec.⁴⁶ The photobleaching of quantum dots is believed to arise from a slow process of photo-induced chemical decomposition. Henglein et al. speculated that CdS

decomposition was initiated by the formation of S or SH radicals upon optical excitation.^{59,60} These radicals can react with O₂ from the air to form a SO₂ complex, resulting in slow particle degradation.

Single quantum dots have been shown to emit photons in an intermittent on–off fashion,^{61,62} like a "blinking" behavior reported for single fluorescent dye molecules, proteins, polymers, and metal nanoparticles.^{63–66} The fluorescence of single quantum dots turns on and off at a rate that depends on the excitation power. This phenomenon has been suggested to arise from a light-induced process involving photoionization and slow charge neutralization of the nanocrystal.⁶¹ When two or more electron–hole pairs are generated in a single nanocrystal, the energy released from the combination of one pair could be transferred to the remaining carriers, one of which is preferentially ejected into the surrounding matrix. Subsequent photogenerated electron–hole pairs transfer their energy to the resident, unpaired carrier, leading to nonradiative delay and dark periods. The luminescence is restored only when the ejected carrier returns to neutralize the particle. Banin et al. believe that thermal trapping of electrons and holes is also a contributing factor because they observed a dependence of the blinking rate on temperature.⁶⁷ A further finding is that single dots exhibit random fluctuations in emission wavelength (spectral wandering) over time.^{62,68} This effect is attributed to interactions between excitons with optically induced surface changes.

58.4 Surface Chemistry

Colloidal-metal nanoparticles have found widespread use in biology and medicine in the last 20 years, but semiconductor nanocrystals have only recently been used for biological labeling.^{5,6} The reason is that high-quality quantum dots are often protected with hydrophobic ligands and are not compatible with biomolecules. Murphy et al.^{69,70} were the first to demonstrate the use of semiconductor nanoparticles as biosensors in which oligonucleotide molecules were detected by nonspecific interactions with the nanocrystal surface. For other applications, there is a great need to develop simple methods for conjugating biomolecules to quantum dots. TOPO-synthesized nanocrystals are preferred over aqueous-synthesized dots due to their superior optical properties. The surface chemistry is a key factor in determining quantum-dot solubility, biocompatibility, and molecular conjugation.

The complex surface of nanocrystals has been studied by nuclear magnetic resonance (NMR) and x-ray photoelectron spectroscopy (XPS).^{71,72} Morphologically, quantum dots are not smooth spherical particles but faceted with many planes and edges. They are generally considered to be negatively charged because of molecules adsorbed on the surface.⁷³ TOPO strongly coordinates to the surface metal atoms, while TOP or TBP is weakly bound and can easily desorb. The surface properties (such as TOPO molecules interacting with each other and their dimerization at the phosphine oxide end)⁷⁴ improve the long-term solubility of quantum dots in organic solvents.

Two methods have been developed to prepare water-soluble quantum dots. Alivisatos et al.⁵ reported the use of a silica/siloxane coating for creating water-soluble ZnS-capped CdSe quantum dots. In this procedure, 3-(mercaptopropyl)trimethoxysilane (MPS) is directly adsorbed onto the nanocrystals in which TOPO-molecules are displaced. A silica/siloxane shell is formed on the surface by introduction of a base and hydrolysis of the silanol-groups (from MPS). Polymerizing silanol groups helps stabilize the nanocrystals against flocculation. The quantum dots become soluble in intermediate polar solvents such as methanol and dimethyl sulfoxide. Further reaction with bifunctional methoxy compounds, such as aminopropyl trimethoxysilane or trimethoxysilyl propyl urea, renders the particles soluble in aqueous buffer. The second method involves direct adsorption of bifunctional ligands such as mercaptoacetic acid or dithiothrietol to the quantum-dot surface.⁶ Here, a mercapto compound and an organic base are added together to TOPO quantum dots dissolved in chloroform. The base deprotonates both the thiol and the carboxylic groups, leading to favorable electrostatic binding between negatively charged sulfur atoms and surface Cd²⁺ or Zn²⁺ ions. The semiconductor quantum dots precipitate out of the solution but can be redissolved in an aqueous solution (pH > 5).

Polymerized siloxane-coated quantum dots are highly stable against flocculation, but only small amounts (in the milligram range) can be prepared per batch. Also, residual silanol groups on the

nanocrystal surface often lead to precipitation and gel formation at neutral pH. In comparison, the direct adsorption procedure yields gram-size quantities of water-soluble dots, but the mercapto ligands are not completely stable. Slow desorption of mercaptoacetic-acid molecules often results in aggregation and precipitation of the solubilized quantum dots. The stability of the mercapto-derivatized dots depends on the density of mercapto molecules on the surface, its size, and the number of thiol functional groups per mercapto molecule. When solubilized with mercaptoacetic acid, the quantum dots are stable for 3 to 7 d in neutral phosphate buffered saline (PBS) buffer. Conjugation of complex proteins onto the surface further stabilizes the particles, making them stable for 3 months to 1 year (depending on the protein).

It should be noted that the quantum efficiencies of ZnS-capped CdSe nanocrystals are generally lower in water than in chloroform. The highest quantum yield reported for water-soluble quantum dots is ca. 20 to 30%. Traditionally, it has been held that capping a second semiconductor layer protects and isolates the core from the outside environment. Recent research in our group indicates that the ZnS layer is not uniform and that surface-adsorbed molecules can still influence the properties of the nanocrystal core. In fact, both large and small molecules, such as polymers, proteins, and ions, have been found to influence the optical properties of ZnS-capped CdSe quantum dots.

58.5 Bioconjugation

For specific biomolecular binding or recognition, it is important to develop stable and functional quantum-dot bioconjugates. Reactive functional groups that can be placed on the nanocrystal surface include primary amines, carboxylic acids, alcohols, and thiols. Primary amines react with carboxylic acids, catalyzed with a carbodiimide or sulfo *N*-hydroxysuccinimide ester, to form a stable amide bond. A thioether bond is formed when sulfhydryl groups react with maleimides. Other methods for linking fluorescent labels to biomolecules are described in a book by Hermanson.⁷⁵ Another approach to linking biomolecules to nanocrystals is to use a thiol-exchange reaction. Here, mercapto-coated quantum dots (by direct adsorption) are mixed with thiolated biomolecules (such as oligonucleotides and proteins).^{8,76} After overnight incubation at room temperature, a chemical equilibrium is reached between the adsorbed thiols and the free thiols. A similar approach has recently been used by Bawendi et al.⁷ in which engineered proteins with a linear polylysine chain are directly adsorbed onto negatively charge nanocrystals through electrostatic interactions. Figure 58.6 shows a number of common bioconjugation methods.

The surface area of quantum dots is large enough for linking to multiple biomolecules. Two to five protein molecules and 50 or more small molecules (such as oligonucleotides and peptides) may be conjugated to a single 4-nm dot.⁷⁵ We envision multifunctional or smart nanostructures being developed by conjugating both DNA and proteins to quantum dots. The attached proteins or peptides could guide the nanoparticles to specific cells (e.g., cancer cells) or to specific locations inside a cell where messenger RNA molecules are detected.

A number of applications have been demonstrated for quantum dots including DNA hybridization, immunoassays, and receptor-mediated endocytosis (Figure 58.7). In addition, Weiss et al.^{77,78} showed the ability to measure distances between ZnS-capped CdSe quantum dots and fluorescent beads beyond the diffraction limit. Lifetime measurement was also used for time-gated fluorescence imaging of tissue sections.⁵² The background fluorescence lifetimes are similar to those of organic dyes and thus interfere with the target signals. For lanthanide-chelating probes, the excited-state lifetimes are very long, but their quantum efficiencies are relatively low.^{79,80} In contrast, semiconductor nanocrystals have excellent emission efficiencies and relatively long decay times, both of which are attractive features for imaging tissue sections.

Quantum dots for mulitplexed optical encoding of biomolecules have recently been demonstrated by Han et al.⁸¹ Polystyrene beads are embedded multicolor CdSe quantum dots at various color and intensity combinations (Figure 58.8). The use of six colors and ten intensity levels can theoretically encode one million protein or nucleic-acid sequences. Specific capturing molecules, such as peptides, proteins, and oligonucleotides, are covalently linked to the beads and encoded by the bead's spectroscopic signature. A single light source is sufficient for reading all the quantum-dot-encoded beads. To determine whether

an unknown analyte is captured or not, conventional assay methodologies (similar to direct or sandwich immunoassay) can be applied. This so-called "bar-coding technology" can be used for gene profiling and high-throughput drug and disease screening.

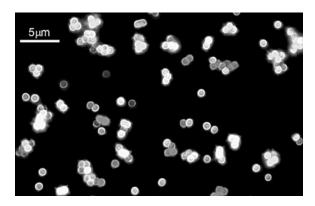

FIGURE 58.8 (Color figure follows p. 28-30.) Fluorescence micrograph of a mixture of CdSe/ZnS QD-tagged beads emitting single-color signals at 484, 508, 547, 575, and 611 nm. The beads were spread and immobilized on a polylysine-coated glass slide, which caused a slight clustering effect. (From Han, M.Y. et al., *Nat. Biotechnol.*, 19, 631, 2001. With permission.)

58.6 Conclusion

A pervasive trend in biotechnology is the development of multiplexed sensing and ultrasensitive imaging technologies for the rapid molecular profiling of cells, tissues, and organs. The ability to quickly screen a large number of genes and proteins is important to both drug discovery and medical diagnostics. In the next 10 years, we envision novel platforms based on multicolor quantum dots being developed for massively parallel biosensing and analytical detection. These multiplexing technologies will likely combine the advantages of quantum dots with those of microfluidics and microarrays. In addition, noninvasive molecular-imaging technologies could be developed by using luminescent quantum dots. This should allow viral particles to be followed *in vivo*, drug molecules to be analyzed in biological systems, and tumor cells to be tracked in real time.⁸²

59.1 Introduction

In medical and biochemical research, when a sample domain is reduced to micrometer regimes, e.g., living cells or their subcompartments, the real-time measurement of chemical and physical parameters with high spatial resolution and negligible perturbation of the sample becomes extremely challenging. A traditional strength of chemical sensors (optical, electrochemical, etc.) is the minimization of chemical interference between sensor and sample, achieved with the use of inert, "biofriendly" matrices or interfaces. However, when it comes to penetrating individual live cells, even the introduction of a submicron sensor tip can cause biological damage and resultant biochemical consequences. In contrast, individual molecular probes (free-sensing dyes) are physically small enough but usually suffer from chemical interference between probe and cellular components. Our recently developed PEBBLE sensors (probes encapsulated by biologically localized embedding) are nanoscale spherical devices consisting of sensor molecules entrapped in a chemically inert matrix. This protective coating eliminates interferences such as protein binding and membrane/organelle sequestration, which alter dye response. Conversely, the nanosensor matrix also provides protection to the cellular contents, enabling dyes that would usually be toxic to cells to be used for intracellular sensing. In addition, the inclusion of reference dyes allows quantitative, ratiometric fluorescence techniques to be used. Furthermore, the matrix phase allows the implementation of synergistic sensing schemes. PEBBLEs have been used to measure analytes such as calcium, potassium, nitric oxide, oxygen, chloride, sodium, and glucose.

PEBBLE nanosensors (see Figure 59.1) are submicron-sized optical sensors designed specifically for minimally invasive analyte monitoring in viable, single cells with applications for real-time analysis of drug, toxin, and environmental effects on cell function. PEBBLE is a general term that describes a family

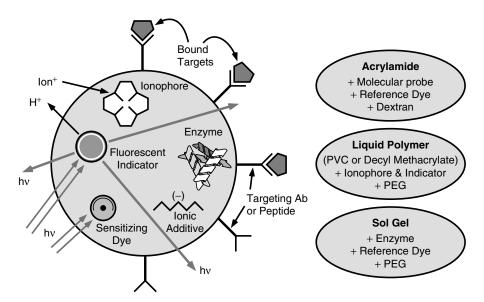

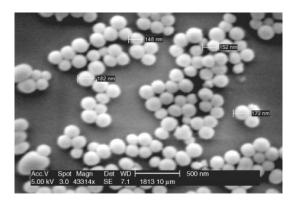

FIGURE 59.1 Schematic diagram of a PEBBLE nanosensor showing many options available within this flexible, integrated device platform. On the right, current matrix materials are presented with typical constituents.

of matrices and nanofabrication techniques used to miniaturize many existing optode technologies. The main classes of PEBBLE nanosensors are based on matrices of polyacrylamide hydrogel, sol-gel silica, and cross-linked decyl methacrylate. These matrices have been used to fabricate sensors for H⁺, Ca²⁺, K⁺, Na⁺, Mg²⁺, Zn²⁺, Cl⁻, NO₂⁻, O₂, NO, and glucose that range from 30 to 600 nm in size. A host of delivery techniques have been used to successfully deliver PEBBLE nanosensors into mouse oocytes, rat alveolar macrophages, rat C6 glioma, and human neuroblastoma cells.

PEBBLEs were developed specifically for biological applications and fill a niche that lies between pulled microoptodes and free molecular probes (naked indicator-dye molecules). The strength of the PEBBLE concept lies in two related but distinct roles. First and foremost, the PEBBLE protects the cell from the toxicity inherent in some free molecular dyes and at the same time protects indicator dyes from cellular interferents such as protein binding. The second role, which is possible because the PEBBLE matrix creates a separate sensing phase distinct from the cellular environment, is that multiple dyes, ionophores, and other components can be combined to create complex sensing schemes. These schemes can include reference dyes to allow ratiometric imaging or ionophore/chromoionophore combinations that allow the use of highly selective, nonfluorescent ionophores. Both the protection and the powerful sensing flexibility come in a nanopackage, which, in terms of minimal mechanical and physical perturbation, is closer to "free molecular dyes" than most other sensing platforms. However, the nanosensor preserves the excellent chemical sensing and biocompatibility of macrosensors and surpasses their performance in terms of response time and absolute detection limit.

PEBBLEs are a direct outgrowth of the pulled optical-fiber nanotechnology developed for biosensing by Tan et al.^{1,2} and continuing in the work of Rosenzweig,^{3,4} Shortreed,^{5,6} and Barker.^{7,8} In their study, Dourado and Kopelman formalized the specific advantages of having nano-scale dimension sensors.⁹ In most instances, there is an explicit functional dependence of optode characteristics on the sensor radius r. For instance, the absolute detection limit decreases with r^3 (good!) and the response time is reduced as r^2 (good!). The signal-to-noise ratio, though, decreases with r (bad!) but not r^3 (luckily!) under standard working conditions. Other features that improve, as sensors get smaller, include sample volume, sensitivity, invasiveness, spatial resolution, dissipation of heat in sensor or sample, toxicity, and materials cost. Features that may worsen include fluorophore leaching and photodamage to sensor and sample.

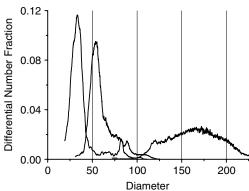

FIGURE 59.2 Left: Typical scanning electron microscope (SEM) image of sol-gel PEBBLEs. Note the 500-nm scale bar in the image legend used to determine ~160-nm average particle size. Right: Light-scattering results for (left to right) one polyacrylamide and two different sol-gel PEBBLE formulations.

59.2 Practical Concept Examples

It is useful to point out concrete examples of the features discussed above before delving into the details of PEBBLE production and application. All PEBBLEs must be well characterized before use, including such measures as nanoparticle size and response calibration. Other essential metrics include tests for constituent leaching, ratiometric stability, response time, and sensitivity to interference from similar analytes and nonspecific protein binding.

59.2.1 Ratiometric Sol-Gel Oxygen Sensor: Size, Signal, and Calibration

Depending on the size and matrix material, transmission electron microscropy (TEM), scanning electron microscopy (SEM), and light-scattering measurements are used for PEBBLE-size characterization. The sol-gel, hybrid organic/inorganic silica matrix is typically produced in the 50- to 200-nm size range, as shown by Figure 59.2.

These sol-gel PEBBLEs contain a ruthenium-based dye, $[Ru(dpp)_3]^{2+}$, that has an intensity decrease due to excited state quenching in the presence of molecular oxygen. As a spectrally separated intensity reference, the PEBBLEs also include Oregon Green-488 $^{\circ}$ (Molecular Probes, Eugene, OR), which is insensitive to changes in local oxygen concentrations. Figure 59.3 shows spectra of these PEBBLEs in aqueous solution, in the presence of varying concentrations of oxygen. It is very clear that the Oregon Green reference peak, on the left, remains constant, while the ruthenium peak, on the right, changes in intensity. Also shown (right) is the Stern-Volmer (calibration) plot of fluorescence-intensity ratio vs. oxygen concentration. Although the performance of the sol-gel PEBBLEs is slightly reduced in the aqueous phase as opposed to the gas phase, the sensors still demonstrate good reversibility and reproducibility. The dashed line in Figure 59.3 (right) shows the extent of the biologically relevant oxygen concentrations. The sensors showed at least 95% recovery each time the sensing environments were changed among air-, O_2 -, or N_2 -saturated sensor solutions.

59.2.2 Ratiometric Zinc PEBBLE Insensitive to Protein Interference

Here, the polyacrylamide (PAA) zinc sensor, based on Newport Green® (Molecular Probes), a zinc-sensitive dye, and Texas Red® (Molecular Probes), a spectrally distinct intensity reference, shows the advantages of PEBBLEs. Quantitative measurements show these sensors to be insensitive to changes in excitation intensity as well as providing protection from nonspecific protein interference. Although Newport Green has good selectivity over intracellular ions, the dye itself is prone to artifacts resulting

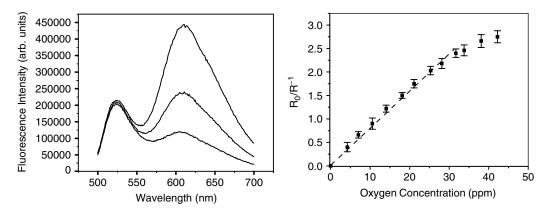

FIGURE 59.3 Left: Aqueous-phase emission spectra of sol-gel oxygen PEBBLEs excited at 488 nm — top line, PEBBLE solution purged with N₂; middle line, PEBBLE solution purged with air; bottom line, PEBBLE solution purged with O₂. Right: Stern-Volmer plot of relative-fluorescence-intensity ratios for ratiometric sol-gel oxygen PEBBLEs in aqueous phase. Dashed line denotes biologically relevant range.

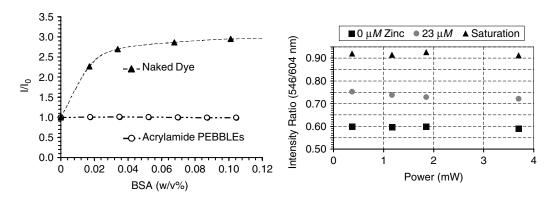

FIGURE 59.4 Left: Normalized Newport Green emission (530 nm) after addition of successive aliquots of a 10% (w/v) bovine serum albumin (BSA) solution. As little as 0.02% BSA causes a greater than 200% increase in Newport Green-free (naked) dye intensity, but the intensity of the dye embedded in a PAA PEBBLE remains unchanged. Right: Fluorescence-emission-intensity ratio (545 nm/604 nm) from a 10 mg/ml PEBBLE suspension in 10 mM Tris buffer monitored using neutral density filters (1.0, 0.5, and 0.3) to attain varied excitation powers at three different zinc concentrations.

from nonspecific binding of proteins, such as bovine serum albumin (BSA), as shown in Figure 59.4 (left). Monitoring of Newport Green's peak at 530 nm reveals a substantial increase in the peak intensity with each successive addition of BSA. The PEBBLEs containing the Newport Green dye, however, are unaffected by the addition of BSA. As little as 0.02% BSA causes an intensity increase of over 200% in the naked Newport Green dye, but the intensity of the Newport Green embedded in the sensor remains unchanged, even at BSA concentrations above 0.10%.¹¹

Figure 59.4 (right) demonstrates the advantage of using an integrated ratiometric device over a single-intensity-based dye. Four different excitation-light levels were used for zinc sensing. Although the absolute intensity of fluorescent emission for each dye decreased with decreasing illumination power, the ratio of peak intensities — of Newport Green and Texas Red — remained constant. It is evident from this that fluctuations in the intensity of either a laser or arc lamp would complicate quantitative analysis for intensity-based measurements, while the ratiometric PEBBLEs eliminate the artifacts resulting from power fluctuations. The equivalent would be true as well for insensitivity to fluctuations in the local PEBBLE concentration.

59.3 PEBBLE Production Techniques

PEBBLEs represent an advance in nanooptode technology. The science of nanooptode production relies on advances in nanoscale production, using emulsion and dispersion fabrication techniques. The nanoemulsion/dispersion process for preparing PEBBLEs is subtle, and there is no universal method for making hydrophilic, hydrophobic, and amphiphilic nanospheres that contain the right matrix and right chemical components in their proper proportions. Thus, switching from single-dye-containing hydrophilic PAA nanospheres to multicomponent, hydrophobic, liquid-polymer sensors or to inert glass, solgel sensors is not yet a routine procedure. However, the production methods, once optimized for a given matrix and its constituents, are based on relatively simple wet-chemistry techniques, as opposed to many complicated physical and chemical nanotechnology schemes. Specific methods for producing sensors from all these matrices as well as the related response mechanisms for each type of sensor are described below.

59.3.1 Polyacrylamide Hydrogel

In PAA polymer PEBBLEs, a dye that has a chromometric response to an analyte is entrapped in the matrix pores. Extraction of analyte ions into the hydrogel is not a consideration, though, because water and small ions diffuse freely through the hydrogel. What does occur is the formation of a chromoiono-phore–analyte complex, similar to the response of the "naked" dye in solution. The dynamic range and selectivity of the PEBBLE depends on the $K_{\rm D}$ of the dye with respect to the analyte and any interfering ions.

The production of acrylamide PEBBLEs is based on the nanoemulsion techniques studied by Daubresse et al. 12 Some control over particle size and shape can be gained by adjusting surfactant-to-water ratios in the emulsion. The typical polymerization solution consists of 0.4 mM fluorescent ionophore (any hydrophilic dye selective for the analyte of interest), 27% acrylamide (monomer), 3% N,N-methylenebis(acrylamide) (cross-linker), all in 0.1 M phosphate buffer, pH 6.5. One milliliter of this solution is then added to a solution containing 20 ml hexane, 1.8 mmol dioctyl sulfosuccinate sodium salt (surfactant), and 4.24 mmol Brij 30 (surfactant). The solution is stirred under nitrogen for 20 min while cooling in an ice bath. The polymerization is initiated with 24 μ l of a 10% ammonium persulfate solution and 12 μ l TEMED (initiators); the solution is then allowed to stir at room temperature for 2 h. Hexane is removed by rotary evaporation, and the probes are then rinsed of surfactant with ethanol to give a majority 40-nm probes. 13,14

59.3.2 Sol-Gel Silica/Organic Hybrid

Sol-gel glass has also been used as the matrix for the fabrication of PEBBLE nanosensors because of the superior properties it has for some applications over organic polymers. Sol-gel glass is a porous, high-purity, optically transparent, and homogeneous material, making it an ideal choice as a sensor matrix for quantitative spectrophotometric measurements. Also, it is chemically inert and more photo and thermally stable than polymer matrices. The preparation of sol-gel "glasses" is technically simple, and tailoring the physicochemical properties (i.e., pore size or inner-surface hydrophobicity) of sensor materials can be achieved easily by varying the processing conditions and the concentration or type of reactants used. This enables the pore sizes to be optimized such that the analyte is able to diffuse easily and interact with the sensing molecules, while the latter are prevented from leaking out of the matrix (also true for PAA-based sensors). Furthermore, this "glass" is produced under so-called soft chemical conditions, i.e., low temperatures and relatively mild pH conditions, allowing the inclusion of organic dyes and even biomolecules. It may also be "hybridized" with organic polymers, as shown in the example below.

The reaction solution for the production of oxygen-sensitive sol-gel PEBBLEs consists of the organic, hydrophilic polymer polyethylene glycol (PEG), MW 5000 monomethyl ether (3 g), ethanol (200 proof, 6 ml), Oregon Green-dextran MW 10,000 (0.1 mM), [Ru(dpp)₃]²⁺ (0.4 mM), and 30% weight ammonia water (3.9 ml), with ammonia serving as catalyst and water being one of the reactants. Upon mixing,

the solution becomes transparent and the inorganic "monomer" tetraethyl orthosilicate (TEOS) (0.5 ml) is added dropwise to initiate the hydrolysis of TEOS. The solution is then stirred at room temperature for 1 h to allow the sol-gel reaction (analogous to polymerization) to reach completion. A liberal amount of ethanol is then added to the reaction solution, and the mixture is transferred to an Amicon ultrafiltration cell (Millipore Corp., Bedford, MA). A 100-kDA membrane is used to separate the reacted solgel particles (PEBBLEs) from the unreacted monomers, PEG, ammonia, and dye molecules, under a pressure of 10 psi. The PEBBLEs are further rinsed with 500 ml ethanol to ensure that all unreacted chemicals have been removed. The PEBBLE solution is then passed through a suction filtration system (Fisher, Pittsburgh, PA), with a 2-µm filter membrane, to separate the larger particles from the smaller ones. The filtrate (containing the smaller particles) is filtered again, this time with a 0.02-µm filter membrane, to collect the particles, which are then dried to yield a final product consisting of sol-gel PEBBLEs in the size range of 100 to 400 nm in diameter.¹⁰

59.3.3 Decyl Methacrylate Hydrophobic Liquid Polymer

The use of fluorescent indicator molecules in encapsulated form (acrylamide PEBBLEs) has proven valuable in the study of a number of intracellular analytes^{11,13,14,16} (H+, Ca²⁺, Mg²⁺, Zn²⁺, O₂); however, many ions exist for which no fluorescent indicator dye is sufficiently selective or even available. An alternate class of tandem optical nanosensors is thus required, driving the development of decyl methacrylate (hydrophobic) liquid-polymer PEBBLEs.

A batch of decyl methacrylate PEBBLE sensors is typically made from 210 mg decyl methacrylate, 180 mg hexanedioldimethacrylate, and 300 mg dioctyl sebacate (DOS), with 10 to 30 mmol/kg each of ionophore, chromoionophore, and ionic additives added after spherical-particle synthesis. The spherical particles are prepared by dissolving decyl methacrylate, hexanedioldimethacrylate, and dioctyl sebacate in 2 ml hexane. To a 100-ml round-bottom flask, in a water bath on a hot plate stirrer, 75 ml of pH 2 HCl is added along with 1793 mg of PEG 5000 monomethyl ether and stirred and degassed. The hexanedissolved monomer cocktail is then added to the reaction flask (under nitrogen) and stirred at full speed, and water bath temperature is raised to 80°C over 30 to 40 min. Potassium peroxodisulfate (6.0 mg) is then added to the reaction, and stirring is reduced to medium speed. The temperature is kept at 80°C for two more hours, after which time the reaction is allowed to return to room temperature and stir for 8 to 12 h. The resulting polymer is suction filtered through a glass microanalysis vacuum filter holder with a Whatman Anodisc filter (0.2-μm pore diameter). The polymer is rinsed three times with water and three times with ethanol to remove excess PEG and unreacted monomer. Tetrahydrofuran (THF) is then used to leach out the DOS and then the PEBBLEs are again filtered and rinsed. They are allowed to dry in a 70°C oven overnight. Dry polymer is then weighed out, and DOS, ionophore, chromoionophore, and ionic additives are added to this dry polymer, so that the resulting polymer will have 40% DOS, 20 mmol/kg ionophore, 10 mmol/kg chromoionophore, and 10 mmol/kg ionic additive. Enough THF is added to this mixture so as to just wet the PEBBLEs. The PEBBLEs are allowed to swell for 8 h, and the THF is then removed by rotary evaporation. The resulting PEBBLE sensors are rinsed with doubly distilled water and allowed to air dry.

59.4 Delivery Methods

One of the most important considerations when applying PEBBLE nanosensors to single-cell studies is the (noninvasive) delivery of the PEBBLEs to the cell. The many methods that have been explored include gene gun, picoinjection, liposomal delivery, and sequestration (phagocytosis and pinocytosis) into macrophages. All of these methods are summarized in Figure 59.5.

The method of PEBBLE delivery by gene gun can best be thought of as a shotgun method. PEBBLEs are dried on a plastic (delivery) disk, and this disk is set in front of a rupture disk. Helium pressure is built up behind the rupture disk, which ruptures at a specific helium pressure and propels the PEBBLEs

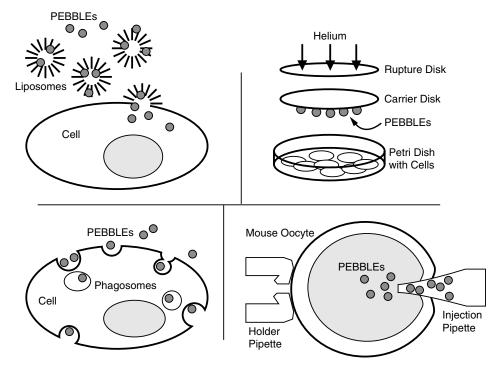

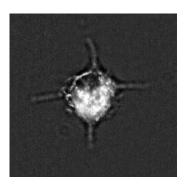

FIGURE 59.5 Range of delivery methods currently available for PEBBLE nanosensors into single cells for bioanalysis. Clockwise, from upper left, liposomal delivery, gene gun, picoinjection, and phagocytosis.

from the plastic disk into a cell culture. The gene gun can be used to deliver one to thousands of PEBBLEs per cell into a large number of cells very quickly (depending on the concentration of PEBBLEs on the delivery disk). 10,13,16,17 Cell viability is excellent (98% vs. control cells 16) for small numbers of PEBBLEs and hinges directly on the number of PEBBLEs delivered, the delivery pressure, and the chamber vacuum. The PEBBLE momentum determines whether the PEBBLEs are internalized mainly in the cytoplasm or in the nucleus.

Picoinjection is used to inject picoliter (pl) volumes of PEBBLE-containing solution into single cells (Figure 59.5). This method of delivery depends on the fabrication of pulled capillary "needles" through the use of a pipette-puller and a microforge. The smallest volume deliverable is 10 pl, and the most concentrated PEBBLE solution to work in the pulled capillary syringe is 5 mg/ml PEBBLEs. The maximum number of PEBBLEs one can put in depends on the volume of solution that can be injected without damaging the cell. Picoinjection can give a wide range of PEBBLE concentrations in the cell, and cell viability is good (if done by an expert), but because each cell must be individually injected, the method is time-consuming and tedious. ¹⁶

Commercially available liposomes can also be used to deliver PEBBLEs to cells. The liposomes are prepared in a solution of PEBBLEs and then placed in the cell culture where the liposomes fuse with the cell membranes and empty their contents (the PEBBLE containing solution) into the cell. Three factors play a key role in determining the number of PEBBLEs delivered to each cell with this method — the original concentration of the PEBBLEs, the concentration of liposomes placed in the cell culture, and the length of time the liposomes are left with the cells. ^{14,16,18} The parameters must be tailored for each cell line used to obtain the desired concentration of PEBBLEs in the cells. While it would be difficult to deliver a single PEBBLE to each cell with this method, it does seem that a low end of 10 to 50 PEBBLEs per cell would be possible, with the high end being the maximum number of PEBBLEs the cell could take without losing viability. Liposomal delivery is useful for delivering PEBBLEs to many cells simultaneously. The challenge is in tailoring the delivery — for the concentrations desirable and for the cell line

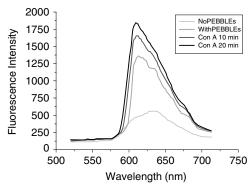

FIGURE 59.6 Confocal-microscope image (left) of alveolar macrophage with embedded, phagocytosed polyacrylamide PEBBLEs containing Calcium Crimson dye. Fluorescence spectra (right) show an increase in intracellular calcium after cells have been challenged by concanavalin A (Con A).

being used. Cell viability is excellent. Obviously, the PEBBLE size needs to be small enough for this method, and delivery is essentially limited to the cell cytoplasm.

Macrophages (specialized immune-system cells) take up PEBBLEs automatically. The number of PEBBLEs that each macrophage takes up depends on the concentration of the PEBBLE solution and the amount of time the macrophages are allowed to stay in the PEBBLE solution. The advantage of this delivery method is that varying concentrations of PEBBLEs can easily be delivered to macrophages. The disadvantages are that it is useful mainly for macrophages (which are hard to culture) and that PEBBLEs are internalized only into certain cell regions. This method also provides excellent cell viability.¹⁶

59.5 In Vitro Bioanalysis

59.5.1 Calcium PAA PEBBLEs

The first PEBBLEs produced were acrylamide-based, and one of the first examples of their successful application to cells was with macrophages. Alveolar macrophages were recovered from rat lung lavage using Krebs-Henseleit buffer. Macrophages were maintained in a 5% CO₂, 37°C incubator in Dulbecco's modified eagle medium (DMEM) containing 10% fetal bovine serum and 0.3% penicillin, streptomycin, and neomycin. PEBBLE suspensions ranging from 0.3 to 1.0 mg/ml were prepared in DMEM and incubated with alveolar macrophage overnight. Macrophage images were then taken on a confocal microscope, and spectra of the same cells were obtained on the fluorescent microscope (shown in Figure 59.6). Acrylamide PEBBLEs selective for calcium (containing Calcium Crimson™, Molecular Probes, in the acrylamide matrix)¹6 were used to monitor calcium in phagosomes within rat alveolar macrophage because of the ease with which macrophage phagocytose particles. This method for delivering the PEBBLEs into cells provided a simple, yet important, test of the PEBBLE sensors in a challenging (acidic) intracellular environment. Macrophages that had phagocytosed 20 nm calcium-selective PEBBLE sensors were challenged with a mitogen, concanavalin A (Con A), inducing a slow increase in intracellular calcium, which was monitored over a period of 20 min. PEBBLE clusters confined to the phagosome enabled correlation of ionic fluxes with stimulation of this organelle.

The calcium PEBBLE in the macrophage experiment clearly demonstrates a time-resolved observation of a biological phenomenon in a single, viable cell. Clearly, relevant time-domain data can be obtained with a fluorescence microscope, spectrograph, and charge-coupled device (CCD). With a confocal-microscope system and the appropriate dye/filter sets, both temporal and spatial resolution can be achieved, as demonstrated below.

Calcium PEBBLEs have also been developed using Calcium Green™-1 (Molecular Probes) dye, in combination with sulforhodamine dye, as sensing components. We note that Calcium Green fluorescence

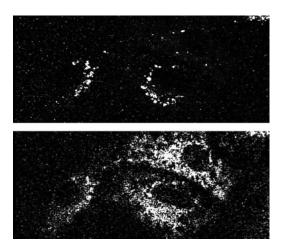

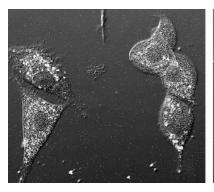

FIGURE 59.7 Confocal-microscope image, split into green (top) and red (bottom) channels, of human C6 glioma cells containing Calcium Green/sulforhodamine (reference dye) PEBBLEs (toxin diffusing left to right releases mitochondrial calcium into cytosol, as seen by lack of green on right side of image).

increases in intensity with increasing calcium concentrations, while the sulforhodamine fluorescence intensity remains unchanged, regardless of the biologically relevant concentration of ions, pH, or other cellular component; thus, the ratio of the Calcium Green/sulforhodamine intensity gives a good indication of cellular calcium levels, regardless of dye or PEBBLE concentration or fluctuations of light source intensity. Figure 59.7 shows a confocal-microscope image of human C6 glioma cells containing Calcium Green/sulforhodamine PEBBLEs. The top image of the pair is the light intensity from the green (calcium sensitive) fluorescence, and the bottom shows the red intensity (reference), with both dyes confined in the same PEBBLEs. The PEBBLEs were delivered by liposomes to the cytoplasm of the cells. The toxin m-dinitrobenzene (DNB) was introduced to the left side of the image and allowed to diffuse to the right. The effect of DNB was the disruption of mitochondrial function, followed by the uncontrolled release of calcium associated with onset of the mitochondrial permeability transition (MPT). Calcium PEBBLEs were used to determine that the half-maximal rate of calcium release (EC50) occurred at a tenfold lower concentration of m-DNB in human SY5Y neuroblastoma cells than in human C6 glioma cells.

59.5.2 Aqueous Oxygen Sol-Gel PEBBLEs

Sol gel, the newest PEBBLE matrix, gives the flexibility of being able to tailor the properties of the matrix to accept either hydrophilic or hydrophobic dyes. Also, for oxygen their dynamic range is much wider than that of similar acrylamide PEBBLEs.¹⁰ It has also proven to be a matrix compatible with the use of protein-based sensors. 15 Sol-gel PEBBLEs were inserted with a gene gun into rat C6 glioma cells to monitor oxygen. A ratiometric sol-gel PEBBLE sensor ([Ru(dpp)₃]²⁺ oxygen-sensitive dye and Oregon Green™ 488-dextran reference dye) was used. 10 Figure 59.8 shows the confocal images of C6 glioma cells containing sol-gel PEBBLEs under Nomarski illumination overlaid with: (left) the green fluorescence of Oregon Green 488-dextran and (right) the red fluorescence of [Ru(dpp)₃]²⁺. Evidently, the cells still maintained their morphology after the gene-gun injection of PEBBLEs and showed no sign of cell death. The dyes were excited by reflecting, respectively, the 488-nm (Ar-Kr) and the 543-nm (He-Ne) laser lines onto the specimen using a double dichroic mirror. The Oregon Green fluorescence from the PEBBLEs inside the cells (Figure 59.8 left) was detected by passage through a 510-nm long-pass and a 530-nm shortpass filter and the fluorescence of [Ru(dpp)₃]²⁺ (Figure 59.8 right) through a 605-nm (45 nm bandpass) barrier filter. A 40×, 1.4 NA oil-immersion objective was used to image the Oregon Green and [Ru(dpp)₃]²⁺ fluorescence. The distribution of PEBBLEs in overlaid images demonstrated that the green and red fluorescence in Figure 59.8 were truly from PEBBLEs inside cells. Most of the PEBBLEs were loaded into the cytoplasm, but there were also some in the nucleus.

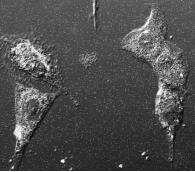

FIGURE 59.8 Confocal images of rat C6 glioma cells loaded with sol-gel PEBBLEs by gene-gun injection. Nomarski illumination image overlaid with Oregon Green fluorescence (reference, left) and $[Ru(dpp)_3]^{2+}$ fluorescence (right) of the same ratiometric PEBBLEs inside cells.

TABLE 59.1 Experimental Ratiometric, in Vitro Oxygen Results

Average Intracellular-Oxygen Concentrations (ppm)	Air-Saturated Buffer Solution 8.8 \pm 0.8
Cells in air saturated buffer	7.9 ± 2.1
Cells in N ₂ saturated buffer (after 25 sec)	6.5 ± 1.7
Cells in N ₂ saturated buffer (after 120 sec)	≤1.5

After gene-gun injection, the cells were immersed in DPBS (Dulbecco's phosphate buffered saline), and a spectrum was taken of these cells using 480 ± 10 nm excitation light. The air-saturated DPBS was then replaced by nitrogen-saturated DPBS, causing a decrease in the intracellular-oxygen concentration, and the response of the oxygen PEBBLE sensors inside the cells was monitored during a time period of 2 min. The fluorescence intensity of $[Ru(dpp)_3]^{2+}$ increased successively, indicating that the oxygen level inside the cells had decreased. Average intracellular-oxygen concentrations were determined on the basis of a Stern-Volmer calibration curve, obtained using the fluorescence-microscope Acton spectrometer system, and are summarized in Table 59.1. The comparatively large errors are due to the low resolution of the spectrometer. Note that the measured intracellular-oxygen value (when cells were in air saturated DPBS) is comparable to the value of ~7.1 ppm measured electrochemically inside the much larger islets of Langerhans. These results show that the PEBBLE sensors are responsive when loaded into cells and that they retain their spectral characteristics, enabling a ratiometric measurement to be made.

59.5.3 Potassium Decyl Methacrylate PEBBLEs

The acrylamide PEBBLE matrix has been proven to work with any hydrophilic sensing components. However, it is unable to take advantage of the rich history of electrochemical sensors where there exist a host of highly selective, hydrophobic ionophores. In many cases, the selectivity of these ionophores has yet to be matched by hydrophilic dyes (chromoionophores). Highly selective intracellular (and extracellular) hydrophilic indicator dyes are limited to a small set of analytes, such as pH and calcium. While the use of PEBBLEs instead of traditional free "naked" indicators results in protection beneficial to both the cell and the dye, it does not solve the selectivity problems. For instance, hydrophilic potassium indicators will not work in the presence of significantly higher sodium concentrations, and, conversely, sodium indicators will not work in the presence of high potassium concentrations. Obviously, this has serious implications for both intracellular (e.g., high potassium/sodium ion ratios) and extracellular (e.g., high sodium/potassium) applications. Moreover, for many important analyte ions, such as nitrite, no satisfactory color indicators are available. The above problem has been solved in optodes by using *in tandem* an optically silent ionophore (which is highly selective) and a next-door optically visible agent

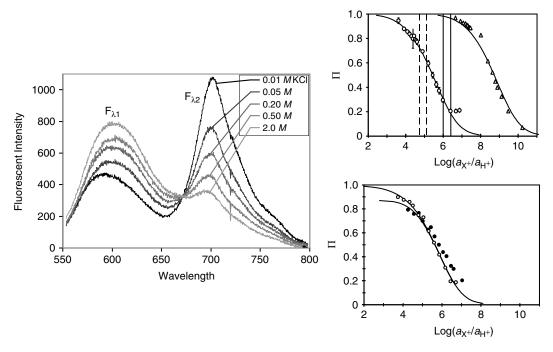

FIGURE 59.9 Left: Normalized emission spectra from suspended K⁺ PEBBLE sensors using the pH chromoionophore ETH5350 for ion-correlation spectroscopy in tandem with BME–44. The spectra show response in going from 10 mM KCl to 2.0 M KCl (well beyond saturation of the sensor), all in 10-mM Tris buffer, pH 7.2. Top right: Response of same PEBBLEs to potassium (o) and sodium (Δ), along with theoretical curves. The lines delimit values for log (a_{K+}/a_{H+}) typically found in intracellular (solid) and extracellular (dashed) media.²⁸ Bottom right: Response to additions of KCl in Tris buffer (o) compared to a similar experiment run in a constant background of 0.5 M Na⁺ (□). Solid lines are calculated (not fit) theoretical curves for the K⁺ response in the presence of 0.5-M interfering Na⁺ using the experimentally determined log-selectivity value of -3.3. X⁺ = K⁺ or Na⁺.

that plays the role of a *spectator*, or *reporter dye*. While the principles of such tandem sensing schemes were worked out by Bakker and Simon,^{21–23} Suzuki,^{24,25} and Wolfbeis,^{26,27} the first demonstration of such a sensing scheme on the nanoscale occurred with the pulled optodes developed by Shortreed et al.^{5,6} The extension of these principles to PEBBLEs required the optimization of a new liquid polymer matrix, decyl methacrylate.¹⁷

The work described here takes advantage of an indicator with two fluorescence-emission maxima (λ_1, λ_2) , giving a relative intensity that changes with the degree of protonation (Π). This degree of protonation, Π , can be evaluated in terms of the ratio of the protonated chromoionophore intensity $F_{\lambda 2}$ to the deprotonated chromoionophore intensity $F_{\lambda 1}$ (see Figure 59.9 for spectra) based on an analytically derived relationship.⁵

The degree of protonation (Π) of the indicator spectra obtained from the PEBBLE calibration is related to the analyte concentration by use of the theoretical treatment of ion-exchange sensors developed by Simon, Bakker et al.^{5,21–23} For the incorporation of a selective neutral ionophore (BME-44) into a matrix, along with a selective chromoionophore (ETH 5350) for indirect ion monitoring (ion exchange sensors), the metal-ion activity (a_{K+}) in solution is a function of the hydrogen-ion activity in solution (a_{H+}), the interfering cation activity (a_{Na+}), and the constants [L_{tot}], [C_{tot}], [R_{tot-}], which are total ionophore (ligand) concentration, total chromoionophore concentration, and total lipophilic charge-site concentration in the membrane. Note that [CH] is the protonated chromoionophore concentration and [C] is the free-base concentration. The parameter Π has been defined^{5–9} as the relative portion of the protonated chromoionophore, $\Pi = [CH]/[C_{tot}]$.

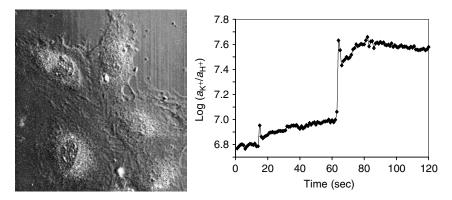

FIGURE 59.10 Left: Confocal image of decyl methacrylate K^+ PEBBLE fluorescence overlaid with Nomarski image of rat C6 glioma cells (488-nm excitation, 580-nm long-pass emission). Right: Ratio data of decyl methacrylate K^+ PEBBLEs in C6-glioma cells during the addition of kainic acid (50 μ l of 0.4 mg/ml) at 20 sec and at 60 sec. Ratios were converted to log (a_{K^+}/a_{H^+}) using solution calibration of the PEBBLEs. Log (a_{K^+}/a_{H^+}) is seen to increase after kainic acid addition (and subsequent K^+ channel openings).

Calibration of a K⁺ sensor based on these principles is shown in Figure 59.9 (right top) along with normalized spectra (left). For potassium sensing, the chromoionophore is ETH 5350, the ionophore is BME-44, and the lipophilic additive is KTFPB.^{6,17} The data points for potassium and sodium responses are plotted along with corresponding theoretical curves. Dashed lines delimit the range of typical extracellular activity ratios, and the solid lines delimit the intracellular levels $[\log (a_{K+}/a_{H+})]$.²⁸

The response was found to match well with the theory, which was gratifying, considering the small size of the systems. The dynamic range at pH 7.2 extended from 0.63 mM to 0.63 M a_{K+} . The log of the selectivity for potassium vs. sodium, determined by measuring the horizontal separation of the response curves at $\Pi = 0.5$, was -3.3. This selectivity value can be used, along with the mathematical theory for this sensing mechanism, to calculate what the K^+ response of the PEBBLEs should be in the presence of 0.5 M interfering Na $^+$. Figure 59.9 (lower right) shows these calculated theoretical curves (not fits) along with the corresponding experimental data. This shows a selectivity similar to or better than that obtained for other and larger matrices incorporating BME-44, e.g., -3.1 in PVC-based fiber-optic work, and -3.0 in PVC-based microelectrodes. It also exactly matches the value given in the review by Buhlmann et al. 23 for a thin PVC film sensor. This selectivity should be more than sufficient for measurements in intracellular media where potassium concentration 28 is about 100 mM and sodium is about 10 mM.

The first application of this liquid-polymer class of PEBBLEs was the observation of potassium uptake in rat C6 glioma cells.¹⁷ Decyl methacrylate PEBBLEs were delivered by gene gun using a BioRad (Hercules, CA) Biolistic PDS-1000/He system, with a firing pressure of 650 psi and a vacuum of 15 torr applied to the system. Immediately following PEBBLE delivery, cells were placed on an inverted fluorescent microscope. The gating software for the CCD was set to take continuous spectra at 1.3-sec intervals. After 20 sec and after 60 sec, 50 μl of 0.4 mg/ml kainic acid was injected into the microscope cell. Kainic acid is known to stimulate cells by causing the opening of ion channels. Figure 59.10 (left) shows the confocal fluorescent image of the PEBBLEs overlaid with a Nomarski differential interference contrast image of the cells. 17 Image analysis indicated that the PEBBLE sensors were localized in the cytoplasm of the glioma cells. Figure 59.10 (right) shows the PEBBLE sensors inside the cells responding to the kainic-acid addition. Log (a_{K+}/a_{H+}) clearly increases, indicating either an increase in K⁺ concentration or a decrease in H⁺ concentration (increase in pH). The amount of kainic acid added is not known to affect the pH of cells in culture, and kainic acid by itself has no effect on the sensors. Thus, the change is likely due to increasing intracellular concentration of K+, which is the expected trend. The membrane of C6 glioma cells can initiate an inward rectifying K+ current, induced by specific K+ channels, a documented role in the control of extracellular potassium.²⁹ Thus, when stimulated with a channel-opening agonist, the K⁺ concentration within the glioma cells is indeed expected to increase.

