The *Biomedical Photonics Handbook* is intended to serve as an authoritative reference source for a broad audience involved in the research, teaching, learning, and practice of medical technologies. Biomedical photonics is defined as the science that harnesses light and other forms of radiant energy to solve problems arising in medicine and biology. This research field has recently experienced an explosive growth due to the noninvasive or minimally invasive nature and cost-effectiveness of photonic modalities in medical diagnostics and therapy.

The field of biomedical photonics did not emerge as a well-defined, single research discipline like chemistry, physics, or biology. Its development and growth have been shaped by the convergence of three scientific and technological revolutions of the 20th century: the quantum theory revolution, the technology revolution, and the genomics revolution.

The quantum theory of atomic phenomena provides a fundamental framework for molecular biology and genetics because of its unique understanding of electrons, atoms, molecules, and light itself. Out of this new scientific framework emerged the discovery of the structure of DNA, the molecular nature of cell machinery, and the genetic cause of diseases, all of which form the basis of molecular medicine. The formulation of quantum theory not only gave birth to the field of molecular spectroscopy but also led to the development of a powerful set of photonics tools — lasers, scanning tunneling microscopes, near-field nanoprobes — for exploring nature and understanding the cause of disease at the fundamental level.

Advances in technology also played, and continue to play, an essential role in the development of biomedical photonics. The invention of the laser was an important milestone; the laser is now the light source most widely used to excite tissues for disease diagnosis as well as to irradiate tumors for tissue removal in interventional surgery ("optical scalpels"). The microchip is another important technological development that has significantly accelerated the evolution of biomedical photonics. Although the laser has provided a new technology for excitation, the miniaturization and mass production of integrated circuits, sensor devices, and their associated electronic circuitry made possible by the microchip has radically transformed the ways in which detection and imaging of molecules, tissues, and organs can be performed *in vivo* and *ex vivo*.

Recently, nanotechnology, which involves research on materials and species at length scales between 1 to 100 nm, has been revolutionizing important areas in biomedical photonics, especially diagnostics and therapy at the molecular and cellular levels. The combination of photonics and nanotechnology has already led to a new generation of devices for probing the cell machinery and elucidating intimate life processes occurring at the molecular level heretofore invisible to human inquiry. This will open the possibility of detecting and manipulating atoms and molecules using nanodevices, which have the potential for a wide variety of medical uses at the cellular level. The marriage of electronics, biomaterials, and photonics is expected to revolutionize many areas of medicine in the 21st century.

A wide variety of biomedical photonic technologies have already been developed for clinical monitoring of early disease states or physiological parameters such as blood pressure, blood chemistry, pH, temperature,

and the presence of pathological organisms or biochemical species of clinical importance. Advanced optical concepts using various spectroscopic modalities (e.g., fluorescence, scattering, reflection, and optical coherence tomography) are emerging in the important area of functional imaging. Many photonic technologies originally developed for other applications (e.g., lasers and sensor systems in defense, energy, and aerospace) have now found important uses in medical applications. From the brain to the sinuses to the abdomen, precision navigation and tracking techniques are critical to position medical instruments precisely within the three-dimensional surgical space. For instance, optical stereotactic systems are being developed for brain surgery and flexible micronavigation devices engineered for medical laser ablation treatments.

With completion of the sequencing of the human genome, one of the greatest impacts of genomics and proteomics is the establishment of an entirely new approach to biomedical research. With whole-genome sequences and new automated, high-throughput systems, photonic technologies such as biochips and microarrays can address biological and medical problems systematically and on a large scale in a massively parallel manner. They provide the tools to study how tens of thousands of genes and proteins work together in interconnected networks to orchestrate the chemistry of life. Specific genes have been deciphered and linked to numerous diseases and disorders, including breast cancer, muscle disease, deafness, and blindness. Furthermore, advanced biophotonics has contributed dramatically to the field of diagnostics, therapy, and drug discovery in the post-genomic area. Genomics and proteomics present the drug discovery community with a wealth of new potential targets.

Biomedical photonics can provide tools capable of identifying specific subsets of genes, encoded within the human genome, which can cause development of disease. Photonic techniques based on molecular probes are being developed to identify the molecular alterations that distinguish a diseased cell from a normal cell. Such technologies will ultimately aid in characterizing and predicting the pathologic behavior of that diseased cell, as well as the cell's responsiveness to drug treatment. Information from the human genome project will one day make personal, molecular medicine an exciting reality.