60.1 Introduction

Over the years, new techniques in chemical and biological sensing have set the stage for great advances in the field of biological research. One of the most recent technological advances in this area has been the development of nanosensors. A nanosensor is a sensor that has dimensions on the nanometer-size scale. Nanosensors of various types (e.g., optical, electrochemical, etc.) have been reported in the literature over the past decade; however, the emphasis of this review will be on optical-based nanosensors.

Optical nanosensors, like larger sensors, can typically be classified into one of two broad categories, depending on the probe used: chemical nanosensors and biological nanosensors.^{1–4} Both types of sensors have been used to provide a reliable method of monitoring various chemicals in microscopic environments. They have even been used in the detection of different species within single cells. Nanosensors offer significant improvements over the current methods of cellular analysis involving the uptake of fluorescent indicator dyes because they do not suffer from problems of cellular diffusion. Although the field of nanosensing is relatively new, there are already several excellent reviews on the subject.^{5–9} This chapter will review the evolution of optical nanosensors from their beginning (near-field optical microscopy) to the present (biosensors capable of probing subcellular compartments of individual mammalian cells) and discuss their application to biological measurements.

60.2 Sensing Principles

A sensor can be generally defined as a device that consists of a recognition element, often called a receptor, and a transducer. Despite the wide variety of receptors and transducers used, all sensors are based on the same principle. First, the sensor is placed in the environment of interest, where the target molecules bind to the receptors in the biosensitive layer of the sensor. These receptors may be ligands for particular chemical species; biological molecules such as antibodies, enzymes, nonenzymatic proteins, and nucleic acids; or even living biological systems such as cells, tissues, or whole organisms. The resulting interaction

^{*}Current affiliation: University of Maryland Baltimore County, Baltimore, Maryland

between the analyte and the receptor then produces an effect that can be measured by the transducer, which converts this effect into some type of measurable signal (e.g., an electrical voltage). Due to this dual-component nature, sensors are typically classified by either the receptor used for molecular recognition or the type of transduction mechanism used for detection. The most common forms of molecular recognition employed in sensors fall into several different categories: (1) nonbiological ligands, (2) antibody/antigen interactions, (3) nucleic-acid interactions, (4) enzymatic interactions, (5) cellular interactions (i.e., microorganisms, proteins), and (6) interactions using biomimetic materials (i.e., synthetic bioreceptors). Common transduction mechanisms used in sensors include optical measurements (e.g., absorption, fluorescence, phosphorescence, Raman, refraction, dispersion, or interference spectrometry, etc.), electrochemical measurements (e.g., amperiometric, potentiometric, etc.), and mass-sensitive measurements (e.g., surface acoustic wave, microbalance, microcantilever, etc.). This chapter will emphasize the principles of operation of sensors that are based on optical transduction and describe some of the most recent applications of nanosensors to single-cell analyses. A more detailed review of the sensing concept and various types of biosensors is provided in greater detail in Chapter 20 of this handbook.

60.2.1 Optical-Transduction Techniques

Optical transduction describes a vast array of measurements (e.g., absorption, fluorescence, phosphorescence, Raman, surfaced-enhanced Raman substrate (SERS), refraction, dispersion spectrometry, etc.) that can be performed with optical sensors. In addition to the large number of optical techniques that can be used in the field of sensing, each of them can be used to measure any of many different optical properties. These properties include amplitude, energy, polarization, decay time, and phase. A brief description of the types of information that can be obtained via optical measurements is described below, while more comprehensive information can be found in other chapters of this handbook.

The most commonly measured parameter of the electromagnetic spectrum is amplitude, as it can generally be easily correlated with the concentration of the analyte of interest. Although amplitude is the most commonly measured parameter, the other parameters can also provide a great deal of information about the analyte of interest. For instance, the energy of the electromagnetic radiation can often provide information about changes in the local environment surrounding the analyte, its intramolecular atomic vibrations (i.e., Raman or infrared-absorption spectroscopies), or the formation of new energy levels (i.e., luminescence, ultraviolet-visible absorption). Measurement of the interaction of a free molecule with a fixed surface can often be determined based on polarization measurements. In the case of free molecules in solution, the emitted light is often randomly polarized, whereas when a molecule becomes bound to a fixed surface, the emitted light generally remains polarized. Therefore, the rate of depolarization of a fluorescence signal can provide information on the movement of a molecule. Information can also be gained by measuring the decay time of a specific emission signal (i.e., fluorescence or phosphorescence) because these decay times depend on the excited state of the molecules and their local molecular environment. Another property that can be measured is the phase of the emitted radiation. When electromagnetic radiation interacts with a surface, the speed or phase of that radiation is altered based on the refractive index of that particular medium (i.e., analyte). Therefore, when an analyte binds to the receptor layer of a sensor, a change in the refractive index of the sensing surface could cause a measurable phase shift in the impinging radiation.

60.2.2 Molecular Receptors

One of the key factors in determining the usefulness of any chemical or biological sensor is its ability to specifically measure the analyte of interest without having other chemical species interfere with the measurement. It is the selective binding properties of these receptors that are the key to a sensor's specificity. A wide variety of receptors have been used in the development of sensors over the years. In fact, the various receptors that have been used are more numerous than the different analytes that have been monitored using optical sensors. Although the amount and type of different receptors used are

continually growing, they can generally be classified into one of six major categories: (1) nonbiological ligands, (2) antibodies, (3) enzymes, (4) nucleic acids, (5) cellular structures/cells, and (6) biomimetic receptors.

60.2.2.1 Nonbiological Ligands

Nonbiological ligands constitute a very broad category of molecules that range from species with only weak molecular interactions (e.g., hydrogen bonding, van der Waals forces, etc.) to molecules capable of binding or complexing ionic species. Optical sensors employing receptors based on weak-force interactions include indicator dyes immobilized in hydrophilic or hydrophobic membranes, which allow only certain chemical species to come into contact with the indicator dye,^{10–13} as well as many other forms of interactions. ^{14–16} Ligands that rely on ionic interactions or analyte binding include species such as ethylene diamine tetra acetic acid (EDTA), Calcium Green™, fluorescein, etc.

Since a large number of these receptor molecules are based simply on the charge state of the analyte, these receptors often experience a great deal of cross reactivity with other similar species. Due to the cross reactivity of these nonbiological receptors and their subsequent lack of specificity when employed in complex environments, such as biological systems (e.g., cells), there has recently been a shift toward biological receptor molecules, or bioreceptors. These bioreceptors generally possess a much greater specificity than their nonbiological counterparts due to a need for shape recognition as well as other forms of interactions (i.e., hydrogen bonding, ionic interactions, etc.).

60.2.2.2 Antibodies

Antibodies are biological molecules that exhibit very selective binding capabilities for specific structures. Two distinctly different classes of antibodies exist, both of which have been employed as bioreceptors for biosensors: monoclonal antibodies and polyclonal antibodies. When measurement of a very specific analyte is desired, monoclonal antibodies are often used, while polyclonal antibodies, which exhibit less specificity, are often used for the measurement of an entire class of compounds (e.g., PAHs). Because most biological systems are complex in their composition, the highly specific binding abilities of antibodies make them one of the most powerful bioreceptors used by biosensors. However, there are also disadvantages to using antibodies for analyte binding. For example, to produce an immune response to a specific molecule, a certain molecular size and complexity are necessary. Therefore, immunogenic proteins typically have molecular weights of greater than 5 kDa.

60.2.2.3 Enzymes

Enzymes represent another class of bioreceptors that are commonly used in biosensors. In addition to the often highly specific binding capabilities of enzymes, their catalytic activity also makes them very useful. With the exception of a small group of catalytic ribonucleic-acid molecules, all enzymes are proteins, and the function of these proteins varies dramatically from enzyme to enzyme. Some enzymes require no additional chemical groups other than their amino-acid residues for activity, while others require an additional chemical component called a cofactor, which may be either one or more inorganic ions (e.g., Fe²⁺, Mg²⁺, Mn²⁺, Zn²⁺, etc.) or a more complex organic or metallo-organic molecule called a coenzyme. Both types of enzymes have been used in the development of biosensors. Sensors employing enzymes that do not require a cofactor or coenzyme are typically used when the analyte of interest is difficult to measure. In such cases, the reaction of the analyte with the enzyme produces a product that is readily measurable by a particular measurement technique. In addition, the catalytic nature of the bioreceptor means that the sensor is often reusable or reversible.

Biosensors employing enzymes that require an additional chemical component can be extremely sensitive and have extremely low detection limits for that additional chemical component. In such a sensor, the indirect detection of the cofactor or coenzyme of interest is typically performed by measuring a product of the enzymatic reaction. Since a single enzyme along with its respective cofactor or coenzyme can catalyze many reactions and thus produce a large number of reaction products, the indirect measurement of very small amounts of cofactor or coenzyme is possible.

60.2.2.4 Nucleic Acids

Another biorecognition mechanism capable of a high degree of specificity involves the hybridization of deoxyribonucleic acid (DNA) or ribonucleic acid (RNA) to a complementary sequence. Within the last decade, the use of nucleic acids as bioreceptors for biosensor and biochip technologies has grown dramatically.^{17–22} The specificity of biorecognition in these DNA-based biosensors, which are often referred to as genosensors, is based on the complementarity of the cytosine:guanosine (C:G) and adenine:thymine (A:T) base pairing. If the sequence of bases comprising a certain segment of the DNA molecule is known, then the complementary sequence, often called a probe, can be synthesized and labeled with an optically detectable compound (e.g., a fluorescent label). By unwinding the double-stranded DNA into single strands, adding the probe, and annealing the strands, the unwound DNA will hybridize to its complementary-probe sequence. Such probe strands were used extensively for the rapid testing of various sequences in the human-genome project.

In addition to simple strands of complementary oligonucleotides with some type of optical label (e.g., fluorescent label, etc.), a relatively new class of bioreceptor, known as a molecular beacon (MB), has been developed. A MB is an oligonucleotide strand that has a long sequence that is complementary to the analyte sequence and, on either end, a small region (several nucleic acids long) that is complementary to the other end. In addition, a fluorescent dye is attached to one end, and a quencher molecule is attached to the opposite end. Therefore, when the MB is not in the presence of the analyte, the two ends bind to each other, keeping the fluorophore and quencher molecules in close proximity and resulting in a nonfluorescent complex. However, in the presence of the analyte, the large loop structure binds to the analyte, causing the two ends to separate and thereby preventing the quencher molecule from acting on the fluorophore and producing a fluorescent complex. Much greater detail about these compounds can be found in Chapter 57 of this handbook.

60.2.2.5 Cellular Structures/Cells

Cellular structures and cells comprise the most diverse category of bioreceptors that have been used in the development of biosensors.^{23–57} These bioreceptors are based on biorecognition by either an entire cell/microorganism or a specific cellular component capable of specific binding to certain chemical or biochemical species. Because of its great diversity, this category of bioreceptor can be further divided into three major subclasses: (1) cellular systems, (2) enzymes, and (3) nonenzymatic proteins. However, due to the importance and the large number of biosensors that employ enzymes as their biorecognition element, these have been given their own classification and were discussed previously. In addition, since the focus of this chapter is nanosensors, and whole cells or cellular systems are too large to fit on a sensor with nanometer dimensions, we will focus in this section solely on nonenzymatic proteins.

Many proteins within cells often serve as bioreceptors for intracellular reactions that will take place later or in another part of the cell (e.g., carrier proteins, channel proteins on a membrane, etc.). Regardless of the purpose, these proteins provide a means of molecular recognition through one type or another (i.e., active site or potential sensitive site). Because of the various biorecognition properties of these different nonenzymatic proteins, many different types of biosensors have been constructed for one application or another.

60.2.2.6 Biomimetic Receptors

The final major class of receptor used in biosensors, known as biomimetic receptors, is not comprised of true biological molecules. In fact, biomimetic receptors are human-made receptors that have been designed to mimic biological molecules. Since the fabrication of the first biomimetic receptor for biosensing applications, several different methods have been developed for the construction of such receptors. These methods include genetic engineering of molecules, artificial membrane fabrication, and molecular imprinting.

Recombinant techniques that allow for the synthesis or modification of a wide variety of binding sites within biological molecules have provided powerful tools for the design and synthesis of bioreceptors

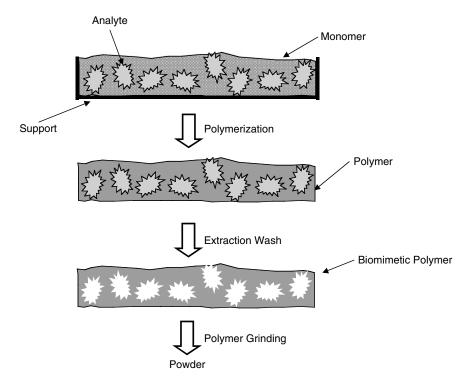

FIGURE 60.1 Conceptual illustration of the molecular imprinting process.

with desired properties. While biochemists and molecular biologists have been modifying various aminoacid sequences in a variety of proteins for many years, it is only in the past decade that such techniques have begun to be applied to biosensors for the enhancement of a bioreceptor's binding properties (i.e., binding affinity, specificity, etc.).

The second major class of biomimetic receptors — artificial membrane fabrication — has also been used for many different applications over the years. In one such application, Stevens et al. developed an artificial membrane by incorporating gangliosides into a matrix of diacetylenic lipids (5 to 10% of which were derivatized with sialic acid).⁷¹ After the lipids self-assembled into Langmuir-Blodgett layers, they were photopolymerized via ultraviolet irradiation into polydiacetylene membranes. These newly fabricated membranes were then attached to biosensors for the detection of cholera toxins. As the cholera toxins became bound to the membrane they caused the membrane to change color from its original blue color to red, which was subsequently monitored via absorption measurements.

The newest and final class of biomimetic receptors is those created by a technique known as molecular imprinting (see Figure 60.1). This technique consists of mixing analyte molecules with a monomer solution and a large amount of cross linkers. As the monomers begin to polymerize, a solid plastic is created that is full of the particular analyte that is to be measured. Following polymerization, the hard polymer is ground into a fine powder and the analyte molecules are extracted with organic solvents to remove them from the polymer network. After extraction, the resulting polymer powder has molecular holes or binding sites that are complementary to the selected analyte. Therefore, by attaching some of the molecularly imprinted polymer powder on a biosensor, receptor sites for molecules with the exact three-dimensional (3D) structure as the analyte used in the imprinting process are now present. One of the primary reasons for the growing popularity of molecular imprinting is the rugged nature of a polymer relative to a biological sample. Unlike biological molecules, molecularly imprinted polymers (MIPs) can withstand harsh environments such as those experienced in an autoclave or denaturing chemical environment. However, MIPs typically exhibit reception abilities slightly less than antibodies or other biological receptor molecules.

60.3 Optical Nanosensors

Over the years, new techniques in sensing have set the stage for great advances in the field of biological research. One of the most recent advances in the field of optical sensors has been the development of optical nanosensors. A nanosensor is a sensor that has dimensions on the nanometer-size scale. Presently, the most common nanosensors employ fiber optics with tip diameters ranging between 20 and 100 nm. These sensors are based on the same basic principles as larger, more conventional optical sensors, except for their excitation process. Because the diameter of the optical fiber's tip is significantly smaller than the wavelength of light used for excitation of the analyte, the photons cannot escape from the tip of the fiber to be absorbed by the species of interest, as is the case in larger fiber-optic sensors. Instead, in a fiber-optic nanosensor, after the photons have traveled as far down the fiber as possible excitons or evanescent fields continue to travel through the remainder of the tip, providing excitation for the fluorescent species of interest present in the sensing layer. An additional feature of this excitation process is that only species that are in extremely close proximity to the fiber's tip can be excited, thereby precluding the excitation of interfering autofluorescent species within other locations of the sample. This is extremely important in biological systems such as cells, where a large number of autofluorescent species are often present.

The nano-scale size of this new class of sensors also allows for measurements in the smallest of environments. One such environment that has evoked a great deal of interest is that of individual cells. These nanosensors make it possible to probe individual chemical species in specific locations within a cell. Previously, such measurements were limited almost entirely to the field of fluorescence microscopy, where a fluorescent dye is inserted into a cell and allowed to diffuse throughout. Depending on the particular fluorescent dye that was chosen, changes in the fluorescence properties of the dye could then be monitored as the dye came into contact with the analyte of interest. By performing these analyses in an imaging format, it is therefore possible to determine the presence of the analyte at various locations. Since this technique relies on imaging the fluorescent dye, it requires the homogenous dispersion of the dye through the various locations in the cell, which is limited by intracellular conditions (i.e., pH, etc.) or often does not even occur due to cellular compartmentalization. Nanosensors therefore offer significant improvements over such methods in many cases as they allow the user to perform analyses at any desired location without a need for homogenous dispersion of the indicator dye.

60.3.1 Fabrication of Optical Nanofibers

The construction of fiber-optic probes with nanometer-sized tips is a prerequisite of optical-fiber-based nanosensors. Depending on the specific application and environment in which the nanosensor is to be used, different tip diameters, taper angles, and smoothnesses of the fiber surfaces are required. To achieve the various diameters and tapers on the tips of these fibers, two different fabrication procedures have been developed.

60.3.1.1 Heated Pulling Process

The most commonly employed procedure involves the use of a heated pulling instrument, such as a laser-based micropipette puller. These instruments use a CO_2 laser to heat the fiber and a tension device that pulls along the major axis of the fiber while it is heated (see Figure 60.2). As the fiber is pulled, the heated region begins to taper down to a point until the fiber has been pulled into two pieces, each having one large end and one tapered end with nanometer-scale dimensions. By varying the parameters associated with the pulling process (i.e., heating temperature, tension applied to the fiber, etc.), it is possible to precisely control the size of the tip, with diameters ranging from less than 20 nm to more than 1000 nm.^{72–76} Figure 60.3 shows a scanning electron micrograph (SEM) of an optical fiber that has been pulled in such an instrument. This technique, while requiring accessibility to a relatively expensive micropipette-pulling instrument, makes it possible to reproducibly create optical fibers with nanometer-scale tips in just seconds.

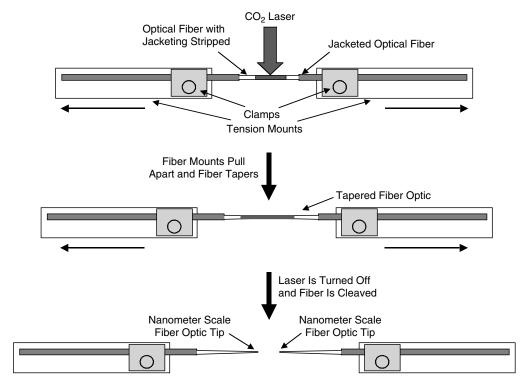

FIGURE 60.2 Diagram depicting the fiber-pulling procedure for construction of a nanofiber.

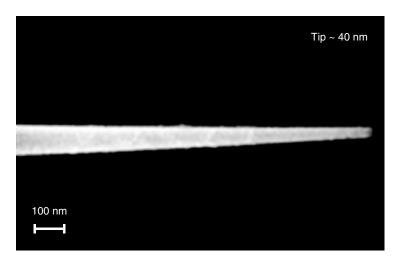

FIGURE 60.3 A scanning electron micrograph of a nanofiber produced by the micropipette-pulling procedure. The tip of this fiber is approximately 50 nm in diameter.

60.3.1.2 Chemical Etching

The second means of producing optical fibers with nanometer-scale tips is through a chemical-etching process. This process has been found to be an inexpensive and effective alternative to the pulling process. Two different types of etching procedures have been reported in the literature: (1) Turner etching, a method involving the mixture of hydrofluoric acid (HF) with an organic solvent,^{77,78} and (2) tube etching,

a method developed by Stockle et al.⁷⁹ In the Turner method, a fiber is placed in the meniscus between the HF and an organic overlayer. Once in place, the HF dissolves the silica fiber, forming a point. With this technique, fibers with large taper angles and tip diameters comparable to the pulling method have been created. Because of the larger taper angles associated with these fibers, excitation light can travel closer to the tip of the fiber before being trapped, thereby causing more energy to be coupled with the fluorophore and resulting in a more efficient excitation process. However, as a result of the dual chemical nature of the etchant solution, environmental parameters such as temperature fluctuations and vibrations can cause the characteristics of the tip to vary significantly from batch to batch.

To overcome the problems associated with this two-phase chemical-etching process and the batch-tobatch variability, a new form of etching, known as tube etching, has recently been developed. Tube etching involves etching an optical fiber with a single-component solution of HF. In this method, a silica fiber that has an organic/polymer cladding is polished optically flat on both ends, prior to placing one end just below the surface of a solution of HF. Over time, the acid begins to etch away the core of the fiber without destroying the cladding. As the silica fiber continues to be etched away, the polymer cladding acts as a wall, causing any microcurrents in the HF to form a blunted tip on the fiber's core. As more time passes, the silica core material continues to dissolve until it is no longer below the surface of the HF solution. At this point, capillary action draws the HF up the walls of the cladding, allowing it to drain down the silica core back into the solution below. As this happens, it causes the fiber to be etched into the shape of a cone with a large smooth taper. Control over the taper angle of the fiber and the diameter of the tip can be performed simply by varying the depth at which the fiber is placed in the HF and the etching time. Using this tube etching process, it is possible to produce a batch of fibers in approximately 2 h and with greater reproducibility than the Turner etching method. However, due to difficulties associated with submerging a large group of fibers to exactly the same depth in the HF, the reproducibility of this etching method is still less than that obtained by pulling the fibers. In addition, due to the large taper angle associated with these etched fibers as well as those fabricated with the Turner etching process, they are limited in the environments in which they can probe. Because the taper angle is so large, they tend to cause a great deal of physical damage when performing cellular analyses with smaller cells (e.g., mammalian somatic cells, etc.) and are therefore useful only with large cells such as oocytes and certain neurons. It is primarily for this reason that the most common method for creating nanometer-sized tips on fiber-optic nanosensors is performed using the heated pulling technique.

60.3.2 Evolution of Optical-Based Nanosensors

60.3.2.1 Near-Field Optics and Spectroscopy

Optical sensors using nanoscale optical fibers arose from an area of research known as near-field optical microscopy. Near-field optical microscopy is a relatively new area of research and uses light sources or detectors with emitting or collecting apertures that are smaller than the wavelength of light used for imaging. The most common method for performing such experiments is by placing a pinhole in front of the detector, thereby effectively reducing the size of the detector aperture.^{80,81} A variation of this technique is to construct an excitation probe with dimensions that are smaller than the wavelength of light being used for sample interrogation. This small excitation probe can then act as a light source with subwavelength dimensions. Betzig et al. have reported the development of such a probe capable of providing images of a sample with an optimum spatial resolution of approximately 12 nm. This probe was constructed by pulling a single-mode optical fiber with a micropipette puller and then coating the wall of the fiber with ~ 100 nm of aluminum. By applying an aluminum coating to the walls of the fiber, leakage of light from the tapered region of the fiber, where the cladding was pulled too thin to maintain the total internal reflection, is prevented, thereby confining the excitation radiation to the fiber tip (~20 nm). Using this first nanofiber-based system operating in the illumination mode (i.e., with the probe acting as a localized excitation source) images of a known pattern were reconstructed by raster scanning the probe over it. In addition, signal enhancements of greater than 10⁴ (see References 72 and 82) over previous near-field probe analyses^{83–86} were obtained.

Due to the high degree of spatial resolution provided by near-field microscopy, these probes have been used for the detection of single molecules. In particular, one of the more recent applications of these nanofibers to single-molecule detection has been for the detection of dye-labeled DNA molecules using near-field surface-enhanced resonance Raman spectroscopy (NFSERRS).^{87,88} This NFSERRS technique made it possible to obtain chemical images of single DNA molecules labeled with the fluorescent dye brilliant cresyl blue (BCB). In that work, the dye-labeled DNA strands were spotted onto a SERS that was prepared by evaporating silver on a nanoparticle-coated substrate.^{87,88} NFSERRS spectra were then obtained by illuminating the sample with the nanoprobe and measuring the Raman signal with a charge-coupled device (CCD) mounted on a spectrometer. By raster scanning the nanoprobe across the sample, a two-dimensional image of the DNA molecules was reconstructed and normalized for surface topography based on the intensity of the Rayleigh scatter.

Near-field optical microscopy using taper fiber optics is an area of research that holds a great deal of potential for the mapping of surfaces for individual biological molecules. In addition, since many biological compounds exhibit properties such as luminescence that are typically much stronger than Raman signals, it might be possible in the near future to map out the location of individual molecules of specific chemicals in human tissues such as neurotransmitters in the brain. Single-molecule detection would therefore represent the absolute limit of detection for any compound and could open new horizons in the investigation of the complex chemical reactions and pathways of biological systems. Near-field microscopy is further described in detail in Chapter 12 of this handbook.

60.3.2.2 Chemical Nanosensors

Shortly after their development for near-field microscopy, nanofibers began to be applied to the field of chemical sensing. With the advent of these nanofibers, it became possible to probe for specific chemicals in 3D structures over very short distances (<50 nm). Because of this ability to perform highly spatially localized analyses, the monitoring of concentration gradients and spatial inhomogeneties in submicroscopic environments (e.g., cells) via various spectroscopic techniques has become possible. However, due to the small sampling volume probed by nanofibers, the number of analyte species in the excitation volume is very small, making it important to use a sensitive spectroscopic technique for the analysis (e.g., fluorescence). In addition to using a sensitive spectroscopic technique, it is also important to use a sensitive detection scheme, such as the one shown in Figure 60.4, which is commonly used with fiberoptic nanosensors and nanobiosensors. In this system, an excitation source of some type (typically a laser) is launched into a fiber optic that is attached to the large, proximal end of the nanosensor. The nanosensor, which is held in place by an x-y-z micromanipulator mounted on an inverted microscope, is then used to position the tip of the sensor to the desired location while looking through the eyepiece of the microscope. Once in place, the excitation source is turned on and the dye, which is sensitive to the presence of the analyte, is excited. As the excited dye relaxes to the ground state, the resulting fluorescence emission is collected by the microscope optics and detected with either a CCD or a photomultiplier tube (PMT).

Since the construction and use of the first optical nanosensors by Tan et al. in 1992^{73,74} several different optical-fiber-based chemical nanosensors have been reported for the measurement of pH,^{89–92} various ion concentrations,^{93,94} and other chemical species.⁹⁵ In this original work, a micropipette puller was used to taper multimode and single-mode fibers down to diameters of 100 to 1000 nm at the tip.^{73,74} These tapered fibers were then used in the production of pH nanosensors via a three-step process. The first step in the process was to apply a thick layer of aluminum to the walls of the fiber using a vacuum evaporator to ensure total internal reflection over the tapered region of the fiber. During this aluminum-deposition process it was important to ensure that the tip of the fiber remained free of metal, thereby providing a silica surface for binding of the probe or receptor molecules to the fiber's tip. To achieve this, the fibers were placed in the evaporator system and rotated with their tips facing away from the source of the evaporating metal. By precisely angling the fibers, their sides would shadow the tips from the evaporating metal.^{75,76,96} This coating method is illustrated in Figure 60.5. Once the walls of the fiber were

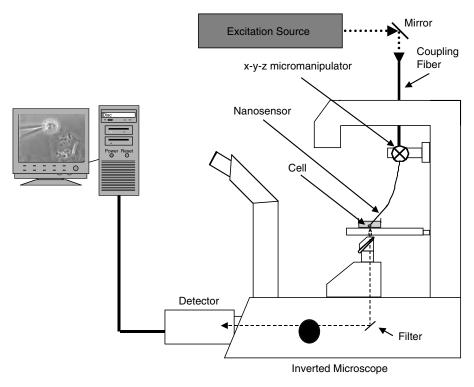

FIGURE 60.4 Schematic diagram showing a typical experimental setup used for nanosensor measurements within a single cell or microscopic sample. The nanosensor is mounted in an x-y-z micropositioning system mounted on an inverted microscope. The fluorescent light is then collected by the mroscope and monitored with a detector.

coated with aluminum, the next step was to silanize the fiber tip to allow for cross linking to a polymer coating. The final step in the fabrication of this pH nanosensor was to then attach the pH-sensitive dye, acrylofluoresceinamine, to the silanized fiber tip through a variation of a photopolymerization process that has been used often in the construction of larger chemical sensors. 97,98 However, because of the near-field excitation provided by these small fiber probes, the cross linking of the polymer solution was restricted to the near field of the fiber. Following fabrication of this sensor, characterization of its properties was performed. During this characterization, the sampling volume of the sensor was determined to be greater than six orders of magnitude smaller than conventional fiber-optic chemical sensors, making it ideal for subcellular measurements. The reduced sampling volume and response time of the sensor were evaluated by measuring the pH in 10-µm-diameter pores in a polycarbonate membrane. This evaluation found that the response time of the sensor (300 msec) was 100-fold faster than conventional fiber-optic chemical sensors and that it was both stable and reversible with respect to pH changes.

The first reported application of fiber-optic nanosensors for biological measurements was performed on rat embryos.⁷³ In this study, pH nanosensors like the ones described above were inserted into the extraembryonic space of a rat conceptus, with minimal damage to the surrounding visceral yolk sac, and pH measurements were made. From these measurements, values of the pH in the extraembryonic fluid of rat conceptuses ranging in age from 10 to 12 d old were then compared for any differences. In a similar study using the same pH sensor, indirect measurements of nitrite and chloride levels in the yolk sac of rat conceptuses were also performed.⁹⁹ Because of the minimally invasive nature of such measurements, such techniques hold much promise for biological analyses and may aid in furthering our understanding of the effect that environmental factors have on embryonic growth.

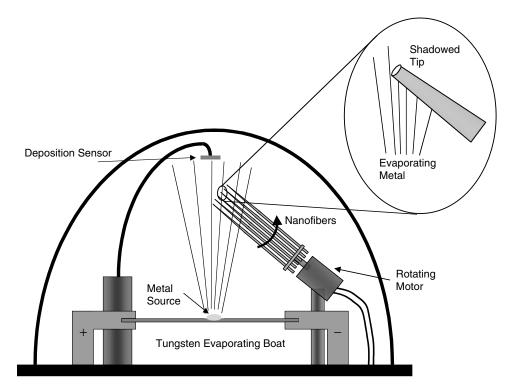

FIGURE 60.5 Illustration of the procedure for coating the walls of fiber-optic nanosensors with a reflective metal.

As the field of optical-fiber-based nanosensors has evolved, the size of the environments in which they probe continues to shrink. In fact, the measurement of chemical species inside individual cells has even been reported using fiber-optic chemical nanosensors. In the first of these studies, optochemical nanosensors for sodium ions (Na⁺) were developed using a process similar to the one described above. These sensors were then used for the measurement of sodium-ion (Na⁺) concentrations in the cytoplasmic space inside a single mouse oocyte, one of the largest mammalian cells (~100 µm in diameter).⁸ These sensors allowed for the monitoring of the relative Na⁺ concentrations while ion channels were opened and closed by the external stimulant, kainic acid. In another application of fiber-optic nanosensors to biological measurements, calcium-ion-sensitive nanosensors were developed and used to measure the calcium-ion fluctuations in vascular smooth muscle cells while the cells were stimulated.¹⁰⁰ These fluctuations were then directly correlated to the stimulation events that were being performed, providing another potential application for these nanometer-sized optical sensors.

60.3.2.3 Nanobiosensors

Due to the complexity of biological systems and the number of possible interferences to chemical nanosensors, an obvious need for added specificity arose. This specificity was achieved by the development of nanobiosensors. As with their larger counterparts, the added specificity provided by biological receptor molecules allowed for the analysis of complex environments with minimal affects from other species. Application of nanofibers to the field of biosensors was first reported in 1996 by Vo-Dinh and coworkers. In this work, antibody-based nanobiosensors were developed and characterized for benzo[a]pyrene tetrol (BPT), a DNA adduct of the carcinogen benzo[a]pyrene (BaP). Because it is a biomarker for human exposure to BaP, the measurement of BPT is of great interest in early cancer diagnosis. Fabrication of these first nanobiosensors was performed in a four-step process. The first step in this process was to taper a 600-µm-diameter fiber optic down to 40 nm at the tip. This is followed by application of a thick layer of silver (approximately 200 nm) to the walls of the fiber to prevent light leakage as well as to enhance light delivery to the end of the fiber. Following the silver coating, the fiber tip was silanized to create

attachment sites for the antibodies. Once silanized, antibodies were attached to the distal end of the nanofiber via a covalent-binding procedure. The first step in this antibody-binding procedure was to activate the silanized fiber with a solution of carbonyl diimidazole, which was then followed by incubation of the activated fiber with the antibody of interest for 3 d at 4°C. Once the antibodies were bound, the biosensors were characterized in terms of retention of antibody-binding ability as well as sensitivity and absolute detection limits. Tests were performed by placing the nanobiosensors in a measurement system like the one described for chemical nanosensors and inserting the distal end of the sensor into a series of solutions of BPT. These measurements revealed that the antibodies had retained more than 95% of their native binding affinity for BPT and that the absolute detection limit for BPT using these sensors was approximately 300 zeptomoles (zepto = 10^{-21}).

In the several years since this work, optical nanobiosensors employing many different forms of bioreceptor molecules have been developed and applied to the analysis of many biologically relevant species. ^{100,101} This has included nanobiosensors for the detection of nitric oxide via fluorescence detection of the nonenzymatic protein cytochrome c or fluorescently labeled cytochrome c¹⁰⁰ as well as an enzymatic-based nanobiosensor for the indirect detection of glutamate. ¹⁰¹ In the latter design, the enzyme glutamate dehydrogenase was used as the bioreceptor. When glutamate was bound to the glutamate dehydrogenase, the reduction of NADH occurred, allowing for NADH to be measured via fluorescence spectroscopy. Enzymatic-based nanobiosensors such as this may make it possible to continuously monitor the glutamate levels released from an individual cell. Such a sensor could prove to be a significant tool in the field of neurophysiology because glutamate is one of the major neurotransmitters in the central nervous system, and a better understanding of the mechanisms by which sensations are transmitted throughout the human body may be achieved by monitoring of the glutamate levels produced by individual cells. Although enzymes have previously been used in the field of biosensors for their ability to be regenerated, this was the first example of the use of an enzyme in the fabrication of a nanobiosensor.

Several studies have been published of fiber-optic nanobiosensors being applied to in vitro measurements of single cells.^{9,76,96,102,103} In one such study, nanobiosensors for BPT were prepared as described earlier and used for the measurement of intracellular concentrations of BPT in the cytosol of two different cell lines: (1) human mammary carcinoma cells and (2) rat liver epithelial cells.⁷⁶ The cells in both lines were spherical in shape and had diameters of approximately 10 μm. Several hours prior to making a measurement a known amount of BPT was added to the culturing medium of the cells. Then immediately prior to making any measurements, the culturing medium was rinsed several times and replaced with BPT-free medium. This work revealed that the concentration of BPT in each of the different cell lines was the same, suggesting that the means of transport of the BPT into the cells was the same in both cases (probably by diffusion). By performing similar measurements inside various subcellular compartments or organelles, it may be possible to obtain critical information about the location of BPT formation within cells and its transport throughout cells during the process of carcinogenesis. In addition, this work also showed that the insertion of a nanobiosensor into a mammalian somatic cell not only appears to have no effect on the cell membrane but also does not effect the cell's normal function. This was demonstrated by inserting a nanobiosensor into a cell that was just beginning to undergo mitosis and monitoring cell division following a 5-min incubation of the fiber in the cytoplasm and fluorescence measurement. Figure 60.6 contains a series of time-lapse images from this experiment showing the initial stages of mitosis in which the fiber-optic nanobiosensor is interrogating the cell all the way through division of the cell into two identical daughter cells.

60.3.2.4 Nanoparticle Chemical Sensors

The development of fiber-optic-based nanosensors and nanobiosensors has already had a large impact on the fields of biological and biomedical research in the short time that they have existed. Nevertheless, significant advances and variations are constantly being made in optical nanosensors, from the use of new, more selective bioreceptors to the development of different types of nanobiosensors for application in various environments. One such advance in the last couple of years has been the development of the first nanoparticle-based optochemical sensors with nanometer-scale sizes in all three dimensions. 104

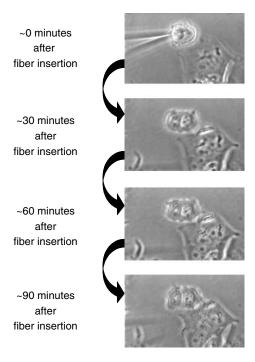

FIGURE 60.6 Series of time-lapse microscopic images of a cell undergoing mitosis prior to and immediately following interrogation with a fiber-optic nanobiosensor. The cell is approximately 10 µm in diameter.

60.3.2.4.1 PEBBLE Sensors

Since this first nanoparticle-based sensor was first described, several types of nanoparticle sensors have been developed, each having its own advantages and disadvantages. One such nanoparticle sensor, known as a PEBBLE (probe encapsulated by biologically localized embedding), is comprised of a fluorescent indicator dye embedded in a 20-nm diameter polymer or sol-gel sphere. This chapter will provide a brief overview of this topic; a much more extensive description of their development and application can be found in Chapter 59 of this handbook. This encapsulating sphere protects the indicator dye from cellular degradation and the cell from the toxic effects of the dyes while allowing ions to penetrate and interact with the indicator dye. Application of these sensors to the measurement of many different ions within a cell has been demonstrated since their first development. In such analyses, large quantities of these sensors are randomly injected in a cell with a gene gun or similar device to ensure the presence of a sensor at every desired location. Once in place, the cell is illuminated and the resulting fluorescence signal measured over the autofluorescent background of the cell. Presently, PEBBLE sensors have been developed for pH, Ca⁺², NO, molecular oxygen, and intracellular free Zn⁺². ¹⁰⁵⁻¹¹⁰

60.3.2.4.2 Quantum-Dot Biosensors

Simultaneous with the development of PEBBLEs was the development of quantum-dot-based biosensors capable of monitoring individual chemical species inside a living cell. These nanoparticle biosensors are comprised of ZnS particles capped with Cd-selenide and attached to biological receptors including antibodies, oligonucleotides, and enzymes. These quantum dots offer several significant advantages over conventional fluorescent indicator dyes used in chemical sensing. First, they are biocompatible, unlike most indicator dyes, which are often toxic to the cell being investigated. Second, their emission is much more intense than typical indicator dyes. Finally, they are more photostable than dye molecules. These last two properties are very important when trying to monitor changes in chemical or biochemical species concentrations over time because most fluorescent dyes exhibit rapid and significant photobleaching with the small amount used in cellular analyses.

60.3.2.4.3 Biologically Encapsulated Chemical Sensors

Another class of nanoparticle-based optochemical sensor that has been developed for cellular analyses employs biological encapsulation of fluorescent indicator dyes to ensure biocompatibility with the cell being investigated. ^{116–121} These biologically encapsulated nanoparticle sensors can be further divided into liposome sensors ^{120,121} and lipobead sensors. ^{116,118} In the case of liposome-based sensors, a fluorescent indicator dye that is sensitive to the particular analyte of interest is encapsulated in the internal aqueous compartment of a liposome. This allows the dye to retain its solution-based characteristics (i.e., spectral emission profile, response time, etc.) while preventing the toxic dye molecules from diffusing throughout the cell. Liposome-based nanoparticle sensors have been developed for both pH and molecular oxygen and applied to various cellular analyses. A variation on these liposome-encapsulated sensors has recently been developed by Rosenzweig et al., in which a phospholipid membrane and fluorescent indicator dye are immobilized onto a polystyrene nanoparticle. These sensors, known as lipobeads, are more stable and less susceptible to biological degradation than liposome-based sensors. In addition, by fabricating these sensors so that the fluorescent indicator dyes are embedded in the phospholipid membrane, they can potentially be used for the measurement of larger chemical species than the liposome sensors or PEBBLEs, which require the analyte to diffuse through a protective coating before interacting with the dye.

60.4 Conclusion

Due to the increasing interest in nanotechnology and its practical use, application of nanosensors and nanobiosensors to different types of cellular measurements is expanding rapidly. Furthermore, it has been shown that these nanosensors and nanobiosensors often provide more reliable measurements of subcellular chemical species than conventional techniques, such as pretreatment with and subsequent monitoring of fluorescent dyes. The use of nanosensor and nanobiosensor technologies has already begun and will continue to revolutionize the field of cellular biology in the future.

Acknowledgments

This research was sponsored in part by the ORNL LDRD project (Advanced Nanosensors Systems Project) as well as the Office of Biological and Environmental Research, U.S. Department of Energy, under contract DE-AC05-00OR22725 managed by UT-Battelle, LLC. B.M. Cullum was also supported by an appointment to the Oak Ridge National Laboratory Postdoctoral Research Associates Program administered jointly by the Oak Ridge National Laboratory and Oak Ridge Institute for Science and Education.

61.1 Introduction

Knowledge about life processes has expanded dramatically during the 20th century and produced the modern disciplines of genomics and proteomics. However, there remains the great challenge of discovering the integration and regulation of living components in time and space within the cell. As we move into the postgenomic period, the complementarity between genomics and proteomics will become apparent, and the connections between them will be exploited, although genomics, proteomics, or their simple combination will not provide the data necessary to interconnect molecular events in living cells in time and space. The cells in a group are different entities, and differences arise even among cells grown in homogeneous conditions considered to have identical genetic information. These cells respond differently to perturbations.¹ The question is why and how these differences arise. They might be caused by unequal distributions of biomolecules in cells, mutations, interactions between cells, fluctuations of environmental elements that affect the cell, etc. To understand the principle underlying the differences, keeping in mind the possibilities mentioned above, a system is necessary that would allow for the continuous observation of specific cells under fully controlled circumstances such as interactions between cells.

Conventional systems such as flow cytometry and direct measurement with a microscope have been used for tracking changes in cells. Flow cytometry enables us to obtain the distributions of parameters like concentration, size, shape, DNA content, etc. at the single-cell level in a group.^{2,3} The problem with these systems is that they cannot track a specific cell's dynamics continuously because the sample drawn from the culture is discarded after the measurement. In addition, these systems cannot keep cells under isolated conditions or identify a particular cell even after cell division has occurred. Thus, these systems can provide information about the average properties of various single cells, that is, how the group changes, but they cannot provide information about how single cells change. On the other hand, direct measurement of cells in solid media, like agarose-gel plate with microscope, is also used widely.⁴⁻⁸ This method makes it possible to identify individual cells and track specific cells continuously. Though the cultivation of cells under isolated conditions can begin by first controlling the spread concentration, cells cannot be kept isolated even after cell divisions have occurred; in addition, it is impossible to control the interactions between particular cells because cell positions are fixed from the beginning of cultivation. Thus, these conventional systems are unsatisfactory for understanding the single-cell-level interaction of particular cells.

Thus, techniques were needed to clarify the relationships among genetically identical cells; to meet this need we have developed an on-chip microculture system based on a combination of recent advances in microfabrication techniques and conventional *in vivo* techniques. ^{9,10} However, the above system lacked a method for controlling the number of cells in a microchamber or for isolating particular cells from the cultured cells. For manipulating cells in microchambers some noncontact forces are required, such as optical tweezers, which have been used as a tool for handling cells, organelles, and biomolecules on a microscope specimen. ^{11–13} By adding optical tweezers, we have also improved the system for controlling the number of cells in microchambers. ¹⁴

In this section, we describe our on-chip microculture system with optical tweezers. We explain the fabrication setup and examine several examples of practical single-cell cultivation, showing that this system is able to control the environment of cells, especially the effects of isolating cells, which has not been achieved with other systems.

61.2 On-Chip Microculture System

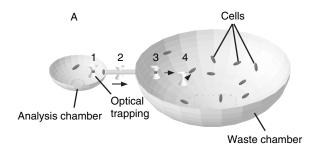

61.2.1 System Concept and Apparatus Design

As shown in Figure 61.1, the on-chip microculture system enables selective transfer of excess cells from an analysis chamber to a waste chamber (cultivation chamber) through a narrow channel (Figure 61.1A) and selective picking up of a particular cell from the cells in the cultivation chamber (Figure 61.1B).

Figure 61.2 shows the entire on-chip microculture system, which consists of four parts: microchamber-array plate, cover chamber, phase-contrast/fluorescent microscope, and optical tweezers. The cover chamber is a glass cube filled with a buffer medium; it is attached to the array plate to enable the medium in the microchambers to be exchanged through the semipermeable membrane. The volume of the cover chamber is 1 ml, and the maximum flow speed is 10 ml/min. The temperature of the buffer medium is controllable with the help of a Peltier temperature controller. The temperature of the stage is also controlled in the same way. The medium can be exchanged easily at any time during culturing by using stock solutions with different chemical and nutrient concentrations.

Phase-contrast/fluorescent microscopy (Olympus IX-70 inverted microscope with an oil-immersion objective lens, $100\times$, NA = 1.35) is used to study the growth and division of cells. Phase-contrast and fluorescent images are acquired simultaneously by using a charge-coupled-device (CCD) camera (Olympus, CS230). The cell images are recorded onto videotape and analyzed using a video-capture system on a personal computer (Sony PCV-R73K). The spatial resolution of the images in this system is 0.4 μ m when the $100\times$ objective lens is used.

A 1064-nm-wavelength neodymium:yttrium-aluminum-garnet (Nd:YAG) laser (T20-8S, Spectra Physics, Mountain View, CA) is used for noncontact handling as optical tweezers, providing the system with the ability to move cells between microchambers. The cells are trapped at the focal point of the

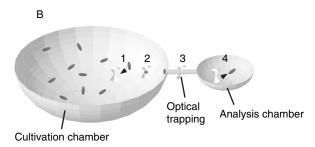

FIGURE 61.1 Schematic drawing illustrating use of on-chip culture system with optical tweezers. (A) To keep the number of cells in the analysis chamber constant a cell in the chamber is trapped by the optical tweezers and transported into a waste chamber through the channel. (B) A particular cell cultivated in the chamber is transported into an analysis chamber.

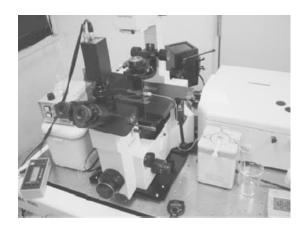

laser beam on the microchamber array and transported by moving the focal point by slightly changing the angle of the 1064-nm dichroic mirror. The maximum laser power at the focal point after passing through the 100× objective lens is 40 mW, although we generally used less than 5 mW, which is the minimum laser power for holding bacteria.

61.2.2 Microchamber-Array Plate

61.2.2.1 Microchamber-Array Glass Slide

As shown in Figure 61.3A, the microchamber-array plate includes an $n \times n$ (n = 20 to 50) array of chambers, where each chamber is 20 to 70 µm in diameter and 5 to 30 µm deep. The biotin-coated microchamber array is covered with a streptavidin-coated cellulose semipermeable membrane (molecular weight [MW] ~25,000) separating the chambers from the nutrient medium circulating through the cover chamber. The semipermeable membrane is fixed on the surface of the glass slide with a streptavidin-biotin attachment, which is strong enough to keep the cells in the microchambers while preventing contamination from the external environment. An example of the spatial arrangement of the microchamber array is shown in Figure 61.3B, where 20-µm (diameter) × 5-µm (depth) microchambers are etched at 100-µm intervals in a 0.17-mm-thick glass slide.

The fabrication process of the microchamber-array plate was as follows. The 0.17-mm-thick glass slide was sonicated in 1 M NaOH aqueous solution and washed with water to clean the surface. After cleaning, the dried glass slide was coated with 100-nm-thick chromium by sputtering and next with positive gline photoresist, OFPR-800 (Tokyo Ohka, Ltd., Kawasaki, Japan) by spinning. Following baking of the slide for 15 min at 85°C, lithography of the microchamber-array patterns was carried out on a contact aligner with a broadband near-ultraviolet (UV) source (G, H, and I lines). The exposed glass slide was then developed and dried again. The exposed region of the glass slide was etched by MPM-E30 solution (Intec Inc., Tokyo, Japan) for chromium and then by hydrofluoric acid (HF) (4.7% [w/v]), NH₄F (36.2% [w/v]) solution (etching velocity = 60 nm/sec at 25°C) for glass. When the shape of the microchambers attained the desired size, the glass slide was washed with water to stop etching and dried again.