This 1800-page handbook presents the most recent scientific and technological advances in biomedical photonics, as well as their practical applications, in a single source. The book represents the work of 150 scientists, engineers, and clinicians. Each of the 65 chapters provides introductory material with an overview of the topic of interest as well as a collection of published data with an extensive list of references for further details. The chapters are grouped in seven sections followed by an appendix of spectroscopic databases:

- I. *Photonics and Tissue Optics* contains three introductory chapters on the fundamental optical properties of tissue, light–tissue interactions, and theoretical models for optical imaging.
- II. Photonic Devices deals with basic instrumentation and hardware systems and contains chapters on lasers and excitation sources, basic optical instrumentation, optical fibers and waveguides, and spectroscopic systems.
- III. Photonic Detection and Imaging Techniques deals with methodologies and contains nine chapters on various detection techniques and systems (lifetime imaging, microscopy, near-field detection, optical coherence tomography, interferometry, Doppler imaging, light scattering, and thermal imaging).
- IV. *Biomedical Diagnostics I* contains ten chapters describing *in vitro* diagnostics (glucose diagnostics, *in vitro* instrumentation, biosensors, capillary electrophoresis, and flow cytometry) and *in vivo* diagnostics (functional imaging and photon migration spectroscopy). Two chapters describe specific techniques and applications of two important and mature technologies x-ray diagnostics and optical pumping in magnetic resonance imaging.

- V. Biomedical Diagnostics II: Optical Biopsy is composed of eight chapters mainly devoted to novel optical techniques for cancer diagnostics, often referred to as "optical biopsy" (fluorescence, scattering, reflectance, Raman, infrared, optoacoustics, and ultrasonically modulated optical imaging).
- VI. Interventional and Treatment Techniques discusses in 15 chapters photodynamic therapy and various laser-based treatment techniques that are applied to various organs and disease endpoints (dermatology, pulmonary, neurosurgery, ophthalmology, otolaryngology, urology, gastroenterology, and dentistry).
- VII. Advanced Biophotonics for Genomics, Proteomics, and Medicine examines the most recent advances in methods and instrumentation for biomedical and biotechnology applications. This section contains 14 chapters on emerging photonic technologies (e.g., biochips, nanosensors, quantum dots, molecular probes, bioluminescent reporters, optical tweezers) being developed for gene expression research, gene diagnostics, protein profiling, and molecular biology investigations for the "new medicine."
- VIII. Appendix provides a comprehensive, single-chapter compilation of useful information on spectroscopic data of biologically and medically relevant species for more than 1000 compounds and systems.

The goal of this handbook is to provide a comprehensive forum that integrates interdisciplinary research and development of interest to scientists, engineers, manufacturers, teachers, students, and clinical providers. The handbook is designed to present the most recent advances in instrumentation and methods as well as clinical applications in important areas of biomedical photonics. Because light is rapidly becoming an important diagnostic tool and a powerful weapon in the armory of the modern physician, it is our hope that this handbook will stimulate a greater appreciation of the usefulness, efficiency, and potential of photonics in medicine.

Tuan Vo-Dinh Oak Ridge National Laboratory Oak Ridge, Tennessee February 2003

Acknowledgments

The completion of this work was made possible with the assistance of many friends and colleagues. It is a great pleasure for me to acknowledge, with deep gratitude, the contributions of the 150 contributors to the 65 chapters of this 1800-page handbook. I am indebted to the members of the Scientific Advisory Board, Drs. Mitchel S. Berger, Britton Chance, Thomas J. Dougherty, Daniel L. Farkas, James G. Fujimoto, Warren S. Grundfest, Leroy Hood, Joseph R. Lakowicz, Vladilen S. Letokhov, Praveen N. Mathur, Nitish V. Thakor, and Tony Wilson. Their thoughtful suggestions and useful advice in the planning phase of the project were important in achieving the breadth and depth of this handbook.

I wish to thank many scientists and co-workers at the Oak Ridge National Laboratory (ORNL) and many colleagues in academia for their kind help with reading and commenting on various chapters of the manuscript. I wish to thank my administrative assistant, Julia B. Cooper, at ORNL for her dedicated, efficient, and timely assistance over many years. The kind assistance of Dr. David Packer, the cheerful help of Debbie Vescio, and the tireless and dedicated afforts of Christine Andreasen at CRC Press are much appreciated. I greatly appreciate the collaboration and friendship of many colleagues, including Drs. Mitchel S. Berger, Martin Holland, Geoff Ling, Praveen N. Mathur, G. Wayne Morrison, Bergein F. Overholt, Masoud Panjehpour, and William P. Wiesmann, with whom I have had the opportunity to initiate various biomedical projects. My gratitude is extended to Dr. Urs P. Wild at the ETH in Zurich, Switzerland and Dr. James D. Winefordner at the University of Florida for kind advice in my early research in photonics. I would like to thank Drs. Barry A. Berven, W. Frank Harris, Lee L. Riedinger, and William J. Madia at ORNL and Drs. Michael Viola and Dean Cole at the Department of Energy (DOE) for their continued support throughout this undertaking.

I gratefully acknowledge the support of the DOE Office of Biological and Environmental Research, the National Institutes of Health, the Army Medical Research and Materiel Command, the Department of Justice, the Federal Bureau of Investigation, the Office of Naval Research, and the Environmental Protection Agency.

The completion of this work was made possible with the encouragement, love, and inspiration of my wife, Kim-Chi, and my daughter, Jade.

Tuan Vo-Dinh

Editor-in-Chief

Tuan Vo-Dinh, Ph.D., is a Corporate Fellow, Group Leader of the Advanced Biomedical Science and Technology Group, and Director of the Center for Advanced Biomedical Photonics, Oak Ridge National Laboratory (ORNL), Oak Ridge, Tennessee. He is also an Adjunct Professor at the University of California, San Francisco and the University of Tennessee, Knoxville. A native of Vietnam and a naturalized U.S. citizen, Dr. Vo-Dinh completed his high school education in Saigon (now Ho Chi Minh City). He continued his studies in Europe, where he received a Ph.D. in biophysical chemistry in 1975 from the Swiss Federal Institute of Technology (known as the ETH) in Zurich, Switzerland. His research interests have focused on the development of advanced technologies for the protection of the environment and the improvement of human health. His research activities involve laser spectroscopy, molecular imaging, medical diagnostics, cancer detection, chemical sensors, biosensors, nanosensors, and biochips.

Dr. Vo-Dinh has published more than 300 peer-reviewed scientific papers. He is an author of a textbook on spectroscopy and the editor of four books. He holds more than 26 patents, 5 of which have been licensed to environmental and biotech companies for commercial development. Dr. Vo-Dinh is a fellow of the American Institute of Chemists and of SPIE, the International Society for Optical Engineering. He serves on editorial boards of various international journals on molecular spectroscopy, analytical chemistry, biomedical optics, and medical diagnostics. He also serves the scientific community through his participation in a wide range of governmental and industrial boards and advisory committees.

Dr. Vo-Dinh has received six R&D 100 Awards for Most Technologically Significant Advance in Research and Development for his pioneering research and inventions of various innovative technologies, including a chemical dosimeter (1981), an antibody biosensor (1987), the SERODS optical data storage system (1992), a spot test for environmental pollutants (1994), the SERS gene probe technology for DNA detection (1996) and the multifunctional biochip for medical diagnostics and pathogen detection (1999). He received the Gold Medal Award, Society for Applied Spectroscopy (1988); the Languedoc-Roussillon Award (France; 1989), the Scientist of the Year Award, Oak Ridge National Laboratory (1992); the Thomas Jefferson Award, Martin Marietta Corporation (1992); two Awards for Excellence in Technology Transfer, Federal Laboratory Consortium (1995, 1986); the Inventor of the Year Award, the Tennessee Inventors Association (1996); and the Lockheed Martin Technology Commercialization Award (1998). In 1997, Dr. Vo-Dinh was awarded the Exceptional Services Award for distinguished contribution to a Healthy Citizenry from the U.S. Department of Energy.

1.1 Introduction

Throughout human history, light has played an important role in medicine. In prehistoric times, the healing power of light was often attributed to mythological, religious, and supernatural powers. The history of light therapy dates back to the ancient Egyptians, Hindus, Romans, and Greeks, all of whom created temples to worship the therapeutic powers of light, especially sunlight, for healing the body as well as the mind and the soul. In Hindu mythology, Dhanvantar, originally a sun god, is physician of the gods and a teacher of healing arts to humans. In Greek mythology, Apollo, the god of healing, who taught medicine to man, is also called the sun god or the "god of light." These and other mythological figures are testaments to humankind's recognition of the healing power of light since the dawn of time.

The contribution of light to medicine has evolved throughout human history with the advent of science and technology. In the 17th century, the invention of the microscope by Dutch investigators was critical to the development of biological and biomedical research for the next 200 years. Cell theory emerged in the 1830s, when German scientists M. J. Schleiden and Theodor Schwann looked into their microscopes and identified the cell as the basic unit of plant and animal tissue and metabolism. The microscope provided the central observation tool for a new style of research, out of which emerged the germ theory of disease, developed by Robert Koch and Louis Pasteur in the 1870s (Figure 1.1).

In the fall of 1895, the German physicist Wilhelm Roentgen, working with a standard piece of laboratory equipment, discovered a new type of radiation: the x-ray. This discovery extended the range of electromagnetic radiation well beyond its conventional limits. Furthermore, this discovery led to the development of a powerful new technique that uses x-rays to look into the intact body for disease diagnosis.

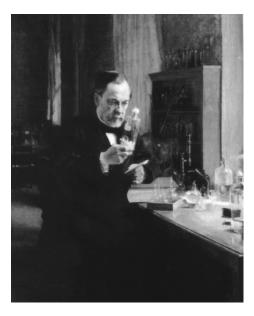

FIGURE 1.1 (Color figure follows p. 28-30.) Louis Pasteur used the microscope, which provided the central observation tool for a new style of research and out of which emerged the germ theory of disease. Albert Edelfelt's *Louis Pasteur* (1865), Musée d'Orsay, Paris, France. (®Réunion des Musées Nationaux/Art Resource, New York. Reproduced with permission of Artists Rights Society, New York.)