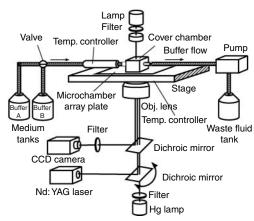

FIGURE 61.2 Photograph and schematic drawing of on-chip system with four parts: microchamber array plate, cover chamber, phase-contrast/fluorescent microscope, and Nd:YAG laser.

61.2.2.2 Streptavidin Decoration on Cellulose Semipermeable Membrane

First, cellulose semipermeable membrane (Spectora/Por M_W 25,000, Spectrum Laboratories Inc., Dominguez, CA) was washed with pure water and cut in proper sizes adequate for sealing the glass slide. Next, the washed membrane was incubated in $0.2~M~NaIO_4$ for 6 h to generate aldehyde functions by oxidation of *cis*-vicinal hydroxyl groups of agarose. Because aldehydic functions react at pH 4 to 6 with primary amines to form Schiff bases, the membrane was washed twice in 0.1~M phosphate buffer (pH 6.0) and $15~\mu g/ml$ streptavidin hydrazide (Pierce Biotechnology Inc., Rockford, IL) were added. After 2 h incubation, the membrane was washed with water and stocked at $4^{\circ}C$ (see Figure 61.4).

61.2.2.3 Biotin Coat on the Surface of Microchamber-Array Glass Slide

The dried microchamber-array glass slide was next dipped in the solution containing 1% 3-(2-amino-ethylaminopropyl) aq. at 25°C to decorate the amino group on the surface of the glass slide. The amino-coated glass slide was dried for 30 min at 120°C. Next, to decorate the biotin on the surface of the glass slide, 1 mg/ml EZ-Link NHS-LC-Biotin (Pierce) aq. was dipped on the surface of the amino glass slide and incubated for 60 min. The biotin-coated glass slide was washed with water, dried at room temperature, and stored (see Figure 61.4).

61.2.2.4 Microchambers Made of Thick Photoresist, SU-8

As shown in Figure 61.5, the microchambers and channels can also be formed on a glass slide lithographically using a thick photoresist, SU-8 (Microlithography Chemical Corp., Watertown, MA) with an aspect ratio of

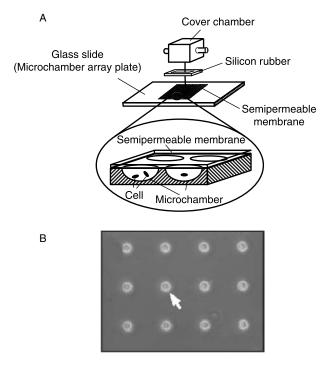

FIGURE 61.3 Design of microchamber-array plate. (A) Schematic drawing of microchamber array plate. An $n \times n$ (n = 20 to 50) array of microchambers is etched into a 0.17-mm-thick glass slide. Each microchamber is covered with a semipermeable membrane separating the chamber from the nutrient medium circulating through the medium bath in the cover chamber. A single cell or group of cells in the microchamber can thus be isolated from others perfused with the same medium. (B) Optical micrograph of the microchamber-array plate. The arrow indicates the position of one microchamber. The bar indicates a length of $100 \mu m$.

 $5 \mu m$ in height and $5 \mu m$ in width, enough to cultivate and transport cells (Figure 61.5A). The process is as follows: (1) spin coat of SU-8 on surface of glass slide at 1400 rpm/sec for 20 sec, (2) soft bake at 125°C on hotplate for 30 min, (3) expose pattern using deep ultraviolet flood at 100 W for 20 sec, (4) bake at 125°C on hotplate for 30 min, and (5) develop and rinse off imaging resist.

Figure 61.5B shows the cross-section view of the microchamber, the core of the microculture system. On a 0.2-mm-thick glass slide, microchambers are fabricated for cell cultivation as described above. The surface of the glass slide is then decorated with biotin and covered with an avidin-decorated cellulose semipermeable membrane (MW \sim 25,000) to separate the microchambers from the nutrient medium circulating through the cover chamber. The membrane is also fixed to the surface of the glass slide using an avidin-biotin attachment, which is strong enough to keep the cells in the microchambers while preventing contamination from the external environment. Cells are transported between the microchambers with optical tweezers. The buffer medium in the chambers is exchanged with that in the cover chamber through the membrane.

61.2.2.5 SU-8 for On-Chip Microculture System

In this experiment, we used a 1064-nm laser for optical trapping. We have chosen the SU-8 photoresist for the following three reasons. First, neither the SU-8 nor the semipermeable membrane has absorbance at 1064 nm. Second, when we used SU-8 for the microchambers, no etching was permitted on the bottom of the glass slide, that is, the bottom of the microchambers was optically flat. In fact, we were able to trap bacteria anywhere in the microchamber array and observed no damage to the microchambers or membrane during our experiments. Third, no nonspecific attachment of cells to the SU-8 surfaces was

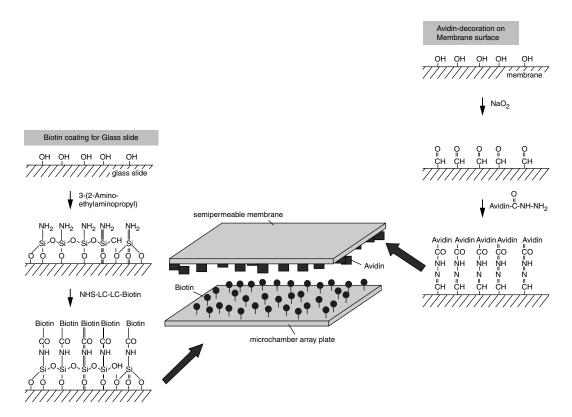

FIGURE 61.4 Streptavidin decoration and biotin coat procedure.

observed. This was due to the constituents of SU-8: 20 to 25% gamma butyrolactone, 1 to 5% propylene carbonate, 70 to 75% epoxy resin, and mixed triarylsulfonium/hexafluor *o* antimonate salt.

61.2.3 Bacterial Assays and Growth Conditions

In our experiments, we used a standard sample of *Escherichia coli* strain JM109 (*end*A1, *rec*A1, *gyr*A96, *thi*, *hsd*R17(r_{k-} , m_k^+), *rel*A1, *sup*E44, λ –, Δ (*lac-pro*AB), [F',*tra*D36, *pro*AB, *lac*IqZ Δ M15]; Toyobo Co., Ltd., Tokyo, Japan). Before the on-chip cultivation, the cells were grown overnight in an orbital shaker at a speed of 250 rpm and temperature of 37°C with 100 ml M9LB medium, which consisted of a minimal medium (M9: 4.5 g/l KH₂PO₄, 10.5 g/l K₂HPO₄, 50 mg/l MgSO₄,7H₂O; pH 7.1) containing 1% (v/v) Luria-Bertani medium (LB) and 100 mg/l ampicillin. When the cultured cells reached the stationary phase (10⁸ to 10⁹ cells/ml), they were fractioned and placed in 500-µl sample tubes and maintained at –80°C as a glycerol stock solution (50% v/v). For each experiment we reactivated the stock cells at 37°C in M9LB medium, using the orbital shaker at 250 rpm. After 20 h of cultivation, the cells returned to the stationary phase and were diluted to 10⁵ cells/ml and cultured again until the concentration reached 10⁸ cells/ml. They were then used as samples for one-cell cultivation. In this cultivation, the number of cells was measured by using a counting glass slide (Erma Optical, Inc., Tokyo, Japan) and the IX-70 optical microscope.

61.2.4 Single-Cell Cultivation in On-Chip Microculture Systems

For single-cell cultivation, prepared *E. coli* cells were spread on the microchamber array plate and sealed in with the streptavidin-coated cellulose semipermeable membrane. Figure 61.7 shows the cell number in each microchambers after the lid was attached. As shown in the figure, about 300 (75% of the total) microchambers were vacant and 50 (12.5% of the total) chambers were packed with isolated single cells.

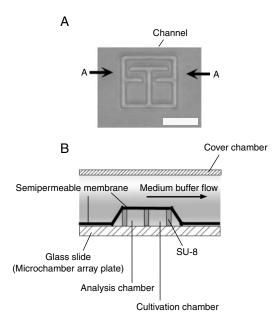

FIGURE 61.5 Microchamber array using thick photoresist SU-8. There are several microchambers on the microchamber-array plate, including an analysis chamber and a cultivation chamber, connected by a channel. The buffer medium in the chambers is exchanged through a semipermeable membrane. Cells in the microchambers are transported by optical tweezers. (A) Optical micrograph of microchambers and channels constructed lithographically using thick photoresist SU-8. Bar = 50 µm. (B) Schematic drawing of A-A cross-sectional view of microchamber (A).

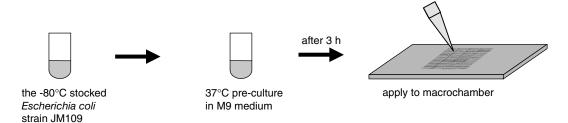

FIGURE 61.6 Schematic diagram of sample preparation.

Cells entrapped in nonwell regions were sandwiched between the glass slide and the membrane and were no longer moved or grown. When the concentration of cells in the dropping buffer exceeded 10^9 cells/ml, the batch culture of cells stopped growing as the cells entered the stationary phase. On the other hand, when the concentration was less than 10^7 cells/ml, cells were in lag phase or early log phase, which was before or just as the number of cells started to increase. Thus, the concentration of *E. coli*, 10^7 to 10^9 cells/ml, was appropriate for packing one cell into each microchamber. Concerning how the lid was attached, we generally used one of the following methods: (1) by incubating the membrane on the glass slide until they became attached or (2) by using centrifugation (× 1000 g) to remove excess water and attach the membrane on the glass slide. After the membrane was attached to the plate, no *E. coli* trapped in the microchambers could escape. The membrane-sealed microchamber-array plate was then covered with the cover chamber and set on the stage of the microscope. Those microchambers that trapped single *E. coli* cells were chosen for observation. The time-course changes of the chosen isolated *E. coli* were continuously observed and recorded by the CCD camera and VCR (max. 405-min recording).

After recording, the time-course growth of the single E. coli cells was analyzed using image-analysis software (1/30 sec and 0.2- μ m resolution). We defined the length of an E. coli cell as the distance between

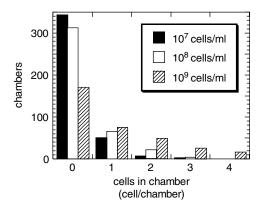

FIGURE 61.7 Number of cells in each chamber of the microchamber array (400 microchambers) after cells were spread and sealed with membrane. The concentrations of culture cells used for packing were 10⁷, 10⁸, and 10⁹ cells/ml, respectively.

its two ends (see Figure 61.8) and the growth of an *E. coli* cell as its elongation rate. The length measurement included 10 to 15% uncertainty because we could only measure the two-dimensional end-to-end length images of three-dimensionally tumbling *E. coli*.

In this system, we used a 0.17-mm-thick glass slide because the maximum working distance of the X100, N.A. 1.35 objective lens was less than 0.3 mm. As shown in Figure 61.8, no *E. coli* attachment on the glass surface in the microchamber wells was observed during cultivation. Thus, we could measure the time-course change of *E. coli* swimming freely in the microchamber.

61.3 Single-Cell Cultivation Using On-Chip Microculture Systems

61.3.1 Observation of Cell Growth Rate and Cell-Division Time in Microchambers

We first examined the growth and division of E. coli under isolated conditions (Figure 61.8). In this experiment, we used the chamber that was the size of the initial concentration for the isolated single cells — 1.0×10^{10} cells/ml. First, in this example, we observed that an isolated E. coli cell, 2.9 µm in length, maintained its length for 80 min (Figure 61.8A). After 80 min of sleep (we call this "sleep time"), the cell started growing at a rate of 0.04 µm/min, frequently bending around the septa. When the cell reached a length of 7.4 μm (160 min after inoculation), it divided into two daughter cells (Figure 61.8C and D), each with a length of 3.6 µm. Following the first division, the two daughter cells started growing and tumbling again like the first "mother" cell. The daughter cells divided again after they had grown for 60 to 70 min (Figure 61.8F). The period of cell division after cell growth began increased exponentially, at a rate of 86 min/cell division. Using this method we examined the division time of daughter cells born from isolated mother cells in microchambers. Figure 61.9 shows the distribution of division time of newborn daughter cells (n = 160). As shown in the graph, the cell division of daughter cells started at least 31 min after they were born, and the cell division time was spread from 31 to 223 min. Mean celldivision time, 86.6 min (S.D. 38.1 min), was longer than the peak value of 50 to 70 min. Figure 61.5 explains the initial length dependency of the division time. The samples with an initial length of 3 to 4 μm (filled bars) and 4 to 5 μm (hatched bars) show the same statistical distributions of division time, or a mean time of 72.9 min (SD 31.1 min) for 63 samples and 75.5 min (SD 28.2 min) for 16 samples, respectively, whereas those measuring 2 to 3 µm (open bars) showed a different distribution, or mean division time — 105.1 min (SD 41.0 min) for 64 samples.

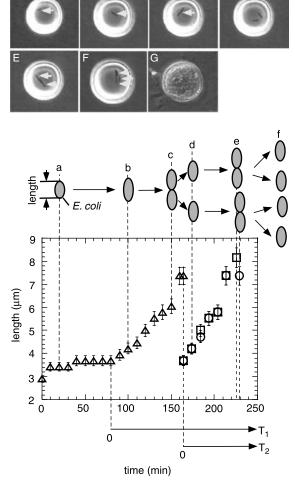

FIGURE 61.8 Time course of isolated single *E. coli* cell growth in a microchamber. The magnified micrographs at the top (A to G) show the time course of one of the microchambers shown in Figure 61.12 at times of (A) 0 min, (B) 100 min, (C) 150 min, (D) 175 min, (E) 225 min, (F) 230 min, and (G) 15 h after inoculation. The arrows in the micrographs show the positions of *E. coli* cells in the microchamber. The bar indicates a length of 10 μm. The graph at the bottom shows the time-course growth of the individual *E. coli* cells.

This experiment demonstrated several advantages of this system. First, neither contamination from the cover chamber nor escape of E. coli cells from the small chamber was observed during the experiment. Second, the direct descendants of single cells could be cultured and compared in the isolated microchambers. Third, the physical properties of the cells in each microchamber could be continuously observed and compared. Finally, the resolution of cell length, $0.2~\mu m$, was an order of magnitude smaller than that of conventional methods like the Coulter Counter (Coulter Electronics, Inc., Hialeah, FL) that determine the sizes of cells electronically.

61.3.2 Growth and Cell Cycles of Daughter Cells after Single-Cell Division

We can also compare cell growth and cell division times among isolated single cells and their daughter cells. Daughter cells have the same DNA and cytoplasm as their mother cell, and in this experiment they grew in the same environment, including physical contact with each other. The graph in Figure 61.10

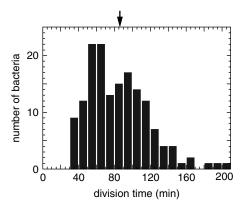

FIGURE 61.9 Distribution of division time of daughter cells. Arrows indicate the mean time of cell division, 86.6 min (SD = 38.2, n = 160).

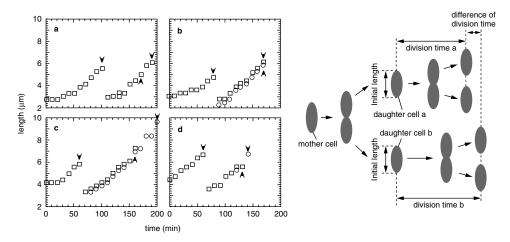

FIGURE 61.10 Time-course growth of isolated individual *E. coli* cells and two daughters. The arrowheads indicate the cell division occurring in the cells.

shows four examples of such a comparison. An isolated mother cell grew at $0.04~\mu m/min$ and divided 85 min after cell growth began, while its daughter cells grew at $0.06~\mu m/min$ and divided after 65 to 70 min. In this case, although the growth rate and cell-division time for the mother and daughter cells were different, those for the two daughter cells were almost the same. But none of the eight other comparisons showed strong correlation either between mother and daughter cells or between daughter cells (data not shown). We also observed that mother cells sometimes divided into two daughter cells of obviously unequal lengths (data not shown).

61.3.3 Flexible-Medium Buffer Exchange through Semipermeable Membrane

Controlling the medium conditions is important for single-cell analysis. A semipermeable membrane attached on the microchamber-array plate exchanges the medium in microchambers within the time resolution of the VCR system, <1/30 sec, which was checked by a real-time confocal optical microscopy system (CSU21, Yokogawa Electric Corp., Tokyo, Japan). The result indicated no delay of diffusion at 5-µm depth with 1/30-sec resolution. That is, there was no difference of increase of the fluorescent dye's

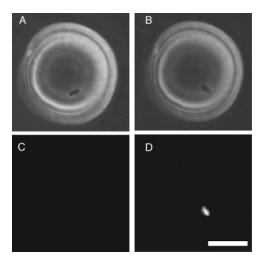

FIGURE 61.11 Green fluorescent protein expression in *E. coli*, shown (A, B) before IPTG induction and (C, D) 60 min after IPTG induction was begun. (A) and (C) are phase-contrast micrographs; (B) and (D) are fluorescent micrographs. The arrows show the positions of *E. coli*. The bar indicates a length of 10 μm.

concentrations between the top and the bottom of the microchamber after the introduction of the dye into the system. Thus, we concluded the diffusion time was 1/30 sec.

As shown in Figure 61.8, after overnight culturing the number of *E. coli* cells had fully increased in the microchamber (Figure 61.8G). In this case, the concentration of *E. coli* corresponded to $>10^{12}$ cells/ml, which is more than a thousand times larger than the stationary-phase concentration of $>10^9$ cells/ml in batch cultivation with the same sample and medium.

We tested another use of the on-chip culture system — for changing the medium solution in the microchambers through the semipermeable membrane. Single *E. coli* cells were cultured in small chambers with an M9LB medium. To express Green Fluorescent Protein (GFP) in *E. coli* (JM109), we used an M9LB-IPTG medium buffer, which is M9LB with 1 mM isopropyl-×-D(-)-thiogalactopyranoside (IPTG; Wako Chemical Co., Tokyo, Japan) and 0.1 mM lactose. As shown in Figure 61.11(A) and (B), no GFP expression was observed before IPTG induction. GFP expression was successfully observed 40 min after the medium exchange from M9LB to M9LB-IPTG. Figure 61.11(C) and (D) shows the GFP fluorescence in the same *E. coli* 60 min after the medium exchange, which is almost the same as batch-cultivation data under the same buffer conditions at 37°C.

These results show good system performance for solution exchange, which is difficult for batch- or plate-cultivation methods.

61.3.4 Flexible-Chamber-Size Control of Single-Cell Cultivation

This on-chip culture system makes it easy to control the environment for cultivation. For example, cultivation volume can be controlled by using microchambers of various sizes. Figure 61.12 shows one example of volume control by using various microchambers. The size of the chamber shown in Figure 61.12B is 20 (diameter) \times 5 μm (depth), which we call a "small chamber," and that in Figure 61.12C is 70 (diameter) \times 30 μm (depth), a "large chamber." The volumes of the chambers are 1.0×10^{-10} and 7.7×10^{-8} ml, respectively. If we culture single cells in these chambers, the estimated concentrations are 1.0×10^{10} cells/ml and 1.3×10^{7} cells/ml, respectively.

Figure 61.13 shows the chamber-size-growth dependence of single *E. coli* cells. The average growth speeds of five samples were 0.06 μm/min, both in the small chamber and in the large chamber. The mean values of cell-division time were also almost the same for both chambers — around 45 min. The results showed no significant differences in mean values of growth speed and cell-division time, even when the chamber sizes were 1000 times different, i.e., the mean free paths were 10 times different.

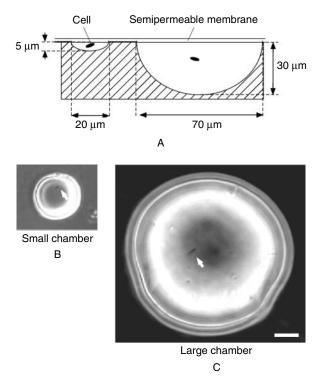

FIGURE 61.12 (A) Schematic drawing of the two sizes of microchambers The "small chamber" on the left is 20 μ m in diameter and 5 μ m deep, while the "large chamber" on the right is 70 μ m in diameter and 30 μ m deep. Optical micrographs of (B) a small chamber and (C) a large chamber. The arrows indicate the positions of *E. coli* cells in the chambers. Bar = 10 μ m.

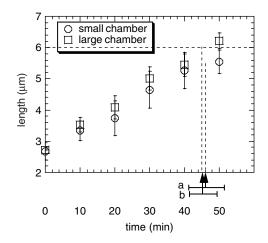

FIGURE 61.13 Chamber-size dependence of *E. coli* cell growth. The circles indicate a small chamber, 20 μm in diameter and 10 μm deep (Figure 61.12B). The squares indicate a large chamber, 70 μm in diameter and 30 μm deep (Figure 61.12C). The plotted points are mean values of cell length at 10-min intervals, with error bars indicating the SD of five cells. The arrow and bar labeled "a" indicate the mean time and SD of the cell-division time for the small chamber; those labeled "b" indicate these values for the large chamber.

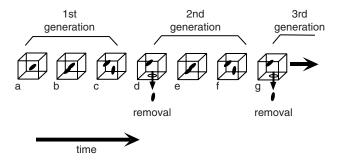

FIGURE 61.14 Concept and process used to continuously observe direct descendants under isolation conditions.

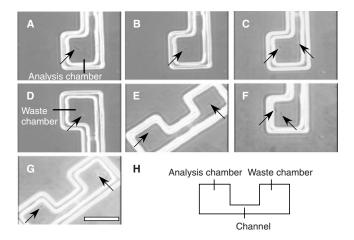

FIGURE 61.15 Example of continuous observation of direct descendants under isolation conditions in the microchamber array: (A) isolated single cell in the analysis chamber almost divides; (B) the cell has divided into two daughter cells; (C) one of the daughter cells is trapped by optical tweezers and is going to be removed from analysis chamber to waste chamber through the channel; (D) the trapped cell has been removed to the waste chamber; (E) the whole image of two daughter cells after removal; (F) the cell in the third generation divided unequally in length; (G) the whole image of analysis chamber and waste chamber in a fourth-generation cell; (H) schematic drawing of the whole image of the chamber. Bar = $30 \mu m$.

61.3.5 Continuous Single-Cell Cultivation with Optical Tweezers

Using this system we also examined whether the direct descendants of an isolated single cell could be observed under the same isolated conditions. For observing the isolated single cells continuously even after cell division occurred, we developed the following method. As shown in Figure 61.14, we first isolated a single cell in the analysis chamber (first generation) and observed its growth (Figure 61.14A). Once cell division occurred, one of the two daughter cells was removed from the chamber quickly before they made physical contact (Figure 61.14C and D). The isolated second-generation cell was observed continuously until it divided again. This process was repeated as many times as possible.

Figure 61.15 shows an example of continuous observation of the direct descendants of a mother cell under isolated conditions, as explained above. First, one mother cell (8.8 μ m long) was enclosed in an analysis chamber and observed continuously (Figure 61.15A). Right after the cell divided one of its daughter cells was trapped by optical tweezers and transported to a waste chamber through a narrow channel (cell trap path) (Figure 61.15B through E). The same procedure was done every time the cell in the analysis chamber divided. In the course of observation, the cell in the third generation divided unequally; one was 5.4 μ m long, and the other was 3.6 μ m (with an error of ± 0.4 μ m because of limitations

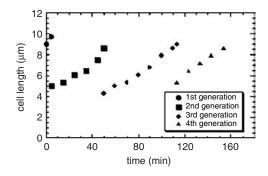

FIGURE 61.16 Time course of cell growth of isolated single cells shown in Figure 61.15.

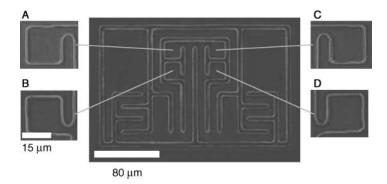

FIGURE 61.17 Another example of continuous observation of direct descendants under isolated conditions in four-room microchambers for simultaneous observation and comparison. In each of the four chambers (A through D) at the center of the microstructure, isolated single cells are cultivated and compared.

in resolution) (Figure 61.5F). The cell in the fourth generation also divided unequally again; one was 5.3 μ m and the other was 3.8 μ m. They were quite different from the cell division in the second generation (Figure 61.5B). The lengths of the two daughter cells were almost equal — around 4.9 μ m. It has been reported that *E. coli* cells divide equally, ¹⁵ but in our system, unequal cell division in length has often been observed.

Figure 61.16 shows the time course of cell growth of four generations of direct descendants in the sample shown in Figure 61.15. As shown in the result, cell cycles for cell division seems independent among generations. In addition, we could not find strong correlation among generations in the elongation velocity or cell-division lengths.

Figure 61.17 shows another example of single-cell cultivation using different chamber designs. In the experiment shown in Figure 61.15, the cells in the waste chamber easily invaded the analysis chamber by swimming because the path (channel) was too simple. Thus, we made the channel pathway in the chambers more labyrinthine. This prevented the escape of the cell from the chambers. Using this chamber array we were able to analyze and compare four cells simultaneously under isolated conditions. The four graphs shown in Figure 61.18 indicate no significant correlation among those four cells during cultivation.

61.3.6 Differential Analysis of Single-Cell Cultivation in Microchamber-Array Systems

The results shown in Figures 61.16 and 61.18 illustrate only half of the two daughter cells' properties. We thus improved the method and the microchamber array to enable us to measure all the descendant cells of an isolated mother cell (Figure 61.19).

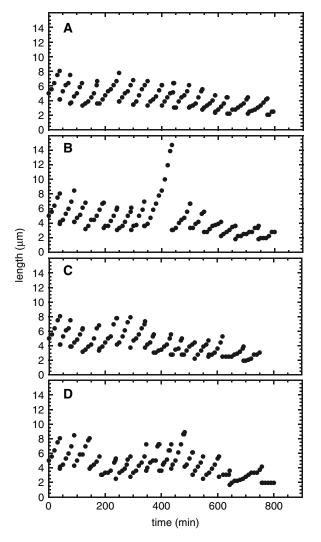

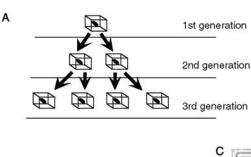

FIGURE 61.18 Time course of the four cousin cells' growth under isolated conditions. (A) through (D) indicate the samples in chambers A through D, respectively, of Figure 61.17.

Figure 61.19B shows the chamber array we used for complete descendant analysis. The cultivation was done as follows. First, a cell was transferred into chamber 1 (first generation) with optical tweezers. When the cells cultivated in chamber 1 divided into two daughter cells, they were transferred one by one into the second generation's chambers. Next, the isolated daughter cells divided again, and the granddaughter cells were transferred into the third generation's chambers. The same process was followed after the cells of the third generation divided again. Note that all the cells were irradiated during the cell trapping, unlike in the other experiments described above.

As shown in Figure 61.8B, the results indicate the existence of fluctuations of cell length, division time, and division length among direct-descendant cells — even between two sister cells. For example, as shown in the lower graph of Figure 61.20, one of the daughter cells (second generation) was 3.1 μ m long at birth and grew as long as 11.9 μ m. At this length, it produced two cells, one 9.2 μ m long and the other 2.8 μ m long, and the ratio of length between newborn cells was almost 3:1. Although the longer cell appeared to be one cell, it might be the size of three cells. If this is true, avoiding several divisions would lead to different patterns of cell reproduction and may affect the proliferation of the cell group.

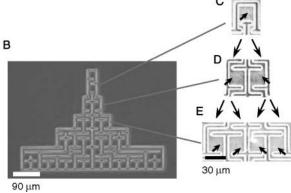

FIGURE 61.19 The process of observation of each descendant cell for generations derived from a single cell (A) and the micrograph of the microchambers for complete descendant analysis (B); (C) microchamber for first generation with isolated single mother cell; (D) two daughters isolated in each chamber; (E) four granddaughters in each of the four microchambers.

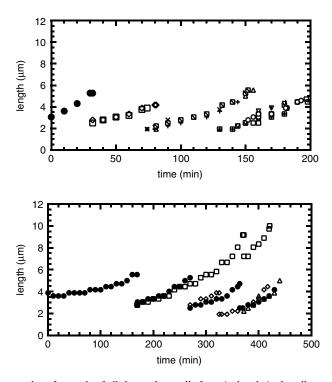

FIGURE 61.20 Two examples of growth of all descendant cells from isolated single cell.

61.4 Conclusion

This chapter described the on-chip microcultivation system, which has four advantages; it allows for (1) continuous cultivation of single cells under isolated conditions; (2) control of spatial distribution of cells, interactions of cells, and the number of cells in the chamber; (3) continuous observation of identical specific cells under contamination-free conditions; and (4) control of the environmental conditions surrounding cells such as the cultivation buffer. We also demonstrated two methods for analysis of single-cell differences using the on-chip microculture system and optical tweezers. Although we showed only a few examples of our experimental results, these results demonstrated the unique potential that our system has for detecting several phenomena. Differential analysis should help clarify heterogeneous phenomena such as unequal cell division and cell differentiation, which will become more and more important in the "cellome" era.

62.1 Functional Imaging in Target-Directed Paradigms

62.1.1 Animal Models in Drug Development

Animal models that are used for biological assessment in drug development typically represent advanced, or even end-stage, disease and often require sacrifice of the animal for analysis. The assays that are subsequently performed on tissue samples can be time-consuming and can only provide a snapshot of the overall disease course, even when performed on large numbers of animals. Therefore, one must consider the limitations of the data that result from conventional animal protocols that employ *ex vivo* assays, which are constrained by sample size, limited to a small number of selected time points, and performed in the absence of intact organ systems. Moreover, in the current paradigm of target-directed drug discovery, the events that occur early in the disease process represent important targets for therapeutic intervention, and therefore development of assays that provide access to information about these targets during therapeutic intervention is essential for evaluating the new classes of compounds that are being developed. Functional imaging that is relatively high-throughput and yields multiparameter data

will be required to sort out the vast numbers of targets and compounds introduced into drug discovery by this evolving paradigm. Imaging strategies have been designed specifically for laboratory animals, and their use for *in vivo* assessment of therapeutic efficacy has the potential to greatly influence the pharmaceutical industry. One of these imaging modalities, *in vivo* bioluminescent imaging (BLI), and its application to drug discovery and drug development are the subject of this chapter.

62.1.2 Optical Imaging

Imaging modalities in the optical regime have the advantages of being sensitive, accessible, relatively low-cost, and rapid. This has led to the development of a number of optical-imaging approaches for *in vivo* analyses. ¹⁻¹⁵ Of these, some are particularly well suited for the purpose of accelerating the drug-development process as they address the unmet need of real-time *in vivo* assays that are ideal for imaging small laboratory animals. ^{5,18–20} From an imaging perspective visible light is safe to use, even in large doses, can penetrate relatively deeply into certain kinds of tissues, does not require a chemical substrate, and is quantifiable under certain circumstances. Light can also be repeatedly introduced into a tissue with safety and is not subject to radioactive decay. As there are few, if any, sources of light in mammalian systems, especially at near-infrared (NIR) wavelengths, background is minimal, if not completely absent, resulting in extraordinary signal-to-noise ratios (SNRs). For tissues and organs like the breast, with low light absorption in the 700- to 850-nm spectral range, optical imaging is clinically feasible; however, there may be significantly fewer clinical applications than those developed for animal studies.

62.1.3 Imaging in the Preclinical Stage

Increasingly, the subject of conservative use of laboratory animals is resonating with those who see the scientific and economic value of responsible animal-use protocols. To address these issues a number of imaging methods that are based on clinical imaging modalities have been modified for studying animal models. These include magnetic resonance imaging (MRI),^{4,5,21–33} positron emission tomography (PET), single-photon-emission tomography (SPECT),^{33–42} and x-ray-computed tomography (CT).^{43,44} The composite of these and the optical methods represents significant advances in the nascent field of molecular imaging, and many of these imaging methods will likely have a dramatic effect on preclinical studies in laboratory animals.⁴⁵

Incorporating imaging technologies that are rapid and accessible into preclinical studies will yield more and higher-quality experimental data per protocol by increasing the number of times that quantitative data can be collected. By imaging the whole intact live animal at multiple time points researchers can analyze biomolecular processes in the presence of the contextual influences of intact organs. It is an added benefit that with these methods fewer animals can deliver data with greater statistical significance and lower stress. Noninvasive methods can be used to create more predictive animal models that share the characteristics of longitudinal-study design, internal experimental control, molecular information, and quantitative data, and these methods will benefit both scientific inquiry and humane animal use.⁴⁵ In addition, imaging can further improve these studies by guiding appropriate endpoint-tissue sampling for histology or biochemical analysis. Imaging of cellular and molecular targets in living-animal models of human biology and disease has been used for animal-research protocols in fields as diverse as cancer biology, microbiology, and gene therapy. Such tools enable noninvasive *in vivo* assessment in individual animals over time, which reveals temporal changes and reduces the number of animals required for a given study.

The advantages of imaging in drug development address many of the limitations at the preclinical stage, and the improved preclinical data sets will lead to better study designs for the clinical trials; in addition, the more user friendly and accessible the methods become the more likely they are to be integrated into these protocols. Optical imaging using bioluminescent reporters for tracking and monitoring cell populations and assessing levels of gene expression or monitoring *in vivo* gene delivery is gaining wide acceptance in the pharmaceutical industry as an accessible and versatile method of approaching the study of animal models of disease.⁴⁵ BLI can be incorporated into target validation during the

discovery phase of drug development, or it can be used to assess *in vivo* efficacy, safety, and toxicity during preclinical development of specific compounds. With BLI several parameters of drug efficacy and pharmacokinetics can be monitored in the same animal over time, yielding benefits for the discovery and development stages of drug evaluation.

62.2 In Vivo Bioluminescent Imaging in Drug Discovery

62.2.1 In Vivo Bioluminescent Imaging

BLI has been used as a noninvasive means of tracking pathogens or tumor cells in animal subjects early in the disease process^{4,5,15,18,46–51} and more recently has been used to develop new animal models that incorporate reporter genes into the rodent genome as markers of transcription that reveal developmental changes or response to stress.^{19,52,53} These transgenic strategies permit monitoring of a wide variety of biological events noninvasively in living animals and enable relatively high-throughput *in vivo* screens that are likely more predictive of the human response to therapy. Given the accessibility and speed of BLI, researchers will be able to perform *in vivo* efficacy, pharmacokinetics, toxicology, and target validation studies on a larger number of compounds than was possible in the past. As these more physiologically relevant assays are conducted earlier in the drug-development cycle than was previously possible,²⁰ the decision of whether or not to pursue a compound can be made at a critical time-saving point in the development process.

BLI exploits the light-emitting properties of photoproteins such as luciferase enzymes and is based on the capacity of certain living organisms, including some species of bacteria, algae, coelenterates, beetles, fish, and fireflies, to emit visible light.^{20,54,55} Since these chemical reactions, which produce light, can be replicated outside of the organisms to which they are native, bioluminescence has proven extremely useful for research at the cellular and molecular levels and have been used in live-cell assays.^{56–59} New developments in detection technology have advanced BLI from biochemical and live-cell assays to include *in vivo* whole-body imaging of pathogens, tumors, and gene-expression patterns in living animals.²⁰

Compared to *in vitro* systems or simple transparent organisms, signal attenuation in whole-rodent systems can be severe and varies according to emission wavelength and type and depth of location of the tissues surrounding the cells containing any fluorescent or bioluminescent reporter. Blue-green light (400 to 590 nm) is strongly attenuated by tissue, while red to NIR light (590 to 800 nm) is less affected. Most types of fluorescent and bioluminescent proteins have peak emission at blue to yellow-green wavelengths, although the emission spectrum from firefly luciferase, the most widely used source of bioluminescent light, is broad enough that there is also significant emission at red wavelengths (>600 nm), which penetrate quite deeply into tissue.⁶⁰ There are a number of dyes that are fluorescent in the NIR that can be conjugated to biomolecules and are being developed as imaging reagents.^{21,61}

Experience with a wide variety of characterized luciferases has yielded methods for *in vivo* discovery using these enzymes as internal sources of light that can be monitored externally as real-time indicators of biological function in living specimens. Ultrasensitive cameras, employing recent technological advances in photon detection, are now being broadly applied to biological questions and can be used successfully to detect the few photons that escape the scattering and absorbing environment of mammalian tissues.⁶⁰ The fundamental biochemistry of light production in these organisms consists of the oxidation of a substrate under the catalysis of luciferase enzymes, which produces, as a decay product of the chemical reaction, a heatless light until the excited-state molecules return to the ground state. The luciferin substrates and the structures of the luciferase enzymes vary by organism, as do the mechanisms controlling the speed and intensity of the luminescence. Certain cofactors, such as the nucleotide ATP or other sources of energy, may need to be present for conversion of the substrate to take place.^{55,62-66}

Since these reactions can be replicated outside the organisms to which they are native, bioluminescence has proven extremely useful for research at the cellular and molecular levels. The availability of instrumentation that can measure the light emitted in these reactions with great sensitivity and dynamic

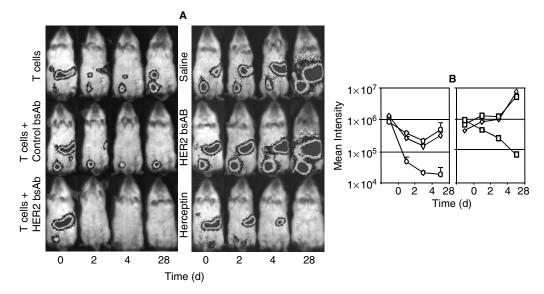

FIGURE 62.1 (Color figure follows p. 28-30.) Advancing complex therapeutic strategies for malignancy through imaging. Evaluation of cell-based therapies complexed with molecular therapies may be complicated by having "too many moving parts," and imaging approaches have been used to optimize these therapies by rapidly providing efficacy data without sacrificing the study subjects. In a study by Scheffold et al., the ability to redirect a tumoricidal NK T cell population to a tumor target using a bispecific antibody was revealed using BLI.⁶⁸ The control groups in this study consisted of the NK T cells alone, the NK T cells with an irrelevant bispecific antibody, normal saline, the bispecific antibody without additional cells, and herceptin (as a positive control). Temporal analyses for representative animals in each treatment group are shown (A) and data from all animals are plotted (B). Color-coded NK T cells only = light blue, NK T cells and control bispecific antibody = red, NK T cells and bispecific antibody = dark blue, saline = aqua, control bispecific antibody = black, and herceptin = dark green. BLI offers the ability to rapidly study multiple animals in each of six treatment groups and provide accurate whole-body data that are quantitative.

range has made them powerful tools for biochemical and clinical analysis because the optical signatures can be detected at a very low level. Compared to other techniques, such as colorimetric or spectrophotometric indicators, bioluminescent analysis offers the advantages of high sensitivity, wide linear range, low cost per test, and relatively simple and inexpensive equipment. Firefly luciferase is the most commonly used bioluminescent system in research, and bacterial luciferases (Lux) are used in prokaryotic systems. The light-producing reaction of the North American firefly, *Photinus pyralis*, is also the most extensively studied bioluminescent system. Firefly bioluminescence, for example, has been used to assay levels of ATP nucleotide, which supplies energy to cells for many important biochemical processes, with extreme sensitivity. Whereas most enzyme assays yield either a product or the disappearance of a substrate, firefly luciferase acts as a quantifiable reactant rather than as a catalyst, whose most significant and easily measured product is light.

62.2.2 Linking Correlative Cell-Culture Assays to Animal Models

A significant advantage of *in vivo* luciferase monitoring is that bioluminescent reporters allow for an integrated approach in which the same label can be used in cell-culture correlates of biological processes and then *in vivo* to test predictions made in cultured cells. In this way, a predictable animal model with highly correlative data can offer validation of an established cell-culture assay. An example of this was demonstrated in a study by Scheffold et al. where cytotoxicity assays were modified to use luciferase-labeled target cells, and the efficacy of tumoricidal activity of NK T cells was assessed.⁶⁸ The assay was then moved into animal models without changing the reporter, and the same cytotoxic T cells and tumor targets could be studied in *in vivo* models of immune-cell therapies (Figure 62.1).

The data from this study also demonstrated that development and testing of complex treatment regimens could be greatly accelerated using imaging.⁶⁸ In this study, the cytotoxicic NK T cells were redirected to the tumor target using a bispecific antibody, and this treatment was compared to herceptin alone and to four other controls including two NK T cell controls and two antibody controls (Figure 62.1). Tumor-burden data were collected twice in the first week and then weekly for 28 d. The number of study groups and data points would not have been possible using conventional assays. Imaging will have an increasing role as therapies are developed that involve immune cells, radiation, DNA-based therapies, and chemotherapies as complementary approaches. The optimization of single drug-treatment regimens can be greatly accelerated using imaging assays that can rapidly measure tumor burden. However, the development of more complex multistep therapeutic strategies such as nonmyeloblative bone-marrow transplantation will depend much more heavily on imaging to assess outcome and determine the mechanisms of action.

62.3 Application Areas

62.3.1 Cancer Therapies

Effective evaluation of new treatment strategies for malignant disease will require that the animal models closely resemble the human diseases that they are designed to model. The subcutaneous xenograft models of human malignancies are, in some respects, less able to model the human disease than are orthotopic or spontaneous tumor models.^{69–71} However, these better models of disease are frequently more difficult to study as the lesions can be located deep within the body and are not accessible for caliper measurements. The disease in these models can involve multiple organ systems and occur in the face of an intact immune system. It is these models that will contribute to our understanding of disease mechanisms as specific genetic elements can be integrated and evaluated in these mice,^{69–71} and imaging will provide access to key information on expression of targets, measuring tumor burden at deep-tissue sites and rapidly assessing the degree of metastasis.

62.3.1.1 Models of Metastatic and Minimal Disease States

The sensitivity and spatiotemporal nature of BLI-generated data provide an opportunity for detecting and localizing small foci of malignant cells rapidly in laboratory rodents using whole-body assays. Thus, this approach has enabled the study of metastatic and minimal residual disease states in animal models. 46,72 In a study by Wetterwald et al., 72 a labeled human breast-cancer cell line was used in mouse xenograft model to efficiently evaluate metastatic lesions in bone. Intracardiac injection of tumor cells allowed metastasis to form in a variety of locations including the bone marrow. Micrometastases in the bone marrow can often elude radiographic detection because this detection method requires osteolysis for a signal. BLI, on the other hand, was used to successfully detect the presence and location of such lesions with volumes as small as 0.5 mm³ comprised of approximately 2×10^4 cells. The microscopic bone-marrow metastases that were detectable by BLI were not associated with osteolytic lesions and hence could not be detected by x-ray imaging. This advancement in the assessment of animal tumor models has greatly accelerated the analyses of these diseases and will improve our ability to develop effective approaches for targeting small numbers of cells present in the early stages of disease progression.

Minimal residual disease remains a major therapeutic hurdle despite the improvements in disease-free survival that have resulted from recent advances in cancer therapies. A majority of cancer patients respond to high-dose chemo- and radiation therapy and enter a state of minimal residual disease. A significant number of these patients will, however, eventually relapse. Effective evaluation of therapies that target small numbers of tumor cells are, therefore, essential for the development of the next generation of cancer therapies that address this critical target. Since protocols that use BLI do not require sacrifice of the animal to obtain sensitive and quantitative data, animals may be followed over time for relapse following the cessation of therapy, and combination therapies that are at first aggressive and secondarily less toxic

can be evaluated. The relatively rapid nature of BLI allows for a variety of therapeutic regimens to be measured in the same animal using time for relapse as a criterion by which to measure success. The use of BLI in combination with other imaging modalities will provide greater opportunities for developing strategies to eradicate minimal disease and prevent relapse.

62.3.1.2 Spontaneous Tumor Models

Advancements in subcutaneous and orthotopic models of disease that have been enabled by the application of BLI may be extended to spontaneous-tumor models. The combination of BLI and transgenic technology may yield more predictive animal models of human disease. The introduction of mutations and transgenes in mice has resulted in animals that spontaneously develop malignancies. ^{69–71} In these mouse models, researchers have been able to study the initial or early events in the initiation of disease, which represent key targets for the treatment of oncogenesis. For example, a conditional transgenic mouse model that develops retinoblastoma-dependent sporadic cancer has been studied. ⁵³ Firefly luciferase was incorporated as a reporter gene in this model, enabling the investigators to follow the animals over the full disease using BLI. The pituitary tumors that developed in these mice could be followed because they were tagged through the expression of the firefly luciferase. The onset of disease and subsequent disease progression and response to therapy in this tumor model were more readily evaluated using a noninvasive approach than could have been accomplished using assays that require sampling of tissues. Coupling spontaneous-tumor models with sensitive imaging modalities will facilitate the analysis of the key processes in the initiation and progression of neoplastic disease, as these models incorporate defined genetic alterations that are linked to oncogenesis.

62.3.2 DNA-Based Therapies

The development of therapeutic strategies based on the delivery of therapeutic genes to replace defective genes for the treatment of genetic diseases or in the treatment of malignancy and other diseases has also been constrained by our inability to rapidly analyze our animal model systems noninvasively. Multimodality imaging studies that pair BLI, as a functional imaging modality, with MRI, as a structural imaging modality, demonstrate the strength of such combination approaches in addressing multiple biological questions *in vivo*. In a study by Rehemtulla et al., BLI was used to determine the levels of gene expression following adenoviral-mediated gene delivery in combination with MRI for determining therapeutic efficacy of a therapeutic transgene for cancer-gene therapy. Yeast cytosine deaminase, an enzyme that converts the nontoxic compound 5-fluorocytosine (5FC) into the drug 5-fluorouracil, was the therapeutic gene, and the tumor target was a glioma (rat 9L glioma) in an orthotopic rat model. The ability of prodrug-converting enzymes to facilitate tumor kill was evaluated, and luciferase expression served as the marker of effective delivery of the gene. Diffusion-weighted MRI was used as a surrogate marker of tumor-cell death. The noninvasive assessments of both the extent of gene delivery and the efficacy of the therapy resulted in a more robust model for evaluation of this multicomponent anticancer therapy.

Successful life-long gene replacement was demonstrated in an *in utero* gene-transfer model.⁷³ In this model, an adeno-associated viral vector carrying a modified luciferase gene was injected into the peritoneal cavity of fetal mice. The luminescent signals from the transduced fetuses were apparent while the animals were *in utero*, indicating that the substrate, luciferin, could cross the placental barrier. After birth these animals continued to express the reporter gene and did so for the 24-month study period. We have developed the ability to diagnose genetic defects in the fetus, and the development of approaches for gene replacement *in utero*, especially for genes encoding secreted proteins where local expression can have a systemic effect, was enabled by this demonstration.