These examples are just some of the numerous cases where scientific discoveries and technological advances in photonics have opened new horizons to medicine and provided critical tools to investigate molecules, analyze tissue, and diagnose diseases.

1.2 Biomedical Photonics: A Definition

The field of biomedical photonics is often not well defined because it is a relatively new field that has emerged from research conducted at the interface of the physical and biological sciences and engineering. Therefore, it is useful to provide a definition here.

A related term that has commonly been used is "biomedical optics." Let us examine the similarity and difference between biomedical photonics and biomedical optics. By general definition, the field of optics involves "optical" light or "visible" light, which is a particular type of electromagnetic radiation that can be seen and sensed by the human eye. On the other hand, the field of photonics, which involves photons, the quanta of energy in the entire spectrum of electromagnetic radiation, is broader than the field of optics. We tend to think of optical radiation as "light," but the rainbow of colors that make up optical or visible light is just a very small part of a much broader range of the energy range of the photon.

Photonics includes optical and nonoptical technologies that deal with electromagnetic radiation, which is the energy propagated through space between electric and magnetic fields. The electromagnetic spectrum is the extent of that energy, ranging from cosmic rays, gamma rays, and x-rays throughout ultraviolet, visible, infrared, microwave, and radio frequency energy.

Biomedical photonics, therefore, may be defined as science and technology that use the entire range of electromagnetic radiation beyond visible light for medical applications. This field involves generating and harnessing light and other forms of radiant energy whose quantum unit is the photon. The science includes the use of light absorption, emission, transmission, scattering, amplification, and detection and uses a wide variety of methods and technologies, such as lasers and other light sources, fiber optics, electro-optical instrumentation, sophisticated microelectromechanical systems, and nanosystems, for medical applications. The range of applications of biomedical photonics extends from medical diagnostics to therapy and disease prevention.

1.3 Scientific and Technological Revolutions Shaping Biomedical Photonics

The field of biomedical photonics did not emerge as a well-defined, single research discipline like chemistry, physics, or biology. Its development and growth have been shaped by the convergence of three scientific and technological revolutions of the 20th century (Figure 1.2):

- The quantum theory revolution (1900–1950s)
- The technology revolution (1940s-1950s)
- The genomics revolution (1950s-2000)

Technological progress is usually represented as an "S curve," rising slowly at first, then more and more rapidly until it approaches natural limits, and then tending to level off to reach theoretical limits. Some examples of scientific discoveries and technological achievements are shown in Figure 1.2. The following sections discuss the three revolutions of the 20th century that have shaped the growth and development of biomedical photonics.

1.3.1 The Quantum Theory Revolution: A Historic Evolution of the Concept of Light

The field of photonics has significantly benefited from the development of quantum theory. With the advent of this theory, scientific fields such as molecular spectroscopy and photonic technologies (such as lasers, optical biopsy, optical tweezers, and near-field probes) have provided powerful tools to diagnose diseases noninvasively, interrogate the cell at the molecular level, and fight diseases at the gene level. The quantum theory of atomic phenomena provides a fundamental framework for molecular biology and genetics because of its unique understanding of electrons, atoms, and molecules, and light itself. Out of

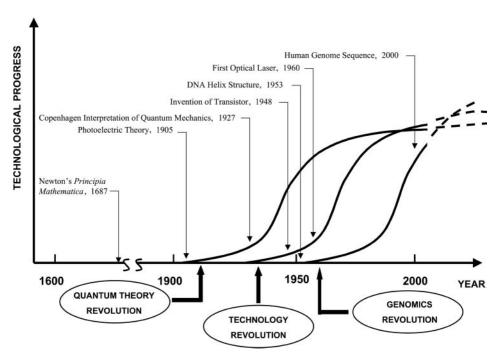

FIGURE 1.2 Three revolutions of the 20th century shaped biomedical photonics. Technological progress is usually represented as an "S curve," rising slowly at first, then more and more rapidly until it approaches natural limits, and then tending to level off to reach theoretical limits.

this new scientific framework emerged the discovery of the DNA structure, the molecular nature of cell machinery, and the genetic cause of diseases, all of which form the basis of molecular medicine.

Quantum theory was one of the most amazing discoveries of the 20th century and brought about a monumental paradigm shift. The concept of a paradigm was proposed by Thomas Kuhn in his seminal book *The Structure of Scientific Revolutions*.² According to Kuhn's thesis, scientists perform their investigation within the framework of a collective background of shared assumptions, which make up a paradigm. During any given period, the scientific community in a particular field of research has a prevailing paradigm that shapes, defines, and directs research activities in that field. People often become attached to their paradigms until a paradigm shift occurs when a major revolutionary discovery triggers a drastic change in beliefs, like the dramatic upheavals occurring in revolutions.