The location and magnitude of expression of therapeutic genes will affect the therapeutic outcome of these experimental therapies. Correlation of gene-delivery parameters with therapeutic outcome is essential for preclinical optimization of such strategies. This is another example of a relatively complex treatment regimen where optimal dosing of the genetic therapy and the prodrug need to be evaluated. Studies that use multimodality imaging should significantly accelerate the decision-making process for

the therapeutic indication, drug formulation, and regimen that should move forward to the clinic. Bioluminescent reporter genes may also find clinical use in evaluating the delivery and efficacy of gene therapies and gene vaccines where these genes are intentionally delivered to a tumor or a tissue site.^{4,73–76}

62.3.3 Infection and Immunity

62.3.3.1 Tracking and Monitoring in Infectious Disease

Thousands of potential antimicrobial compounds can be generated using combinatorial chemistries and high-throughput assays, and from this set of compounds potential drug candidates for preclinical testing can be identified using labeled bacteria as targets. Bacterial pathogens that express the bacterial *lux* operon produce light without the need for exogenous substrate addition, and plates of these organisms can be screened rapidly using the same low-light imaging systems that are employed for BLI. The bacterial *lux* operon that has been widely used for labeling pathogens was originally derived from *Photorhabdus luminescens* and has since been modified to optimize labeling and use in these assays. The same labeled organisms that are used in the correlative culture assays can be used in the animal models, thereby eliminating the need for different reporters or assays for studies in culture and in animal models. BLI offers opportunities not previously available in the study of infectious disease. The goal in these protocols is integrated studies where a single optical signature can be used to study the pathogen in culture, noninvasively detect the infection throughout the course of infection, and then recover the labeled bacteria, readily distinguishing it from normal flora. A number of published examples reveal how this approach can be used to rapidly assess the efficacy of a drug therapy while using fewer animals than would be required using more traditional assays. 18,47,48,78,79

The utility of BLI for monitoring bacterial infections *in vivo* was first demonstrated in a mouse model of human typhoid fever. Is In these early studies, the bacterial pathogens were labeled with a plasmid encoding the *lux* operon; since that time *Salmonella* strains have been labeled by incorporating the *lux* operon into the chromosome of the pathogen by transposon insertion. This eliminates the need for using antibiotics in the animal models to maintain the plasmid and reduces the likelihood of losing the signal due to loss of the plasmid. In these models, the intensity of the luminescent signal is quantitative and correlates with the number of bacteria at oxygenated tissue sites. Because of their small size mice are the most suitable for BLI; however, larger animals such as rats have also been studied using this approach. As the animal increases in size, emitted photons must pass through more tissue that is both absorbing and scattering, and the number of bacteria that is detectable is reduced. Variability is often observed in infectious-disease models, even if the animals are similarly inoculated. The animals in a single-treatment group may have slightly different disease courses. BLI offers the investigator the advantage of identifying these inherent differences prior to initiation of therapy and then assessing the fate of animals with different initial patterns of disease in a given treatment group.

As noninvasive assays permit repeated measurements of the same animal over time, more information can be generated using fewer animals, and each animal becomes its own control, which improves the statistics. In more traditional animal models, data are obtained after serial sacrifices, homogenization of tissue samples, and determination of the number of pathogens present in the tissue. Imaging strategies can be superimposed on these types of studies and also used to direct the *ex vivo* assays by identifying important times and tissues. Where this has been used to validate the imaging approach the intensity of the signal at the sites of infection has been found to correlate well with the number of organisms present.^{18,48,78} Whole-body imaging of infected animals often reveals pathogens in tissues not thought to be involved in the disease process, and additional sites of infection are often revealed.⁷⁹ These observations may have implications for the molecular mechanisms of disease and routes of infection that had not been previously realized or understood

Although not fully investigated, the use of bioluminescent reporters as indicators of bacterial gene expression *in vivo* will reveal molecular determinants of disease and identify new targets for therapy. Directed gene fusions with *lux* or random integrations of promoterless reporters could not previously

be studied in living animals. BLI has opened this door, and spatiotemporal regulation patterns can now be revealed *in vivo*. The patterns of expression would be especially informative in diseases with multiple foci of infection where unique patterns may be apparent at specific times or in specific tissues.

62.3.3.2 Local Delivery of Therapies Using Immune-Cell Homing

BLI is an ideal method for assessing the dynamic changes in immune-cell populations that take place on a whole-body scale. Such data are not available using flow cytometry or immunofluorescence. As the migratory pathways of immune cells within the body relate to the temporal changes of the immune response, they may also relate to treatment approaches. There are several examples of monitoring immune-cell trafficking patterns using BLI and using these data to optimize the delivery therapeutic proteins in specific immune-cell populations. 49,76,82

In a mouse model for multiple sclerosis in humans, experimental autoimmune encephalomyelitis (EAE), the migratory patterns of autoantigen-reactive CD4+ T cells specific to myelin basic protein (MBP), were monitored and used to deliver an immune modulator. The effector cells of the immune-mediated destruction were transduced with a retrovirus that encoded both a reporter construct (green fluorescent protein [GFP]-luc fusion) and interleukin 12 p40 (IL12-p40) as a therapeutic protein.⁴⁹ The transduced cells could be selected using a fluorescence-activated cell sorter (FACS), and following adoptive transfer BLI demonstrated that labeled CD4+ T cells expressing IL-12 p40 trafficked to the central nervous system of symptomatic animals. These animals demonstrated a significant reduction in clinical disease. This approach was further substantiated using type II collagen-specific CD4+ T hybridomas and primary CD4+ T cells as vehicles for local delivery of IL-12 p40 in a mouse model of rheumatoid arthritis.⁷⁶

Adoptive immunotherapy, where expression of a proinflammatory antagonist can be localized within the site of tissue destruction, obviates the inherent problems of nonspecific toxicity following systemic administration. Understanding the trafficking patterns of immune cells is a key component of effective development of these types of cell-based therapies, and BLI enabled these studies such that the protocols for local delivery of immunoregulatory proteins could be optimized.

62.3.4 Building Transgenic Imaging Markers into Rodent Models of Physiology and Toxicology

Our knowledge of the mouse and human genomes allows transgenic animals to be made that contain a gene modification (insertion, deletion, mutation) in a specific gene that has been identified and characterized. Altered genes can be introduced into the genome by random integration or into specific sites by homologous recombination. As such, transgenic models can be those in which a specific gene has been altered to cause loss of function, overexpression, or anomalous expression of a target gene for increased or altered activity, or they can be those in which reporter genes have been incorporated and coexpressed with an endogenous target gene (Figure 62.2). 19,83 These animals are models for many genetic diseases for which the etiology is known. Conventional transgenic animals with no luciferase reporter must be characterized by traditional methods of genotypic and phenotypic analyses. Phenotypic assays generate data about how a specific gene or mutation may play a role in disease. The assays may be observational, biochemical, or histological or may rely on various whole-body-imaging techniques, as described below. Phenotypic assays identify variations in the transgenic organism relative to the parent strain. With traditional methods, however, these comparisons have been limited to the presence of observable traits or behaviors and by the repertoire of phenotypic assays.

Genetically modified transgenic animals may contain luciferases as markers for gene expression, protein activity, or simply as a tracking molecule to study the effects of genetic mutations on development, immunity, host response, and other metabolic diseases.^{20,45,52} These light-producing transgenic animals have been analyzed by BLI, including expression from the HIV-1 promoter⁵² and heat-shock protein 32 (ak.a heme oxygenase 1; HO-1)¹⁹ and in the development of spontaneous-tumor models.⁵³ These types of animal models have demonstrated utility in drug discovery and in toxicity screening (Figure 62.2).

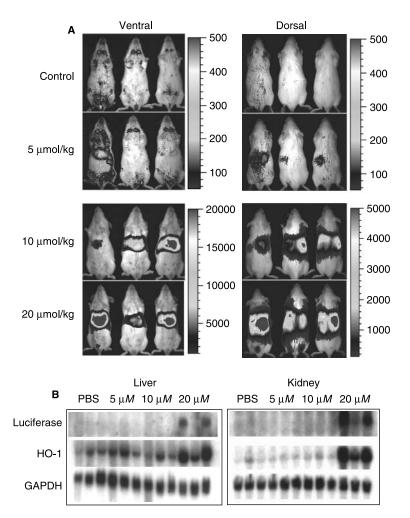

FIGURE 62.2 (Color figure follows p. 28-30.) Screening heavy-metal toxicity in a transgenic mouse model.¹⁹ Using a Tg model where the transgene consisted of the heme oxygenase promoter fused to the firefly luciferase coding sequence; dose-dependent increases in luciferase transcription in the liver and kidney following systemic treatment with PBS or three doses of CdCl₂ (5, 10, and 20 μmol/kg) were revealed by BLI (A). After imaging the animals were sacrificed and the tissues removed, and total RNA was isolated from the liver and kidneys and analyzed by Northern blot hybridization (B). Levels of mRNA for HO-1, luciferase, and GAPDH were determined for both tissues from three mice at each concentration. Luc signals increased with increasing concentrations of CdCl₂ as measured by imaging, and levels of Luc and HO-1 mRNA were elevated in the treatment group that received the highest concentration of CdCl₂.

62.4 Advances in in Vivo Bioluminescence Imaging

62.4.1 Dual-Reporter Strategies

Luciferases have been studied for decades and effectively developed as reporter genes for cells and as sensors for use in biochemical assays. Luciferases are used for evaluating gene expression in cultured cells and even in live-cell assays, ^{56–59,84,85} for revealing the circadian rhythms of small relatively transparent organisms, ^{86,87} and now for imaging biological processes in living laboratory animals. ²⁰ By virtue of the curious biology conferred upon a variety of organisms that produce luciferases, a detailed understanding

of the mechanism of light production and the constraints on light emission is available for some of these enzymes. Our understanding of the luciferase from the firefly (*Photinus pyralis*) is at the level of knowing the relative contribution of single amino-acid residues to light emission. ^{62,88} This long and active inquiry has provided a broad base of knowledge from which we draw to advance the *in vivo* applications of bioluminescence

Luciferases that use other substrates or emit at peak wavelengths other than that of the commonly used firefly luciferase have been used to develop multiparameter assays in cell cultures. ⁸⁹ Extending this approach to *in vivo* studies would enable evaluation of two or even several parameters in a given animal. One of the enzymes that has been employed in the cell culture and biochemical assays is the luciferase from the sea pansy (*Renilla reniformis*), a blue-emitting luciferase that uses the substrate coelenterazine. ^{90,91} Several groups have begun to evaluate this reporter for use *in vivo*. ^{74,92} Since the *Renilla* luciferase uses a substrate other than firefly luciferase, it may be possible to distinguish the two enzymes biochemically *in vivo*. Distinguishing bioluminescent reporters spectrally is constrained by the wavelengths of emission, which are largely absorbed by mammalian tissue. Despite the fact that *Renilla* luciferase is a blue emitter, its expression has been detected *in vivo*. ⁷⁴ Use of this enzyme is limited, however, by the absorption of blue light by tissues as well as by poor biodistribution of the substrate. The sensitivity of detection for this reporter will be less than that of the firefly enzyme assuming similar expression levels and specific enzymatic activities. The ability to image two or more parameters *in vivo* would be a tremendous advance in the field, and the initial steps made in this area⁷⁴ will serve as a foundation for continued investigation.

Another approach is to create dual-function reporter genes comprised of coding sequences for reporters that can be detected by two different modalities. Such approaches can enhance the utility of a singe reporter gene, which was demonstrated by Day et al. in a study of expression patterns in fruit flies.⁹³ The dual-function reporters have enabled the studies of immune-cell trafficking.^{49,76,82} In addition, a fusion protein comprised of the coding sequences for *Renilla* luciferase and GFP has been generated for the purpose of using resonance energy transfer between luciferase and GFP to develop protein-proximity assays based on a spectral shift.⁹⁴ Bioluminescence resonance energy transfer from *Renilla* luciferase to GFP has been used to study protein–protein interaction in cultured cells⁹⁵ and may have utility *in vivo*. However, the emission wavelengths of these two proteins will also be absorbed by tissues, and the sensitivity of detection will not be great.

Two other approaches for studying protein–protein interaction *in vivo* have been described. One is based on principles that were used in the yeast two-hybrid system, and in the mouse counterpart the association of two proteins resulted in transcription of the reporter gene firefly luciferase. The yeast two-hybrid system was developed for the purpose of screening libraries of fusion proteins to identify protein–protein interactions, and the opportunity to perform similar assays *in vivo* may enable similar screening strategies in mammalian cells in the context of the living body. The other approach, first described by Ozawa et al., used the phenomenon of protein–protein splicing that was first described in bacteria. This set of approaches may lead to assays that will enhance the development of therapies whose mechanism of action is the disruption of protein–protein associations.

62.4.2 Signal-Amplification Strategies

Many promoters that are of interest for drug development may not have high levels of expression and would therefore be difficult to study using reporter-gene strategies. Iyer et al. have addressed this problem by creating transcriptional-amplification methods that enhance the levels of reporter-gene expression in a manner still representative of the regulation of the target gene, in this case for prostate-specific antigen. ¹⁰¹ Nearly a 50-fold amplification was observed for luciferase using this approach, demonstrating that it may be possible to noninvasively assess subtle changes in transcription. Zhang et al. have used such an amplification method in an androgen-responsive DNA-based therapy directed against prostate cancer. ¹⁰² Many of the molecular tools developed for cell-based assays can now be extended to *in vivo* studies using BLI, and this is one such application.

Further improvements in the BLI technology's spatial resolution (approaching the millimeter level) may be expected using physics-based diffusion models currently in development. Recent advances in mathematical modeling of light propagation in tissue (photon migration in scattering media and data inversion for image reconstruction), light sources, and detection techniques have improved the quality of measurement analysis and made it possible to array data from diffuse light tomographically.

62.5 Summary and Conclusions

For years molecular biologists have been able to study gene regulation in cells and in tissue lysates, and the use of reporter genes has greatly increased our ability to study the tempo of expression. The application of reporter genes in in vivo imaging now offers the opportunity to similarly evaluate expression in the living body and interrogate the biology of intact cells noninvasively in living animals where the contextual influences of the intact functional organ systems are retained. Successful sequencing of the human and mouse genomes has formed a foundation that supports functional studies such as BLI, and a logical extension is to study spatiotemporal expression patterns of specific genes in the living body. This will be further complemented by the progress in proteomics, and in vivo assays of protein function are among the next steps for BLI. Advances in genetics have made it practical for the first time to approach generegulation questions from several directions simultaneously, which will inevitably point the way to many more potential drug targets and, ultimately, the development of new potential therapeutic compounds. The advances in cellular and molecular imaging will allow for more comprehensive analyses of responses to therapy within intact animals. The use of multimodality approaches for structural and functional correlations, and multiple reporter systems to expose related pathways, will enable us to approach questions within the complexity of intact physiology in whole-animal models. Whole-animal imaging has generated high-quality spatiotemporal information and is amenable to highly specific and even multifactorial genetic experiments.

Taken together, the new knowledge from genomics, transgenic methods, and imaging tools is forcing changes in the traditional paradigm of drug development. The animal-testing bottleneck has prompted efforts in many therapeutic areas to develop more accurate animal models that can be evaluated more rapidly using multimodality imaging techniques. Early discovery-phase bottlenecks that develop at the target validation and lead optimization stages also can be addressed by use of new animal models. The goal is to produce more qualified compounds that will progress to the clinic surrounded by complete and relevant preclinical safety and efficacy data. The utility, cost, flexibility, and especially high-quality predictive data generated from whole-animal cellular and molecular imaging define a "value proposition" to the industry. This acknowledged value will, over time, contribute to increased efficiency and effectiveness of drug-discovery and development programs. The gauge that we will use to ultimately evaluate the influence of this technology on drug discovery and development will be the success of compounds in the clinic.

BLI holds great promise for the acceleration of data generation and analysis for the development of new drug candidates by the pharmaceutical industry. This is because 80% of drug candidates fail to satisfy safety and efficacy requirements in clinical trials, and the need to conduct biological assessments in animal models to determine safety and efficacy is the principal obstacle to making the development process more efficient and effective. BLI offers a rapid means of conducting *in vivo* analysis to improve the predictive quality of data used in the assessment of new drug candidates. The technology provides data sets from relevant, intact animal systems, increasing both the efficiency and the effectiveness of selecting new drug candidates for clinical development. Because it is an *in vivo* technology, fewer animals are needed, while time and costs are reduced and more data per protocol are obtained. Overcoming the problems of animal-to-animal variation by using the zero time point as an internal control improves the biostatistics in animal modeling. Rapid animal models, based on internal bioluminescent reporters, are now being developed that will make more predictive and physiologically relevant *in vivo* systems available earlier in the drug-development cycle than was previously possible. ^{4,5} Given the accessibility and speed

of BLI, researchers will be able to perform *in vivo* efficacy, pharmacokinetics, toxicology, and target-validation studies on a larger number of compounds than they were able to do in the past.

Bioluminescent reporter genes may eventually find clinical use in evaluating the delivery and efficacy of gene therapies and gene vaccines where these genes are intentionally delivered to a tumor or a tissue site. Further improvements in the BLI technology's spatial resolution (approaching the millimeter level) may be expected using physics-based diffusion models currently in development. This is an area of investigation that will greatly improve drug development by accelerating the process and providing quantitative *in vivo* data.

63.1 Introduction

Phospholipid vesicles, e.g., liposomes, have been used as drug-delivery vesicles in the last three decades. The main advantages of liposomes as drug-delivery carriers include their biocompatibility, ability to effectively encapsulate hydrophilic or hydrophobic drugs, and the sensitivity of their fluid-like membrane to temperature and pH, which enables controlled drug release. ¹⁻⁶ Several reviews published in recent years describe in detail the use of liposomes as drug-delivery carriers of anticancer drugs. ⁷⁻¹⁰ In this review, we describe the results of recent studies in our laboratory that focus on the use of liposomes in diagnostics and therapy. We describe the methods used in our laboratory to prepare and characterize liposomes, recent applications of liposomes as fluorescent nanosenors, and extraction and detection tools. We also describe the development of new digital fluorescence-imaging techniques to monitor the release of fluorescent drug analogs from liposomes into single cells.

63.2 Basics of Liposomes

Liposomes are spherical phospholipid vesicles that form spontaneously when phospholipids are introduced into aqueous media. The phospholipids are self-assembled to form a bilayer membrane similar to

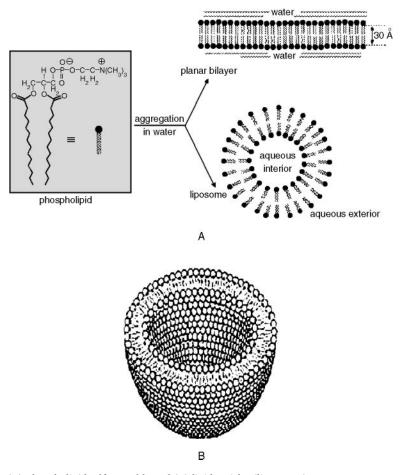

FIGURE 63.1 (A) Phospholipid self-assembly and (B) lipid vesicles (liposomes).

cell membranes (Figure 63.1). In liposomes, the phospholipid head groups point toward the internal and external aqueous phases of the vesicles. The bilayer membrane may also contain cholesterol and fatty acids to increase its fluidity and flexibility. The morphology of liposomes is classified according to the compartmentalization of aqueous regions between bilayer shells. In unilamellar liposomes, the aqueous compartment is segregated from the external solution by only one membranal bilayer. Unilamellar liposomes are further classified according to their size. Small unilamellar liposomes (SUV) average 100 nm in diameter, while large unilamellar liposomes (LUV) are more than 100 nm in diameter with a maximal size of up to 10 μ m. Multilamellar liposomes have more than one bilayer surrounding each aqueous compartment. Multilamellar liposomes typically form large complex honeycomb structures that are difficult to reproduce.

63.3 Preparation of Liposomes

There are numerous approaches to preparing liposomes and to modifying their size and shape after formation. The general elements of these approaches involve preparation of the phospholipids for hydration, hydration with agitation, sizing a homogeneous distribution of liposomes, and purification of the products. Typically, the phospholipids are first dissolved in a suitable organic solvent — e.g., chloroform — to get a homogeneous mixture. Then, the solvent is completely removed to yield a dried

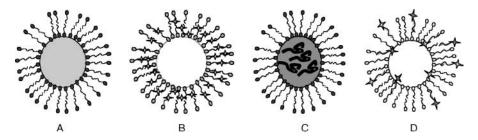

FIGURE 63.2 Tailoring liposomes. (A) Dyes encapsulated in the internal compartment of the liposomes. (B) Dyes encapsulated in phospholipid membrane of the liposomes. film. Drying the phospholipids from solution volumes of smaller than 1 ml is accomplished using a nitrogen stream for 20 to 30 min. Samples larger than 1 ml are dried by rotary evaporation using a round-bottom flask in a cooling bath. In our laboratory we prepared different fluorescent liposomes using three common methods. The liposomes prepared in our laboratory are illustrated in Figure 63.2. The injection method¹¹ is used to encapsulate hydrophilic dyes in the internal compartment of liposomes (Figure 63.2A). In this technique, the dried phospholipids are reconstituted with dry isopropanol. The sample is then injected, while vortexing, into a test tube containing an aqueous sample of the molecules (dye, protein) to be encapsulated. As the liposomes form, these molecules are captured in the aqueous compartment of the liposomes with approximately 1 to 10% efficiency. Hydrophobic compounds and dye-labeled phospholipid derivatives are incorporated into the bilayer membrane of liposomes by drying the phospholipids from an organic solvent that already contains the hydrophobic compounds (Figure 63.2B). The dry film is then rehydrated in a buffer solution. This simple method yields liposomes ranging between 100 and 300 nm in diameter. High-energy ultrasonic radiation is useful in preparing small unilamellar liposomes from large multilamellar liposomes.¹² However, as the large liposomes are disrupted, any material previously encapsulated is lost and must be recovered upon formation of the smaller liposomes, normally at lower encapsulation efficiency. Sonication can be performed using either a probe tip or a bath sonicator. Probe sonication is used for reducing the size of larger liposomes to as small as 25 to 50 nm in diameter. However, the high energy used may produce heat capable of degrading the phospholipids.

Another preparation technique is based on dehydration and subsequent rehydration of phospholipids in the presence of the encapsulated material. This method is used primarily to encapsulate water-soluble macromolecules, i.e., fluorescent conjugates of dextrans and proteins (Figure 63.2C). 13,14 Since organic solvents may damage such types of molecules, the entire preparation is carried out in aqueous solution. An aqueous liposome suspension (made by probe sonication) is mixed with the water-soluble macromolecules and dried by rotary evaporation, leaving a multilamellar phospholipid film and the material to be encapsulated. Upon rehydration of the sample and continued incubation in a rotating flask, large liposomes are formed that are capable of encapsulating a high concentration of the solute. Uniformity in liposome size is achieved using an extrusion device, where a preformed liposome sample is passed across a sealed 100-nm-pore-size polycarbonate membrane between two gas-tight glass syringes. 15 When hydrophilic compounds are encapsulated in liposomes, nonencapsulated molecules must be removed from the liposome sample. Passing the liposome sample through a gel-filtration column is a very effective way to trap nonencapsulated molecules in the column while passing the larger liposomes through the column for collection. Using this method we were able to encapsulate dye molecules — dextran-dye conjugates with a molecular weight of up 70 kDA — and even larger protein molecules. Liposomes containing phospholipids labeled with fluorophores are prepared using the injection technique (Figure 63.2D). The fluorophores in these liposomes are attached covalently to the phospholipid headgroup or to the hydrophobic alkyl tail of the phospholipids.

63.4 Characterization of Liposomes

Characterization studies of liposomes have been previously reviewed.^{16,17} The main characterization techniques are based on light scattering, electronic and atomic force microscopy (AFM), and capillary electrophoresis (CE). Static and dynamic light-scattering measurements are used to characterize the size, size distribution, and shape of extruded vesicles under isotonic conditions. 18 Transmission electron microscopy (TEM) and AFM are used to determine the morphology of liposomes. While light-scattering techniques provide average values of the physical characteristics of liposome suspensions, TEM and AFM provide information on individual liposomes that may or may not represent the entire liposome population. AFM imaging measurements could be conducted on untreated samples in air or in solution, avoiding all the processing, such as fixation, dehydration embedded sectioning, and staining, required in TEM. 19 Since liposomes appear to be stable under conditions of high electric fields like the ones applied in CE, CE can be used to obtain qualitative and quantitative information about the size-to-charge ratio of liposomes.^{20,21} The size-to-charge ratio of liposomes is directly related to their mobility in the capillary when a high potential difference is applied. Since an equal distribution of charge on the liposomes is assumed, the electrophoretic distribution observed is due primarily to liposome size. The peak shape of the electropherogram is indicative of liposome size distribution and uniformity. Under normal CE conditions, liposomes produce electropherograms with a smooth broad Gaussian distribution with few spiking events.

63.5 Liposomes in Diagnostics

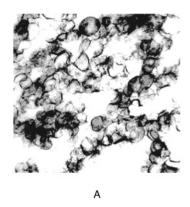

Liposomes have been used as fluorescent labels in homogeneous and heterogeneous assays. Homogeneous assays often rely on the catalytic activity of enzyme-labeled antibodies that are incorporated into the membrane of liposomes.²² Heterogeneous liposome immunoassays may be performed in a competitive or noncompetitive assay format.²³ They resemble standard enzyme-linked immunosorbent assays, with the second antibody labeled with a fluorescent liposome instead of an enzyme. Single liposomes, which could contain up to 1000 fluorescent molecules, act in these assays as signal amplifiers. Due to the large number of fluorophores in the liposome, its fluorescence is self-quenched. Following several washing steps to remove unbound liposomes that contain the second antibody from the sample, the bound liposomes are lysed with a detergent. The fluorescent molecules are dispersed in the sample, leading to an instantaneous amplification.²⁴

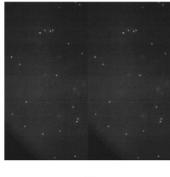

Taking advantage of the large signal enhancement obtained when fluorescent liposomes are used in immunoassays, Durst et al.²⁵ developed an automated flow-injection liposome immunoanalysis (FILIA) system for the measurement of environmental toxicants, using alachlor as a model analyte. In their system, liposomes tagged with alachlor and containing the fluorescent dye sulforhodamine B pass through an immunoreactor column containing antialachlor covalently coupled to glass beads. In the presence of free alachlor, the free alachlor and the alachlor-containing liposomes compete for the binding sites available on the glass beads. The number of liposomes bound to the column is inversely proportional to the concentration of free alachlor. The bound liposomes are lysed, and the level of released dye is quantified and correlated with the free alachlor in the sample.

The successful application of fluorescent liposomes in immunoassays has led to the development of a new research direction in our laboratory that focuses on the fluorescence response of liposomes to environmental stimulation. Our studies in this area are described in the following section.

63.6 Liposomes as Fluorescence Nanosensors

Recently we reported the use of fluorescent-dye-encapsulating liposomes for nanoscale sensing of pH, molecular-oxygen, and calcium-ion levels in aqueous solutions.^{26,27} The fluorescent liposomes were tested as individual probes and as an assembly in a thin film format. The liposome-containing suspensions and

В

FIGURE 63.3 (A) An 82,600× TEM of uranyl-acetate-labeled liposomes averaging 70 nm in diameter. (B) Digital fluorescence image of Ru(phen)₃-encapsulating liposomes. A 5-μl liposome sample is placed between two microscope cover slips, and fluorescence is detected and imaged by a charge-coupled-device camera. The fluorescence of each liposome is captured on one to ten pixels owing to their lateral diffusion in the sample.

films were stable for up to 14 days when stored under conditions of pH 7.2 and 4°C. Figure 63.3 shows microscopic images of fluorescent liposomes. Figure 63.3A shows a TEM of uranyl-acetate-labeled liposomes. The presence of a relatively homogeneous population of round-shaped unilamellar liposomes averaging about 70 nm in diameter is evident. Figure 63.3B shows a fluorescence image of the dyeencapsulating liposomes. A digital analysis of this image indicates that the ratio between the fluorescence intensity of individual liposomes and the background noise, signal-to-noise, in an air-saturated environment is about 50.

63.6.1 pH-Sensing Liposomes

pH-Sensing liposomes were prepared by incorporating fluorescein (a pH-sensitive dye) and tetramethyl rhodamine (pH-insensitive dye) in unilamellar liposomes using the injection method. The liposomes were calibrated against standard solutions of pH 5.0 to 8.0. The pH was determined based on the ratio between the emission peaks of fluorescein at 525 nm and those of tetramethylrhodamine at 575 nm. The pH dependence of the ratio between the fluorescence signals of fluorescein and tetramethylrhodamine, I_f/I_p, obtained from 50 pH-sensing liposomes is shown in Figure 63.4A. The dynamic range of the particles was found to be between pH 5.5 and 7.5, with a pH sensitivity of 0.1 pH units.

63.6.2 Oxygen-Sensing Liposomes

The fluorescence spectra of nano-sized Ru(phen)₃-encapsulating liposomes in oxygenated, air-saturated, and nitrogenated solutions is shown in Figure 63.4B. Due to dynamic quenching by molecular oxygen, the fluorescence intensity of the Ru(phen)₃-encapsulating liposome in nitrogenated solution, $I_f(N_2)$, is higher than the fluorescence intensity of the liposome in air-saturated solution, $I_f(air)$, and oxygenated solution, $I_f(O_2)$. The obtained response factor $I_f(N_2)/I_f(O_2) = 7$ is two times higher than the response factor of the same ruthenium diimine complex when trapped in a polymer. In fact, the oxygen response of the Ru(phen)₃-encapsulating liposomes is very similar to the oxygen response of a Ru(phen)₃ aqueous solution. The increase in the oxygen response over polymer supports indicates that the dye molecules in the liposomes show a free-solution-like behavior. The increased oxygen response partially negates the loss of fluorescence signal due to the miniaturized nanodimensions of the liposomes.

63.6.3 Calcium-Ion-Sensing Liposomes

The calcium-ion sensor developed in our laboratory is the first example of a liposome-based biosensor. It employs a calcium-ion-binding protein for recognition and a sensing fluorophore for signal transduction.

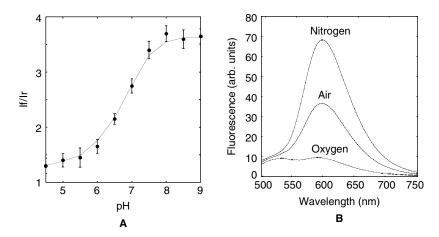

FIGURE 63.4 (A) pH Response of the fluorescein encapsulating liposomes in solution. (B) Fluorescence response of Ru(phen)₃ encapsulating liposomes to oxygenated and nitrogenated solutions in a phosphate-buffered solution at pH 7.2.

To fabricate the sensor, Alexa-488-labeled calmodulin (CaM) molecules were encapsulated in the membrane of liposomes. Upon binding calcium ions, CaM undergoes a conformational change that exposes its hydrophobic cores, which may act as active sites for the interactions with target enzymes or CaM antagonists. Both the carboxy- and amino-terminal domains of CaM then undergo large structural rearrangements from the "closed" conformation (the two helices of each hand are almost antiparallel) to the "open" conformation (the two helices are more perpendicular).^{28–35} This conformational change strongly affects the fluorescence intensity of the fluorophore Alexa-488 that is covalently bound to calmodulin. Liposomes containing Alexa-labeled calmodulin show high sensitivity to calcium ions in the micromolar range. The calcium-ion response of Alexa-labeled calmodulin liposomes is fourfold higher than the calcium-ion response of Alexa-labeled calmodulin in solution. This is attributed to the increasing stability of calmodulin when embedded in the liposome membrane. Unlike in commonly used fluorescence indicators, physiological levels of magnesium ions do not interfere with the calcium-ion response of Alexa-CaM-containing liposomes.

Current studies in our laboratory in the area of liposome-based biosensors include the development of a glucose biosensor. Another research direction involves the synthesis of nanometric lipobeads as fluorescence sensors. In lipobeads, the aqueous compartment of liposomes is replaced with a polymer core. While maintaining the biocompatibility of liposomes, lipobeads are expected to show higher mechanical and chemical stability in the cellular environment.

63.7 Magnetoliposomes in Extraction and Detection of Antibodies in Biological Samples

Another research direction in our laboratory has been the use of liposomes to extract and detect antibodies in biological samples. We prepared magnetoliposomes following a procedure first developed by Joniau et al.,^{36,37} which is based on an entropy-driven exchange of lipids that occurs when fatty-acid-coated magnetic nanoparticles are mixed with a preprepared liposome suspension. Using this technique we synthesized magnetoliposomes containing gold-coated cobalt platinum alloy nanoparticles that were annealed prior to encapsulation. To demonstrate their extraction power, magnetoliposomes labeled with BODIPY fluorescein were used to extract antibodies against BODIPY fluorescein from aqueous solution. Figure 63.5 describes the fluorescence intensity of the sample during three cycles of extraction of antibodies by magnetoliposomes containing BODIPY fluorescein.

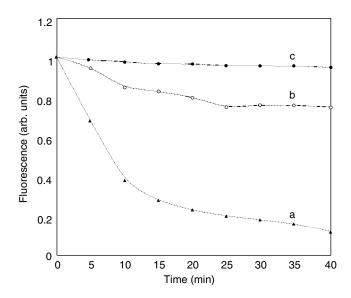

FIGURE 63.5 Extraction of anti-BODIPY fluorescein from aqueous samples using repeated cycles of application of BODIPY-fluorescein coated magnetoliposomes. A removal of about 90% of the anti-BODIPY-fluorescein molecules is observed.

Curve a shows a 90% decrease in the fluorescence intensity, which is attributed to quenching by antibody molecules of the fluorescence of BODIPY fluorescein when the organic dye molecules bind to the antibody molecules in the solution. Following an incubation period of 40 min at room temperature the particles were separated from the sample solution by passing through a column mounted in the bore of a horseshoe magnet that is used to attract the magnetoliposomes out of the sample. A fresh batch of magnetoliposomes was then added to the antibody solution. Curve b shows that the fluorescence signal decreased by only 20%, indicating a significant reduction in the level of antibody molecules in the solution. This cycle was repeated until a fluorescence decrease of less than 3% was observed over the 40-min incubation time (curve c). Total protein fluorescence-spectroscopy measurements of the solution following three cycles of extraction by magnetoliposomes showed subnanomolar levels of antibodies.

63.8 Liposomes in Therapy

The interactions of liposomes with cells have been studied extensively *in vitro* and *in vivo* to explore their possible use as drug carries. 38–40 Significant advances have been made in the use of liposomes in cancer therapy. 41,42 Liposomes tend to localize in solid tumors, and their use increases therapeutic efficacy and decreases nonspecific toxicity. The use of antracycline-containing liposomes to treat stage IV breast cancer has recently become the standard of care. 43 Recent advances in liposome technology include the development of sterically stabilized liposomes to increase their stability *in vivo*44 and the use of liposome-labeled monoclonal antibodies to selectively target specific cancer cells bearing their corresponding antigens. 45 In our laboratory we developed new fluorescence microscopy techniques to monitor real-time delivery of drugs into single cells. Efficient delivery of drugs from liposomes into cells was expected to increase their efficiency and reduce the effect of the drug on normal cells. The results of this study are described in the following section.

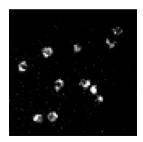

FIGURE 63.6 A fluorescence of J774 murine macrophages loaded with liposomes containing sulforhodamine. An uneven distribution of the dye in the cells can be seen, which is indicative of compartmentalization of sulforhodamine in the cells. The results of these experiments could be interpreted as limited success. The liposomes were able to deliver sulforhodamine, which is a hydrophilic dye, into the cells. This dye is normally cell impermeable. The use of fusogenic liposomes does not seem to provide an escape route to the dye molecules from the endosomes to the cytoplasm. This suggests that the conditions for endosomal release require further optimization.

63.9 Real-Time Monitoring of Drug Delivery from Liposomes Using Fluorescence Microscopy

An efficient liposome-mediated delivery of drugs into cells involves binding the liposomes to the cell membrane, fusion of the liposome with the membrane, and delivery of the liposomal content to the cell cytoplasm. However, in many cellular systems, endocytosis of liposomes takes place rather than fusion. The result of endocytosis is the compartmentalization of the liposomes and the drug in cellular endosomes. In the absence of an escape mechanism, the drug would be ineffective under these conditions. New fusogenic-liposome formulations have been developed to overcome this problem. These liposomes contain active molecules that disrupt the endosomal membrane to facilitate the delivery of the encapsulated drug into the cell cytoplasm. 46-52 Recently introduced fusogenic liposomes are based on the polymorphic-phase transition of dioleoylphosphatidylethanolamine (DOPE).^{53–56} DOPE molecules form a bilayer membrane structure at pH 7.2. Under acidic conditions these liposomes undergo a phase transition to adopt a less stable hexagonal-II phase, which enables leakage of the liposomal content to the endosome. The delivery mechanism of the liposomal content from the endosomes to the cytoplasm from these pH-sensitive liposomes is not well understood.⁵⁷⁻⁶² It was recently suggested that both fusogenic and conventional liposomes fuse with the membrane of the endosome. However, unlike conventional liposomes (e.g., liposomes made of dimyristoyl phosphatidylcholine [DMPC]), fusogenic liposomes also generate pores in the endosome membrane. These pores facilitate the release of the liposomal content to the cytoplasm.

The objective of our study was to find out whether the endosome membrane of cells was destabilized by fusogenic liposomes and to monitor in real time the release of a fluorescent-drug analog from fusogenic liposomes engulfed in the endosome. DOPE/N-succinyl DOPE liposomes (7/3, mol/mol ratio), which are liposomes encapsulating sulforhodamine, were used in these experiments. The liposomes were incubated with J 774 murine macrophages because macrophages use endocytosis as the main mechanism of entry for liposomes. Figure 63.6 shows a digital fluorescence image of macrophages loaded with liposomes containing sulforhodamine.

63.10 Summary

Studies conducted in our laboratory and by other researchers show that liposomes may be used as highly sensitive analytical probes. Fluorescent liposomes have been previously used as signal enhancers in immunoassays. In our laboratory, we demonstrated for the first time that liposomes could be used as optochemical sensors to monitor the pH, oxygen, and calcium-ion levels of physiological samples. We also showed that liposomes could be used effectively to extract and detect antibodies in biological samples.

Liposomes have been used as effective drug-delivery carriers for the last 30 years. Recent advances in their composition enable a more efficient delivery of drugs. The release of drugs trapped in cellular endosomes remained a challenge. Our studies show that, while liposomes are able to deliver hydrophilic impermeable molecules into cells, their release from endosomes to the cytoplasm is not effective, even when new fusogenic liposomes are used for drug delivery. Further studies are needed to optimize the composition of liposomes and the conditions necessary for endosomal release.

Due to their unique physical and chemical properties and biocompatibility, liposomes will continue to attract the attention of researchers in the foreseeable future. It is expected that recent achievements in the field of liposome research will enable the development of "smart liposomes" that possess targeting capabilities, variety of drug-release properties, and feedback mechanisms based on chemical sensing that will facilitate pulsed delivery of drugs from liposomes when a condition of pathological significance is recorded. To demonstrate this pinciple we are currently developing liposome formulations that release antihistamines in response to the presence of histamines in biological fluids.

64.1 Introduction

Raman spectroscopy is based on vibrational transitions that yield very narrow spectral features characteristic of the investigated sample. Thus, it has long been regarded as a valuable tool for the identification of chemical and biological samples as well as the elucidation of molecular structure, surface processes, and interface reactions. Despite such advantages, Raman scattering suffers from extremely poor efficiency. Compared to luminescence-based processes Raman spectroscopy has an inherently small cross section (e.g., 10⁻³⁰ cm² per molecule), precluding the possibility of analyte detection at low concentration levels without special enhancement processes. Some modes of signal enhancement have included resonance Raman scattering and nonlinear processes such as coherent anti-Stokes Raman scattering. However, the need for high-power, multiple-wavelength excitation sources has limited the widespread use of these techniques.

Nevertheless, there has been a renewed interest in Raman techniques in the past two decades due to the discovery of the surface-enhanced Raman scattering (SERS) effect, which results from the adsorption of molecules on specially textured metallic surfaces. The giant enhancement was first reported in 1974 by Fleischmann et al., who observed the effect for pyridine molecules adsorbed on electrochemically roughened silver electrodes.¹ It was initially believed that the enhancement resulted from the increased surface area produced by the electrochemical roughening, giving rise to increased probed sample density. The teams of Jeanmaire and Van Duyne² and Albrecht and Creighton³ later confirmed the enhancement (up to 10⁸) but attributed the effect to more complex surface-enhancement processes, which continue to be the subject of intense theoretical studies. More recent reports have cited SERS enhancements from 10¹³ to 10¹⁵, thereby demonstrating the potential for single-molecule detection with SERS.⁴⁻⁹

In the early years following the discovery of SERS (mid-1970s), the focus of SERS studies was on the development of theoretical models to account for the SERS effect. 10-16 However, these studies were limited to a small number of highly polarizable molecules in the 1- to 100-mM-concentration range. As a result, despite the great theoretical progress achieved in early SERS studies, interest in SERS as a practical analytical tool was delayed largely because of the common belief that the SERS effect occurred only for a few compounds under specific experimental conditions. Nevertheless, the 1980s marked the beginning of a new phase in SERS evolution, which was characterized by the development of a wide variety of SERS-inducing media and applications to a wide range of chemicals. For example, the use of planar solid-surface-based substrates for SERS-based measurements of a variety of chemicals, including several homocyclic and heterocyclic polyaromatic compounds, was first reported in 1984.¹⁷ These substrates were composed of a planar support material that was covered with dielectric nanoparticles to impart the roughness required for the SERS effect, and then overcoated with a layer of silver. In a similar approach, silver-coated frosted glass was demonstrated to be SERS-active. 18 Silver colloids were investigated for analytical applications.^{19–22} Indeed, silver colloids were a popular medium for early SERS-based applications due to the fact that with some skill and patience they could be prepared with chemical reagents available in most common analytical laboratories. In addition, research demonstrated that silver colloids could be used in solid^{23,24} as well as free-solution matrices. Researchers also found that through a variety of innovative techniques the reduction process for producing elemental silver colloids could be made to match the chemical and environmental conditions of specific applications. For example, SERS-active "photocolloids" were produced through in situ laser-induced photoreduction of silver nitrate solutions.²⁵ The development of a wide variety of additional SERS-inducing media had been described in the early 1980s; these included electrolyte interfaces, mechanically ground silver, matrix-isolated metal clusters, holographic gratings, silver island films, gold colloids, and tunnel junctions with a silver electrode on a rough surface. 14 Because of the aggressive development of SERS substrates and application to a wide range of chemicals, the potential of SERS as a routine analytical technique was recognized by the mid-1980s.

The SERS technique has since continued to receive increased interest, as is evidenced by the large numbers of papers and review articles. ^{10–14,26–32} Furthermore, the scope of SERS has been extended to include other surface-enhanced spectroscopies such as surface-enhanced second-harmonic generation³³ and surface-enhanced hyper-Raman scattering. ³⁴

This chapter provides a brief theoretical background of the SERS effect, followed by a synopsis of the development of SERS-inducing media that have demonstrated repeated success and show great potential for use in biomedical analysis. The chapter also summarizes some of the most significant applications of SERS to date, with a focus on both chemical and biomedical areas. Some highlights of this chapter include reports of various fiber-optic SERS monitors, SERS nanoprobes, near-field SERS probes, SERS-based bioassays, and single-molecule detection.

64.2 Theoretical Background

Since the discovery of the SERS effect in the 1970s, extensive fundamental studies have been undertaken to gain a better understanding of the enhancement mechanisms. Nevertheless, it is believed that our current understanding of SERS is still incomplete. For instance, the most established theoretical models predict maximum Raman enhancements on the order of 10⁶ to 10⁸ for the SERS effect. However, recent near-field SERS measurements have shown evidence of SERS enhancement factors as high as 10¹³.8,9 Single-molecule studies have further indicated that enhancement factors on the order of 10¹⁴ to 10¹⁵ may

be possible at specific sites referred to as "hot spots."^{4–7,35} Although new experimental observations in SERS studies are expected to spur the development of new or refined theoretical models, several current theoretical models could explain some of the more general observations associated with the SERS effect.

A qualitative understanding of the SERS process can be gained through the classical theory of light scattering. Consider an incident-light beam inducing an oscillating dipole, Φ , in a particle that scatters light at the frequency of the dipole oscillation.³⁶ The dipole moment consists generally of many different harmonic-frequency components; each component may be represented by the following equation:

$$\Phi(t) = \Phi^{\circ} \cos(2\pi \nu t), \tag{64.1}$$

where ν is the dipole oscillation (i.e., scattering) frequency and Φ^o is the maximum induced dipole moment for a given frequency component of Φ . When the magnitude of the incident electric field, E_{inc} , is not too large, the induced dipole moment can be approximated as:

$$\Phi(t) = P \cdot E_{inc}(t), \tag{64.2}$$

where *P* is the polarizability of the molecule. The polarizability, which is a tensor quantity, can be qualitatively described as the ease with which molecular orbitals are distorted in the presence of an external field.

Because Raman intensity is proportional to the square of the induced dipole, Φ , it can be inferred from Equation 64.2 that enhancements of either the incident field or the molecular polarizability or both can contribute to Raman enhancements observed via SERS. As a result, theoretical models generally involve two major types of enhancement mechanisms: (1) an "electromagnetic effect" (sometimes referred to as the field effect) in which the molecule experiences large local fields caused by electromagnetic resonances occurring near metal surface structures and (2) a "chemical effect" (also referred to as the molecular effect) in which the molecular polarizability is affected by interactions between the molecule and the metal surface.

The relative contributions of the two mechanisms can vary widely for different molecules largely because of the specificity of the "chemical effect." Electromagnetic interactions, which are more general and relatively long-range (i.e., inversely dependent on the distance cubed between the adsorbed molecule and the metal surface), have been extensively investigated and are reasonably well understood. On the other hand, short-range "chemical effects," which may depend on atomic-scale features of both the metal surface and the adsorbed molecule, are less well known and are currently topics of extensive research. A detailed summary of these studies is far beyond the scope of this chapter but can be found in a number of excellent reviews. ^{10–15,27,30,37}

64.3 Development of SERS Substrates

Roughened metal electrodes, the first SERS-active surfaces to be discovered, served as the basis for extensive theoretical studies. Subsequently, metal colloids gained widespread use in SERS studies because they could easily be prepared chemically with commonly used reagents. While the popularity of metal colloids has persisted since the early 1980s, alternative media — e.g., metal nanoparticle films and nanostructured probes — have since been developed for a wide variety of applications with improved reproducibility. Etched quartz posts coated with silver have also exhibited a great deal of reproducibility. In an effort to simplify fabrication of solid SERS probes, materials have been mechanically roughened to induce the SERS effect. Inherently rough silver membranes, requiring little additional preparation, have also been investigated. Many of these technologies have been the basis of recently developed innovative probes, such as silver-nanoparticle-embedded sol gels and polymers, *in situ* photoreduced sols, and a variety of fiber-optic-based SERS probes.

Some particularly exciting movements in SERS probe development have focused on SERS nanoprobes and near-field probes, which have introduced the possibility of extremely spatially specific SERS analysis as well as single-molecule detection. Another area of intense research has been the development of highly

specific solid SERS probes that incorporate coatings of polymers, self-assembled monolayers (SAMs), and bioreceptors. As a result of the extensive development of SERS-based probes, the scope of applications of SERS has been dramatically expanded to include solid, liquid, and airborne samples in many major areas (e.g., environmental, biotechnical, biomedical, and remote-sensing analyses).

64.3.1 Metal Electrodes

Electrochemically roughened electrodes were the first medium with which the SERS effect was observed.¹ The observation of this effect resulted in further inaugural studies to confirm it and to establish enhancement factors.^{2,3,14} While several metals have been investigated for SERS activity in electrochemical cells, ^{16,38–41} silver has been most commonly used. During electrochemical preparation, silver at the electrode surface is first oxidized by the reaction $Ag \rightarrow Ag^+ + e^-$; elemental silver is then redeposited in the ensuing reduction process, $Ag^+ + e^- \rightarrow Ag$. This oxidation-reduction procedure generally produces protrusions on the electrode surface in the size range of 25 to 500 nm. Strong SERS signals appear only after several electrochemical oxidation-reduction cycles, often referred to as "activation cycles."