A dramatic paradigm shift occurred in the 17th century with René Descartes' mechanistic philosophy and Isaac Newton's scientific revolution. Descartes, a French mathematician and philosopher, established the firm belief in scientific knowledge that forms the basis of Cartesian philosophy and the worldview derived from it. According to Bertrand Russell, such a shift in thought "had not happened since Aristotle There is a freshness about [Descartes'] work that is not to be found in any eminent previous philosopher since Plato." For Descartes, the essence of human nature lies in thought, and all things conceived clearly and distinctly are true. Descartes' rational philosophy integrated a complete mechanistic interpretation of physics, biology, psychology, and medicine. His celebrated statement *Cogito, ergo sum* ("I think, therefore I am") has profoundly influenced Western civilization.

With Newton, a new agenda for scientific research in optics, mechanics, astronomy, and a wide variety of other fields was born. Newton's *Principia Mathematica Philosophica Naturalis*, a series of three books completed in 1687, laid the foundation for our understanding of the underlying physics of the world, which shaped the history of science and remained the main paradigm for the classical worldview for over two centuries. Newton's work concluded the intellectual quest that extended back through Galileo, Kepler, and Copernicus and, ultimately, back to Aristotle.

Since 300 B.C., Aristotle's work — which encompassed logic, physics, cosmology, psychology, natural history, anatomy, metaphysics, ethics, and aesthetics — had represented the culmination of the Hellenic Enlightenment Age and the source of science and higher learning for the following 2000 years. In the Aristotelian worldview, light was not considered among one of the four basic elements — air, earth, fire, and water — that made up the physical universe. In Newton's work, by contrast, light plays an important role in a series of three books called *Opticks*, which describes in detail a wide variety of light phenomena (such as the refraction of light, the nature of white light colors, thin-film phenomena) and optical instruments (such as the microscope and the telescope). Pewton performed groundbreaking experiments using optical instruments demonstrating that light was actually a mixture of colors by using a glass prism to separate the colors. In 1865, the British physicist James Clerk Maxwell developed the theory of light propagation by unifying the theories that describe the forces of electricity and magnetism.

Then a series of unexpected discoveries concerning the nature of light brought into question the underlying reality of the Newtonian worldview and set the stage for yet another monumental paradigm shift: the 20th century revolution in quantum physics launched by Albert Einstein. A phenomenon called the "photoelectric effect" raised intriguing questions about the exact nature of light. Discovered by Heinrich Hertz, the photoelectric effect dealt with an apparent paradox: when light irradiates certain materials, an electric current is produced, but only above a certain frequency (i.e., energy). Increasing the intensity of light that has a frequency below the requisite threshold will not induce a current. In 1901, the German physicist Max Planck suggested that light came only as discrete packets of energy.

However, Einstein, while working in the Swiss patent office after graduating from the Swiss Federal Institute of Technology in Zurich (known as the ETH), provided a comprehensive explanation of the photoelectric effect in a paper published in 1905 and launched the field of quantum mechanics. Einstein called the particles of light *quanta* (after the Latin *quantus* for "how much"); hence, the origin of the term "quantum theory." He showed that light consists neither of continuous waves, nor of small, hard particles. Instead, it exists as bundles of wave energy called photons. Each photon has an energy that corresponds to the frequency of the waves in the bundle. The higher the frequency (the bluer the color),

FIGURE 1.3 Albert Einstein launched the field of quantum mechanics, which provides the theoretical foundation for molecular spectroscopy and photonics. Einstein called the particles of light quanta (after the Latin *quantus* for "how much"); hence, the origin of the term "quantum theory." Einstein showed that light consists neither of continuous waves nor of small, hard particles. Instead, it exists as bundles of wave energy called photons. (Photo from Bildarchiv ETH-Bibliothek, Zurich, Switzerland. With permission.)

the greater the energy carried by that bundle. Einstein's Nobel Prize was awarded in 1921, not for his theories on relativity (the Nobel Committee thought them too speculative at the time), but for his quantum theory on the photoelectric effect (Figure 1.3).

Einstein published another extraordinary paper in 1905 that drastically redirected modern physics. This paper dealt with special relativity, or the physics of bodies moving uniformly relative to one another. Here again, light took a central role as the ultimate reference element having the highest speed in the universe. By postulating that nothing can move faster than light, Einstein reformulated Newtonian mechanics, which contains no such limitation. This is the heart of his celebrated formula $E = mc^2$, which equates mass (m) and energy (E), and makes the speed of light (c) a constant in the equation. Einstein's theory of relativity shattered the classical worldview based on the three-dimensional space of classical Euclidean geometry, Newtonian mechanics, and the concept of absolute space and time. In Einstein's worldview, the universe has no privileged frames of references, no master clock, and no absolute time, because the velocity of light is the ultimate limit in speed, constant in all directions.