Other metal electrodes roughened by oxidation-reduction cycles have been investigated for use as SERS substrates; these include platinum³⁹ and copper.^{42,43} A distinct advantage of roughened metal electrodes is that they allow selective detection *in situ* by promoting adsorption of particular compounds at specific applied voltages. For example, both SERS and surface-enhanced hyper-Raman spectroscopy (SEHRS) have been reported for pyrazine and pyridine adsorbed on silver electrodes at varying potentials.⁴⁴ Oxidized forms of metal electrodes have also been demonstrated to promote enhanced adsorption of compounds otherwise exhibiting low SERS intensity. For example, oxidized silver electrodes have made possible enhanced detection of nerve-agent simulants.⁴⁵ In addition, aluminum oxide surfaces have been used for the detection of phthalic-acid isomers and phenylphosphate in the near-infrared (NIR) region.^{46,47}

64.3.2 Metal Colloids

SERS-active suspensions of elemental metal colloids or nanoparticles of various sizes can be chemically formed in solution. Hence, they can be readily used in suspension for *in situ* solution SERS measurements. Alternatively, they can be immobilized on various solid media for use as surface-based SERS substrates. As with roughened metal electrodes, silver is the most commonly used material. Silver colloids can easily be prepared by reducing a solution of AgNO₃ with ice-cold NaBH₄, ^{19–25,48–50} trisodium citrate, ^{51,52} or hydrogen peroxide under basic conditions. ⁵³ Other more innovative techniques that reduce the need for wet chemistry have been demonstrated. For example, Ahern and Garrell described a unique *in situ* photoreduction method to produce photocolloids in solutions, ²⁵ while another innovative method involved laser ablation of colloids from silver foils into aqueous solutions. ⁵⁴

Gold colloids have also been investigated as SERS-active media. Because gold is virtually bioinert, it may prove to be a valuable material for biomedical applications of SERS. Furthermore, gold produces large SERS-enhancement factors when NIR excitation sources are used. NIR excitation radiation is particularly useful in biomedical studies because it allows greater penetration depths in tissues while causing less fluorescence background relative to visible radiation. Gold sols have been used for the SERS detection of various dyes. ^{55,56} In particular, Kneipp et al. have observed extremely large enhancement factors (up to 10¹⁴) for dyes adsorbed on gold colloids when using NIR excitation. ⁷ Silver-encapsulated gold nanoparticles ³⁷ and silver oxide sols ⁵⁸ have also been reported to induce SERS activity.

A primary advantage of colloid hydrosols is that they make SERS an accessible technology. For example, they are easily produced with common chemical reagents. Furthermore, they can be readily characterized by simple UV-absorption spectroscopy. Production of hydrosols does not require the use of expensive, bulky vacuum evaporation chambers, which are common to the production of solid silver-coated nanoparticle-based substrates (see Sections 64.3.3.2 and 64.3.3.3). On the other hand, this wet-chemistry-based procedure is vulnerable to environmental factors as well as experimental error. As a result, the

reproducibility in hydrosol sizes can be problematic. Furthermore, the size range can be quite large for particles produced in a single batch. Selection of colloidal particles with optimal sizes requires a tedious procedure.⁵⁹ Although some reports have indicated that carefully prepared colloid solutions can last for more than 3 weeks,^{20–22,60} they more often tend to be unstable. More specifically, the colloids have a propensity to aggregate into particles that are too large to induce the SERS effect. To offset this disadvantage, stabilizers such as poly(vinylalcohol), poly(vinylpyrrolidone) (PVPL), and sodium dodecyl sulfate have been used to hinder this coagulation process.^{61–63}

Metal colloids have also been adapted for use in solid-surface-based substrates, For example, silver colloids have been immobilized on filter-paper supports (cellulose, glass, and quartz fibers) for the SERS detection of various dyes.^{23,24} However, the SERS effect was found to depend highly on the specific type of filter paper being used. In a similar approach, filter paper treated with silver colloids has been used for the collection and detection of trace amounts of atmospheric contaminants in aerosols.⁶⁴ Extensive studies have been devoted to immobilization of colloids on various substrates pretreated with organic coatings having affinities for both silver and gold. For example, Freeman et al. have demonstrated selfassembly of monodisperse silver and gold-colloid polymers on substrates coated with polymers having cyanide, amine, and thiol functional groups.⁶⁵ Self-assembled monolayers (SAMs) of paminothiophenol66,67 and p-mercaptopyridine68 have also been used to adsorb gold colloids onto solid gold surfaces. A disadvantage of using SAMs to immobilize colloids is an inherent background SERS signal yielded by the underlying SAM. Nevertheless, such signals have been the basis for fundamental studies regarding the self-assembly of the colloid overlayer. For example, kinetic studies of the assembly of silver and gold colloids on organosilane-polymer-treated surfaces have been pursued. 69,70 Results of these studies have permitted the control and optimization of intercolloid spacing in the production of SAM-based SERS probes. In an innovative method for producing patterns of gold nanoparticles, microcontact printing has been used to deposit corresponding patterns of the underlying poly(dimethyl)siloxane SAMs with amine and thiol functionalities. 71 Finally, SAMs of 3-aminopropyl trimethoxysilane have even been used to immobilize silver colloids on optical fibers for the production of SERS-active fiberoptic sensors.72

63.3.3 Solid SERS Substrates Based on Metallic Nanostructures

In addition to immobilized colloids, researchers have developed a variety of solid-surface-based SERS substrates that are produced entirely from solid materials, as depicted schematically in Figure 64.1. In contrast to immobilized colloids, the solid-SERS-based probes described in this section exhibit a high degree of reproducibility. Figures 64.2 and 64.3 are scanning electron micrograph (SEM) photographs that illustrate the highly uniform surface features achievable with various solid-surface-based substrate technologies, several of which are described in the following section.

64.3.3.1 Metal-Nanoparticle-Island Films

Metallic nanostructured SERS substrates based on metal-island films (Figure 64.1A) are among the most easily prepared surface-based media, granted the availability of a vacuum evaporation system. Such systems are commonly equipped with crystal microbalances for monitoring metal-film thickness. Metal-island films can be produced by depositing a thin (<10 nm) layer of a metal directly onto a smooth solid-base support via sputter-deposition⁴⁹ or vacuum evaporation. At such a small thickness, the metal layer forms as aggregated, isolated metal islands, the size and shape of which can be influenced largely by the metal thickness, deposition rate, geometry, and temperature, as well as post-deposition annealing. To optimize the production of SERS-active metal-island films, various diagnostic techniques have been used including optical absorption, atomic force microscopy (AFM), SERS, or combinations thereof.^{73,74} More recently, silver-island films have been characterized by combining scanning near-field optical microscopy (SNOM) with Raman spectroscopy, thereby achieving <70-nm resolution.⁷⁵ A disadvantage of metal-island films is that they are easily disturbed by solvents encountered in typical biomedical analyses.^{76,77} To minimize this disadvantage, buffer metal layers, (3-mercaptopropyl)-trimethoxysilane (MCTMS) layers, and organometallic paint layers have been applied

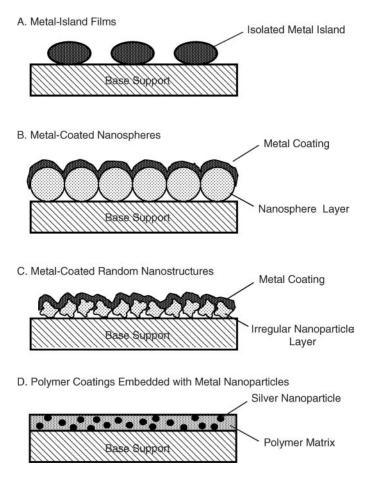

FIGURE 64.1 Schematic representation of various types of solid-surface-based SERS substrates. (Adapted from From Vo-Dinh T. et al., *J. Raman Spectrosc.*, 30(9), 785, 1999.)

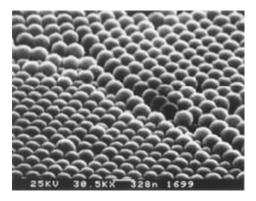

FIGURE 64.2 Scanning electron micrograph (SEM) of a silver-coated nanosphere-based substrate having 261-nm-radius nanospheres.

to glass supports to stabilize gold island films.⁷⁸ Likewise, support media investigated for SERS-active silver islands have included sapphire, carbon, stochastically distributed posts, optical gratings, mica, glass, derivatized glass, and formvar-coated glass.^{76,79}

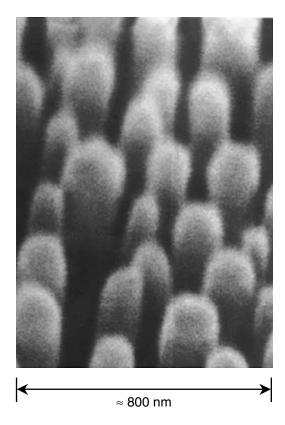

FIGURE 64.3 SEM photograph of acid-etched quartz posts.

In addition to gold and silver, indium^{80,81} and copper⁸² have been used in SERS-active metal-island films. Among these metals, silver is the most commonly used. Extensive evaluations of silver-island films have included comparisons to a variety of other silver nanostructured SERS substrates.^{83,84} Nevertheless, the less commonly used gold- and copper-island films have been developed for use with NIR (1064.1-nm) excitation.⁸² This report is especially promising for biomedical applications because of minimal incidence of fluorescent background in the NIR region. Furthermore, NIR radiation can be propagated through greater distances in tissues than UV or visible light.

64.3.3.2 Metal-Coated Nanosphere Substrates

In our laboratory, we have developed a very dependable solid-surface-based SERS-substrate technology that can be generally described as metal-coated dielectric nanospheres (Figure 64.1B) supported by various planar support media. Nanospheres within a specific size range (e.g., 50 to 500 nm) are spin-coated on a solid support to produce the roughness required to induce the SERS effect. The resulting nanostructured plate is then coated with a layer of silver (50 to 150 nm), which provides the conduction electrons required for the surface plasmon mechanisms. All factors of surface morphology are easily controlled, enabling high batch-to-batch reproducibility. An additional advantage is that the relatively thick layer of silver is less vulnerable to air oxidation than silver islands. Furthermore, the surface is highly resistant to disturbance by sample solvents, making this type of SERS substrate very practical for biomedical applications. Teflon and latex are particularly well suited for SERS substrates because they are commercially available in a wide variety of sizes that can be selected for optimal enhancement.

Preparation of a nanosphere substrate is relatively easy. A 50-μl aliquot of a suspension of nanospheres is deposited evenly over the surface of a dielectric planar support medium, such as filter paper, cellulosic membrane, glass, or quartz.^{17,31,85–88} Using a photoresist spinner to produce uniform monolayer coverage,

the substrate is then spun at 800 to 2000 rpm for about 20 sec. The spheres adhere to the glass surface, providing uniform coverage. The nanosphere-coated support is then placed in a vacuum evaporator, where silver is deposited on the roughened surface at a rate of 0.15 to 0.2 nm/sec. Figure 64.2 shows a SEM of a silver-coated substrate having 261-nm-radius nanospheres (deposited from a 10% suspension). As demonstrated by the figure, the sphere surfaces exhibit excellent uniformity with respect to nanosphere size, shape, and surface coverage.

Nanosphere-based substrates were among the first to be applied to the detection of a wide variety of compounds of health and environmental interest including organophosphorus agents, chlorinated pesticides, polynuclear aromatic hydrocarbons (PNAs), and DNA adducts.^{89–93}

64.3.3.3 Metal-Coated Nanoparticle Subtrates

Nanoparticles with irregular shapes (Figure 64.1C) can also be used in place of regularly shaped nanospheres in the production of dependable, cost-effective SERS substrates. Dieletric nanoparticle materials investigated in our laboratory have included alumina,⁹⁴ titanium dioxide,⁹⁵ and fumed silica.⁸⁶ The production of irregular nanoparticle-based substrates is achieved with an ease equivalent to that for nanosphere-based substrates described above. Generally, 5 to 10% (w/v) aqueous suspensions of the nanoparticles are spin-coated onto solid support media and then coated with 75 to 150 nm of silver via vacuum evaporation. As an alternative to the vacuum-evaporation process, other groups have investigated silver coating via chemical processes.^{96,97} Nevertheless, substrates prepared via vacuum evaporation yield exceptional reproducibility.

Alumina-based substrates produced by vacuum evaporation have proven to be among the most dependable, with a typical bath-to-batch variability of <10% RSO for induced signals of selected model compounds. The surface of an alumina-based substrate consists of randomly distributed surface agglomerates and protrusions in the 10- to 100-nm range. These structures produce large electromagnetic fields on the surface when the incident photon energy is in resonance with the localized surface plasmons. Alumina-based substrates have numerous applications. ^{92,93,96,98–103} In the studies performed in our laboratory, these substrates have been incorporated into a passive vapor dosimeter for the detection of airborne chemicals ^{98,104} and used for the detection of SERS-active gene probes. ¹⁰³ Gold coating has also been applied to alumina-coated plates for use in the visible to NIR region, ¹⁰⁵ thereby demonstrating greater utility in biomedical applications.

Silver-coated titanium dioxide 95 and fumed silica 86 surfaces also provide efficient SERS-active substrates. Titanium dioxide provides the necessary nano-sized surface roughness for the SERS effect; the nominal particle diameter of titanium dioxide used in our probes is 0.2 μ m. When coated with 50 to 100 nm of silver, this type of probe can yield exceptional SERS enhancement with limits of detection of various compounds in the parts-per-billion (ppb) range. Fumed silica substrates have allowed trace detection of PNAs and pesticides. 89,95

64.3.4 SERS Substrates Based on Metal-Coated Quartz Posts

Silver-coated, regularly spaced submicron posts formed in quartz substrates have proven to be a dependable, yet labor-intensive, SERS substrate. Lithographic techniques have been used to control the surface roughness to a degree suitable for testing the electromagnetic model of SERS. 106,107 While these surfaces produce a Raman enhancement on the order of 107, they are difficult to produce with a large surface area. However, an alternative etching procedure for producing quartz posts overcomes this limitation by using an island film as an etching mask on a silica substrate. 17,83,84,107,108 The preparation of silica prolate posts is a multistep operation, as depicted in Figure 64.4. A 500-nm layer of silica is first thermally evaporated onto a fused quartz base support at a rate of 0.1 to 0.2 nm/sec. The resulting thermally deposited crystalline quartz is annealed at 950°C to the fused quartz for 45 min. A 5-nm silver layer is then evaporated onto the thermal silica layer, and the substrate is flash-heated (500°C) for 20 sec, causing the thin silver layer to bead up in small globules. These isolated silver globules act as etch masks when the substrate is subsequently etched for 30 to 60 min in a CHF₃ plasma. This etching produces submicron

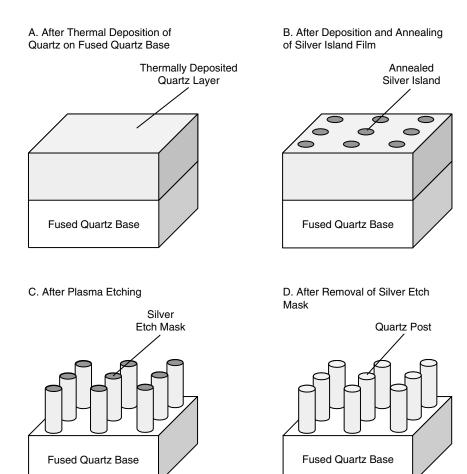

FIGURE 64.4 Schematic diagram of the production of quartz-post-based SERS-active substrates.

prolate silica posts under the silver globules. Since fused quartz is etched much more slowly than is thermally deposited quartz, the fused quartz base survives the etching process. The posts are then cleaned to remove the silver etch mask and coated with either a continuous 80-nm silver layer¹⁰⁸ or a discontinuous layer with the silver deposition restricted to the tips of the quartz posts.^{83,84} Figure 64.3 shows the SEM photograph of the resulting uniformly shaped and distributed quartz posts.

A disadvantage of quartz-post-based substrates is the difficult, time-consuming etching procedure required for post fabrication. Nevertheless, optimized quartz posts can serve as the base for a reusable SERS substrate, provided the silver coating is replaced between uses. It is worthwhile to note, however, that the posts are fragile and hence not amenable to field studies. In contrast, the nanosphere- and nanoparticle-based substrates described above are generally simpler to prepare and very easy to handle. Furthermore, comparative studies indicate that the simple fumed silica-, alumina-, or nanosphere-based probes provide SERS enhancements similar or superior to quartz-post-based probes. Consequently, practical applications involving quartz-post-based SERS probes have been extremely limited.

64.3.5 SERS Substrates Based on Chemically and Abrasively Roughened Solid Surfaces

Smooth surfaces can be roughened by chemical and abrasive techniques to impart the required roughness for the SERS effect. In several cases, SERS substrates have been produced through a one-step procedure

of roughening metal foils, analogous to redox-roughened metal electrodes. Because the foils act as a source of surface plasmons, no metallic overlayer is required. Copper^{109,110} and silver^{111–115} foils have been acid-etched to impart roughness. These SERS substrates exhibit exceptional thermal stability, are cost-effective, and can be reused. As a result, the SERS activity of acid-etched silver foils compare favorably with a variety of other types of SERS substrates.^{111–115}

Another procedure involves a combination of sandblasting and acid-etching steps to produce 10- to 100-nm-scale surface features. In a more innovative technique, silver foils have been selectively etched with ferrocyanide (III) and potassium thiocyanate using SAMs as etch masks, 116 producing 100-nm surface features with excellent uniform coverage. Dielectric materials have also been chemically and mechanically roughened to induce SERS, but with the requirement of subsequent metal-coating steps. For example, silver-coated, chemically etched polymer supports have been developed and compared to SERS-active crossed gratings and posted quartz wafers. 117 In an exciting development toward biomedical applications, Mullen and Carron have described abrasively roughened optical fibers coated with silver. 118 This integration of a SERS-active surface fiber-optic tip could be useful in a single-fiber SERS probe for low-volume measurements.

64.3.6 SERS Substrates Based on Inherently Rough Materials

Certain planar support materials have inherent roughness suitable for inducing the SERS effect. For example, direct metal coating of special cellulosic filter papers produces useful substrates. ^{27,91,119} SEMs of these cellulosic materials have shown that these surfaces consist of fibrous 10-µm strands with numerous tendrils that provide the necessary protrusions required for the SERS enhancement. For example, silver-coated paper substrates have been used to detect approximately 3 ng/ml methyl red. ¹²⁰ Solid-phase extraction membranes and thin-layer chromatographic (TLC) plates have also been SERS-activated through silver coating via chemical reduction. ^{121,122} Furthermore, such SERS probes have been used for combined TLC separation and detection of sulfonamides, ^{121,122} illicit drugs, ¹²³ and nucleic-purine derivatives. ⁵⁰

Inherently rough materials can sometimes induce the SERS effect with little or no additional preparation. One such example investigated in our laboratory is a silver membrane used for air-particulate sampling.²⁷ The membrane already has micropores and interstices that provide the roughness features required to induce SERS. Furthermore, because it is solid silver, it can be used directly as a SERS-active substrate without applying any additional silver. Another example is black-and-white photographic paper, for which SERS activation is achieved simply through low-level light illumination and development steps.¹²⁴ It is important to note, however, that the inherently rough materials suitable for SERS are a very rare find.

64.3.7 SERS Substrates Based on Metal-Nanoparticle-Embedded Media

Silver nanoparticles embedded in various solid porous media (Figure 64.1D) have recently been investigated as stable SERS substrates with the potential for selective detection. The *in situ* production of these nanoparticles in solid matrices provides several advantages. For example, a solid matrix not only spatially stabilizes but also physically protects the colloids. In addition, the porosity of such materials as sol gels, cellulose acetate gels, and polycarbonate films permits interaction of analyte compounds with the embedded metal nanoparticles. Furthermore, control of pore size and matrix polarity through simple chemical means (particularly when using the sol-gel technique) can impart selectivity. Finally, the chemical processes generally used to prepare such substrates make the SERS technique accessible to general analytical laboratories.

A silver-nanoparticle-embedded sol-gel substrate produced through the chemical reduction of silver halide particles distributed in the sol-gel matrix has been reported for the detection of neurotransmitters and dopamine. ^{125,126} *In situ* precipitation of silver chloride nanoparticles via reaction of silver nitrate with trichloroacetic acid throughout the sol-gel matrix was performed before curing. Immediately prior to

use, the silver chloride particles were reduced to elemental silver nanoparticles with FeSO₄·7H₂0. An advantage of this technique is that the sol gel can be stored for long periods in the nonreduced form, precluding vulnerability to air oxidation. In a similar approach, chemically reduced silver and gold colloids have been produced in sol-gel-derived xerogel, ¹²⁷ and silver-doped sol-gel films have been formed through *in situ* chemical reduction of [Ag(NH₃)₂+]. ¹²⁸ Polycarbonate films doped with silver via chemical reduction have been reported as well. ¹²⁹ As an alternative to chemical reduction, photodeposited gold particles have been produced through UV irradiation of organometallic gold precursors dispersed in sol gels. ¹³⁰ In a quite different approach, a counter-diffusion technique has been used to embed cellulose acetate films through impregnation with preformed fine silver particles. ^{131,132}

64.3.8 Overcoatings on SERS Substrates

The application of a wide variety of coatings to many of the SERS substrates described in previous sections has been the focus of extensive research in recent years, with the goals of imparting selectivity and robustness to the SERS technology. These coatings have generally been in the form of organic coatings distributed as relatively thick polymer layers or SAMs, ultrathin metal films, dielectric films, and monolayers of bioreceptors. These coatings have improved detection selectivity through enhanced adsorption or selective permeability mechanisms. In some cases, coatings have stabilized SERS-active surface features, thereby extending their shelf lives.

64.3.8.1 General Organic, Metallic, and Dielectric Overcoatings

Polymer coatings have been applied to a variety of solid-surface-based SERS substrates. In one study, a relatively thick layer ($\sim 10\,\mu m$) of PVPL was applied to alumina-based silver SERS substrates. ¹³³ In addition to prolonging shelf life, this procedure was demonstrated to preserve surface features vital to the SERS effect by offering resistance to physical disturbance. Furthermore, chemical selectivity was imparted via selective permeability, particularly for compounds having hydrogen-bonding properties. The procedure involved simply dipping the bare silver SERS substrates into a 5% (w/v) methanolic solution of the polymer, followed by room-temperature curing on a level surface for ~ 30 min. PVPL coatings have also been applied to silver-island-based SERS substrates for selective detection of airborne chemicals. ^{104,134} In that study, the coating was observed to preserve the delicate silver-island films over a 20-d period.

A combination of polybenzimidazol and mercaptobenzimidazol has been applied to SERS-active, nitric-acid-etched copper foils. ¹³⁵ This coating inhibited corrosion and thus prolonged the shelf life of the SERS-active substrate. In addition, treatment of silver SERS substrates with various thiols can provide long-term stability, even for substrates stored in water for a month. ¹³⁶ Propanethiol-coated silver SERS substrates, investigated as potential SERS-based detectors in gas chromatography, have also exhibited enhanced adsorption and detection of hydrophilic compounds. ¹³⁷ To promote enhanced adsorption of metal ions (Cu⁺², Pb⁺², Cd⁺²), 4-(2-pyridylazo) resorcinol coatings have been applied to SERS-active silver. ¹³⁸ As an example of the enhanced selectivity offered by reactive coatings in the analysis of complex biological matrices, bilirubin and salicylate have been detected at below normal therapeutic levels via direct SERS analysis of whole blood. ¹³⁹ In that study, application of the coating, diazonium, precluded the need for a time-consuming and possibly risky preparation of a less complex serum sample. A reactive coating has also been proposed for the one-step detection of the illicit drugs amphetamine and methamphetamine. ¹⁴⁰

Extensive efforts have also been devoted to the development of coatings based on inorganic materials. For example, transition metals (Pd, Rh, Pt, Ir, Ru) have been applied to gold substrates as pin-hole-free, ultrathin (2 to 3 monolayers) films to enhance adsorption of CO and NO while preserving the SERS-inducing properties of the underlying gold substrates. The ultrathin coatings were achieved through a special electrodeposition process. Silica-coated silver-island-based substrates have also been reported as viable SERS substrates. These dielectric-coated substrates have made possible the quantitative detection of dyes adsorbed from solutions. Furthermore, they have been used in fundamental adsorption-kinetics studies. Silica-coated substrates could prove to be especially useful in SERS-based biosensors

because of the well-defined hydrophilic and stabilizing properties of the coating. Such substrates could be resistant to oxidation and physical damage, thereby both prolonging shelf life and offering the potential for reuse.

64.3.8.2 SAM Overcoatings

SAMs have proven to be a valuable factor in SERS substrate development and theoretical applications of SERS. For example, they have been used to immobilize SERS-active metal colloids on planar supports in a highly ordered fashion. 67,68,71,129 In fact, specific colloidal patterns have been prepared by microcontact printing of SAMs on planar surfaces before exposure to SERS-active colloids. 71 SAMs have also been used for the production of UV-induced SERS-active photopatterns on silver films coated with p-nitrophenol. 148 In more fundamental studies, the inherent SERS signals of SAMs have been used to evaluate the surface uniformity of SERS-probe surfaces including electrochemically roughened gold electrodes and immobilized gold colloids. 149 The application of SAMs to SERS-substrate surfaces also allows selective detection. For example, SAMs of mercaptoalkalinic acids on colloidal-silver substrates have been used for the SERS detection of selectively adsorbed cytochrome c^{150} and have formed the basis for anchoring DNA capture probes for SERS-active hybridization platforms. 151 Monolayers of cysteamine on silver SERS subtrates have also been reported. 152,153 Such monolayers could promote the selective adsorption of proteins. The effects of electrolytes and pH on the molecular structure and distribution of cysteamine layers have been investigated. 152,153

64.3.8.3 Bioreceptor Monolayer Overcoatings

The potential use of SERS in biodiagnostic tests has been demonstrated through the use of immobilized monolayers of bioreceptors including oligonucleotides and antibodies. The use of surface-enhanced Raman gene (SERG) probes for medical diagnostics^{103,151,154–157} is covered in greater detail in later sections. In the production of SERG probes, SERS-active dye labels can be attached to oligonucleotide primers used in polymerase chain reaction (PCR) amplification of specific target DNA sequences. Following PCR, the resulting labeled target DNA can be denatured, allowing hybridization of specific, single-stranded, labeled DNA to oligonucleotide capture probes, which can be immobilized on solid supports. Contact with SERS-active media permits subsequent detection of the SERG probe. This method combines the high sensitivity of the SERS technique with the inherent molecular specificity offered by DNA-sequence hybridization.

Antibody monolayers have also been the basis of SERS detection with molecular selectivity, ^{158,159} thus demonstrating the potential for SERS in immunoassays. In one study, Ni et al. demonstrated the simultaneous detection of two antigens in a single sandwich immunoassay using two reporter molecules. ¹⁵⁹ Capture antibodies selective for the target antigens were bound to gold colloids. The capture-antibody-coated colloids were then exposed to a mixture of target antigens. Finally, reporter antibodies specific to the immobilized target antigens were immobilized on the colloid via interaction with the target antigens. SERS-active markers on the reporter antibodies permitted extrinsic detection of the immobilized antigens. Each antigen was assigned a different marker, yet both reporters could be detected in a single measurement because of minimal overlap of the respective Raman spectra. In another study, Dou et al. demonstrated the potential for a SERS-based immunoassay with no need for reporter molecules. ¹⁵⁸ Instead, they monitored the native SERS signatures of antimouse IgG antibodies adsorbed on gold nanoparticles. Because of the structure-specific nature of Raman scattering, they were able to directly confirm conjugation with antigens through the observation of changes in relative intensities of spectral features of the IgG spectrum. Neither reporter probes nor rinsing steps to remove unbound antigens were required in this assay.

64.4 Biomedical Applications of SERS Probes

64.4.1 SERS Bioanalysis

The extensive progress in the development of dependable SERS substrates over the past few decades has promoted the application of SERS in the rapidly expanding field of biotechnology, as is demonstrated

in several excellent reviews. ^{154,160–163} The variety of substrates has made these applications far-reaching indeed, spanning liquid- and gas-phase samples from the meso- to nanovolume scale. For example, various SERS-active fiber-optic probes have been developed for analyzing biological samples, as is discussed below. Furthermore, the development of nanoscale fiber-optic probe tips offers the potential for intracellular measurements as well as the integration of SERS with SNOM. ^{8,9,154,160–163} Reliable substrates have been the basis of SERS-based screening for illicit drugs ^{123,140,164–168} as well as bioassays based on DNA ^{103,154,155} and antibody ^{158,159,169–171} probes. SERS has been applied to the low-level detection of therapeutic drugs ^{20,172–188} and has even been used to evaluate the interaction between drugs and target species as well as complex matrices, ^{189–203} sometimes within cells. ^{204–207} A host of biological compounds (e.g., proteins, amino acids, lipids, fats, fatty acids, DNA, RNA, antibodies, and enzymes) and systems (e.g., lipid bilayers and intracellular environments) have been studied via SERS. Further examples can be found in Table 65.8 of Chapter 65 of this handbook. Such studies could provide valuable insights into cellular processes (some of which promote diseases), thereby aiding in the establishment of the mechanisms of therapeutic drugs and in the development and evaluation of new therapeutic species.

64.4.1.1 SERS-Based Bioassays

Among the most innovative biomedical applications of SERS have been bioassays. DNA-based bioassays are discussed in great detail below. Immunoassays have also received considerable attention for more than a decade. For instance, an early example of a SERS-based immunoassay was reported by Rohr et al. in 1989.¹⁷¹ The same year, Grabbe and Buck reported on SERS studies of native human immunoglobulin-G.²⁰⁸ More recently, SERS signatures of native antibodies have been the basis of a simplified immunoassay¹⁵⁸ in which conjugation of the antibody with a target antigen was confirmed through observance of alterations of the SERS spectrum for the native antibody.

As an alternative, extremely sensitive detection can be achieved with reporter-antibody probes tagged with intensely SERS-active compounds or with enzymes that react with substrates to yield SERS-active products. These methods often involve sandwich-immunoassay techniques, which increase the number of required steps but offer the advantages of excellent sensitivity and the potential for "label multiplexing." For example, Ni et al. recently reported the simultaneous detection of two types of antigens in a single assay by using two reporter antibodies.¹⁵⁹ The labels of the reporter probes yielded SERS spectral features with minimal overlap, permitting exploitation of a label multiplex advantage. In a sandwich-assay format, one set of antibodies immobilized the target antigens on gold colloids, while the reporter-antibody probes were subsequently immobilized at allosteric sites of the target antigens.

In other studies, reporter antibodies have been tagged with the enzyme peroxidase. ^{169,170} Once the peroxidase-labeled antigen was immobilized on the target, it could be exposed to the substrates ophenylenediamine and hydrogen peroxide. A sustained reaction of the enzyme with a multitude of substrate molecules produced an extremely high yield of the SERS-active product, azoaniline. This method has thus far been limited to sandwich-immunoassay formats. For example, in a study to detect membrane-bound enzymes in cells, cells were first exposed to primary antibodies specific to the membrane-bound enzymes, then exposed to a peroxidase-tagged reporter antibody specific to the primary antibody. ¹⁶⁹ A format that uses a capture antibody to immobilize a target antigen, and a reporter antibody to bind to an allosteric site of the immobilized target antigen, has also been reported. ¹⁷⁰

64.4.1.2 SERS Detection of Illicit Drugs

Another potential biomedical application of SERS-based analysis is drug screening. Several studies have demonstrated SERS detection of illicit drugs on a variety of substrates. ^{123,140,164–168} These works have collectively yielded SERS spectra for cocaine–HCl, crack cocaine, amphetamine, methamphetamine, mefenorex, pentylenetetrazole, pemoline, heroin, codeine, and other drugs banned in sports. In one study, stimulant drugs were detected in human urine spiked at μg/ml levels. ¹⁶⁸ In other work, SERS was used to distinguish between cocaine and common cutting agents and impurities including benzocaine and lidocaine. ¹⁶⁴

While these studies have demonstrated the potential for direct analysis of complex media with SERS, other efforts have been directed toward the development of reactive coatings to enhance selectivity. For example, Sulk et al. have proposed a reactive coating for the selective detection of amphetamine and methamphetamine. Silver colloids have been most commonly used for this application, but some solid-surface-based media have also been reported, including colloidal silver supported by cellulose paper and ion-exchange paper, as well as acid-etched silver foils. TLC plates coated with silver through vacuum evaporation have also been used for the detection of illicit drugs. TLC plates have the unique advantage of not only providing the roughness needed to induce SERS but also serving as a separation medium. In the TLC study, a mixture of heroin, codeine, and cocaine was separated on bare TLC plates that were subsequently coated with silver to allow detection at approximately 0.2 µg/mm². Separation-based SERS detection of drugs banned in sports has also been achieved through the coupling of SERS with liquid chromatography via a post-column windowless detection flow cell that was supplied with a stream of silver colloids. Separation-based silver colloids.

64.4.1.3 SERS Studies of Therapeutic Drugs

SERS has been used to detect a large number of therapeutic drugs, as indicated in Table 64.1. A key advantage of SERS spectroscopy is the structural information it provides. In several studies, this advantage has been exploited to confirm interactions between therapeutic drugs and targets. In many cases, such studies have even yielded the establishment of interaction mechanisms, including the identification of specific active sites, complex molecules, and modes of bonding. Observable changes in SERS spectra for drugs and targets before and after interactions have served as the basis for such determinations. Fortunately, interaction between the complexes and the SERS-inducing medium (e.g., silver colloids) often has negligible effects on the drug/target interactions. There have been extensive studies of interactions between a variety of antitumor drugs and DNA including doxorubicin,200,207 fagaronine,197 ethoxidine,197 mitoxanthrone,¹⁸⁴ intoplicine,^{201,206} aclacinomycin,²⁰² saintoplin,²⁰² acridines,²¹² and various ellictipicines. 186,203 Several studies of interactions between topoisomerases and topoisomerase-inhibiting antitumor drugs, including amsacrine²⁰⁵ and intoplicine,^{201,206} have been reported as well. For both drugs, interactions have been confirmed in K562 cancer cells. 205,206 Furthermore, interactions within ternary complexes of topoisomerase-inhibiting drugs, DNA, and topoisomerases have been reported for intoplicine, 201,206 In other in vivo studies, the interaction between the antitumor drug doxorubicin and targets has been studied in K562 cancer cells.²⁰⁷ Interaction between another antitumor drug, dimethylcrocetin, and the retinoic acid receptor, RAR-gamma, has been confirmed in HL60 cancer cells.²⁰⁴ Both ionic bonds and ring stacking have been determined via SERS as modes of interaction between 9-amino acridine and the metastasis-related protease guanidobenzoatase. 189,190 SERS has been used to identify active sites for the interaction between the antiviral/antiparkinsonian drug amantidine and histidine.¹⁹² The antiviral drugs hypocrellin A¹⁹⁶ and hypericin¹⁹⁸ have been evaluated for interaction with human serum albumin. Another interesting study has demonstrated that SERS spectral changes resulting from the interaction between the antimalarial drug quinacrine and oligonucleotides depend on the nucleotide sequence. 193

64.4.2 SERS Genomics

The last few years have seen a great deal of interest in the development of optical techniques for genomics analysis such as nonradioactive DNA probes for use in biomedical diagnostics, pathogen detection, gene identification, gene mapping, and DNA sequencing. This section presents an overview of SERS methods and instruments, such as DNA mapping and sequencing applications, that can be used in genomics analysis. The hybridization of a nucleic-acid probe to DNA biotargets (e.g., gene sequences, bacteria, viral DNA) permits a very high degree of accuracy in identifying DNA sequences complementary to that probe. The possibility of using SERS for low-level detection of the DNA bases and oligonucleotides was demonstrated in several studies in the 1980s.^{50,213–218} More recently, the possibility of using Raman and SERS labels for extremely sensitive detection of DNA has been demonstrated.^{103,151,154,155,157} For example, Graham et al. have claimed adequate sensitivity for single-molecule DNA detection via surface-enhanced

resonance Raman scattering (SERRS).¹⁵⁷ With the use of labeled DNA as gene probes, the SERS technique has been recently applied to the detection of DNA fragments of the human immunodeficiency virus (HIV)¹⁵⁵ as well as oncogenes.¹⁵¹

A critical aspect of sequencing the entire human genome involves defining and identifying large insert clones of DNA corresponding to specific regions of the human genome. These maps will be composed of overlapping fragments of human DNA and allow the direct acquisition of DNA fragments that correspond to specific genes.^{219–222} An approach that facilitates large-scale genomic sequencing involves developing maps of human chromosomes into maps based on large insert bacterial clones such as bacterial

artificial chromosomes (BACs).^{220–222} A time-saving method for detecting multiple BAC-clone-labeled probes simultaneously would be especially appealing for the BAC approach to genome sequencing and mapping. The SERS technique can provide this label-multiplex capability. The SERG probes described in this section preclude the need for radioactive labels and have great potential to provide sensitivity, selectivity, and label multiplexing for DNA sequencing as well as clinical assays.

64.4.2.1 Instrumental Systems for SERS Genomics

This section describes two detection systems that allow two different recording modes: (1) spectral recording of individual spots and (2) imaging of the entire two-dimensional (2D) hybridization array plate.

A detection system used for recording the SERS spectrum of individual spots is illustrated in Figure 64.5. An individual spot could correspond to an individual microdot on a hybridization platform. This system can readily be assembled using commercially available or off-the-shelf components. A focused, low-power laser beam is used to excite an individual spot on the hybridization platform. In our studies, a helium-neon laser is used to provide 632.8-nm excitation with approximately 5 mW power. A bandpass filter is used to isolate the 632.8-nm line prior to sample excitation. A signal-collection optical module is used to collect the SERS signal at 180° with respect to propagation of the incident laser beam. The collection module includes a Raman holographic filter, which rejects the Rayleigh scattered radiation before it enters the collection fiber. Finally, the collection fiber is coupled to a spectrograph (ISA, HR-320) equipped with a Princeton Instruments red-enhanced intensified CCD (RE-ICCD)-576S detection system. The signal-collection module can be coupled directly to the spectrograph, bypassing the optical fiber. However, the optical fiber greatly simplifies measurements and improves reproducibility by minimizing critical optical alignment steps.

Since the SERG probe hybridization platform consists of a 2D array of DNA hybridization spots, a method for recording signals from all spots simultaneously would be highly advantageous, reducing analysis time as well as precluding the need for platform scanning. For analysis of SERG-probe-based assays this feat can be accomplished through multispectral imaging (MSI). The concept of MSI is illustrated in Figure 64.6. With conventional imaging, the optical emission from every pixel of an image is without tunable wavelength selection capability (Figure 64.6A). With conventional spectroscopy, the signal at every wavelength within a spectral range can be recorded, but for only a single analyte spot. This condition is the basis for the single-point-analysis system described above. The MSI concept (Figure 64.6C) combines these two recording modalities, thereby allowing the acquisition of a Raman spectrum for every hybridization spot on the assay platform, provided that the entire platform can be included in the instrument field of view. Critical to the success of this concept is an imaging spectrometer. In our studies, a rapid-scanning solid-state device, an acousto-optic tunable filter (AOTF), is used for tunable wavelength selection with image-preserving capability. This compact solid-state device has an effective wavelength range of 450 to 700 nm with a spectral resolution of 2 Å and a diffraction efficiency of 70%. Wavelength tuning is achieved simply by supplying the AOTF with a tunable RF signal.

Figure 64.7 illustrates a system developed to implement the MSI concept. In this system, an expanded, collimated laser beam is used to stimulate a 0.5-cm-diameter region of the assay array platform. In these studies, a krypton ion laser (Coherent, I-70) is used as the excitation source (at 25 to 50 mW). A bandpass filter is used to isolate the 647.1-nm line of the laser. After passing through a bandpass filter (Corion), the laser beam is expanded and collimated using a spatial filter/beam expansion module. An imaging optical module collects and projects the image of the back-illuminated SERG-probe hybridization platform through an AOTF (Brimrose, Model TEAF 10-45-70-S) and onto a charge-coupled-device (CCD) camera (Photometrics, Model CH210). A holographic notch filter (Kaiser, HNPF-647–1.0) is placed in front of the CCD detector for rejection of laser Rayleigh scatter. For these studies, the imaging optical module is a microscope (Nikon, Microphot-SA) equipped with an image port to which the AOTF/CCD detection complex is attached. The image is collected with a 10× objective lens.

Figure 64.8 shows the 2D SERS image of an array pattern of *p*-aminobenzoic acid (PABA), acquired with the MSI system. ¹⁵⁴ The diameter of each spot observed in this image is approximately 500 µm. This

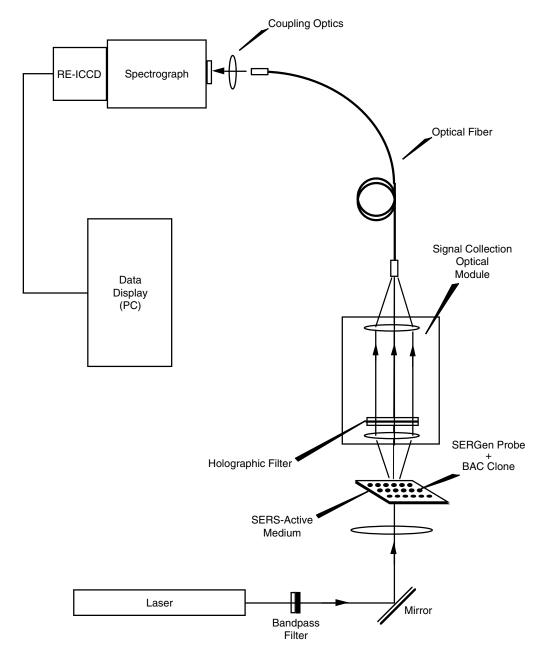

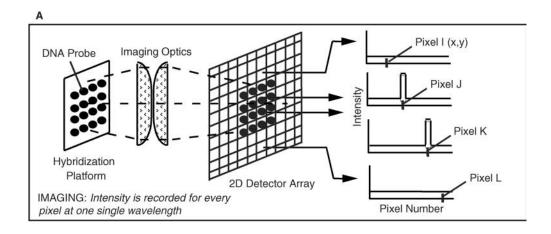

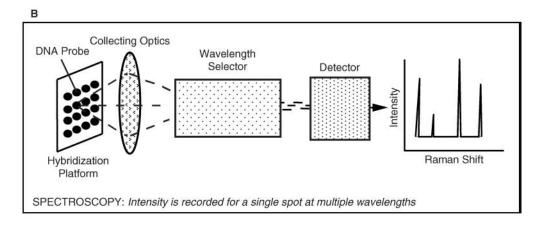

FIGURE 64.5 Schematic diagram of the instrumental set-up for spectral acquisition from individual spots on a bioassay platform. (Adapted from Vo-Dinh, T. et al., *J. Raman Spectrosc.*, 30(9), 785, 1999.)

result demonstrates the capability of the MSI system to detect a SERS-label spot array deposited on the 5×5 mm substrate. The MSI technique has also been used for imaging creasyl fast violet (CFV)-based SERS patterns at a much smaller scale. For example, pattern features with <20- μ m diameters and 75- μ m spacing were fully resolved when using a 50× objective lens. CFV has been successfully used as a SERS label for the detection of the HIV gene system. These examples, though not based on true hybridizations, illustrate the possibility of performing MSI on DNA-hybridization array platforms with high resolution.

64.4.2.2 The SERS Advantage in Label Multiplexing

To fully exploit the label multiplex advantage for DNA-hybridization and SERG detection, several factors must be considered. First, a label must be selected that is SERS-active and compatible with the hybridization platform. The ideal label would exhibit a strong SERS signal when used with the SERS-active

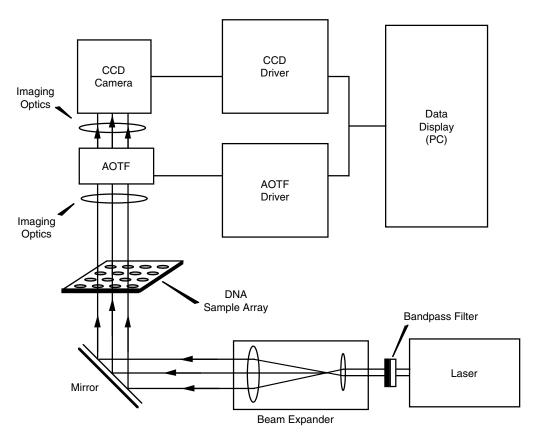

FIGURE 64.7 Schematic diagram of an instrument for multispectral imaging of bioassay platforms. (Adapted from Vo-Dinh, T. et al., *J. Raman Spectrosc.*, 30(9), 785, 1999.)

substrate of interest (Figure 64.9A). Second, the strong SERS signal should not be affected by being attached to the oligonucleotide selected for the gene probe (Figure 64.9B). Third, the unlabeled oligonucleotide should not exhibit a significant SERS signal relative to the label's signal (Figure 64.9C). Finally, the SERS signal from the labeled probe should not be affected by the hybridization process (Figure 64.9D).

Luminescence labels have been shown to have adequate sensitivity for gene detection.²²³ Nevertheless, a more desirable technique would both offer better spectral selectivity than is yielded by broadband luminescence and overcome the need for radioactive labels. The SERG probe is an excellent alternative to the other spectroscopic-based probes. For example, Figure 64.10 compares the fluorescence and SERS spectra of CFV, a SERG-probe label. As shown in the figure, the spectral bandwidth of the CFV label in the fluorescence spectrum is relatively broad (approximately 50 to 60 nm halfwidth), whereas the bandwidth of a characteristic feature (e.g., 585 cm⁻¹ band) of the corresponding SERS spectrum of the same CFV label is orders of magnitude narrower (<0.5-nm halfwidth). This observation clearly illustrates the advantage of using SERS for label multiplexing. More specifically, this example demonstrates a 100-factor increase in label multiplexing capacity relative to fluorescence. In a typical Raman spectrum, a 2000-cm⁻¹ spectral range can provide approximately 1000 resolvable spectral "intervals" at any given time. Assuming a deduction factor of 10 due to possible spectral overlap, it should be possible to find 100 labels that can be used for the detection of multiple SERG probes simultaneously. This multiplex advantage is particularly useful in high-throughput analyses where multiple gene targets can be screened in a highly parallel multiplex modality.

64.4.2.3 SERS Detection of SERS-Labeled DNA on Solid SERS Substrates

The importance of BAC clone DNA in genome sequencing and mapping has been discussed in previous sections. We recently demonstrated the potential of using SERG probes for BAC clone DNA detection. ¹⁵⁴ In this study, CFV was covalently attached to a 20mer oligonucleotide (5′-TAA-TAC-GAC-TCA-CTA-TAG-GG-3′) of a BAC clone model system. The labeled probe was then spotted on a SERS-active substrate for analysis. Figure 64.11 illustrates the SERS spectrum of this CFV-labeled BAC clone DNA fragment. This spectrum exhibits a series of narrow lines characteristic of CFV, with the strongest at 590 cm⁻¹. This intense, sharp line can be attributed to the benzene ring deformation mode. Another less intense but also sharp line at 1195 cm⁻¹ could be related to benzene-ring breathing vibrations. Another group of small peaks between 1000 and 1400 cm⁻¹ could be associated with aromatic-ring-substitution-sensitive modes. Finally, several peaks that could correspond to benzene-stretch vibrations occur between 1500 and 1650 cm⁻¹.

To further demonstrate the applicability of the SERS method in DNA gene-probe technology we have performed hybridization and SERS-detection experiments with BAC clone probes. Hybridization, which involves the joining of a strand of nucleic acid with its corresponding complementary-sequence strand, is a powerful technique for identifying DNA sequences of interest. BAC clone capture probes were immobilized in the wells of an Immuno Maxisorb 96-well plate using Reacti-Bind DNA coating solution (Pierce, Rockford, IL). The capture probes were then incubated with the CFV-labeled BAC clone SERG probes. After stringency washes, silver colloids were added to the wells for SERS detection of the hybridized probes. Hybridization of the labeled probe to BAC DNA could be readily detected via the CFV spectral signature. Selective detection of HIV via hybridization of SERG probes has also been demonstrated.¹⁵⁵

64.4.2.4 Selective Amplification and Detection of SERS Gene Probes via PCR with Labeled Primers

Isola et al. recently demonstrated that primers labeled with SERS-active compounds can be implemented in the PCR process. ¹⁵⁵ Furthermore, these researchers hybridized PCR-amplified products to DNA capture probes immobilized on *N*-oxysuccinimide (NOS)-derivatized polystyrene plates (DNA-BIND, Corning-

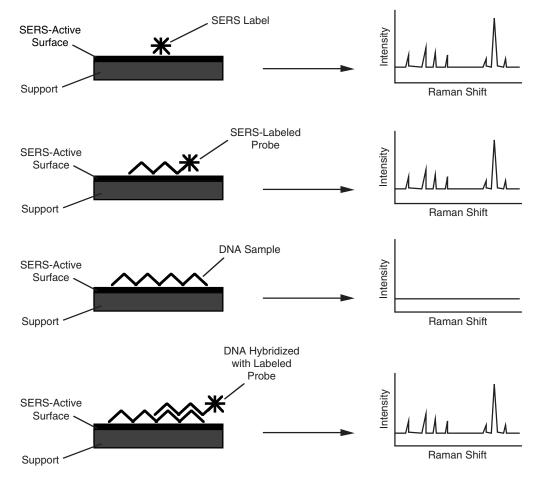

FIGURE 64.9 Factors considered for development of the SERG probe technology. (Adapted from Vo-Dinh, T. et al., *J. Raman Spectrosc.*, 30(9), 785, 1999.)