Acceptance of quantum theory was further reinforced by research conducted by Ernest Rutherford and Niels Bohr, using radioactive emission as a tool to investigate the structure of the atom. Essentially, quantum theory replaced the mechanical model of the atom with one where atoms and all material objects are not sharply defined entities in the physical world but rather "fuzzy clouds" with a dual wave–particle nature. According to quantum theory, all objects, even the subatomic particles (electrons, protons, neutrons in the nucleus), are entities that have a dual aspect. Light and matter exhibit this duality, sometimes behaving as electromagnetic waves, sometimes as particles called photons. The existence of any molecule or object can be defined by a "probability wave," which predicts the likelihood of finding the object at a particular place within specific limits. The mathematical formulations developed by Werner Heisenberg, Erwin Schrodinger, and Paul Dirac from 1926 through 1933 firmly established the theoretical foundation of the quantum theory.

The rules that govern the subatomic world of blurry particles and nuclear forces are called quantum mechanics. In quantum mechanics, the state of a molecule is described by a wavefunction ψ , a function of the position and spins of all electrons and nuclei and the presence of any external field. The probability of finding the molecule at a particular position or spin is represented by the square of the amplitude of

wavefunction ψ . In other words, at the subatomic level, matter does not exist with certainty at definite places, but rather shows "probabilities to exist." Even Einstein could hardly accept the fundamental nature of probability in the quantum concept of reality, saying "God does not play dice with the universe."

By the 1930s, with such bizarre quantum entities as "spin" formulated by Wolfgang Pauli at the ETH (the Pauli exclusion principle), the worldview of quantum theory had completed its paradigm shift. Following a historic meeting in 1927, scientists acknowledged that a complete understanding of physical reality lies beyond the capabilities of rational thought, a conclusion known as the "Copenhagen Interpretation of Quantum Mechanics." The quantum worldview implies that the structure of matter is often not mechanical or visible, and that the reality of the world cannot be explained by the physical perceptions of the human senses. Coming into full circle, a seed of this new scientific concept of the 21st century rejoined an important aspect of Plato's philosophy in 400 B.C. that referred to the concrete objects of the visible world as imperfect copies of the forms of which they "partake." Similarities between quantum physics and many metaphysical concepts in Eastern philosophies and Western religions have been a topic of great interest.⁵

Quantum theory also had a profound effect on many fields beyond science, such as art. It is noteworthy that modern art, with its seemingly strange distortions of visual reality, also appeared in the 1930s. It was no coincidence that, during the quantum revolution in science, Cubist and Surrealist art abolished realistic shapes referenced in fixed space and fixed time. Pablo Picasso's renderings of the human face with their multifaceted perspectives often reflected the dual nature of reality (Figure 1.4); Salvador Dali's vision of melting clocks evoked the elasticity of a relativistic time. Henry Moore's sculptures reshaping the physical form of the human body marked a departure from geometric forms (Figure 1.5) and Joan Miró's paintings often instilled a feeling of cosmic interrelationship of space—time of the new physics.

FIGURE 1.4 (Color figure follows p. 28-30.) Quantum theory also had a profound effect on many fields beyond science, such as art. It was no coincidence that, during the quantum revolution in science, Cubist and Surrealist art abolished realistic shapes referenced in fixed space and fixed time. Pablo Picasso's renderings of the human face with multifaceted perspectives often reflected the dual nature of reality. *Portrait of Dora Maar* (1937), Musée Picasso, Paris, France. FIGURE 1.5 (Color figure follows p. 28-30.) It is noteworthy that modern art, with its seemingly strange distortions of visual reality, also appeared in the epoch of quantum theory. Henry Moore's sculptures reshaping the physical form of the human body marked a departure from geometric forms. *Reclining Figure* (1931), Dallas Museum of Art, Dallas, Texas. (From Kosinski, D., *Henry Moore: Sculpting the 20th Century*, Yale University Press, New Haven, CT, 2001, p. 91. Reprinted with permission from The Henry Moore Foundation.)

The Euclidean geometry of physical reality was further shattered by the creative movement of abstract art, which surged in the early 1910s with Wassili Kandinsky and Piet Mondrian and culminated in the 1950s with Jackson Pollock and Mark Rothko of the so-called New York School of Abstract Expressionism, where defined shapes and forms were replaced by shades, colors, and lines of fields — perhaps the visual equivalents of molecular waveforms, probability clouds, and energy fields of the new physics. The interdependence of science, technology, and art was well expressed in 1948 by Pollock in the avant-garde review *Possibilities*: "It seems to me that modern painting cannot express our area (the airplane, the atomic bomb, the radio) through forms inherited from the Renaissance and from any other culture of the past. Each area finds its own technique."