Costar). Following hybridization, the plates were SERS-activated through the deposition of a silver-island coating. This method has the potential for combining the spectral selectivity and high sensitivity of SERS with the inherent molecular specificity of PCR and the ensuing DNA-sequence hybridization. The effectiveness of this technique has been demonstrated using the *gag* gene sequence of HIV. This is an especially encouraging result because there is a need for a direct nucleic-acid-based test for the detection of HIV. For example, standard HIV serologic tests, including the enzyme-linked immunoassay and the Western blot assay, do not provide a useful diagnosis of HIV in early infancy because of the overwhelming presence of transplacentally derived maternal antibody in the infant's blood.

Figure 64.12 illustrates the results of the HIV *gag* gene hybridization following PCR amplification with a primer labeled with CFV. Curve 1 shows the SERS spectrum of the hybridized CFV-labeled probe. For comparison, the detection of a nonhybridized CFV-labeled probe (single-stranded DNA, ssDNA) is also shown in curve 2. Curve 3 illustrates a SERS spectrum of free CFV. This study showed that no major alteration in the CFV spectrum occurred as a result of being bound to single- or double-stranded DNA. Furthermore, the researchers observed no CFV spectrum for hybridization evaluation for nonspecific binding between noncomplementary DNA strands. This is demonstrated by the hybridization control spectrum illustrated in curve 4. In this case, the CFV-labeled DNA was a single-stranded primer (designed for PCR). Without the PCR step, there was no complementarity between the CFV-labeled primer and the immobilized capture probe. Curve 5, a blank spectrum for SERS-activated NOS plate with immobilized DNA capture probes, exhibits no major spectral background in the region of interest.

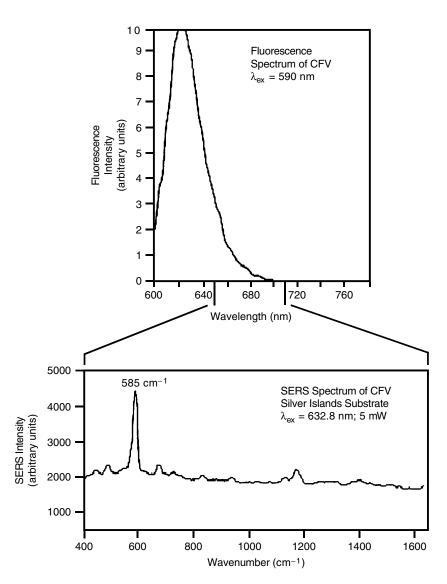

FIGURE 64.10 Comparison of fluorescence and SERS spectra for the SERG probe label. (Adapted from Vo-Dinh, T. et al., *J. Raman Spectrosc.*, 30(9), 785, 1999.)

64.4.2.5 Selective Detection of Labeled DNA Probes via Hybridization on SERS-Active Bioassay Platforms

We have recently developed in our laboratory a SERS-active DNA hybridization platform that greatly enhances the utility of the SERS gene-probe technology.¹⁵¹ In previous work, hybridization of labeled DNA probes was performed on conventional commercially available platforms (e.g., DNA-bind plates), followed by SERS activation of the platform.^{154,155} To make the SERS gene-probe technology more practical, we have developed an inherently SERS-active hybridization platform.¹⁵¹ No SERS activation of the assay is required following the hybridization step. The new DNA-assay platform is an array of oligonucleotide capture probes immobilized directly on a silver-island-based substrate prepared on glass. The capture probes were anchored directly to the silver surface via reaction with a SAM of alkyl mercaptans, as illustrated in Figure 64.13. The coupling approach involved the esterification under mild conditions of a carboxylic acid (immobilized mercaptoundecanoic acid) with a labile group, an *N*-hydroxysuccinimide (NHS) derivative, and further reaction with a 5′-amine-labeled DNA capture probe,

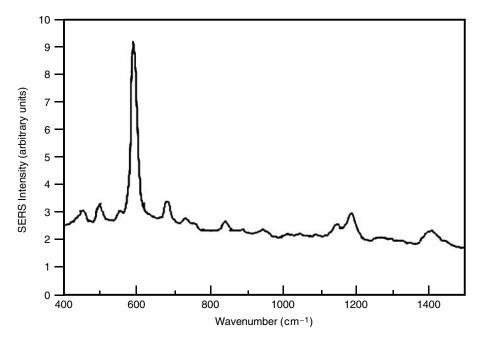

FIGURE 64.11 SERS spectrum of CFV-labeled BAC clone DNA, krypton laser, 647.1 nm, 10 mW. (Adapted from Vo-Dinh, T. et al., *J. Raman Spectrosc.*, 30(9), 785, 1999.)

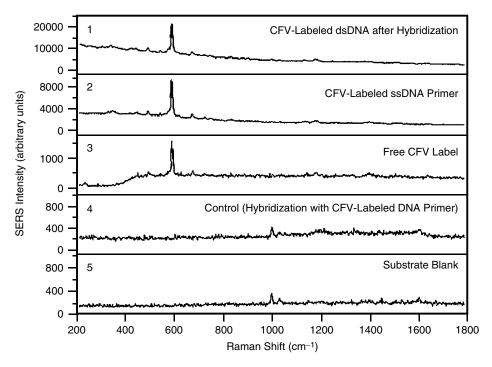

FIGURE 64.12 Demonstration of the SERG probe technology for the selective detection of the HIV1 *gag* gene using via hybridization after PCR amplification. (Adapted from Isola, N.R. et al., *Anal. Chem.*, 70(7), 1352, 1998.)

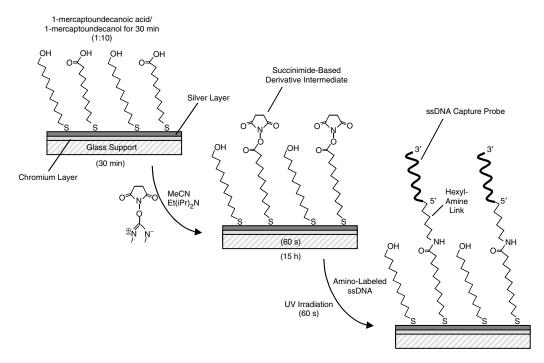

FIGURE 64.13 Schematic diagram of the production of a SERS-active hybridization platform using a SAM of mercaptoundecanoic acid.

producing a stable amide.²²⁴ Our recent study¹⁵¹ demonstrated the potential of this technology in cancergene detection (BRCA1 and BAX genes).

The breast cancer susceptibility genes BRCA1 and BRCA2 are associated with genetically predisposed breast cancer development. Breast cancer is diagnosed annually in about 180,000 women in the United States.²²⁵ Of these cases, only 5 to 10% are estimated to arise from genetic predisposition. Nevertheless, within the population with a family history of breast cancer, germline mutations in BRCA1 account for a predisposing genetic factor >80% for breast and ovarian cancers.²²⁶ Therefore, intense research has been conducted on the principle of action of BRCA1 and BRCA2 genes, as well as their detection.^{227,228}

In our laboratory, we have demonstrated the potential for detecting the BRCA1 gene through hybridization of a rhodamine-B-labeled SERG probe on the new SERS-active hybridization platform. Figure 64.14 illustrates the results of this study. Curve (a) is the SERS spectrum of the rhodamine-B-labeled gene probe after hybridization with the BRCA1 capture probe, which was previously immobilized on the SERS-active platform. This spectrum is a clear signature of the rhodamine-B label. For example, the majority of the peaks in 1200 to 1500 cm⁻¹ region can be attributed to Raman-active aromatic vibrations. Furthermore, no new spectral features are observed in the hybridized probe spectrum, indicating that neither the ssDNA capture probe nor the reagents used in the capture probe anchoring steps contribute significant background signals. In contrast, the spectrum for the hybridization control, illustrated in curve (b), shows no spectral features characteristic of rhodamine-B. The hybridization control was a silver surface modified with alkylthiol SAMS but lacking the BRCA1 DNA capture probes, and hence ideally offering no means for attracting the BRCA1 gene probe during the hybridization step. Indeed, the lack of the spectral features characteristic of rhodamine-B indicates that nonspecific binding is insignificant. Similar results have been reported for BAX gene detection using a rhodamine-110-labeled SERG probe.¹⁵¹

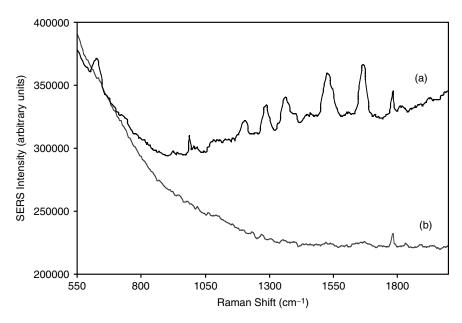

FIGURE 64.14 Demonstration of the SERG probe technology for the detection of the oncogene BRCA1 via hybridization on a prefabricated SERS-active hybridization platform. (Adapted from Vo-Dinh, T. et al., *J. Raman Spectrosc.*, 33(7), 511, 2002.).

64.4.3 Fiber-Optic SERS Monitors for Bioanalysis

SERS-based fiber-optic probes have been developed for remote and *in situ* monitoring for a wide variety of applications.^{99,229–231} The general interest in fiber-optic sensors has arisen from the development of SERS substrates that allow direct measurements in liquid samples. The direct measurement of potentially complex samples is afforded by the spectral selectivity of SERS, which can allow discrimination of multiple components detected simultaneously. Such SERS substrates have been incorporated into remote fiber-optic monitors.

The first SERS-based fiber-optic probes developed in our laboratory had a dual-fiber design in which the SERS-inducing substrate was a separate entity to which the fibers were optically coupled. 99,229,230 One optical fiber was used to transmit the laser excitation to the SERS substrate, and a second fiber was used to collect the scattered radiation from the sample. 99 The SERS substrate was a glass-backed, translucent medium based on silver-coated nanoparticles. With this substrate, the excitation and collection fibers could be configured with one of two geometries: either head on (with the fibers positioned on opposite sides of the SERS substrate) or side by side (with the two fibers on the glass-backed side of the substrate). The collection fiber was coupled to a spectrograph. Using a red-enhanced intensified CCD, we were able to detect trace levels of various analytes in milliseconds, even when using excitation and collection fibers as long as 20 m. Dual-fiber systems have also been the basis of several remote sensors based on normal Raman detection, but these systems typically have much lower sensitivity. 232-234

More recently, several studies have reported use of SERS-based fiber-optic sensors with single-fiber designs in which the SERS-inducing medium is integrated on the tip of the optical fiber.^{72,118,231,235,236} In an early report of integrated single-fiber SERS sensors, Mullen and Carron abrasively roughened the optical fiber before applying a metal layer directly to the tip.¹¹⁸ More recently, we have applied a nanoparticle layer directly to an optical fiber to impart a uniform and reproducible roughness that is critical to the SERS effect. The fiber was simply dipped in an aqueous suspension of 0.1-µm alumina nanoparticles and then coated with a 100-nm layer of silver via vacuum evaporation.²³⁵ Integrated single-fiber SERS

sensors have also been fabricated through immobilization of silver-colloid particles on the tips of optical fibers pretreated with (3-aminopropyl)-trimethoxysilane.⁷² The simplicity of these integrated single-fiber SERS sensors may enable nanoscale fabrication for more practical biomedical applications (e.g., probing single cells). While nanoscale fibers are not commercially available, it is possible to use a special, commercially available fiber-tapering device (Sutter Instrument Co., Model P-2000) to routinely taper fibers with core diameters as large as 600 µm down to tips of approximately 25 nm in diameter. Alternatively, a tapered tip can be formed more passively through etching with hydrofluoric acid. The tapered end can then be SERS-activated with a dependable SERS-inducing medium (e.g., silver islands or immobilized colloids).

64.4.4 SERS-Scanning Near-Field Optical Microscopy (SERS-SNOM)

SNOM has received considerable attention in recent years largely because of the exceptional resolution offered by this new technology. Indeed, SNOM routinely provides optical imaging with resolutions exceeding the diffraction limit.^{237,238} Furthermore, SNOM has been coupled with molecular spectroscopy, most commonly through the use of luminescence. The combination of SNOM and SERS has been reported recently.^{8,9,237,238} In this study, researchers used a planar silver-island-based SERS substrate to generate SERS signals and a chemically etched, 200-nm optical-fiber tip to deliver the excitation radiation from an argon ion laser (488 nm). The tapered sides of the fiber tip were coated with a thick, opaque layer of metal to limit escape of the excitation radiation to the 200-nm tip, hence permitting extremely localized sample excitation. This factor, combined with a substrate-to-fiber tip spacing of approximately 0.1 nm, enabled the acquisition of spectral and spatial information with subwavelength lateral resolution for CFV and rhodamine-6G molecules distributed on the silver-island substrate. Furthermore, the SERS-SNOM technique demonstrated exceptional sensitivity. Spectra from as few as 300 molecules have been recorded.

64.4.5 SERS Single-Molecule Detection

There have been several reports of single-molecule detection using SERS in recent years.^{4-7,157,239} A critical factor in these milestone studies has been the development of exceptional SERS substrates. Most of the reports of single-molecule SERS detection have involved the use of metal colloids in suspensions. For example, Kneipp et al. demonstrated single-molecule detection of crystal violet and other dyes in both silver^{5,6} and gold colloid suspensions.⁷ In these studies, an effective cross section of approximately 10⁻¹⁶ cm² per molecule was observed, corresponding to a 10¹⁴ enhancement factor. The gold nanoparticles were commercially available but required proper agglomeration through the addition of NaCl. These results are promising because these dyes could be used as bioassay markers.

In some cases, bioassay markers can be resonance enhanced in addition to benefiting from SERS. For example, a DNA marker, 2,5,1',3',7',9'-hexachloro-6-carboxyfluorescein (HEX) has been used to achieve single-molecule detection via SERRS in a silver-colloid suspension. The HEX signature was observed for $8 \times 10^{-13} M$ DNA, which corresponded to less than 1 molecule per probed volume at any time required for measurement. Single-molecule detection has also been demonstrated on planar-surface-based substrates. For example, enhancements to factors of 10^{14} to 10^{15} have been observed for rhodamine-6G molecules adsorbed on silver colloids immobilized on a polylysine-coated glass surfaces. Similarly, 10^{14} to 10^{15} factor enhancements have been reported for hemoglobin molecules adsorbed on silver nanoparticles immobilized on a polymer-coated silicon wafer. Researchers in this study reported, however, that single-molecule detection was observed only for hemoglobin molecules situated between and adsorbed to two silver nanoparticles.

In our group, we have progressed toward the goal of single-molecule detection using silver-island-based SERS substrates.³⁵ We have demonstrated extremely low-level detection of CFV, which is a label we normally use for SERS gene probes. In addition to the giant SERS enhancement produced by the silver islands, a helium-neon laser enabled an additional resonance-enhancement factor at 632.8 nm. Furthermore, the detection system used a spectrograph equipped with a RE-ICCD. A confocal excitation/

collection geometry was implemented with a $100\times$ objective lens. The 0.9 numerical aperture of this lens helped ensure a tight focus and efficient signal collection. Sample preparation for the low-level CFV detection simply involved spotting a 1- μ l aliquot of 5×10^{-11} M CFV solution (i.e., 3×10^7 molecules) on the silver-island SERS substrate and allowing it to dry after spreading it to a 6.5-mm diameter. Assuming a laser spot diameter of 10 μ m and even distribution of CFV molecules within the 6.5-mm diameter spot, we estimated the number of probed molecules to be approximately 70. Nevertheless, signal-to-noise levels on this measurement indicated that this number could be reduced by at least a factor of three. Furthermore, we observed "hot spots" in the area of sample deposition, or micron-scale points of enhanced SERS signal. This phenomenon, along with an improved collection optics and longer signal-integration times, may allow for detection of single CFV molecules on silver-island-based solid substrates.

64.5 Conclusions

The development of dependable SERS substrates has spurred renewed interest in Raman scattering as a practical analytical tool in biomedical applications. Until such developments were achieved, there was little interest in Raman-scattering-based analysis because the cross section of normal Raman scattering is miniscule (10⁻³⁰ cm² per molecule) relative to the cross sections available through other molecular spectroscopies, particularly luminescence. In the past, high laser powers were used to compensate for this shortcoming. However, this procedure had limited effectiveness, largely because it induced photodecomposition on probed molecules, particularly at trace-level concentrations. By contrast, SERS-inducing media enable trace-level detection with relatively low laser powers.

Both liquid- and solid-based SERS-inducing media are now being used for the detection of biomedically significant compounds; moreover, innovative SERS-based biomedical applications are being developed. The development of such substrates and their use in practical analytical applications has required a triumph over the daunting challenge of producing nanoscale structures in reproducible and cost-effective ways. A significant portion of recent efforts has been devoted to investigating SERS coatings to improve selectivity, longevity, and ruggedness. As a result of this work, the scope of applications of SERS has been greatly expanded in the past two decades, evolving from environmental to biomedical applications. Some highlights of SERS-based applications have included single-molecule detection, SERS-based fiber-optic probes and nanoprobes, SERS-based bioassays, and hyphenated techniques such as scanning near-field microscopy (SNOM)/SERS and liquid chromatography (LC)/SERS. As we enter a new century, researchers continue to explore the potential of SERS, opening new horizons in the development of biophotonic probes.

65.1 Introduction

This chapter provides several tables summarizing spectroscopic properties of various biologically and medically relevant species and samples. It is divided into two main sections: (1) Fundamental Spectroscopic Properties of Biologically and Medically Relevant Molecules and (2) Spectroscopic Data for Biological and Medical Applications. The spectroscopic data for the first section are provided in the following tables:

- Table 65.1, Characteristic Raman Frequencies
- Table 65.2, Characteristic IR Band Positions of Functional Chemical Groups and Molecules
- Table 65.3, Characteristic IR Absorption Frequencies of Compounds
- Table 65.4. Characteristics of Electronic Transitions between σ , η , and π Orbitals
- Table 65.5, Absorption Characteristics of Common Fluorophores

For the second section, the spectroscopic data are provided in the following tables, which are grouped into specific spectroscopic methods:

Current affiliations:

- * U.S. Army Research Laboratory, Adelphi, Maryland
- ** University of Maryland Baltimore County, Baltimore, Maryland

- Table 65.6, UV-Visible Absorption Data
- Table 65.7, Infrared Absorption Data
- Table 65.8, Raman Data
- Table 65.9A, Fluorescence Data: Biochemical Studies and 65.9B, Fluorescence Data: Cellular Studies, Tissue and Biofluid Studies (*in Vitro*), Animal Studies (*in Vivo*), and Human Clinical Studies (*in Vivo*)
- Table 65.10, Elemental Analysis Data

The spectroscopic information provided in these tables was compiled from a variety of sources: reviews, articles, and book chapters, and almost 700 references, as indicated in the individual tables. We have made special efforts to group the data in each table whenever possible into subclasses that are relevant to biological and biomedical applications. These subclassifications include:

- Biochemical studies (individual compounds)
- Cellular studies (in vitro applications)
- Tissue and biofluid studies (in vitro)
- Animal studies (in vivo)
- Human clinical studies (in vivo)

Due to space limitations, the information is not meant to be comprehensive; rather, the aim is to serve as a starting point for a researcher who is unfamiliar with a certain field but would like to obtain the initial information to begin an investigation in a specific area or topic related to biological or medical research. We hope that this chapter will serve as a useful reference source for a broad audience involved in research, teaching, learning, or practice of medical technologies.

Acknowledgments

This research was sponsored by the U.S. Department of Energy, managed by UT-Battelle under contract DE-AC05-00OR22725. D.N. Stratis-Cullum, D.L. Stokes, B.M. Cullum, R. Jagannathan, J. Mobley, and J.-M. Song were also supported by appointments to the Oak Ridge National Laboratory Postdoctoral Research Associates Program administered jointly by the Oak Ridge National Laboratory and Oak Ridge Institute for Science and Education.

65.2 Fundamental Spectroscopic Properties of Biologically and Medically Relevant Species

65.2.1 Raman Spectroscopy: Characteristic Frequencies

Table 65.1 provides characteristic Raman frequencies of organic compounds. This table consists of the vibrational frequencies (cm⁻¹) for main chemical groups, the type of vibration energy absorbed due to vibrations of polar covalent bonds, the functional groups that cause the vibration, and the kind of compound in which this characteristic vibration would be found.

TABLE 65.1 Characteristic Raman Frequencies

Frequency (cm ⁻¹)	Vibration	Compound	
3300–3400	Bonded antisymmetric NH ₂ stretch	Primary amines	
3340-3380	Bonded OH stretch	Aliphatic alcohols	
3374	CH stretch	Acetylene (gas)	
3325-3355	Bonded antisymmetric NH ₂ stretch	Primary amides	
3300-3350	Bonded NH stretch	Secondary amines	
3300-3335	≡CH stretch	Alkyl acetylenes	
3250-3300	Bonded symmetric NH ₂ stretch	Primary amines	
3290-3310	Bonded NH stretch	Secondary amines	

 TABLE 65.1 Characteristic Raman Frequencies (continued)

Frequency (cm ⁻¹)	Vibration	Compound
3145-3190	Bonded symmetric NH ₂ stretch	Primary amides
3154-3175	Bonded NH stretch	Pyrazoles
3103	Antisymmetric = CH_2 stretch	Ethylene (gas)
3020-3100	CH ₂ stretches	Cyclopropane
3000-3100	Aromatic CH stretch	Benzene derivatives
3070-3095	Antisymmetric = CH_2 stretch	C=CH ₂ derivatives
3062	CH stretch	Benzene
3057	Aromatic CH stretch	Alkyl benzenes
3000-3040	CH stretch	C=CHR derivatives
3026	Symmetric = CH_2 stretch	Ethylene (gas)
2980-2990	Symmetric =CH ₂ stretch	C=CH ₂ derivatives
2974–2986	Symmetric NH ₃ ⁺ stretch	Alkyl ammonium chlorides (aq. soln.)
2965–2969	Antisymmetric CH ₃ stretch	n-Alkanes
2912–2929	Antisymmetric CH ₂ stretch	<i>n</i> -Alkanes
2883–2884	Symmetric CH ₃ stretch	n-Alkanes
2849–2861	Symmetric CH ₂ stretch	n-Alkanes
2700–2850	CHO group (2 bands)	Aliphatic aldehydes
2560–2590	SH stretch	Thiols
2233–2316	C≡C stretch (2 bands)	R–C≡C–CH ₃
2231–2301	C≡C stretch (2 bands)	R-C≡C-R'
2250–2300	Pseudoantisymmetric N=C=O stretch	Isocyanates
2251–2264	Symmetric C=C-C=C stretch	Alkyl diacetylenes
2259	C≡N stretch	Cyanamide
2232–2251	C≡N stretch	Aliphatic nitriles
2220–2100	Pseudoantisymmetric N=C=S stretch (2 bands)	Alkyl isothiocyanates
2220–2100	C≡N stretch	Dialkyl cyanamides
2172	Symmetric C=C-C=C stretch	Diacetylene
2134–2161	N+≡C- stretch	Aliphatic isonitriles
2100–2160	C≡C stretch	Alkyl acetylenes
2140–2156	C≡N stretch	Alkyl thiocynates
2104	Antisymmetric N=N=N stretch	CH ₃ N ₃
2094	C≡N stretch	HCN
2049	Pseudoantisymmetric C=C=O stretch	Ketene
1974	C≡C stretch	Acetylene (gas)
		Allenes
1958–1964	Antisymmetric C=C=C stretch	
1840–1870	Symmetric C=O stretch	Saturated five-membered ring cyclic anhydrid
1820 1788–1810	Symmetric C=O stretch C=O stretch	Acetic anhydride
		Acid halides
1807	C=O stretch	Phosgene
1799–1805	Symmetric C=O stretch	Noncyclic anhydrides
1800	C=C stretch	$F_2C=CF_2$ (gas)
1795	C=O stretch	Ethylene carbonate
1792	C=C stretch	$F_2C = CFCH_3$
1782	C=O stretch	Cyclobutanone
1730–1770	C=O stretch	Halogenated aldehydes
1744	C=O stretch	Cyclopentanone
1729–1743	C=O stretch	Cationic <i>a</i> -amino acids (aq. soln.)
1734–1741	C=O stretch	O-Alkyl acetates
1720–1740	C=O stretch	Aliphatic aldehydes
1714–1739	C=C stretch	C=CF ₂ derivatives
1736	C=C stretch	Methylene cyclopropane
1727–1734	C=O stretch	O-Alkyl propionates
1700–1725	C=O stretch	Aliphatic ketones
1715–1720	C=O stretch	O-Alkyl formates
1694-1712	C=C stretch	RCF=CFR
1695	Nonconjugated C=O stretch	Uracil derivatives (aq. soln.)

 TABLE 65.1 Characteristic Raman Frequencies (continued)

Frequency (cm ⁻¹)	Vibration	Compound
1644–1689	C=C stretch	Monofluoroalkenes
1651-1687	C=C stretch	Alkylidene cyclopentanes
1636–1686	Amide I band	Primary amides (solids)
1665–1680	C=C stretch	Tetralkyl ethylenes
1679	C=C stretch	Methylene cyclobutane
1664-1678	C=C stretch	Trialkyl ethylenes
1665–1676	C=C stretch	trans-Dialkyl ethylenes
1675	Symmetric C=O stretch (cyclic dimer)	Acetic acid
1666–1673	C=N stretch	Aldimines
1672	Symmetric C=O stretch (cyclic dimer)	Formic acid (aq. soln.)
1655-1670	Conjugated C=O stretch	Uracil, cytosine, and guanine derivatives (aq. soln
1630-1670	Amide I band	Tertiary amides
1652–1666	C=N stretch	Ketoximes
1650-1665	C=N stretch	Semicarbazones (solid)
1636-1663	Symmetric C=N stretch	Aldazines, ketazines
1654-1660	C=C stretch	cis-Dialkyl ethylenes
1650-1660	Amide I band	Secondary amides
1649–1660	C=N stretch	Aldoximes
1610-1660	C=N stretch	Hydrazones (solids)
1644-1658	C=C stretch	$R_2C=CH_2$
1656	C=C stretch	Cyclohexene, cycloheptene
1649–1654	Symmetric C=C stretch (cyclic dimer)	Carboxylic acids
1642-1652	C=N stretch	Thiosemicarbazones (solid)
1590–1650	NH, scissors	Primary amines (weak)
1625–1649	C=C stretch	Allyl derivatives
1640–1648	N=O stretch	Alkyl nitrites
1638–1648	C=C stretch	H ₂ C=CHR
1647	C=C stretch	Cyclopropene
1638	C=O stretch	Ethylene dithiocarbonate
1637	Symmetric C=C stretch	Isoprene
1622–1634	Antisymmetric NO ₂ stretch	Alkyl nitrates
1550–1630	Ring stretches (doublet)	Benzene derivatives
1623	C=C stretch	Ethylene (gas)
1540–1620	Three or more coupled C=C stretches	Polyenes
1571–1616	C=C stretch	Chloroalkenes
1614	C=C stretch	Cyclopentene
1547–1596	C=C stretch	Bromoalkenes
1465–1581	C=C stretch	Iodoalkenes
1575	Symmetric C=C stretch	1,3-Cyclohexadiene
1573	N=N stretch	Azomethane (in soln.)
1566	C=C stretch	Cyclobutene
1550–1560	Antisymmetric NO ₂ stretch	Primary nitroalkanes
	, ,	Secondary nitroalkanes
1550–1555	Antisymmetric NO ₂ stretch	•
1548	N=N stretch	1-Pyrazoline
1535–1545	Antisymmetric NO ₂ stretch	Tertiary nitroalkanes
1490–1515	Ring stretch	2-Furfuryl group
1500	Symmetric C=C stretch	Cyclopentadiene
1470–1480	OCH ₃ , OCH ₂ deformations	Aliphatic ethers
1460–1480	Ring stretch	2-Furfurylidene or 2-furoyl group
1446–1473	CH ₃ , CH ₂ deformations	n-Alkanes
1465–1466	CH ₃ deformation	n-Alkanes
1400–1450	Pseudoantisymmetric N=C=O stretch	Isocyanates
1398–1443	Ring stretch	2-Substituted thiophenes
1442	N=N stretch	Azobenzene
1340-1440	Symmetric CO ₂ stretch	Carboxylate ions (aq. soln.)
1400-1415	Symmetric CO ₂ stretch	Dipolar and anionic a-amino acids (aq. soln.)

 TABLE 65.1 Characteristic Raman Frequencies (continued)

Frequency (cm ⁻¹)	Vibration	Compound
1385–1415	Ring stretch	Anthracenes
1380-1395	Symmetric NO ₂ stretch	Primary nitroalkanes
1370-1390	Ring stretch	Naphthalenes
1368-1385	CH ₃ symmetric deformation	n-Alkanes
1360-1375	Symmetric NO ₂ stretch	Secondary nitroalkanes
1345-1355	Symmetric NO ₂ stretch	Tertiary nitroalkanes
1330-1350	CH deformation	Isopropyl group
1320	Ring vibration	1,1-Dialkyl cyclopropanes
1290-1314	In-plane CH deformation	trans-Dialkyl ethylenes
1250-1310	Amide III band	Secondary amides
1175-1310	CH ₂ twist and rock	n-Alkanes
1295-1305	CH, in-phase twist	<i>n</i> -Alkanes
1280-1300	CC bridge bond stretch	Biphenyls
1275-1282	Symmetric NO ₂ stretch	Alkyl nitrates
1240-1280	Ring stretch	Epoxy derivatives
1276	Symmetric N=N=N stretch	CH ₃ N ₃
1251-1270	In-plane CH deformation	cis-Dialkyl ethylenes
1266	Ring "breathing"	Ethylene oxide (oxirane)
1200-1230	Ring vibration	para-Disubstituted benzenes
1200-1220	Ring vibration	Mono- and 1,2-dialkyl cyclopropanes
1212	Ring "breathing"	Ethylene imine (aziridine)
1205	C ₆ H ₅ –C vibration	Alkyl benzenes
1188–1196	Symmetric SO ₂ stretch	Alkyl sulfates
1188	Ring "breathing"	Cyclopropane
1165–1172	Symmetric SO ₂ stretch	Alkyl sulfonates
950–1150	CC stretches	n-Alkanes
1125–1145	Symmetric SO ₂ stretch	Dialkyl sulfones
1144	Ring "breathing"	Pyrrole
1140	Ring "breathing"	Furan
1100–1130	Symmetric C=C=C stretch (2 bands)	Allenes
1130	Pseudosymmetric C=C=O stretch	Ketene
1112	Ring "breathing"	Ethylene sulfide
1111	NN stretch	Hydrazine
1040–1070	S=O stretch (1 or 2 bands)	Aliphatic sulfoxides
1040-1070	C=S stretch	Ethylene trithiocarbonate
1020–1060	Ring vibration	ortho-Disubstituted benzenes
990–1040	Ring vibration	Pyrazoles
1015–1030	In-plane CH deformation	Monosubstituted benzenes
1010–1030	Trigonal ring "breathing"	3-Substituted pyridines
1030	Trigonal ring "breathing"	Pyridine Pyridines

65.2.2 Infrared (IR) Spectroscopy: Characteristic IR Band Positions of Functional Chemical Groups and Molecules

Table 65.2 provides the characteristic IR band positions (frequencies) of organic compounds. This table consists of vibrational frequencies (cm⁻¹) of functional groups and the functional groups found within organic molecules that absorb IR energy. These frequencies and assignments have been collected from various references such as http://infrared.als.lbl.gov/IRbands.html, a Web site maintained by the Lawrence Berkeley National Laboratory.

Table 65.3 provides characteristic vibrational frequencies of main organic bonds. This table consists of the frequency range (cm⁻¹), compound type that displays the characteristic absorptions, and organic bonds involved. These frequencies and assignments have been collected from a variety of sources, such as a Web site (http://www.chem.ucla.edu/) maintained by the University of California, Los Angeles.

TABLE 65.3 Characteristic IR Absorption Frequencies of Compounds

Frequency Range (cm ⁻¹)	Compound Type	Bond
2960-2850 (Strong) stretch	Alkanes	С–Н
1470–1350 (Variable) scissoring and bending	Alkanes	C-H
1380 (Medium-Weak) — doublet — isopropyl, <i>t</i> -butyl	CH ₃ umbrella deformation	C-H
3080-3020 (Medium) stretch	Alkenes	C-H
1000-675 (Strong) bend	Alkenes	C-H
3100-3000 (Medium) stretch	Aromatic rings	C-H
870–675 (Strong) bend	Phenyl ring substitution bands	C-H
2000-1600 (Weak) — fingerprint region	Phenyl ring substitution overtones	C-H
3333–3267 (Strong) stretch	Alkynes	C-H
700–610 (Broad) bend	Alkynes	C-H
1680-1640 (Medium, weak) stretch	Alkenes	C=C
2260-2100 (Weak, strong) stretch	Alkynes	C≡C
1600, 1500 (Weak) stretch	Aromatic rings	C=C
1260-1000 (Strong) stretch	Alcohols, ethers, carboxylic acids, esters	C-O
1760–1670 (Strong) stretch	Aldehydes, ketones, carboxylic acids, esters	C=O
3640–3160 (Strong, broad) stretch	Monomeric — alcohols, phenols	О-Н
3600–3200 (Broad) stretch	Hydrogen-bonded — alcohols, phenols	О-Н
3000-2500 (Broad) stretch	Carboxylic acids	О-Н
3500-3300 (Medium) stretch	Amines	N-H
1650-1580 (Medium) bend	Amines	N–H
1340-1020 (Medium) stretch	Amines	C-N
2260-2220 (Variable) stretch	Nitriles	C≡N
1660-1500 (Strong) asymmetrical stretch	Nitro compounds	NO_2
1390–1260 (Strong) symmetrical stretch	Nitro compounds	NO_2

65.2.3 Molecular Spectroscopy: Characteristics of Electronic Transitions between Orbitals

Table 65.4 provides the characteristics of electronic transitions between σ , η , and π orbitals. This table lists the transition type, wavelength (nm), molar absorptivity, ε (L mol⁻¹ cm⁻¹), and examples of organic compounds with electronic transitions.

TABLE 65.4 Characteristics of Electronic Transitions between σ , η , and π Orbitals

Transition	Wavelength (nm)	$\epsilon~(l~mol^{\scriptscriptstyle -1}cm^{\scriptscriptstyle -1})$	Examples
σ-σ [*] π-π [*] η-σ [*] η-π [*]	<200 200–500 160–260 250–600	$ \begin{array}{c}\\ \approx 10^4\\ 10^2-10^3\\ 10^1-10^2 \end{array} $	Saturated hydrocarbons Alkenes, alkynes, aromatics H ₂ O, CH ₃ OH, CH ₃ Cl, CH ₃ NH ₂ Carbonyls, nitro, nitrate, carboxyl

65.2.4 Absorption Characteristics of Common Chromophores

Table 65.5 provides the absorption characteristics of common chromophores. This table consists of groups that are responsible for absorption, wavelength, λ (nm), wavenumbers, ν (10³ cm⁻¹), and molar absorptivity, ϵ (1 mol⁻¹cm⁻¹).

TABLE 65.5 Absorption Characteristics of Common Fluorophores

		V	λ	ε

65.3 Spectroscopic Data for Biological and Medical Applications

65.3.1 UV-Visible Absorption Spectroscopy

Table 65.6 provides information on application of UV-visible absorption technique to biomedical research. This table covers only representative biochemical species that have been analyzed using UV-visible absorption technique. Absorbance maximum corresponds to the wavelength that was used for the detections of biochemical species in UV-visible absorption technique.

65.3.2 Infrared Absorption Spectroscopy

Table 65.7 provides information related to applications of FTIR spectroscopy in the field of biomolecular and biomedical research. Extensive literature is available on FTIR of biomolecules; only illustrative examples are given in the Biochemical Studies section, including data on side chains of amino acids (in water), along with a few examples on phospholipids, carbohydrates, and energy metabolites. The subsequent sections — Cellular Studies, Tissue and Biofluid Studies (*in Vitro*), and Animal Studies (*in Vivo*) — are arranged alphabetically based on target organ or disease, beginning on p. 65-24. The following nomenclature is used in this table. The band position of functional groups is given in cm⁻¹. Number in parentheses next to band position represents the extinction coefficient (ε) in M⁻¹ cm⁻¹. Relative band intensities are classified as very strong (VS), strong (S), medium (M), medium to weak (MW), weak (W), and very weak (VW). Table 65.7 is compiled from data from a large cross section of publications, including journals, review articles, and books.

TABLE 65.7 Infrared Absorption Data

Species	Major IR Bands Functional Group	Shifts (cm ⁻¹)	Matrix	Comments	Ref.
		Biochemical Studies			
Acetyl choline receptor				Alpha helical conformation	1
Alanine	CH ₃	1470		In-plane bending (asymmetric)	2
Alanine	CH ₃	1378		In-plane bending (symmetric)	2
Alanine-based	- 3			Random coil and helix	3

 TABLE 65.7 Infrared Absorption Data (continued)

Target Organ or Disease	Shifts (cm ⁻¹)	Matrix	Comments	Ref.
	, ,	Cellular S		1(01.
Pa atonia	·	Cennin 3		4.4
Bacteria			Differentiation process of bacteria studied by ATR-FTIR (bacteria)	44
Bacteria			Quantification from a binary mixture using FTIR (bacteria)	45
Bacteria			Characterization (bacteria)	46
Bacteria			Effect of antibiotics on bacteria studied by FTIR (bacteria)	47
Bacteria			Identification of bacteria using FTIR (bacteria)	48
BALB/c		ZnSe	Transformed by H-ras	49
Bone marrow cells			Detection of hydroxyapatite (rat)	50
Bronchial	820–890, O–O stretching		Detection of damage to airway cells (human)	51
Cervical cancer			Detection of cervical cancer (human)	52
Cervical cancer			Detection of cervical cancer using ATR/FTIR study (human)	53
Cervical cancer	1025, Glycogen; 1080, glycogen and nucleic acids; 1240, nucleic acids; 1400, CH ₃ from lipids and proteins; 1450, CH ₂ from lipids and proteins		Detection of cervical cancer (human)	54
Cervical cancer	Peak at 972 is main indicator of malignancy		Detection of cervical cancer (human)	55
Deinococcus radiodurans	ζ ,		Pharmacological application of FTIR (bacteria)	56
HL60			Differentiation and apoptosis process studied by FTIR	57
Keratinocytes			Lower organization of lipids compare to human skin (human)	58
Leukemia		BaF_2	Detection of leukemia (human)	59
Leukemia			Isolated from thrombocythemic patients (human)	60
Lung cancer cells	1030, Glycogen		FTIR microscopic study (human)	61
Lung fibroblast			Cell cycle and death studied by synchrotron FTIR	62
			microscopy (human)	
Lymphocytes			Histocompatibility matching using FTIR microscopy (human)	63
Megakaryocytes				60
NIH3T3		ZnSe	Fibroblasts transformed by retrovirus	64
Normal and malignant			Characterization using FTIR microscopy (human)	65
fibroblast	Normal 1002 malianant 1006	7,50	Calle transformed by mause carcome virus (rabbit)	66
Primary cells Sperm, erythrocytes	Normal 1082, malignant 1086	Ziise	Cells transformed by mouse sarcoma virus (rabbit) FTIR microscopic study (human)	67
	Tissue and	Biofluid S	Studies (in Vitro)	
Alzheimer's disease			Brain tissue studied using synchrotron FTIR microscopy (human)	68
Amniotic fluid			Analysis of amniotic fluid using FTIR (human)	69
Blood			Analysis of blood (human)	70
Brain			Enhanced resolution due to deuteration (rat)	71
Brain			Characterization using IR imaging (monkey)	72
Brain			Effect of ARA-C on brain tissue studied using FTIR microscopy (rat)	73
Brain tumor			Characterization of pituitary adenomas (human)	74
Brain, breast			Characterization (human)	75
Breast			Structural variation of proteins from normal to carcinomal states (human)	76

 TABLE 65.7 Infrared Absorption Data (continued)

Target Organ or Disease	Shifts (cm ⁻¹)	Matrix	Comments	Ref.
Breast			Breast cancer detection using FTIR (human)	77
Breast			Grading of tumors using FTIR (human)	78
Breast cancer			Detection of breast cancer using ATR-FTIR (human)	79
Breast implant			Characterization (human)	80
biopsies			Granacter Eutron (marrian)	00
Breast implants			FTIR imaging (human)	81
Cartilage		CaF ₂	FTIR imaging studies (bovine)	82
·		Car ₂	FTIR imaging studies (bovine)	
Cartilage				83
Cells, tissues			Detection of trapped CO ₂ (human)	84
Cervical cancer			Detection of cervical cancer using FTIR microscopy (human)	85
Cirrhotic liver tissue			Liver tissue analysis (human)	86
Colon cancer		ZnSe	Identification of polyp and carcinoma (human)	87
Colon carcinoma	995-1045, 1195-1245		ATR studies (human)	88
	Phosphate symmetric and asymmetric stretching		,,,,,,,,,,,,,,,,,,,,,,,,,,,,,,,,,,,,,,,	
Demineralized bone tissue			FTIR imaging studies (bovine)	89
Dentin biopsies			Maturation of organic and mineral contents	90
Follicle fluid			Characterization (human)	91
Heart			Collagen deposition using FTIR microscopy	92
			(hamster UM-X 7.1)	
Heart			Characterization (human)	93
Heart tissue			Detection of myocardial infarction (rat)	94
Iliac crest biopsies			Osteoporosis detected by IR imaging (human)	95
Iliac crest biopsies			FTIR imaging (human)	96
Implanted tissue			Biodiagnostics (dog)	97
Implants			Vascular healing studies using ATR-FTIR (manmade)	98
Liver			Detection of hypercholesterolemicitry using FTIR microscopy (rabbit)	99
Liver			Tissue oxygenation studied in liver transplants using NIR	100
Liver and heart	2800–3000, CH ₂ and CH ₃ symmetric and asymmetric stretching		Detection of diabetes	101
Lung	1045, Glycogen; 1467, cholesterol		Lung cancer detection using FTIR microscopy (human)	102
Lung			Detection of mercury poisoning using ATR-FTIR (mouse)	103
Lymphoid tumors			Grading of lymphoid tumors using FTIR microscopy (human)	104
Mineralized tissue			Maturation in horse secondary dentin (horse)	105
Multiple sclerosis			Studies on multiple sclerosis using FTIR microscopy (human)	106
Multiple cites			Glucose sensing using NIR transmission (human)	107
Multiple sites				
Myocardial			Detection of myocardial dysfunction (hamster	108
dysfunction			CMP)	
Niemann-Pick			Detection of Niemann-Pick type C (NPC)	109
type C			(mice BALB/c)	
Oral			Oral cell carcinoma detection using FTIR (human)	110
Oral tissue	1745, Triglycerides, absent in malignant samples		FTIR-FEWS studies (human)	111
Oral/oropharyngeal squamous cell carcinoma			Oral/oropharyngeal squamous cell carcinoma detection using FTIR microscopy and statistical analysis (human)	112

TABLE 65.7 Infrared Absorption Data (continued)

Target Organ or Disease	Shifts (cm ⁻¹)	Matrix	Comments	Ref.
Placenta			Detection of gynecological diseases (human)	113
Plasma	B–H band 2493		Detection of boron after boron neutron capture therapy (human)	114
Polymer implants			Biodiagnostics (manmade)	115
Retinal tissue			Studies on oxidative stress using FTIR microscopy (rat)	116
Saliva, urine, serum			Measuring body water (human)	117
Scrapie infected			Scrapie detection in CNS using FTIR microscopy	118
Serum			Quantification of serum components (human)	119
Serum			Quantification of serum components (human)	120
Serum			Quantification of cholesterol (human)	121
Skin			Skin cancer diagnosis using FTIR-FEWS	122
Skin			Basal cell carcinoma detection using FTIR (human)	123
Stool			Quantifying lipid content in biological fluids (human)	124
Synovial fluid			Diagnosis of arthritis using NIR (human)	125
Urine			Quantification of urine components (human)	126
		Animal Studies	s (in Vivo)	
Brain			Noninvasive blood glucose monitoring using ATR-FTIR (human)	127
Brain			Monitoring local cortical blood flow using thermal IR imaging (human)	128
Brain			Thermal IR imaging (monkey)	129
Lip			FTIR-FEWS study (human)	130
Skin			Influence of environmental factors on skin studied using FTIR-FEWS (human)	131
Skin			Cerebrovascular activity studied by NIR (human)	132
Skin			Penetration depth study (human)	133

65.3.3 Raman Spectroscopy

Table 65.8 provides a quick reference for the reader to consult to find Raman-based publications regarding a variety of chemical and biochemical compounds and systems. Works were selected based on both their application and potential significance in the field of biophotonics. As a consequence, this table includes examples of a variety of Raman-based techniques. The following abbreviations are used in this table: NIR = near infrared; IR = infrared; FT = Fourier transform; SERS = surface-enhanced Raman scattering; SERRS = surface-enhanced resonance Raman scattering; UV = ultraviolet; FT SERS = Fourier transform surface-enhanced Raman scattering; LOD = limit of detection; NIR FT = near-infrared Fourier transform; CCD = charge-coupled device; HIV = human immunodeficiency virus; YC-1 = a synthetic benzylindazole derivative or [3-(5'-hydroxymethyl-2'-furyl)-1-benzylindazole; PEO = polyethylene. The instrumental requirements may vary significantly for different techniques; for such details the reader can refer to appropriate chapters of this handbook. Because Raman band assignments can be quite extensive and matrix dependent in Raman scattering, such details are only supplied where reported in great confidence. While the authors hope subsequent editions of this handbook will offer more complete spectral information, this version clearly demonstrates the recently found potential of Raman in biomedical applications. The information in Table 65.8 was compiled using data from more than 200 publications, monographs, and review articles.

			Major Raman		
Species	Target Organ or Disease	Excitation λ (nm)	Shifts (cm ⁻¹)	Comments	Ref.
		Biocl	hemical Studie	s	
Aminoglutethimide	Cancer (drug)			Examined environmental and solvent effects (e.g., CCl ₄ , CHCl ₃ , and CH ₃ CN) on IR and Raman spectra of aminoglutethimide	1
Amsacrine	Cancer (drug)	UV		UV resonance Raman; spectroscopically characterized	2
Amsacrine	Cancer (drug)	NIR		FT Raman; spectroscopically characterized	2
Amsacrine	Leukemia (drug)	UV	1165, 1265, 1380	UV resonance; monitored interaction of anticancer drug, amsacrine, with calf thymus DNA; observed spectral changes between free and DNA-bound amsacrine	3
Amsacrine (m-AMSA)	Topoisomerase II inhibitor/cancer (drug)			SERS; monitored intracellular interactions of amsacrine (m-AMSA) within living K562 cancer cells	
Antineoplaston-A10	Cancer (drug)			Characterized with vibrational assignments; vibrational modes similar to uracil derivatives, implying that therapy based on resemblance to pyrimidine bases	5
Avidin				Demonstrated the importance of the side chains of biotin when interacting with avidin	6
Avidin				Demonstrated the importance of the side chains of biotin when interacting with avidin	7
Benzo(a)pyrene	Cancer			Theoretical study of the oxygenation of benzo(a)pyrene	8
Biotin				Demonstrated the importance of the side chains of biotin when interacting with avidin	6
Biotin				Demonstrated the importance of the side chains of biotin when interacting with avidin	7
Blenoxane (bleomycins A2 and B2)	DNA/cancer (drug)			A study in drug/DNA interaction; spectral changes observed between calf thymus DNA and bleomycin/DNA complex	9
Cinchonine	Malaria (drug)		1374	Phosphate stretch band of cinchonine observed to shift upon interaction with DNA, indicative of coulombic interaction	10
<i>cis</i> -Dichloroplatinum derivatives	Telomerase inhibitor/cancer (drug)			Characterized <i>cis</i> -dichloroplatinum derivatives with N-donor ligands such as pyridine and 5-substituted quinolines	11
CO ₂	Lung (respiratory quotient test)			Inspired, end-tidal, and mixed expired gas compositions analyzed by Raman spectroscopy	12
Dimethylcrocetin	Retinoic acid nuclear receptor interaction/ cancer (drug)		1210, 1165, 1541	FT Raman; FT SERS; evaluated spectra for free-form dimethylcrocethin (DMCRT) and DMCRT/retinoic acid nuclear receptor in HL60 and K562 cancer cells	13
DNA				SERS; SERRS; studied adsorption of DNA onto substrates	14
DNA (via cresyl fast violet)	HIV/AIDS	633		SERS; HIV DNA amplified (PCR) with cresyl fast violet-labeled primers and selectively hybridized to a bioassay platform	15

Species	Target Organ or Disease	Excitation λ (nm)	Major Raman Shifts (cm ⁻¹)	Comments	Ref.
DNA (via dye label)				SERS; gene probes hybridized to target DNA	16
Gelonin	Type 1 ribosome inactivating protein/AIDS (drug)			in solution, spotted on SERS substrate Determined secondary structure of gelonin to be mainly alpha-helix and beta-sheet with some turn and disordered structure	17
Gelonin	Type 1 ribosome inactivating protein/cancer (drug)			Determined secondary structure of gelonin to be mainly alpha-helix and beta-sheet with some turn and disordered structure.	17
Guanylate cyclase	Nitric oxide receptor/lung		474–492	Investigated interaction of YC-1 with enzyme soluble guanylate cyclase (sGC) in presence of CO for sGC expressed by baculovirus/Sf9 cell	18
Guanylate cyclase	Nitric oxide receptor/lung	UV	478, 495, 525, 567, 572, 1676	Resonance Raman; characterized the heme domain of rat lung soluble guanylate cyclase	19
Guanylate cyclase	Nitric oxide receptor/lung	UV	212, 221	Resonance Raman; identified histidine 105 in the beta 1 subunit of soluble guanylate cyclase from rat and bovine lung	20
Guanylate cyclase	Nitric oxide receptor/lung	UV	497, 520, 1959	Resonance Raman; spectra illustrated for the alpha(1) beta(1) isoform of lung soluble guanylate cyclase expressed from baculovirus	21
Guanylate cyclase	Nitric oxide receptor/lung	UV	1357, 1375, 1473	Resonance Raman; spectra reported for ferrous and ferric forms of soluble guanylate cyclase from bovine lung	22
Guanylate cyclase	Nitric oxide receptor/lung	UV	203, 473, 521, 1681, 1700	Resonance Raman; spectra reported for reduced, GO-bound, NO-bound, oxidized and oxidized NO-bound forms of soluble guanylate cyclase from bovine lung with/without GTP	23
H+, K+-ATPase	Stomach			Investigated conformational changes induced by replacing K ⁺ ions with Na ⁺ ions; no significant Raman spectral changes observed	24
H ⁺ , K ⁺ -ATPase	Stomach			Investigated secondary structure of membrane-bound regions of H+, K+- ATPase; determined structure to be largely beta-sheet in character	25
Heme protein	Heme protein CO activation			Investigated mechanism for heme protein activation	26
Hydroxyapatite	Inclusions (bone)			Compared biological hydroxyapatite samples to ox femur	27
Intoplicine	Topoisomerase II inhibitor/cancer (drug)			SERS; intoplicine found to unwind DNA and inhibit calf thymus topisomerase II; intoplicine spectrum eliminated when in the presence of topoisomerase II	28
Lysozyme		632.8 nm		First interpretable laser-excited spectrum of a native protein	29
Methotrexate	Dihydrofolate reductase inhibitor/cancer (drug)			Ultrasensitive Raman difference spectroscopy illustrated light-induced reaction of methotrexate with NADPH in dihydrofolate active site	30

	Target Organ	Excitation	Major Raman Shifts		
Species	or Disease	$\lambda \ (nm)$	(cm^{-1})	Comments	Ref.
Methotrexate	Dihydrofolate reductase inhibitor/ rheumatoid arthritis (drug)			Ultrasensitive Raman difference spectroscopy illustrated light-induced reaction of methotrexate with NADPH in dihydrofolate active site	30
Nitrogen	Lung (respiratory quotient test)			Inspired, end-tidal, and mixed expired gas compositions analyzed by Raman spectroscopy	12
Oxygen	Lung (respiratory quotient test)			Inspired, end-tidal, and mixed expired gas compositions analyzed by Raman spectroscopy	12
Proteins				Elucidated kinetics and structures of proteins	31
Proteins				Elucidated kinetics and structures of proteins	32
Proteins				Elucidated kinetics and structures of proteins	33
Proteins				Identified Raman vibrational bands through isotopic substitution	34
Proteins				Identified Raman vibrational bands through isotopic substitution	35
Proteins				Identified Raman vibrational bands through isotopic substitution	36
Proteins				Identified Raman vibrational bands through isotopic substitution	37
Theraphthal	Cancer (drug- binary catalytic system)			Resonance Raman; studied effects of molecular interactions (e.g., with Ca ⁺) and environmental factors (e.g., pH < 6) on spectra of theraphthal	38
	Drug			Studied kinetics and interaction mechanisms between drugs and receptors	39
		Cellul	ar Studies		
Amsacrine (m-AMSA)	K562 cells/cancer (drug)			SERS; monitored intracellular interactions of amsacrine (m-AMSA) within living K562 cancer cells	4
Bacteriochlorophyll a	Photosynthetic bacteria			Resonance Raman; substitution of Mg ion by Zn, Ni, Co, and Cu ions studied via Raman scattering; molecule core size shifts caused shifts in resonance	40
Calcium dipicolinate	Bacteria	UV			41
Carotenoids	Liposomes			Egg phosphatidylcholine and egg phosphatidylglycerol; observed β-carotene rapidly taken up <i>in vitro</i> and transported to "Gall bodies"	42
Carotenoids	Lymphocytes			Lymphocytes from human blood; observed that carotenoids concentrated in "Gall bodies"; associated carotenoid concentrations with age, decreasing with age	42
Carotenoids	Lymphocytes/lung cancer			Human; compared carotenoid levels in lymphocytes of lung cancer patients and healthy individuals; observed lower carotenoid levels in lung carcinoma patients	43
Chromatid	Ovary cells/ mutagenesis (photo-induced)	193		Chinese hamster; reported monitoring of mutagenesis and sister chromatin exchange induction via UV irradiation	44

Species	Target Organ or Disease	Excitation λ (nm)	Major Raman Shifts (cm ⁻¹)	Comments	Ref.
Chromatid	Ovary cells/ mutagenesis (photo-induced)	308		Chinese hamster; reported monitoring of mutagenesis and sister chromatin exchange induction via UV irradiation	44
Chromatid	Ovary cells/ mutagenesis (photo-induced)	254		Chinese hamster; reported monitoring of mutagenesis and sister chromatin exchange induction via UV irradiation	44
Demoic acid (neurotoxin)	Phytoplankton	UV			45
Dimethylcrocetin	HL60 and K562 cells/cancer (therapy)		1210, 1165, 1541	FT Raman; FT SERS; evaluated spectra for free-form dimethylcrocethin (DMCRT) and DMCRT/retinoic acid nuclear receptor in HL60 and K562 cancer cells	13
DNA	FD Virus	UV			46
DNA	Virus	257			47
DNA	Virus	244			47
DNA	Virus	238			47
DNA	Virus	229			47
DNA	Virus			Resonance Raman; DNA monitored during assembly of viruses	47
DNA	Virus (T7 bacteriophage)			Resonance Raman; monitored DNA spectra for DNA during packaging into viral plasmid with little changes; Mg ions observed to influence packaging	49
DNA		Visible		DNA in chromosomes; investigation of cellular damage at different wavelengths demonstrated that 514.5 nm radiation causes damage while 660 nm radiation does not	50
DNA		514.5; 660		DNA in chromosomes	51
DNA		Visible		DNA in chromosomes	52
DNA		Tuned		Resonance Raman; DNA preferentially detected in cells	53
DNA		Tuned		Resonance Raman; DNA preferentially detected in cells	53
Glucose (via quinoline red)				Attached quinoline red to monitor intake of glucose into cells; glucose intake detected by intensity changes in quinolin red Raman spectrum	54
Hemoglobin	Rheumatoid arthritis	Visible		Monitoring of oxygen uptake in human cells; concluded that patients with rheumatoid arthritis uptake oxygen faster but incompletely	55
Hepatocytes	Liver cancer	Visible	1040, 1083, 1182, 1241, 1253	Distinguished between normal and malignant hepatocytes	56
Hydroxyapatite	C4-2B cell/ prostate cancer			Mineral deposition monitored for C4-2B prostate cancer cell line in promineralization media	57
Intoplicine	K562 cells/cancer (drug)			SERS; intoplicine spectrum eliminated when in the presence of topoisomerase II; intoplicine observed as complexed in nucleus and free form in cytoplasm of K562 cells	28

TABLE 65.8 Raman Data

	Tanget O	English	Major Raman		
Species	Target Organ or Disease	Excitation λ (nm)	Shifts (cm ⁻¹)	Comments	Ref
Nucleic acids	Breast cells/cancer	257		Reported spectra for cultured normal and malignant breast cells; differences attributed to relative amounts of nucleic acids and proteins and nuclear hypochromism	58
Nucleic acids	Cervical cells/ cancer	257		Reported spectra for cultured normal and malignant cervical cells; differences attributed to relative amounts of nucleic acids and proteins and nuclear hypochromism	58
Nucleic acids	T84 cancer cell	257			59
Photosensitizers	Cancer cells			Monitored accumulation of photosensitizers in cancer cells	60
Photosensitizers	Cancer cells			Monitored accumulation of photosensitizers in cancer cells	61
Phthalocyanates	Cancer cells		1538	Determined hydrophilic phthalocyanates accumulate in lysosomes while hydrophobic phthalocyanates accumulate in cytoplasm	62
Pigments	Lung cancer	Visible		Pigments in human lymphocytes with high spatial resolution	63
Pigments		Visible		Pigments in human granulocytes with high spatial resolution	64
Pigments		Visible			51
Pigments		Visible		Pigments in human lymphocytes with high spatial resolution	66
Protein	Breast cells/cancer	257		Reported spectra for cultured normal and malignant breast cells; differences attributed to relative amounts of nucleic acids and proteins and nuclear hypochromism	58
Protein	Cervical cells/ cancer	257		Reported spectra for cultured normal and malignant cervical cells; differences attributed to relative amounts of nucleic acids and proteins and nuclear hypochromism	58
Protein	FD virus	UV			66
Protein	Virus	257			47
Protein	Virus	244			47
Protein	Virus	238			47
Protein	Virus	229			47
Protein (active site)	Virus (HAV 3C)			Active site structure of HAV 3C monitored as a function of pH	67
Proteins	Bacteria and viruses	231		UV resonance Raman; obtained fluorescence-free, selective Raman detection of protein aromatic group residues in bacteria and viruses	68
Proteins	Virus (P22)/ replication			Protein side chain and secondary structure monitored as a virus (P22) entered a host cell, replicated components, and assembled new viruses	69
Protoplasts	Bacteria	UV			41
Purines	Bacteria and viruses	242		UV resonance Raman; obtained fluorescence-free, selective Raman detection of purine aromatic group residues in bacteria and viruses	68

Species	Target Organ or Disease	Excitation λ (nm)	Major Raman Shifts (cm ⁻¹)	Comments	Ref.
Pyrimidines	Bacteria and viruses	251		UV resonance Raman; obtained fluorescence-free, selective Raman detection of pyrimidine aromatic group residues in bacteria and viruses	68
Theraphthal	A549 cells/cancer (BCS therapy)			Resonance Raman confocal microspectroscopy and imaging; monitored intracellular accumulation, localization, and retention of theraphthal in living cancer cells	38
	Bacteria	UV			70
	Bacteria	UV			71
	Bacteria	UV			41
	Bacteria	UV		Examined effects of cultural conditions on deep UV resonance Raman spectra of bacteria	72
	Bacterial spores	UV			41
		Tissue/Biof	luid Studies (in	Vitro)	
Acetone	Urine		796.5	Introduced compact, highly sensitive Raman system with integration sphere cell holder. LOD for acetone was 8 mg/dl	73
Acetone	Urine		789	Human; anti-Stokes Raman; demonstrated quantitative analysis of acetone in urine	74
Acetone	Urine	NIR	790	Human; demonstrated quantitative analysis of acetone in urine with an LOD of 40 mg/dl	75
Alumina	Bone/implants			Changes in alumina spectra investigated after implantation to establish biocompatibility	76
Ameloride	Urine (drug test)			Human; SERS; demonstrated quantitative capability in urine with colloidal silver	77
Amides	Breast/cancer	1064	Normal tissue: 1078, 1300, 1445, 1651; malignant tissue: 1445, 1651; benign tumors: 1240, 1445, 1659	NIR FT Raman; human	78
Amides	Skin (stratum corneum)	NIR		Human; FT Raman; forensic science; demonstrated nondestructive investigation of skin samples from late Neolithic man and contemporary samples	79
Amides	Various tissues	NIR		CCD; mammalian tissues; evaluated effects of drying, snap freezing, thawing, and formalin fixation	80
Amphetamine	Urine (drug test)			Human; SERS; first phase of development of 1-step drug test using selective reactive SERS substrate coating; LODs < 20 ppm observed, required amide derivatization	81

Species	Target Organ or Disease	Excitation λ (nm)	Major Raman Shifts (cm ⁻¹)	Comments	Ref
Aromatic amino acids	Colon/cancer	240		Human; reported Raman spectra for normal and neoplastic colon mucosa; neoplastic samples showed lower amino-acid-to- nucleotide content ratio	82
Aromatic amino acids	Colon/cancer	251		Human; reported Raman spectra for normal and neoplastic colon mucosa; neoplastic samples showed lower amino-acid-to- nucleotide content ratio	82
β -Amylose	Brain/Alzheimer's		1628	Human; post-mortem; distinguished between diseased and healthy tissue	83
β-Carotene	Breast/cancer	406.7		Human; distinguished between normal and malignant breast tissue, attributing differences to relative concentrations of fatty acids and β-carotene	84
β-Carotene	Breast/cancer	457.9		Human; distinguished between normal and malignant breast tissue, attributing differences to relative concentrations of fatty acids and β-carotene	84
β-Carotene	Breast/cancer	514.5		Human; distinguished between normal and malignant breast tissue, attributing differences to relative concentrations of fatty acids and β-carotene	84
Blood plasma	Cancer	488		Distinguished between cancer patients and healthy individuals by differences in carotenoid spectral regions	85
Blue particles???	Cancer tumors			Raman microspectroscopy with resolution better than 1 µm ²	86
Calcium oxalates	Kidney stone (calcium oxalate- type)		1465, 1492	Human; quantitative analysis performed on calcium oxalate-type kidney stones	87
Calcium oxalates	Urine/stones			Human; review	88
Calcium salts	Artery (coronary)/ atherosclerosis			Human; combined intravascular ultrasound with Raman spectroscopy	89
Calculi (assorted)	Urine/stones	NIR		Human; NIR FT Raman; generated a Raman library and used it to correctly identify composition of various calculi	90
Carotenoids	Breast/cancer	488–515.5		CCD; human; determined 488–515 nm radiation well suited for monitoring carotenoid features due to resonance enhancement	91
Carotenoids	Brain/cancer	NIR		NIR FT Raman; human	92
Carotenoids	Cardiocvascular tissue/fatty plaques	514.5			93
Cholesterol	Artery (coronary)/ atherosclerosis			Human; combined intravascular ultrasound with Raman spectroscopy	89
Cholesterol	Eye (lens)/ cataracts			Human; studied changing cholesterol content in lens fibers via Raman scattering; reported cholesterol and protein distribution in eye lens	94
Cholesterol	Eye (lens)/ cataracts			Human; studied changing cholesterol content in lens fibers via Raman scattering; reported cholesterol and protein distribution in eye lens	95

	Target Organ	Excitation	Major Raman Shifts		
Species	or Disease	λ (nm)	(cm ⁻¹)	Comments	Ref.
Cholesterol	Ocular lens/ cataracts	Visible			96
Cholesterol	Ocular lens/ cataracts	Visible			97
Collagen	Achilles tendon	Visible		Bovine	98
Collagen	Cervix/cancer	NIR		CCD; human; differentiated between precancerous and normal cervical tissues	99
Collagen	Cervix/cancer	NIR		CCD; human; differentiated between precancerous and normal cervical tissues	100
Collagen	Ocular lens/ cataracts	Visible		Aggregation and pigmentation monitored	101
Creatine	Urine	NIR	692	Human; demonstrated quantitative analysis of creatine in urine with an LOD of 1.5 mg/dl	75
Creatinine	Urine			Human; SERS needed for creatinine analysis	102
Cystine	Kidney stone		498, 677	Human; spectra of cystine-type stones almost identical to cystine powder, particularly for S-S and C-S stretches	103
Cystine	Liver/cystinosis	Visible	501, 2916–2967	Human; cystine crystals identified in liver sections	104
Cystine	Spleen/cystinosis	Visible	501, 2916–2967	Human; cystine crystals identified in spleen sections	104
Cystine	Urine/stones			Human; review	88
Dentin	Teeth	1064		Human; microscope; cross sections of teeth mapped by chemical functionality; dentin and enamel distinguished	105
Dentin	Teeth			Human; studied demineralization of dentin	106
Dentin		Visible			107
Elastin	Achilles tendon	Visible		Bovine	98
Enamel	Teeth	1064		Human; microscope; cross sections of teeth mapped by chemical functionality; dentin and enamel distinguished	105
Extracellular proteins	Breast/cancer	782–830		CCD; human; determined that NIR excitation better than blue-green radiation for lipids	91
Extracellular proteins	Breast/cancer	785	Normal:	CCD; human; formalin fixed tissue; observed	108
•	(ductal		1439, 1654;	dramatic spectral differences between	
	carcinoma)		malignant:	normal and malignant tissue samples;	
			1450, 1654	diseased tissue dominated by proteins	
Extracellular proteins	Breast/cancer (fibrocystic disease)	785		CCD; human; formalin fixed tissue; observed dramatic spectral differences between normal and malignant tissue samples;	108
Fatty acids	Breast/cancer	406.7		diseased tissue dominated by proteins Human; distinguished between normal and malignant breast tissue, attributing differences to relative concentrations of fatty	84
Fatty acids	Breast/cancer	457.9		acids and β-carotene Human; distinguished between normal and malignant breast tissue, attributing differences to relative concentrations of fatty	84
Fatty acids	Breast/cancer	514.5		acids and β -carotene Human; distinguished between normal and malignant breast tissue, attributing differences to relative concentrations of fatty acids and β -carotene	84

			Major Raman		
	Target Organ	Excitation	Shifts		
Species	or Disease	λ (nm)	(cm ⁻¹)	Comments	Ref.
Gelatin	Achilles tendon	Visible		Bovine	98
Glucose	Blood aqueous humor			Human; stimulated Raman scattering; analysis of aqueous humor precluded absorption and scattering complications associated with whole blood	109
Glucose	Blood plasma			Human; anti-Stokes Raman	110
Glucose	Blood serum			Human; anti-Stokes Raman	110
Glucose	Blood serum		1120.5	Human	111
Glucose	Urine/diabetes		1130.5	Introduced compact, highly sensitive Raman system with integration sphere cell holder; LOD for glucose was 31 mg/dl	73
Glucose	Urine/diabetes		1130	Human; anti-Stokes Raman; demonstrated quantitative analysis of glucose in urine	74
Glucose	Urine/diabetes	NIR	1130	Human; demonstrated quantitative analysis of glucose in urine with an LOD of 41 mg/dl	75
Hepatocytes	Liver/cancer	Visible	1040, 1083, 1182,1241, 1253	Distinguished between normal and malignant hepatocytes	56
Hydroxyapatites	Bone/implants			Changes in hydroxyapatite spectra investigated after implantation to establish biocompatibility	76
Hydroxyapatites	Bone/titanium implants	NIR	592–1048 (hydroxy- apatite) 960–1450 (bone)	FT Raman; distinguished between hydroxyapatite and bone when studying hydroxyapatite-treated titanium implants	112
Hydroxyapatites	Cardiovascular tissue/calcified tissue	514.5			113
Hydroxyapatites	Metallic medical implants	NIR		NIR FT Raman; hydroxyapatite powder spectra compared to spectra for hydroxyapatite coatings from metallic medical implants	114
Inclusions	Breast			Human; studied the effects of silicone breast implants via Raman scattering	115
L-amphetamine	Urine (Drug test)			Human; SERS; vibrational modes used to identify L-amphetamine at concentrations at the mg/ml level with colloidal silver; spectra of drug mixtures in urine reported	116
Lipids	Colon/cancer	240			82
Lipids	Colon/cancer	251		Human; reported Raman spectra for normal and neoplastic colon mucosa; neoplastic samples showed lower amino-acid-to- nucleotide content ratio	82
Lipids	Cornea	NIR		NIR FT Raman; human; investigated thermally induced molecular disorder	117
Lipids	Eye (lens)			Human; studied regional changes in the lens membrane lipid composition	118
Lipids	Hair	NIR		corresponding to lens membrane functions NIR FT Raman; human; investigated thermally induced molecular disorder	119

			Major Raman		
Species	Target Organ or Disease	Excitation λ (nm)	Shifts (cm ⁻¹)	Comments	Ref.
Lipids	Nail	NIR		NIR FT Raman; human; investigated thermally induced molecular disorder	119
Lipids	Skin	NIR		NIR FT Raman; human; investigated thermally induced molecular disorder	119
Lipids	Skin/cancer			Human; examined 11 skin lesion types and noted changes in lipid spectral bands when compared to healthy tissue	120
Lipids	Skin/cancer (basal cell carcinoma)	1064	1300, 1420–1450	Human; NIR FT Raman; observed differences between normal skin and basal cell carcinoma attributed to CH ₂ and (CH ₂)(n)-in-phase twist	121
Mefenorex	Urine (drug test)			Human; SERS; vibrational modes used to identify mefenorex at concentrations at the mg/ml level with colloidal silver; spectra of drug mixtures in urine reported	116
Methamphetamine	Urine (drug test)			Human; SERS; first phase of development of 1-step drug test using selective reactive SERS substrate coating; LODs < 20 ppm observed, required amide derivatization	81
Multicomponent	Blood (whole)	NIR		CCD; human; performed quantitative analysis via partial least squares model	122
Multicomponent	Blood serum	NIR		CCD; human; performed quantitative analysis via partial least squares model	122
Nucleic acids	Cervix/cancer	NIR		CCD; human; differentiated between precancerous and normal cervical tissues	99
Nucleic acids	Cervix/cancer	NIR		CCD; human; differentiated between precancerous and normal cervical tissues	100
Nucleotides	Colon/cancer	240		Human; reported Raman spectra for normal and neoplastic colon mucosa; neoplastic samples showed lower amino acid to nucleotide content ratio	82
Nucleotides	Colon/cancer	251		Human; reported Raman spectra for normal and neoplastic colon mucosa; neoplastic samples showed lower amino acid to nucleotide content ratio	82
Organic enamel	Teeth		2941	Human; archaeological application; samples ranging up to 6000 years old analyzed and dated based on ratio of organic: inorganic band intensities	123
Pemoline	Urine (drug test)			Human; SERS; vibrational modes used to identify pemoline at concentrations at the mg/ml level with colloidal silver; spectra of drug mixtures in urine reported	116
Pentration enhancers	Skin (stratum corneum)			Human; investigated mechanisms of reversible lipid disruption by drug penetration enhancers	124
Pentration enhancers	Skin (stratum corneum)			Human; investigated mechanisms of reversible lipid disruption by drug penetration enhancers	125
Pentylenetetrazole	Urine (drug test)			Human; SERS; vibrational modes used to identify pentylenetetrazole at concentrations at the mg/ml level with colloidal silver; spectra of drug mixtures in urine reported	110

Species	Target Organ or Disease	Excitation λ (nm)	Major Raman Shifts (cm ⁻¹)	Comments	Ref.
Phosphates	Kidney stone (phosphate- type)	Visible		Identified phosphate-type kidney stones	126
Phosphates	Teeth		960	Human; archaeological application; samples ranging up to 6000 years old analyzed and dated based on ratio of organic: inorganic band intensities	123
Phosphates	Urine/stones) IIID		Human; review	88
Phospholipids	Cervix/cancer	NIR		CCD; human; differentiated between precancerous and normal cervical tissues	99
Phospholipids	Cervix/cancer	NIR		CCD; human; differentiated between precancerous and normal cervical tissues	100
Phospholipids	Ocular lens/ cataracts	Visible		•	97
Plaque	Artery			Human; distinguished areas of plaque in arteries	127
Plaque	Artery			Human; distinguished areas of plaque in arteries	128
Poly(butylene terephthalate) (PBT)	Implants			Goat; confocal Raman microspectroscopy; evaluated influence of PEO on degradation and calcification of dense PEO-PBT copolymer implants	129
Poly(ethylene oxide) (PEO)	Implants			Goat; confocal Raman microspectroscopy; evaluated influence of PEO on degradation and calcification of dense PEO-PBT copolymer implants	129
Poly(methyl methacrylate) (PMMA)	Bone/implants			Changes in PMMA spectra investigated after implantation to establish biocompatibility	76
Polyethylene	Bone/implants			Changes in high-density polyethylene spectra investigated after implantation to establish biocompatibility	76
Polysaccharides	Skin/cancer (basal cell carcinoma)	1064	840–860	Human; NIR FT Raman; observed differences between normal skin and basal cell carcinoma attributed to changes in polysaccharide structure	121
Proteins	Eye (lens)/ cataracts			Human; studied changing cholesterol content in lens fibers via Raman scattering; reported cholesterol and protein distribution in eye lens	94
Proteins	Eye (lens)/ cataracts			Human; studied changing cholesterol content in lens fibers via Raman scattering; reported cholesterol and protein distribution in eye lens	95
Proteins	Hair	NIR		NIR FT Raman; human; investigated thermally induced molecular disorder	119
Proteins	Nail	NIR		NIR FT Raman; human; investigated thermally induced molecular disorder	119
Proteins	Ocular lens/ Cataracts	Visible		,	119
Proteins	Skin	NIR		NIR FT Raman; human; investigated thermally induced molecular disorder	119

			Major Raman		
Species	Target Organ or Disease	Excitation λ (nm)	Shifts (cm ⁻¹)	Comments	Ref.
		N (IIII)	(CIII)		
Proteins	Skin/cancer			Human; examined 11 skin lesion types and noted changes in protein spectral bands when compared to healthy tissue	120
Proteins	Skin/cancer (basal cell carcinoma)	1064	1640–1680, 1220–1300, 928–940	Human; NIR FT Raman; observed differences between normal skin and basal cell carcinoma attributed to amide I, amide III, nu (C-C) (valine and proline) vibrational modes	121
Urates	Urine/stones			Human; review	88
Urea	Urine			Human; urea high enough in concentration to monitor with normal Raman	102
Urea	Urine		1016	Human; anti-Stokes Raman; demonstrated quantitative analysis of urea in urine	74
Urea	Urine	NIR	1013	Human; demonstrated quantitative analysis of urea in urine with an LOD of 4.9 mg/dl	75
Uric acid	Kidney stone (uric-acid-type)	Visible		Identified uric-acid-type kidney stones	130
Uric acid	Urine			Human; SERS needed for uric acid analysis	102
Uric acid	Urine/stones			Human; review	88
	Arterey (coronary)	NIR		CCD; human	131
	Artery	NIR		NIR FT Raman; human	132
	Artery	NIR		NIR FT Raman; human	133
	Artery	NIR		NIR FT Raman; human	134
	Artery	NIR		NIR FT Raman; human	135
	Artery (aorta)	NIR		NIR FT Raman; human	136
	Artery/ atherosclerosis	NIR		CCD; APOE*3 Leiden transgenic mice	137
	Blood	NIR		Human; FT	138
	Blood serum/ various cancers			Human; Raman spectra of blood serum demonstrated to be an indicator for various cancers, each with a unique Raman spectrum	139
	Bone	NIR		Investigated sheep and human samples; compared results with pure hydroxy and carbonated apatite; NIR FT Raman	140
	Bone	NIR		Investigated sheep and human samples; compared results with pure hydroxy and carbonated apatite; NIR FT Raman	141
	Brain/cancer	NIR		NIR FT Raman; rat	142
	Brain/cancer	NIR		NIR FT Raman; human	143
	Brain/Parkinson's disease	488		Monkey; distinguished between white and gray matter	144
	Breast	NIR		Human; NIR FT Raman fiber optics; examined normal breast tissues, comparing effectiveness of Koehler laser illumination and the confocal principle	145
	Breast/cancer	830		CCD; human; demonstrated potential of differentiating between malignant and benign lesions in breast tissues	146
	Breast/cancer	NIR		CCD; human	147
	Breast/cancer	NIR		CCD; human; spectral imaging of lipids and proteins in thin sections of breast tissue	148

Species	Target Organ or Disease	Excitation λ (nm)	Major Raman Shifts (cm ⁻¹)	Comments	Ref.
	Cardiovascular tissue/calcified aorta	Visible			149
	Colon/cancer	NIR		CCD; human; determined Raman has limited utility due to low sensitivity in comparison to fluorescence and absorption; observed excessive interference	147
	Colon/cancer	UV		Human	150
	Connective tissue	NIR		Human; FT	138
	Cornea	Visible		Feline	151
	Cornea	Visible		Monitored hydration gradients across the cornea	152
	Cornea	NIR		Near IR FT Raman; human.	153
	Coronary artery/ atherosclerosis	NIR		CCD; human; classified coronary artery lesions as nonatherosclerotic, noncalcified plaque, and calcified plaque	154
	Coronary artery/ atherosclerosis	NIR		CCD; human; classified coronary artery lesions as nonatherosclerotic, noncalcified plaque, and calcified plaque	155
	Eye	Visible		Various layers of ocular tissues investigated	156
	Gallstone	Visible		,	157
	Gallstone	NIR		Human; FT Raman; spectral data reported for a range of gallstones	158
	Gastrointestinal cancer	NIR		CCD; human	159
	Gastrointestinal cancer			Human; Raman spectroscopy described as yielding the greatest information in comparison to fluorescence, optical coherence tomography, and ultrasound	160
	Gynecological tissues/cancer	NIR		Near IR FT Raman; human	161
	Gynecological tissue/cancer	NIR		Human; FT; distinguished between normal, benign, and cancerous tissues	161
	Hair	NIR		Human; FT Raman spectra reported with band assignments for hair	162
	Larynx/cancer	830		Human; differentiated between normal, dysplastic, and squamous cell carcinoma of the larynx; salient spectral features observed in 850–950 and 1200–1350 cm ⁻¹ ranges	163
	Lung/cancer	1064		Human; totally fluorescence-free Raman spectra obtained for normal and malignant lung tissues	164
	Mineral deposition disease	Visible			165
	Mineral deposition disease	Visible		Human; differentiated between mono- and dihydrate oxalates in the myocardium and the pituitary	166
	Mineral deposition disease/lung	Visible			167
	Mineral deposits/ prosthetic implants	Visible			168

Species	Target Organ or Disease	Excitation λ (nm)	Major Raman Shifts (cm ⁻¹)	Comments	Ref.
	Mineral deposits/ prosthetic	Visible			169
	implants Mineral deposits/ prosthetic implants	Visible			170
	Mineral deposits/ silicone breast implants	Visible			171
	Nail	NIR		Human; FT Raman spectra reported with band assignments for nails	162
	Ocular lens	Visible		-	172
	Ocular lens	Visible		Monitored disulfide bond formation in eye lens	173
	Ocular lens	Visible			174
	Ocular lens	Visible			175
	Ocular lens	Visible			176
	Ocular lens	Visible		Human and rabbit	177
	Ocular lens	Visible		Human	178
	Ocular lens	Visible		Human	179
	Ocular lens	NIR		NIR FT Raman	180
	Oral tissues/ Cancer			Human; distinguished between normal and malignant oral tissues	181
	Pathological inclusions in breast tissue	Visible			182
	Pathological tissues (inclusions)	Visible			183
	Peripheral artery	NIR		CCD; human	184
	Retina/diabetes	NIR		NIR FT Raman	185
	Skin (stratum corneum)	NIR		Human; FT Raman; spectra of human corneum reported with band assignments	186
	Skin (stratum corneum)			Snake; modeled drug diffusion across skin	187
	Skin (stratum corneum)			Pig; modeled drug diffusion across skin	187
	Skin (stratum corneum)	NIR		Human; FT Raman; compared normal, hyperkeratotic, and psoriatic stratum corneum	188
	Skin/cancer	NIR		NIR FT Raman; human	189
	Skin/cancer	NIR		NIR FT Raman; human	190
	Skin/cancer	NIR		NIR FT Raman; human	191
	Skin/cancer	NIR		FT; human	138
	(melanoma)				
	Soft tissue/sarcoma	NIR		CCD; human	147
	Stomach/cancer			Human; malignant tissues observed to yield stringer bands related to OH, NH, C=O stretching and H-O-H bending	192
	Tooth	NIR		Human; FT Raman; reported compositional changes in children's teeth	193
	Tooth dentin	NIR		Investigated sheep and human samples; compared results with pure hydroxy and carbonated apatite; NIR FT Raman	140

Species	Target Organ or Disease	Excitation λ (nm)	Major Raman Shifts (cm ⁻¹)	Comments	Ref
	Tooth enamel	NIR		Investigated sheep and human samples; compared results with pure hydroxy and carbonated apatite; NIR FT Raman	140
	Urinary bladder/ cancer	NIR		CCD; human; determined Raman has limited utility due to low sensitivity in comparison to fluorescence and absorption; observed excessive interference	147
	Various tissues	UV 830		CCD; human	147 194
			O. 1. /. IV	,	171
	Cornea	Animal	Studies (in Vi	,	195
	Cornea			Rabbit; confocal Raman; fiber optics; investigated effects of corneal dehydration via observation of changes in stretching modes of OH and CH groups	193
	Eye (aqueous humor)			Rabbit; confocal Raman; compared rabbit and blind human eyes; assessed biochemical properties of eye-specific Raman signatures	196
	Eye (cornea)			Rabbit; confocal Raman; compared rabbit and blind human eyes; assessed biochemical properties of eye-specific Raman signatures	196
	Eye (lens)			Rabbit; confocal Raman; compared rabbit and blind human eyes; assessed biochemical properties of eye-specific Raman signatures	196
	Ocular lens Oral tissue/cancer (dysplasia)			Rabbit Rat; in vivo spectra obtained for normal and dysplastic rat palate tissue; distinguished between normal tissue, low-grade dysplasia, and high-grade dysplasia/carcinoma	175 197
		Clinical	Studies (in Vi	vo)	
Carotenoids	Skin/cancer			Human; noninvasive; determined that carotenoid concentration is lower in malignant than healthy skin tissue	198
	Adipose tissue	785	1077, 1265, 1303, 1444, 1658, 1755	Human; noninvasive; fiber-optic probe; CCD; distinguished between fat tissue and bone; >200 mW laser power	199
	Arterey (aorta)	810		CCD; human	151
	Arterey (aorta) Bone	810 785	957, 1032,	CCD; human Human; noninvasive; fiber-optic probe;	200 199
	Done	703	1087, 1188, 1248, 1454, 1670	CCD; distinguished between fat tissue and bone; >200 mW laser power	1))
	Cervix/cancer	NIR		CCD; human; collected spectra via fiber- optic probe	201
	Eye (aqueous humor)			Confocal Raman; compared rabbit and blind human eyes; assessed biochemical properties of eye-specific Raman signatures	196
	Eye (cornea)			Confocal Raman; compared rabbit and blind human eyes; assessed biochemical properties of eye-specific Raman signatures	196

Species	Target Organ or Disease	Excitation λ (nm)	Major Raman Shifts (cm ⁻¹)	Comments	Ref.
	Eye (lens)			Confocal Raman; compared rabbit and blind human eyes; assessed biochemical properties of eye-specific Raman signatures	196
	Gastrointestinal tissues			Human; Raman spectra collected via fiber- optic probe during routine endoscopy; subtle differences between normal and diseased tissues observed	202
	Hair	785		Human; noninvasive; fiber-optic probe; CCD; >200 mW laser power	199
	Mouth	785		Human; noninvasive; fiber-optic probe; CCD; >200 mW laser power	199
	Nail	NIR		Human; NIR FT Raman; measured fingernails and discussed feasibility of technique for determination of metabolic disorders, drug use, poisoning, and local infections	203
	Skin	785		Human; noninvasive; fiber-optic probe; CCD; >200 mW laser power	199
	Skin/cancer	NIR		NIR FT Raman; human	191
		830		CCD; human	194

65.3.4 Fluorescence Spectroscopy

Table 65.9 provides introductory-level information about the various fluorescence properties of many different chemical and biochemical species that have proven useful in the field of biomedical photonics. Due to the overwhelming number of fluorescent chemical species of biomedical importance and the limited space available for compiling this information, this table is far from comprehensive. However, it is the hope of the authors that this table will serve as a useful starting reference for researchers interested in biomedical applications of fluorescence techniques. The information in Table 65.9 was compiled using data from almost 150 publications, review articles, and monographs.

TABLE 65.9A Fluorescence Data: Biochemical Studies

Species	Endogenous/ Exogenous Origin	Absorbance Maxima (nm)	Extinction Coefficient (M ⁻¹)	Excitation λ_{ex} (nm)	Emission λ_{em} (nm)	Quantum Yield	Matrix	Lifetime $\tau 1$ (rel % $\tau 1$)	Lifetime τ2 (rel % τ2)	Lifetime $\tau 3$ (rel % $\tau 3$)	Comments	Ref.
3-Hydroxy- kynuremine	Endogenous fluorophore	_	_	355	>355	_	Extracts of human eye (young)	24000	400000	_	_	1
3-Hydroxy- kynuremine	Endogenous fluorophore	_	_	355	>355	_	Extracts of human eye (old)	0.031-0.061	_	_	_	1
4-Pyridoxic acid (PA)	Endogenous fluorophore	307	_	315	425	_	_	_	_	_	Physiologic pH	2
Beta-carotene	Endogenous fluorophore	_	_	blue	520	_	Powder/solution	9.6	2	0.3	_	3
Ceroid	Endogenous fluorophore	_	_	340–395	430–460	_	_	_	_	_	Physiologic pH	4
Ceroid	Endogenous fluorophore	_	_	340–395	540–640	_	_	_	_	_	Physiologic pH	5
Collagen	Endogenous fluorophore	_	_	280, 265, 330, 450	310, 385, 390, 530	_	Powder	_	_	_	Physiologic pH	6
Collagen	Endogenous fluorophore	_	_	Ultraviolet	Violet- blue	_	Powder	2.7 (25)	8.9 (35)	_	_	7

					(Cellular Stud	lies					
1-Pyreneiso- thiocyanatelabeled antimouse IgG	Various cancers	_	_	Blue/ visible	Visible	_	Labeled antibodies attached to surface proteins on mouse cells	20–55	_	_	Long lifetime allowed for differentiation of diferent types of cells via flow cytometry	34
1-Pyrenesulfonyl chloride labeled antimouse IgG	Various cancers	_	_	Blue/ visible	Visible	_	Labeled antibodies attached to surface proteins on mouse cells	20–55	_	_	Long lifetime allowed for differentiation of diferent types of cells via flow cytometry	34
9-Acetoxy-tetra-n- propylporphycene (ATPPn)	Bladder cancer	_	_	Visible	Red/near infrared	_	Human bladder carcinoma cell line	_	_	_	This is a recently developed photosensitizer that has shown promise based on cellular studies with bladder carcinoma cells in vitro	35
Aluminum phthalocyanine	Various cancers	_	_	610	>645	_	Cultured leukemic cells (human erythro- leukemic cells)	$2.2 \pm 0.4 (50)$	$6.1 \pm 0.2 (50)$		_	24
Aluminum phthalocyanine	Various cancers	_	_	364	630	_	In L1210 mouse cells, 4 h following i.p. administration	5.18 (86.33)	1.52 (13.67)	_	_	23

Aluminum phthalocyanine	Various cancers	_	_	364	630	_	In L1210 mouse cells, 12 h following i.v. administration	5.9 (39.74)	2.87 (50.24)	0.93 (10.01)	_	23
Chlorophyll-derived photosensitizers	Lung cancer	760	_	760	Near infrared	_	In OAT 75 small cell lung carcinoma cells	_	_	_	Absorption maximum of the photosensitizer can shift between 20–100 nm depending up local environment within the cell	36
Flavins	Various diseases	_	_	365	500	_	Intact yeast cells	0.2–0.35 (45)	2.0–3.0 (25)	6.0–8.0 (30)	_	20
Flavins	Various diseases	_	_	365	500	_	Defective yeast cells	0.30-0.50 (35)	2.0–3.0 (30)	6.0–8.0 (35)	τ1 is shorter than τ2 and τ3, but represents the majority of fluorescence signal in intact cells	20
Flavoproteins, oxidized	Bladder cancer	_	_	488	550–560	_	Human urothelial cells (normal and malignant) in media	_	_	_	Normal cells exhibited greater than ten times the autofluorescence intensity of tumor cells	37
Hematoporphyrin derivative (HpD)	Various cancers	_	_	364	630	_	In L1210 mouse cells, 12 h following i.v. administration	14.36 (10.83)	3.12 (20.07)	0.61 (69.1)	_	23
Hematoporphyrin	Various cancers	_	_	364	630	_	In L1210 mouse cells, 4 h following i.p. administration	15.3 (45.39)	4.32 (18.16)	1.11 (36.46)	_	23
Hematoporphyrin aggregates	Various cancers	_	_	Visible	675	_	Various types of cells	_	_	_	Fluorescence emission at 675 nm was assigned to hematoporphyrin monomers	38

TABLE 65.9B Fluorescence Data: Cellular Studies, Tissue and Biofluid Studies (in Vitro), Animal Studies (in Vivo), and Human Clinical Studies (in Vivo) (continued)

Species	Target Organ or Disease	Absorbance Maxima (nm)	Molar Extinction Coefficient (M ⁻¹)	Excitation λ_{ex} (nm)	Emission λ_{em} (nm)	Quantum Yield	Matrix	Lifetime τ1 (rel % τ1)	Lifetime τ2 (rel % τ2)	Lifetime τ3 (rel % τ3)	Comments	Ref.
Hematoporphyrin monomers	Various cancers	_	_	Visible	635	_	Various types of cells	_	_	_	Fluorescence emission at 635 nm was assigned to hematoporphyrin monomers	38
Human breast cells (normal and malignant)	Breast cancer	_	_	Ultraviolet/ blue	340, 440	_	Human breast cancer cells (normal and malignant) in media	_	_	_	Ratiometric analyses of the fluorescence autofluorescence intensity of the cells at 340 to 440 nm allows for the differentiation of normal and malignant cells	35
Human semen Human seminal plasma	Infertility Infertility	_	_	488 488	622 622	_	Ξ	_	_	_	Sperm motility could be correlated to the autofluorescence emission	39 39
Human spermatozoa	Infertility	_	_	488	622	_	_	_	_	_	Spermatozoa and sperm motility could be correlated to the autofluorescence emission	39

Murine fibroblast cells (normal and malignant)	Various cancers	_	_	290	Blue- green	_	Murine fibroblast cell lines	_	_	_	Autofluorescence intensity of malignant cells was significantly less than that of normal cells, with tryptophan being the primary component responsible for the difference	40
N-(1-pyrene)- maleimide labeled antimouse IgG	Various cancers	_	_	Blue/ visible	Visible	_	Labeled antibodies attached to surface proteins on mouse cells	20–55	_	_	Long lifetime allowed for differentiation of diferent types of cells via flow cytometry	34
Nicotinamide adenine dinucleotide phosphate (NADPH)	Various diseases	_	_	365	450	_	Intact and defective yeast cells	0.2–0.3 (30)	1.4–2.4 (40)	6.0–8.0 (30)	Deficient cell fluorescence is four times higher	20
Oral epithelial cells (normal and squamous)	Oral cancer	_	_	300	320–580	_	Several different culturing media selected to cause cell differentiation	_	_	_	No difference between the differentiated cells could be determined from the resulting spectra	41
Oral epithelial cells (normal and squamous)	Oral cancer	_	_	340	360–620	_	Several different culturing media selected to cause cell differentiation	_	_	_	Spectral shifts occurred between the three types of cell differentiation	41
Oral epithelial cells (normal and squamous)	Oral cancer	_	_	365	400–630	_	Several different culturing media selected to cause cell differentiation	_	_	_	Small changes in fluorescence intensity and spectral shape occurred between the various differentiated cells	41

TABLE 65.9B Fluorescence Data: Cellular Studies, Tissue and Biofluid Studies (in Vitro), Animal Studies (in Vivo), and Human Clinical Studies (in Vivo) (continued)

Species	Target Organ or Disease	Absorbance Maxima (nm)	$\begin{array}{c} Molar \\ Extinction \\ Coefficient \\ (M^{-1}) \end{array}$	Excitation λ_{ex} (nm)	Emission λ_{em} (nm)	Quantum Yield	Matrix	Lifetime τ1 (rel % τ1)	Lifetime τ2 (rel % τ2)	Lifetime $\tau 3$ (rel % $\tau 3$)	Comments	Ref.
Oral epithelial cells (normal and squamous)	Oral cancer	_	_	420	440–630	_	Several different culturing media selected to cause cell differentiation	_	_	_	Small changes in fluorescence intensity and spectral shape occurred between the various differentiated cells	41
Oral epithelial cells (normal and squamous)	Oral cancer	_	_	200–360	380	_	Several different culturing media selected to cause cell differentiation	_	_	_	Significant changes in intensity and spectral profile occurred between the various differentiated cells	
Oral epithelial cells (normal and squamous)	Oral cancer	_	_	240–415	450	_	Several different culturing media selected to cause cell differentiation	_	_	_	Significant changes in intensity and spectral profile occurred between the various differentiated cells	
Oral epithelial cells (normal and squamous)	Oral cancer	_	_	250–420	480	_	Several different culturing media selected to cause cell differentiation	_	_	_	Significant changes in intensity and spectral profile occurred between the various differentiated cells	
Oral epithelial cells (normal and squamous)	Oral cancer	_	_	270–480	520	_	Several different culturing media selected to cause cell differentiation	_	_	_	Significant changes in intensity and spectral profile occurred between the various differentiated cells	

Ovary cells	Photo- conversion	_	_	320–400	455	_	Chinese hamster ovary cells	_	_	_	Optical trapping of ovary cells using 730 nm was found to induce an increase in autofluorescnece intensity and a 6-nm red shift in its maxima	42
Phorbol-13-acetate- 12-N-methyl-N-4- (N,N'-di(2- hydroxy- ethyl)amino-7- nitrobenz-2-oxa- 1,3-diazole- aminododecanoate (N-C12-Ac(13))	Cellular signal transduction	488	_	488	Visible	_	P3HR-1 Burkitt lymphoma cells	_	_	_	Used in the investigation of protein kinase C and its role in signal transduction	43
Photofrin II	Various cancers	_	_	364	630	_	In L1210 mouse cells, 4 h following i.p. administration	14.9 (40.9)	4.91 (18.32)	1.18 (41.58)	Cationic micelles influence aggregation	23
Photofrin II	Various cancers	_	_	364	630	_	In L1210 mouse cells, 12 h following i.v. administration	14.81 (7.3)	4.65 (25.49)	1.08 (67.27)	Cationic micelles influence aggregation	23

Eosinophils, tissue dwelling	Hodgkin's disease/ lymphomas	_	_	365	Amber- gold	_	Eosinophils isolated from various tumor tissues	_	_	_	_	14
Excised and frozen colon tissue sections (normal and tumor)	Colon cancer	_	_	351–364	Visible	_	Human colon tissue	_	_	_	This article characterizes resulting fluorescence emission from various locations in the tissue	49

TABLE 65.9B Fluorescence Data: Cellular Studies, Tissue and Biofluid Studies (in Vitro), Animal Studies (in Vivo), and Human Clinical Studies (in Vivo) (continued)