At the same time that Niels Bohr introduced his theory of complementarity on the dual wave–particle nature of light, the Swiss psychologist and philosopher Carl Jung proposed his theory of synchronicity, an "acausal connecting" phenomenon where an event in the physical world coincides meaningfully with a psychological state of mind. Jung associated synchronistic experiences with the relativity of space and time and a degree of unconsciousness. Synchronicity reflected an almost mystical connection between the personal psyche and the material world, which are essentially different forms of energy.^{7,8} Complementarity and synchronicity are concepts belonging to different fields, but both concepts, with their nature of duality, reflected the 20th century *Zeitgeist* of the quantum reality in the psyche and the physical world.

Quantum theory revolutionized molecular spectroscopy, an important field of photonics research. Molecular spectroscopy, which deals with the study of the interaction of light with matter, has been a cornerstone of the renaissance in biomedical photonics since the mid-1950s, mainly because of the foundations of quantum theory. How do we learn about the molecules that make up the cell, the tissues, and the organs when most of them are too small to be seen even with the most powerful microscopes? There is no simple answer to this question, but a large amount of information has come from various techniques of molecular spectroscopy.

Classical concepts of the world provide no simple way to explain the interaction of light with matter. The most satisfactory and complete description of the absorption and emission of light by matter is based on time-dependent wave mechanics. It analyzes what happens to the wavefunctions of molecules in the presence of light. Light is a rapidly oscillating electromagnetic field. Matter (including living species) is made up of molecules, which contain distributions of charges and spins that give matter its electrical and magnetic properties. These distributions are altered when a molecule is exposed to light.

The discovery of quantum theory has not only given birth to the new field of molecular spectroscopy, but also led to the development of a powerful set of photonics tools for exploring nature and understanding the cause of disease at the fundamental level. In essence, our current knowledge of how molecules

bind together, how the building blocks of DNA cause a cell to grow, and how disease progresses on the molecular level has its fundamental basis in quantum theory.

With molecular spectroscopy, light can be used in many different ways to analyze complex biological systems and understand nature at the molecular level. Light at a certain wavelength λ (or frequency $v = c/\lambda$) is used to irradiate the sample (e.g., a bodily fluid, a tissue, or an organ) in a process called excitation. Then some of the properties of the light that emerges from the sample are measured and analyzed. Some analyses deal with the fraction of the incident radiation absorbed by a sample; the techniques involved are called absorption spectroscopies (e.g., ultraviolet, visible, infrared absorption techniques). Other analyses examine the incident radiation dissipated and reflected back from the samples (elastic scattering techniques). Alternatively, it is possible to measure the light emitted and scattered by a sample, that occurs at wavelengths different from the excitation wavelength: in this case, the techniques involved are fluorescence, phosphorescence, Raman scattering, and inelastic scattering. Other specialized techniques can also be used to detect specific properties of emitted light (circular dichroism, polarization, lifetime, etc.).

The range of wavelengths used in molecular spectroscopy to study biological molecules is quite extensive. Molecular spectroscopic techniques have led to the development of a wide variety of practical techniques for minimally invasive monitoring of disease. For example, Britton Chance and co-workers have developed and used near-infrared absorption techniques to monitor physiological processes and brain function noninvasively. Today, a wide variety of molecular spectroscopic techniques, including fluorescence, Raman scattering, and bioluminescence, are being developed for cancer diagnosis, disease monitoring, and drug discovery. Table 1.1 summarizes the different types of spectroscopies and the wavelength of the electromagnetic radiation.

1.3.2 The Technology Revolution

In Western civilization science has often been associated with fundamental research and theoretical studies, whereas technology has often been viewed as originating from applied and experimental studies. Although the value of applied science was recognized very early by the mathematician Heron, who founded the first College of Technology in Alexandria in 105 B.C., ²⁶ science and technology have remained largely separate since the early times of Hellenic Greece. Aristotelian tradition held that the laws that govern the universe could be understood by pure thought, without requiring any experimental observation. In the 17th century, science and technology started to become interdependent. Galileo Galilei became a pivotal figure in the scientific revolution with his experimental observation of the movement of bodies by rolling balls of different weights down a slope. He also improved an important optical instrument, the telescope, which led to his revolutionary discoveries in astronomy.

The development and use of the microscope provided another revealing example of the interdependence between science and technology. It is very clear that it was indeed the discovery of a practical

instrument that led to fundamental discoveries supporting the germ theory of diseases two centuries later. The 17th century witnessed the rise and spread of experimental science. This interdependence began to emerge when people believed that science should be useful and applied. Francis Bacon advocated his empirical, inductive method of investigation and envisioned a role for experiments designed to test nature and verify a hypothesis using an inductive process.

Descartes proposed a completely mechanical view of the world, a physical universe of objects that moves as a clockwork according to the laws of physics and the principles of geometry; this represented a radical departure from the more abstract worldview that dated back to Aristotle. Father of the rationalistic mathematical philosophy, where rational thought and reason are the most important sources and tests of truth, Descartes was also influential in advocating what he called "practical philosophy" and the idea that knowledge should be applied "for the general good of all men." Opposing Cartesian rationalism based on pure thought and reason, British philosopher David Hume formulated his philosophy of empiricism, which regards empirical observation by the senses as the only reliable source of knowledge.