Species	Target Organ or Disease	Absorbance Maxima (nm)	Molar Extinction Coefficient (M ⁻¹)	Excitation λ_{ex} (nm)	Emission λ_{em} (nm)	Quantum Yield	Matrix	Lifetime τ1 (rel % τ1)	Lifetime τ2 (rel % τ2)	Lifetime $\tau 3$ (rel % $\tau 3$)	Comments	Ref.
Excised and frozen human cervical tissues (normal and malignant)	Cervical cancer	_	_	365	460	_	Frozen cervical tissue	_	_	_	Autofluorescence emission in the epithelia showed small differences in intensity between severe and mild dysplasia of tissues; epithelial fluorescence is less in malignant tissue than normal tissue	50
Excised and frozen human cervical tissues (normal and malignant)	Cervical cancer	_	_	440	525	_	Frozen cervical tissue	_	_	_	Autofluorescence emission in the stroma showed small differences in intensity between inflammatory and severely dysplastic tissues; epithelial fluorescence is less in malignant tissue than normal tissue	50
Excised arterial tissue	Atherosclerosis	_	_	458	Visible	_	Arterial tissue	_	_	_	Good differentiation of normal and atherosclerotic tissue can be seen after excitation with visible wavelengths	51

xcised arterial tissue	Atherosclerosis	_	_	476	Visible	_	Arterial tissue	_	_	_	Good differentiation of normal and atherosclerotic tissue can be seen after excitation with visible wavelengths	52
xcised arterial tissue (calcified and noncalcified)	Atherosclerosis	_	_	495	520–800	_	Arterial tissue	_	_	_	Characteristic spectral and temporal characteristics of 495-nm-induced autofluorescence of normal intima, calcified plaques, and fibro-fatty plaques were determined	53
xcised arterial tissue (calcified and noncalcified)	Atherosclerosis		_	380	400–600	_	Arterial tissue	_	_	_	Differentiation of atherosclerotic lesions from normal tissue was attempted based on autofluorescence emission (it was found that a better excitation wavelength was 325 nm)	54

TABLE 65.9B Fluorescence Data: Cellular Studies, Tissue and Biofluid Studies (in Vitro), Animal Studies (in Vivo), and Human Clinical Studies (in Vivo) (continued)

Species	Target Organ or Disease	Absorbance Maxima (nm)	Molar Extinction Coefficient (M ⁻¹)	Excitation λ_{ex} (nm)	Emission λ_{em} (nm)	Quantum Yield	Matrix	Lifetime $\tau 1$ (rel % $\tau 1$)	Lifetime τ2 (rel % τ2)	Lifetime $\tau 3$ (rel % $\tau 3$)	Comments	Ref.
Excised arterial tissue (calcified and noncalcified)	Atherosclerosis	_	_	450	400–600	_	Arterial tissue	_	_	_	Differentiation of atherosclerotic lesions from normal tissue was attempted based on autofluorescence emission (it was found that a better excitation wavelength was 325 nm)	54
Excised arterial tissue (calcified and noncalcified)	Atherosclerosis	_	_	308	321–657	_	Arterial tissue	_	_	_	A XeCl laser was used for the simultaneous ablation and autofluorescence- based diagnosis of atherosclerosis by providing a means of differentiating normal tissue from	55
Excised arterial tissue (calcified and noncalcified)	Atherosclerosis	_	_	351–364	Visible	_	Arterial tissue	_	_	_	various plaques Autofluorescence of collagen, elastin, and ceroid can be used to differentiate normal and atherosclerotic tissues	56

Excised arterial tissue (calcified and noncalcified)	Atherosclerosis	_	_	476	Visible	_	Arterial tissue	_	_	_	Determination of chemical and morphological characteristics responsible for autofluorescence signals were determined	57,58
Excised arterial tissue (calcified and noncalcified)	Atherosclerosis	_	_	325	443	_	Arterial tissue	_	_	_	Normalized fluorescence intensities at 443 nm can be used to differentiate between normal and calcified tissues	51
Excised arterial tissue (calcified and noncalcified)	Atherosclerosis	_	_	325	375–385 and 435–445	_	Arterial tissue filled with blood	_	_	_	An autoguidance system for angioplasty was investigated based on ratiometric analyses of autofluorescence at 380 and 440 nm	59
Excised arterial tissue (calcified)	Atherosclerosis	_	_	325	400–600 (no peak at 480)	_	Arterial tissue	_	_	_	Noncalcified tissue has a distinct peak at 480 nm and calcified tissue shows only a broadband emission	54

TABLE 65.9B Fluorescence Data: Cellular Studies, Tissue and Biofluid Studies (in Vitro), Animal Studies (in Vivo), and Human Clinical Studies (in Vivo) (continued)

Species	Target Organ or Disease	Absorbance Maxima (nm)	Molar Extinction Coefficient (M ⁻¹)	Excitation λ_{ex} (nm)	Emission λ_{em} (nm)	Quantum Yield	Matrix	Lifetime τ1 (rel % τ1)	Lifetime τ2 (rel % τ2)	Lifetime $\tau 3$ (rel % $\tau 3$)	Comments	Ref.
Excised arterial tissue (collagen and elastin components)	Atherosclerosis	_	_	306–310	380	_	Arterial tissue	_	_	_	By ratioing tryptophan fluorescence intensity to collagen and elastin component, classification of tissue is possible	60
Excised arterial tissue (noncalcified)	Atherosclerosis	_	_	248	370–460	_	Arterial tissue	_	_	_	Autofluorescence shows broadband fluorescence emission	61
Excised arterial tissue (noncalcified)	Atherosclerosis	_	_	325	400–600 (peak at 480)	_	Arterial tissue	_	_	_	Noncalcified tissue has a distinct peak at 480 nm and calcified tissue shows only a broadband emission	54
Excised arterial tissue (tryptophan component)	Atherosclerosis	_	_	306–310	340	_	Arterial tissue	_	_	_	By ratioing tryptophan fluorescence intensity to collagen and elastin component, classification of tissue is possible	60

Excised bladder tissue (normal mucosa, flat lesions, and papillary tumors)	Bladder cancer		_	337	385 and 455	_	Bladder tissue			_	Ratiometric measurements of the autofluorescence intensities at 385 and 440 nm were used to distinguish malignant tumors from nonmalignant and inflamed tissue	62
Excised bladder tissue (normal mucosa, flat lesions, and papillary tumors)	Bladder cancer	_	_	375–440 (D-light)	Visible	_	Bladder tissue	_	_	_	Autofluorescence imaging could distinguish between normal mucosa, flat lesions, and papillary tumors	63
Excised brain tissue (normal and Alzheimer's)	Alzheimer's disease	_	_	647	650–850	_	Human brain tissue (temporal cortex)	_	_	_	Autofluorescence emission from temporal cortex samples was used to correctly diagnose Alzheimer's disease	64
Excised brain tissue (normal and tumorous)	Brain cancer	_	_	337	460	_	Human brain tissue	_	_	_	The autofluorescence intensity of normal brain tissue was significantly greater than that of primary brain tumorous regions	65

TABLE 65.9B Fluorescence Data: Cellular Studies, Tissue and Biofluid Studies (in Vitro), Animal Studies (in Vivo), and Human Clinical Studies (in Vivo) (continued)

Species	Target Organ or Disease	Absorbance Maxima (nm)	Molar Extinction Coefficient (M ⁻¹)	Excitation λ_{ex} (nm)	Emission λ_{em} (nm)	Quantum Yield	Matrix	Lifetime τ1 (rel % τ1)	Lifetime τ2 (rel % τ2)	Lifetime τ3 (rel % τ3)	Comments	Ref.
Excised breast tissue (normal)	Breast cancer	_	_	488	530, 550, and 590	_	Normal breast tissue	_	_	_	Presence of three peaks due to absorption by hemoglobin at 420, 542, and 575 nm	66
Excised breast tissue (tumor)	Breast cancer	_	_	488	530	_	Tumor breast tissue	_	_	_	Only a single peak is visible in the fluorescence profile	66
Excised calcified arterial tissue	Atherosclerosis	_	_	248	397, 442, 450, 461, 528, and 558	_	Arterial tissue	_	_	_	Autofluorescence shows multiple, prominent atomic fluorescence lines	61
Excised carotid atherosclerotic plaques	Atherosclerosis	_	_	337	Visible	_	Carotid arterial tissue	_	_	_	Autofluorescence of carotid atherosclerotic plaques was used to determine the three primary components; fibrous tissue, lipid constituents, and calcified plaque	67
Excised carotid atherosclerotic plaques	Atherosclerosis	_	_	476	Visible	_	Carotid arterial tissue	_	_	_	Autofluorescence of carotid atherosclerotic plaques was used to determine the three primary components; fibrous tissue, lipid constituents, and calcified plaque	67

Excised carotid atherosclerotic plaques	Atherosclerosis	_		488	Visible	_	Carotid arterial tissue	_	_	_	Autofluorescence of carotid atherosclerotic plaques was used to determine the three primary components; fibrous tissue, lipid constituents, and calcified plaque	67
Excised carotid atherosclerotic plaques	Atherosclerosis	_	_	458	Visible	_	Carotid arterial tissue	_	_	_	Autofluorescence of carotid atherosclerotic plaques was used to determine the three primary components; fibrous tissue, lipid constituents, and calcified plaque	67
Excised cervical tissue (normal and tumor)	Cervical cancer	_	_	330	385	_	Cervical tissue	_	_	_	Fluorescence intensity of normalized emission spectra is greater for normal tissue than tumor tissue	68
Excised cervical tissue (normal and tumor)	Cervical cancer	_	_	365	475	_	Cervical tissue	_	_	_	Fluorescence intensity at 475 nm increases with degree of dysplasia/ malignancy	69
Excised colon tissue (normal and adenomatous)	Colon cancer	_	_	330, 370, and 430	404, 480, and 680	_	Human colon tissue	_	_	_	_	70

TABLE 65.9B Fluorescence Data: Cellular Studies, Tissue and Biofluid Studies (in Vitro), Animal Studies (in Vivo), and Human Clinical Studies (in Vivo) (continued)

Species	Target Organ or Disease	Absorbance Maxima (nm)	Molar Extinction Coefficient (M ⁻¹)	Excitation λ_{ex} (nm)	Emission λ_{em} (nm)	Quantum Yield	Matrix	Lifetime τ1 (rel % τ1)	Lifetime τ2 (rel % τ2)	Lifetime $\tau 3$ (rel % $\tau 3$)	Comments	Ref.
Excised colon tissue (normal and adenomatous)	Colon cancer	_	_	325	350–600	_	Human colon tissue	_	_	_	370 nm was found to be the optimal excitation wavelength for discrimination of normal and adenomatous tissues	71
Excised colon tissue (normal and tumor)	Colon cancer			366	480–580	_	Human colon tissue	_		_	Relative fluorescence emission amplitudes of normal and tumor tissue between 480–580 nm varied significantly and tumor tissue displayed more evident shoulder than normal tissue	72
Excised colon tissue (normal mucosa and adenomatous polyps)	Colon cancer	_	_	325	Visible	_	Human colon tissue	_	_	_	Autofluorescence intensity in adenomatous polyps is lower than for normal tissue and small spectral differences can be seen	73

Excised heart tissue (nodal conductive and atrial endomyocardial)	Heart arrhythmia	_		308	440–500	_	Heart tissue	_	_		Nodal tissue demonstrated a decrease in normalized fluorescence intensity and peak width relative to atrial endomyocardial tissue	74
Excised heart tissue (nodal conductive and ventricular endocardium)	Heart arrhythmia	_	_	308	430–550	_	Heart tissue	_	_	_	Nodal tissue demonstrated an increase in fluorescence intensity relative to atrial endomyocardial tissue	74
Excised human eye lens	Vision problems	_	_	430–490	530–630	_	Human eye lens	_	_	_	Intrinsic eye lens transmittance can be determined based on autofluorescence analyses	75
Excised lung tissue (normal)	Lung cancer	_	_	488	530, 550, and 590	_	Normal lung tissue	_	_	_	Presence of three peaks due to absorption by hemoglogin at 420, 542, and 575 nm	66
Excised lung tissue (tumor)	Lung cancer	_	_	488	530	_	Tumor lung tissue	_	_	_	Only a single peak is visible in the fluorescence profile	66

TABLE 65.9B Fluorescence Data: Cellular Studies, Tissue and Biofluid Studies (in Vitro), Animal Studies (in Vivo), and Human Clinical Studies (in Vivo) (continued)

Species	Target Organ or Disease	Absorbance Maxima (nm)	Molar Extinction Coefficient (M ⁻¹)	Excitation λ_{ex} (nm)	Emission λ_{em} (nm)	Quantum Yield	Matrix	Lifetime τ1 (rel % τ1)	Lifetime τ2 (rel % τ2)	Lifetime τ3 (rel % τ3)	Comments	Ref.
Excised oral tissue (normal and tumor)	Oral cancer	_	_	410	Visible	_	Oral tissue	_	_	_	Autofluorescence emission spectra excited with 410-nm light are capable of differentiating normal and abnormal tissues	76
Excised oral tissue (normal, malignant, and dysplastic)	Oral cancer	_	_	410	635	_	Oral tissue	_	_	_	Abnormal tissues exhibited an increase in fluorescence intensity at 635 nm	76, 77
Excised oral tissue (normal, malignant, and premalignant)	Oral cancer	_	_	300	330–470	_	Oral tissue	_	_	_	Ratiometric fluorescence measurements at 330 and 470 nm allowed for the differentiation of malignant and premalignant lesions from normal tissues	78
Excised skin tissue	Skin cancer	_	_	365	Visible	_	Skin tissue (147 samples)	_	_	_	Based upon the resulting autofluorescence, it was possible to differentiate non-dysplastic nevi from melanomas and dysplastic nevi (tumor tissue exhibited reduced fluorescence)	79

Excised stomach tissue (normal, dysplastic, and tumor)	Stomach cancer	_	_	325	440 and 395	_	Stomach tissue	_	_	_	Normalized fluorescence intensities at both 440 and 395 nm exhibit significant differences between normal and tumor tissues	80
Extracts of human eye (soluble and insoluble)	Cataracto- genesis	_	_	Ultraviolet	Blue/ green	_	Cortical and nuclear extracts	_	_	_		81
Flavins	Various diseases	_	_	488	500-550	_	Normal rat kidney	0.357 ± 0.018 (27)	1.220 ± 0.035 (63)	_	_	23
Flavins	Various diseases	_	_	488	600–650	_	Normal rat kidney	0.204 ± 0.011 (47)	1.0 ± 0.006 (53)	_	_	23

Flavins	Various diseases	_	_	488	600–650	_	Cancerous rat	0.236 ± 0.014 (67)	1.963 ± 0.037 (33)	_	_	23
Haematoporphyrin derivative	Various cancers	_	_	320	630	_	Tumor tissue in DHE-injected rat	17	6	0.7	_	82
Haematoporphyrin derivative	Various cancers	_	_	320	630	_	Normal tissue in surrounding muscle	17	_	_	_	82
Melanins derived from 3-hydroxy- anthranilic acid	Colon cancer	_	_	324	413	_	Human colon tissue	_	_	_	This article characterizes the autofluorescence properties of plasma-soluble melanins	83

TABLE 65.9B Fluorescence Data: Cellular Studies, Tissue and Biofluid Studies (in Vitro), Animal Studies (in Vivo), and Human Clinical Studies (in Vivo) (continued)

Species	Target Organ or Disease	Absorbance Maxima (nm)	Molar Extinction Coefficient (M ⁻¹)	Excitation λ_{ex} (nm)	Emission λ_{em} (nm)	Quantum Yield	Matrix	Lifetime τ1 (rel % τ1)	Lifetime τ2 (rel % τ2)	Lifetime τ3 (rel % τ3)	Comments	Ref.
Melanins derived from dopa, catecholamines, catechol, and 3-hydroxy- kynurenine	Colon cancer	_	_	345	445	_	Human colon tissue	_	_	_	This article characterizes the autofluorescence properties of plasma-soluble melanins	83
Nicotinamide adenine dinucleotide (NADH) reduced form	Various diseases	_	_	380	Visible	_	Cervical tissue	_	_	_	Increases in fluorescence emission due to NADH were found for dysplastic tissue relative to normal tissues	46
Nicotinamide adenine dinucleotide phosphate (NADPH)	Various diseases	_	_	320	400	_	Normal arterial wall	0.3	2	7	Calcified plaques have a higher ratio of slow (400 nm) to fast fluorescence (480 nm)	84
					Anim	al Studies (i	in Vivo)					
2',7'-bis-(2 carboxy-ethyl)-5-(and -6)-carboxyfluorescein	Various cancers	_	_	465	Visible	_	Grafted tumors on mice	_	_	_	Differentiation of tumors from normal tissue was accomplished based on intracellular pH measurements with this exogenous dye	85

Arterial tissue (atherosclerotic)	Atherosclerosis	_	_	Ultraviolet/ blue	410–490	_	Rabbit arteries	_	_	_	Autofluorescence analyses were capable of monitoring the disruption of atherosclerotic plaques following injection of Russell's viper venom	86
Benzoporphyrin derivatized- monoacid (BPD-MA)	Various cancers	_	_	337	380–750	_	Rat tumors (various organs)	_	_	_	BPD-MA exhibited approximately the same demarcation ability as other common photosensitizers	84
Brain tissue (normal and glioma)	Brain cancer	_	_	360	470	_	Rat brain	_	_	_	Fluorescence due to NAD(P)H; decreased autofluorescence intensity for gliomas relative to normal tissue	87
Brain tissue (normal and glioma)	Brain cancer	_	_	440	520	_	Rat brain	_	_	_	Fluorescence due to flavins; decreased autofluorescence intensity for gliomas relative to normal tissue	87
Brain tissue (normal and glioma)	Brain cancer	_	_	490	630	_	Rat brain	_	_	_	Fluorescence due to porphyrins; decreased autofluorescence intensity for gliomas relative to normal tissue	87

TABLE 65.9B Fluorescence Data: Cellular Studies, Tissue and Biofluid Studies (in Vitro), Animal Studies (in Vivo), and Human Clinical Studies (in Vivo) (continued)

Species	Target Organ or Disease	Absorbance Maxima (nm)	Molar Extinction Coefficient (M ⁻¹)	Excitation λ_{ex} (nm)	$Emission \\ \lambda_{em} \ (nm)$	Quantum Yield	Matrix	Lifetime τ1 (rel % τ1)	Lifetime τ2 (rel % τ2)	Lifetime τ3 (rel % τ3)	Comments	Ref.
Esophageal multispheroidal tumor (induced by trans-retinoic acid)	Esophageal cancer	_	_	Ultraviolet/ blue	340, 450, and 520	_	Rat esophagus	_	_	_	Autofluorescence intensities at 340, 450, and 520 nm demonstrated differences between normal and cancerous tissues	88
Esophageal tumor (induced by <i>N</i> - nitroso- <i>N</i> - methylbenzylamine (NMBA))	Esophageal cancer	_	_	Ultraviolet/ violet	380	_	Rat esophagus	_	_	_	Alteration of fluorescence emission correlated to disease progression, from normal to dysplasia to invasive cancer	89
Foam cell lesions	Atherosclerosis	_	_	308	Visible	_	Hyper- cholesterolemic rabbit arteries	_	_	_	Autofluorescence from foam cell lesions exhibited red shifts and spectral broadening similar to oxidized low-density lipoproteins	90
Heart tissue (native and transplanted)	Heart transplant rejection	_	_	Blue	Visible	_	Rat heart tissue (midtransverse ventricular)	_	_	_	A correlation was found between the severity of tissue rejection and the autofluorescence from the heart	91

Hearttissue(normal and hypoxic)	Myocardial hypoxia		_	308	350–600	_	Mouse heart tissue			_	Hypoxia was found to reduce the autofluorescence between 455–505 nm and remove two spectral peaks at 540 and 580 nm, relative to normal tissue, leaving only a single peak at 555 nm	92
Hematoporphyrins	Various cancers	_	_	337	630	_	Rat tumors (various organs)	_	_	_	_	93
K1735P melanoma	Skin cancer		_	Ultraviolet/ violet	360–700	_	Melanomas implanted intradermally in the ears of C3H/ HeN mice			_	Resulting autofluorescence spectra showed decreases in the fluorescence intensity over the spectral range of 385–425 nm; however, no spectral differences could be determined between the normal tissue and unpigmented melanomas	94

TABLE 65.9B Fluorescence Data: Cellular Studies, Tissue and Biofluid Studies (in Vitro), Animal Studies (in Vivo), and Human Clinical Studies (in Vivo) (continued)

Species	Target Organ or Disease	Absorbance Maxima (nm)	Molar Extinction Coefficient (M ⁻¹)	Excitation λ_{ex} (nm)	Emission λ_{em} (nm)	Quantum Yield	Matrix	Lifetime τ1 (rel % τ1)	Lifetime τ2 (rel % τ2)	Lifetime τ3 (rel % τ3)	Comments	Ref.
Kidney tissue (normal and hypoxic)	Renal hypoxia	_	_	308	350–600	_	Mouse kidney tissue	_	_	_	Hypoxia was found to reduce the autofluorescence between 455–505 nm and remove two spectral peaks at 540 and 580 nm, relative to normal tissue, leaving only a single peak at 555 nm	92
MS-2 fibrosarcoma	Various cancers	_	_	337	400–500	_	Implanted in NALB-CDF1 mice	_	_	_	Autofluorescence intensity was found to be lower in the tumor tissue than in the healthy tissue and the fast component of the biexponential fluorescence decay is significantly lower in the tumor as well	95
Oral tissue (normal and malignant)	Oral cancer	_	_	410	635	_	Hamster cheek pouch (tumors induced with 7,12-dimethyl- benz(a)- anthracene)	_	_	_	Neoplastic lesions showed a characteristic fluorescence between 630–640 nm	96

Oral tissue (normal and malignant)	Oral cancer	_	_	350–370	Visible	_	Hamster cheek pouch	_	_	_	Neoplastic tissue showed an increase in fluorescence intensity relative to normal tissue with excitation between 350–370 nm	97
Oral tissue (normal and malignant)	Oral cancer	_	_	400–450	Visible	_	Hamster cheek pouch	_	_	_	Neoplastic tissue showed an decrease in fluorescence intensity relative to normal tissue with excitation between 400–450 nm, with an optimal wavelength of 410 nm	97
Oral tissue (normal, hyperplastic, papilloma, and invasive carcinoma)	Oral cancer	_	_	405	430–700	_	Hamster cheek pouch (tumors induced with 7,12-dimethyl- benz(a)- anthracene)	_	_	_	Ratiometric analyses of the autofluorescence emission at 530/ 620 nm and 530/ 630 nm provided a means of differentiating the various stages and types of tumors present	98
Pancreas tissue (normal and tumor)	Pancreatic cancer	_	_	355	470 and 640	_	Rat pancreatic tissue (normal and tumor)	_	_	_	_	99

TABLE 65.9B Fluorescence Data: Cellular Studies, Tissue and Biofluid Studies (in Vitro), Animal Studies (in Vivo), and Human Clinical Studies (in Vivo) (continued)

Species	Target Organ or Disease	Absorbance Maxima (nm)	Molar Extinction Coefficient (M ⁻¹)	Excitation λ_{ex} (nm)	Emission λ_{em} (nm)	Quantum Yield	Matrix	Lifetime τ1 (rel % τ1)	Lifetime τ2 (rel % τ2)	Lifetime τ3 (rel % τ3)	Comments	Ref.
Pheophorbide-a (Ph-a)	Pancreatic cancer	_	_	355	680	_	Rat pancreatic tissue (normal and tumor)	_	_	_	Normalization of Ph-a fluorescence intensity was performed via ratiometric analyses with preas autofluorescent signals	99
Protoporphyrin IX (5-aminolevulinic acid induced)	Liver cancer	_	_	Visible	635	_	Heptic tumors in rats	_	_	_	Large quantities of PpIX were found to accumulate in both normal and tumor liver tissue	100
Protoporphyrin IX (5-aminolevulinic acid induced)	Various cancers	_	_	405	635–705	_	Rat tumors (various organs)	_	_	_	Maximum build- up of PpIX occurred within 1 h	101
Trimethoxylated carotenoporphyrin	Various cancers	_	_	425	655 and 720	_	MS-2 fibrosarcoma in BALB/c mice	_	_	_	The greatest extent of caroteno- porphyrin fluorescence occurred in the liver	102
Trimethylated carotenoporphyrin	Various cancers	_	_	425	655 and 720	_	MS-2 fibrosarcoma in BALB/c mice	_	_	_	The greatest extent of caroteno- porphyrin fluorescence occurred in the liver	102

Human Clinical Studies (in Vivo)

5,10,15,20-tetra (m-hydroxy- phenyl)chlorin (mTHPC)	Various cancers	_	_	_	_	_	In vivo esophageal tissue	8.5 ± 0.8	_	_	mTHPC was found to have a fluorescence lifetime of 8.5 ns in esophageal tissue	103
Bladder tissue (normal and tumor)	Bladder cancer	_	_	337	370–490	_	<i>In vivo</i> bladder tissue	_	_	_	Spectral and temporal differences in the autofluorescence emission were used to differentiate normal and tumor tissues	103
Bladder tissue (normal and tumor)	Bladder cancer	_	_	337	385–455	_	<i>In vivo</i> bladder tissue	_	_	_	By ratioing the autofluorescence intensity at 385 to the intensity at 455 nm, it was possible to diagnose the tissue with 98% sensitivity	62

TABLE 65.9B Fluorescence Data: Cellular Studies, Tissue and Biofluid Studies (in Vitro), Animal Studies (in Vivo), and Human Clinical Studies (in Vivo) (continued)

Species	Target Organ or Disease	Absorbance Maxima (nm)	Molar Extinction Coefficient (M ⁻¹)	Excitation λ_{ex} (nm)	Emission λ_{em} (nm)	Quantum Yield	Matrix	Lifetime τ1 (rel % τ1)	Lifetime τ2 (rel % τ2)	Lifetime $\tau 3$ (rel % $\tau 3$)	Comments	Ref.
Bladder tissue (normal, inflammatory mucosa, and neoplastic urothelial lesion)	Bladder cancer	_		308	Visible	_	In vivo bladder tissue	_	_	_	The shape of the autofluorescence emission of carcinoma in situ tissue was significantly different from both normal and inflamed mucosa, allowing a ratiometric measurement of the intensities at 360 and 440 nm to be used for diagnosis	104
Bladder tissue (normal, inflammatory mucosa, and neoplastic urothelial lesion)	Bladder cancer	_	_	337	Visible	_	<i>In vivo</i> bladder tissue	_	_	_	The overall fluorescence intensity of bladder tumor tissue was found to be much less than that of normal tissue, regardless of stage	104
Bladder tissue (normal, inflammatory mucosa, and neoplastic urothelial lesion)	Bladder cancer	_	_	480	Visible	_	In vivo bladder tissue	_	_	_	The overall fluorescence intensity of bladder tumor tissue was found to be much less than that of normal tissue, regardless of stage	104

Bladder tissue (normal, inflammatory mucosa, and neoplastic urothelial lesion)	Bladder cancer	_	_	308	360 and 440	_	<i>In vivo</i> bladder tissue	_	_	_	Ratiometric analyses of the autofluorescence intensity at 360 to 440 nm were used to differentiate normal or inflamed tissue from neoplastic lesions	105
Bladder tissue (normal, inflammatory mucosa, and neoplastic urothelial lesion)	Bladder cancer	_	_	337	Visible	_	In vivo bladder tissue	_	_	_	Autofluorescence intensity of tumors was significantly less than that of normal tissue	105
Bladder tissue (normal, inflammatory mucosa, and neoplastic urothelial lesion)	Bladder cancer	_	_	488	Visible	_	<i>In vivo</i> bladder tissue	_	_	_	Autofluorescence intensity of tumors was significantly less than that of normal tissue	105
Bladder tissue (normal, inflammatory mucosa, and neoplastic urothelial lesion)	Bladder cancer	_	_	337	385 and 455	_	<i>In vivo</i> bladder tissue	_	_	_	Ratiometric analyses based on tissue autofluorescence were used to correctly identify bladder lesions	106
Brain tissue (normal and malignant gliomas)	Brain cancer	_	_	460 and 625	Visible/ red/near infrared		<i>In vivo</i> brain tissue		_	_	By combining autofluorescence and diffuse reflectance, differentiation of normal and malignant brain tissue has been shown to be feasible	107

TABLE 65.9B Fluorescence Data: Cellular Studies, Tissue and Biofluid Studies (in Vitro), Animal Studies (in Vivo), and Human Clinical Studies (in Vivo) (continued)

Species	Target Organ or Disease	Absorbance Maxima (nm)	Molar Extinction Coefficient (M ⁻¹)	Excitation λ_{ex} (nm)	Emission λ_{em} (nm)	Quantum Yield	Matrix	Lifetime τ1 (rel % τ1)	Lifetime τ2 (rel % τ2)	Lifetime τ3 (rel % τ3)	Comments	Ref.
Bronchial tissue (normal and tumor)	Lung cancer	_	_	480	Visible	_	In vivo lung tissue	_	_	_	Spectral and temporal differences in the autofluorescence emission were used to differentiate normal and tumor tissues	103
Bronchial tissue (normal, dyplastic, and carcinoma <i>in</i> <i>situ</i> (CIS))	Lung cancer	_	_	325	Green/red	_	In vivo lung tissue	_	_	_	Ratiometric measurements of lung tissue over the red and green regions of the spectrum were used to diagnose the tissue as normal, dysplastic, or CIS	108
Bronchial tissue (normal, metaplastic, and early cancer)	Lung cancer	_	_	350–495	Green-red	_	In vivo lung tissue	_	_	_	Absolute autofluorescence measurements allowed for the differentiation of normal, metaplastic, and early cancerous stages of lung tissue	109

Bronchial tissue (normal, metaplastic, and early cancer)	Lung cancer	_	_	400–480	600–800	_	In vivo lung tissue	_	_	_	Autofluorescence differences between normal, metaplastic, and dysplastic tissue were found, with the optimal excitation wavelength for differentiation being 405 nm	110
Cervical tissue (normal and tumor)	Cervical cancer	_	_	330	385	_	In vivo cervical tissue	_	_	_	The averaged normalized fluorescence intensity was found to be greater for normal tissue as compared to abnormal tissue	68
Cervical tissue (normal, non- neoplastic normal, and intraepithelial neoplasia (CIN))	Cervical cancer	_	_	337	Visible	_	In vivo cervical tissue	_	_	_	Differentiation of tissues was performed based on changes in tissue autofluorescence related to the species collagen, oxyhemoglobin, and NAD(P)H	112
Collagen	Colon cancer	_	_	337	390	_	In vivo colon tissue	_	_	_	Normal colonic tissue showed a decrease in autofluorescence intensity due to collagen relative to hyperplastic or adenomatous tissues	113

TABLE 65.9B Fluorescence Data: Cellular Studies, Tissue and Biofluid Studies (in Vitro), Animal Studies (in Vivo), and Human Clinical Studies (in Vivo) (continued)

Species	Target Organ or Disease	Absorbance Maxima (nm)	$\begin{array}{c} Molar \\ Extinction \\ Coefficient \\ (M^{-1}) \end{array}$	Excitation λ_{ex} (nm)	$Emission \\ \lambda_{em} \ (nm)$	Quantum Yield	Matrix	Lifetime τ1 (rel % τ1)	Lifetime τ2 (rel % τ2)	Lifetime τ3 (rel % τ3)	Comments	Ref.
Endogenous skin protoporphyrins	Skin cancer	_	_	Visible	600, 620, 640, and 670	_	In vivo skin tissue	1–5	_	_	Lipophile skin bacterium, Propionibacterium acnes, that upon irradiation caused photodynamic activity, was studied	114
Esophageal tissue (normal and tumor)	Esophageal cancer	_	_	410	450–600	_	In vivo esophageal tissue	_	_	_	Tumor tissue exhibited a decrease in normalized fluorescence intensity at 480 nm relative to normal tissue	115, 116
Esophageal tissue (normal and tumor)	Esophageal cancer	_	_	Violet-blue	450–700	_	In vivo esophageal tissue	_	_	_	Specific differences in the autofluorescence spectra of esophageal squamous cell carcinoma, adenocarcinoma of the esphophagus, and adenocarcinoma of the stomach were found	117, 118

Esophageal tissue (normal and tumor)	Esophageal cancer	_	_	337	370–490	_	In vivo esophageal tissue	_	_	_	Spectral and temporal differences in the autofluorescence emission were used to differentiate normal and tumor tissues	103
Flavoproteins in skin tissue	Skin cancer	_	_	960 (2 photon absorp- tion)	520	_	<i>In vivo</i> skin tissue	_	_	_	Confocal microscopy was used to determine the spatial location of various autofluorescent species within skin cells	119
Human cornea	Diabetes	_	_	360–370	532–630	_	<i>In vivo</i> human eyes	_	_	_	Autofluorescence measurements were used to distinguish healthy patients from patients with diabetes mellitus	120
Human cornea	Diabetes	_	_	400–410	532–630	_	<i>In vivo</i> human eyes	_	_	_	Autofluorescence measurements were used to distinguish healthy patients from patients with diabetes mellitus	120
Human cornea	Diabetes	_	_	415–425	532–630	_	<i>In vivo</i> human eyes	_	_	_	Autofluorescence measurements were used to distinguish healthy patients from patients with diabetes mellitus	120

Species	Target Organ or Disease	Absorbance Maxima (nm)	Molar Extinction Coefficient (M ⁻¹)	Excitation λ_{ex} (nm)	Emission λ_{em} (nm)	Quantum Yield	Matrix	Lifetime τ1 (rel % τ1)	Lifetime τ2 (rel % τ2)	Lifetime τ3 (rel % τ3)	Comments	Ref.
Human cornea	Diabetes	_	_	425–435	532–630	_	<i>In vivo</i> human eyes	_	_	_	Autofluorescence measurements were used to distinguish healthy patients from patients with diabetes mellitus	120
Human cornea	Diabetes	_	_	431–441	532–630	_	<i>In vivo</i> human eyes	_	_	_	Autofluorescence measurements were used to distinguish healthy patients from patients with diabetes mellitus	120
Human cornea	Diabetes	_	_	435–445	532–630	_	<i>In vivo</i> human eyes	_	_	_	Autofluorescence measurements were used to distinguish healthy patients from patients with diabetes mellitus	120
Human cornea	Diabetes	_	_	445–455	532–630	_	In vivo human eyes	_	_	_	Autofluorescence measurements were used to distinguish healthy patients from patients with diabetes mellitus	120

Human cornea	Diabetes	_	_	465–475	532–630	_	<i>In vivo</i> human eyes	_	_	_	Autofluorescence measurements were used to distinguish healthy patients from patients with diabetes mellitus	120
Human cornea	Diabetes	_	_	475–485	532–630	_	<i>In vivo</i> human eyes	_	_	_	Autofluorescence measurements were used to distinguish healthy patients from patients with diabetes mellitus	120
Human cornea	Diabetes	_	_	415–491	515–630	_	<i>In vivo</i> human eyes	_	_	_	Corneal autofluorescence was found to increase in people with diabetes mellitus	121
Human eye lens	Vision problems	_	_	Ultraviolet/ blue	495–520	_	<i>In vivo</i> human eyes	_	_	_	Lens autofluorescence could be correlated to coloration and opalescence of the lens nucleus in humans	122
Human eye lens	Vision problems	_	_	430–490	530–630	_	Human eye lens	_	_	_	Intrinsic eye lens transmittance can be determined based on autofluorescence analyses	75

TABLE 65.9B Fluorescence Data: Cellular Studies, Tissue and Biofluid Studies (in Vitro), Animal Studies (in Vivo), and Human Clinical Studies (in Vivo) (continued)

Species	Target Organ or Disease	Absorbance Maxima (nm)	Molar Extinction Coefficient (M ⁻¹)	Excitation λ_{ex} (nm)	Emission λ_{em} (nm)	Quantum Yield	Matrix	Lifetime τ1 (rel % τ1)	Lifetime τ2 (rel % τ2)	Lifetime τ3 (rel % τ3)	Comments	Ref.
Laryngeal tissues (normal and tumor)	Laryngeal cancer	_	_	325	Visible	_	In vivo laryngeal tissue	_	_	_	Images were obtained over several emission bands and ratiometric analyses were performed to differentiate normal tissue from carcinoma tissue	123
Laryngeal tissues (normal and tumor)	Laryngeal cancer	_	_	375–440	Green	_	In vivo laryngeal tissue	_	_	_	Tumor autofluorescence intensity was greatly reduced relative to surrounding normal tissue	124
Laryngeal tissues (normal, dysplastic, carcinoma in situ, and microinvasive lesions)	Laryngeal cancer	_	_	380–460	Light green	_	In vivo laryngeal tissue	_	_	_	Autofluorescence diagnoses were capable of distinguishing normal tissue, dysplastic tissue, carcinoma in situ, and microinvasive lesions	125
Lipofuscin	Vision problems	_	_	Visible	710	_	<i>In vivo</i> human eyes	_	_	_	Measurements of macular pigment density could be determined based on autofluorescence	126

Nicotinamide adenine dinucleotide	Colon cancer	_	_	337	460	_	In vivo colon tissue	_	_	_	_	127
(NADH) reduced Nicotinamide adenine dinucleotide (NADH) reduced	Colon cancer	_	_	370	460	_	In vivo colon tissue	_	_	_	Ratiometric analyses of autofluorescence emission were used to identify tissues as normal, hyperplastic, or adenomatous	128
Oral tissues (connective tissues)	Oral cancer	_	_	365	Visible	_	In vivo oral tissue	_	_	_	Tumor margining was performed using 365-nm light to excite the edges of the tumor	129
Oral tissues (normal and tumor)	Oral cancer	_	_	370	630–640	_	<i>In vivo</i> oral tissue	_	_	_	Differences between normal and neoplastic tissues were found based on its autofluorescence emission	130
Oral tissues (normal and tumor)	Oral cancer	_	_	410	630–640	_	In vivo oral tissue	_	_	_	Differences in the autofluorescence emission between normal and neoplastic tissues was found to be optimal following 410-nm excitation	130
Oral tissues (normal and tumor)	Oral cancer	_	_	337	Visible	_	In vivo oral tissue	_	_	_	Autofluorescence intensity of contralateral sites was much greater than the abnormal sites	131

TABLE 65.9B Fluorescence Data: Cellular Studies, Tissue and Biofluid Studies (in Vitro), Animal Studies (in Vivo), and Human Clinical Studies (in Vivo) (continued)

Species	Target Organ or Disease	Absorbance Maxima (nm)	Molar Extinction Coefficient (M ⁻¹)	Excitation λ_{ex} (nm)	Emission λ_{em} (nm)	Quantum Yield	Matrix	Lifetime τ1 (rel % τ1)	Lifetime τ2 (rel % τ2)	Lifetime τ3 (rel % τ3)	Comments	Ref.
Oral tissues (normal and tumor)	Oral cancer	_	_	410	Red/blue	_	In vivo oral tissue		_	_	The ratio of red fluorescence to blue fluorescence was greater in abnormal tissue than contralateral areas	131
Oral tissues (normal and tumor)	Oral cancer	_	_	442	Red/green	_	In vivo oral tissue	_	_	_	Ratiometric images of red autofluorescence and green autofluorescence images were used to identify oral cavity neoplasia	132
Oral tissues (normal and tumor)	Oral cancer	_	_	360	> 480	_	In vivo oral tissue	_	_	_	Fluorescence photography of the tissue autofluorescence could be used to distinguish between benign and malignant oral cavity tumors	133
Oral tissues (normal and tumor)	Oral cancer	_	_	350	472	_	In vivo oral tissue	_	_	_	Identification of oral cavity neoplasia was demonstrated based on the tissue autofluorescence	134

Oral tissues (normal and tumor)	Oral cancer	_	_	380	472	_	In vivo oral tissue	_	_	_	Identification of oral cavity neoplasia was demonstrated based on the tissue autofluorescence	134
Oral tissues (normal and tumor)	Oral cancer	_	_	400	472	_	In vivo oral tissue	_	_	_	Identification of oral cavity neoplasia was demonstrated based on the tissue autofluorescence	134
Oral tissues (normal and tumor)	Oral cancer	_	_	330	380	_	<i>In vivo</i> oral tissue	_	_	_	Differentiation of normal and tumor tissues was performed based on a decrease in the 330-nm exciation band in tumor tissue	135
Oral tissues (normal and tumor)	Oral cancer	_	_	340	390	_	<i>In vivo</i> oral tissue	_	_	_	Diagnosis of the stage of dysplasia was determined based on changes in the autofluorescence emission intensity at 390 nm	135
Oral tissues (normal and tumor)	Oral cancer	_	_	370	Visible	_	In vivo oral tissue	_	_	_	—	130
Oral tissues (normal and tumor)	Oral cancer	_	_	410	Visible	_	In vivo oral tissue	_	_	_	_	130
Pharynx tissues (normal and tumor)	Oral cancer	_	_	370	Visible	_	In vivo pharynx tissue	_	_	_	_	130
Pharynx tissues (normal and tumor)	Oral cancer	_	_	410	Visible	_	<i>In vivo</i> pharynx tissue	_	_	_	_	130

TABLE 65.9B Fluorescence Data: Cellular Studies, Tissue and Biofluid Studies (in Vitro), Animal Studies (in Vivo), and Human Clinical Studies (in Vivo) (continued)

Species	Target Organ or Disease	Absorbance Maxima (nm)	Molar Extinction Coefficient (M ⁻¹)	Excitation λ_{ex} (nm)	Emission λ_{em} (nm)	Quantum Yield	Matrix	Lifetime τ1 (rel % τ1)	Lifetime τ2 (rel % τ2)	Lifetime τ3 (rel % τ3)	Comments	Ref.
Pharynx tissues (normal and tumor)	Oropharyngeal cancer	_	_	330	380	_	In vivo pharynx tissue	_	_	_	Differentiation of normal and tumor tissues was performed based on a decrease in the 330-nm excitation band in tumor tissue	135
Pharynx tissues (normal and tumor)	Oropharyngeal cancer	_	_	340	390	_	In vivo pharynx tissue	_	_	_	Diagnosis of the stage of dysplasia was determined based on changes in the autofluorescence emission intensity at 390 nm	135
Photogem	Various cancers	_	_	510	Red/near infrared	_	In vivo tissues (lungs, larynx, skin, gastric, esophageal, and gynecological)	_	_	_	Drug accumulation studies were performed and it was found that the accumulation depended dramatically on the tissue type and	136
Protoporphyrin (5- aminolevulinic acid hexylester hydrochloride- induced)	Various cancers	_	_	Visible	Red	_	In vivo bladder tissue	15.9 ± 1.2	_	_	stage of cancer PpIX was found to exhibit an mono- exponential decay of 15.9 ns in bladder tissue	103

Protoporphyrin (ALA-induced)	Various cancers	_	_	405	550–750	_	In vivo skin tissue	_	_	_	Diagnoses of malignant melanomas based on multiple ratiometric measurements were performed	137
Protoporphyrin (ALA-induced)	Various cancers	_	_	435	550–750	_	In vivo skin tissue	_	_	_	Diagnoses of malignant melanomas based on multiple ratiometric measurements were performed	137
Protoporphyrin (ALA-induced)	Various cancers	_	_	375–440	Green/red	_	In vivo oral tissue	_	_	_	Ratiometric images of both the red (PpIX) fluorescence and green (background) fluorescence were used to differentiate normal and tumor tissues	138
Protoporphyrin (ALA-induced)	Various cancers	_	_	Visible	Red	_	<i>In vivo</i> tumor flank before irradiation	0.230 (17)	17.1 (83)	_	_	139
Protoporphyrin (ALA-induced)	Various cancers	_	_	visible	Red	_	In vivo tumor flank after irradiation	0.270 (5.5)	5 (45)	_	_	139
Protoporphyrin (ALA-induced)	Various cancers	_	_	375–440	Red	_	In vivo laryngeal tissue	_	_	_	PpIX fluorescence allowed for the differentiation of normal tissue from malignant neoplasms	124

TABLE 65.9B Fluorescence Data: Cellular Studies, Tissue and Biofluid Studies (in Vitro), Animal Studies (in Vivo), and Human Clinical Studies (in Vivo) (continued)

Species	Target Organ or Disease	Absorbance Maxima (nm)	Molar Extinction Coefficient (M ⁻¹)	Excitation λ_{ex} (nm)	$Emission \\ \lambda_{em} \ (nm)$	Quantum Yield	Matrix	Lifetime τ1 (rel % τ1)	Lifetime τ2 (rel % τ2)	Lifetime τ3 (rel % τ3)	Comments	Ref.
Protoporphyrin (ALA-induced)	Various cancers	_	_	375–440	Red	_	In vivo oral tissue	_	_	_	PpIX fluorescence allowed for the differentiation of normal tissue from malignant neoplasms and was found to have a 10:1 contrast between malignant and normal tissues	140
Reduced pyridine nucleotides in skin tissue	Skin cancer	_	_	730 (2 photon absorp- tion)	Visible	_	In vivo skin tissue	_	_	_	Confocal microscopy was used to determine the spatial location of various autofluorescent species within skin cells	119
Skin tissue	Skin cancer	_	_	960 (3 photon absorp- tion)	425	_	In vivo skin tissue	_	_	_	Confocal microscopy was used to determine the spatial location of various autofluorescent species within skin cells	119
Skin tissue	Skin cancer	_	_	325	Visible	_	In vivo skin tissue	_	_	_	Autofluorescence emission was found to correlate to photoaging of the skin	141

Skin tissue	Skin cancer	_	_	365	440	_	In vivo skin tissue	_	_	_	Results demonstrated that there was no difference between normal and non- melanoma tumors	
Skin tissue	Skin cancer	_	_	375	400–700 (peak at 436)	_	<i>In vivo</i> skin tissue	_	_	_	Results demonstrated that there was no difference between normal and non- melanoma tumors	
Skin tissue	Skin cancer	_	_	380	470	_	<i>In vivo</i> skin tissue	_	_	_	Autofluorescence emission resulting from a skin sample was found to strongly depend on the absorption and scattering properties of the tissue	143
Tongue tissue (normal and moderately differentiated squamous cell carcinoma)	Oral cancer	_	_	350	390–625	_	In vivo tongue tissue	_	_	_	Abnormal tissue displayed a reduced fluorescence emission between 400 and 450 nm relative to normal tissue	144

TABLE 65.9B Fluorescence Data: Cellular Studies, Tissue and Biofluid Studies (in Vitro), Animal Studies (in Vivo), and Human Clinical Studies (in Vivo) (continued)

Species	Target Organ or Disease	Absorbance Maxima (nm)	Molar Extinction Coefficient (M ⁻¹)	Excitation λ_{ex} (nm)	Emission λ_{em} (nm)	Quantum Yield	Matrix	Lifetime τ1 (rel % τ1)	Lifetime τ2 (rel % τ2)	Lifetime τ3 (rel % τ3)	Comments	Ref.
Tongue tissue (normal and moderately differentiated squamous cell carcinoma)	Oral cancer	_	_	410	460–675	-	In vivo tongue tissue	_	_	_	Abnormal tissue displayed a dramatic decrease in fluorescence intensity over the entire specrum, as well as a distinct peak at approximately 630 nm	144
Tongue tissue (normal and moderately differentiated squamous cell carcinoma)	Oral cancer	_	_	460	490–720	_	In vivo tongue tissue	_	_	_	Abnormal tissue displayed a dramatic decrease in fluorescence intensity over the entire specrum	144

65.3.5 Elemental Analysis

Table 65.10 provides a quick reference of publications pertaining to the elemental analysis using a variety of techniques for biomedical applications. The techniques used to perform the analyses are abbreviated as follows: AAS = atomic absorption spectroscopy; AES = atomic emission spectroscopy; AES = atomic emission spectroscopy; AES = atomic emission spectroscopy; AES = particle-induced x-ray emission; AES = microwave-induced plasma-atomic emission spectroscopy; AES = inductively coupled plasma-atomic emission spectroscopy; AES = microwave plasma atomic emission spectroscopy. AES = microwave plasma atomic emission spectroscopy; AES = microwave plasma atomic emission spectroscopy. AES = microwave plasma atomic emission spectroscopy; AES = microw