Shortly thereafter, the German philosopher Immanuel Kant built a bridge between pure thought and sensory perception and reconciled the philosophical divide between rationalists and empiricists (the so-called Battle of Descartes vs. Hume). In Kantian philosophy, the structure of consciousness, through an activity of thought called "synthesis," turns appearances observed by the senses into objects and perceptions, without which there would be nothing. Kant found roles for both the empiricist and the rationalist elements by including a rational element in his theory of knowledge (the 12 rational concepts of the understanding) with the publication in 1781 of his influential work *The Critique of Pure Reason.*²⁷

In the 19th century the interdependence between science and technology became more important, culminating in the important technological discoveries of electricity and electromagnetic induction by Michael Faraday in 1831, the first electric telegraph in 1837 by Charles Wheaton, and the creation of the incandescent light bulb in 1879 by Thomas Edison in New Jersey and Joseph Swan in England. The discovery of the light bulb foreshadowed the next revolution in photonics in the 20th century. The following sections discuss three important examples of technological developments that have greatly affected the field of biomedical photonics.

1.3.2.1 The Laser

The invention of the laser was an important milestone in the development of biomedical photonics. The laser is becoming the most widely used light source to excite tissues for disease diagnosis as well as to irradiate tumors for tissue removal in interventional treatment. The word "laser" is an acronym for "light amplification by stimulated emission of radiation." Einstein, who postulated photons and the phenomenon of stimulated emission, can be considered the grandfather of the laser. After Arthur Schawlow and Charles Townes published their paper on the possibility of laser action in the infrared and visible spectrum,²⁸ it was not long before many researchers began seriously considering practical devices. The first successful optical laser, constructed by Maiman in 1960, consisted of a ruby crystal surrounded by a helicoidal flash tube enclosed within a polished aluminum cylindrical cavity cooled by forced air.²⁹ Light was amplified (laser action) within a ruby cylinder, which formed a Fabry–Perot cavity by optically polishing the ends to be parallel to within a third of a wavelength of light. Each end was coated with evaporated silver; one end was made less reflective to allow some radiation to escape as the laser beam.

Lasers are now used as excitation light sources in disease diagnostics and as optical scalpels in interventional surgery. Ideal light sources because of their monochromaticity and intensity, lasers can be coupled to optical fibers inserted into endoscope for *in vivo* diagnosis of diseases (Figure 1.6). They also have the advantages of increased precision and reduced rates of infection and bleeding. Computers are used to control the intensity and direction of the laser beam, thus reducing human error. Nowadays lasers are commonly used to perform surgery on the skin and can be used to remove wrinkles, tattoos, birthmarks, tumors, and warts. Other types of growths can also be removed. Lasers are used to treat eye conditions; in some individuals, vision problems can be corrected with laser surgery. Lasers can help treat some forms of glaucoma and eye problems related to diabetes and are being incorporated into

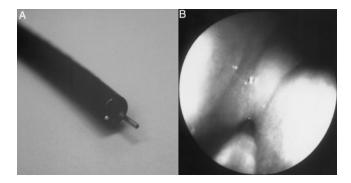

FIGURE 1.6 Fiber-optic probes are used for *in vivo* laser-induced diagnostics of cancer. Laser-induced fluorescence has been used for gastrointestinal (GI) endoscopy examinations to directly diagnose cancer of patients without requiring physical biopsy. The LIF measurement was completed in approximately 0.6 s for each tissue site. The fiber-optic probe was inserted into the biopsy channel of an endoscope (A). The fiber-optic probe lightly touched the surface of the GI tissue being monitored (B).

surgical procedures for other parts of the body as well. These include the heart, prostate gland, and throat. Lasers are also used to open clogged arteries and remove blockages caused by tumors. Knives and scalpels may be completely eliminated one day.

1.3.2.2 The Microchip

The advent of the microchip is another important development that has significantly affected the evolution of biomedical photonics. Whereas the discovery of the laser has provided a new technology for excitation, the miniaturization and mass production of sensor devices and their associated electronic circuitry has radically transformed the ways in which detection and imaging of molecules, tissues, and organs can be performed *in vivo* and *ex vivo*.

Microchip technology comes from the development and widespread use of large-scale integrated circuits, consisting of hundreds of thousands of components packed onto a single tiny chip that can be mass-produced for a few cents each (Figure 1.7). This technology has enabled fabrication of microelectronic circuitries (microchips) and photonic detectors such as photodiode arrays (PDA), charge-coupled device (CCD) cameras, and complementary metal oxide silicon (CMOS) sensor arrays in large numbers at sufficiently low costs to open a mass market and permit the widespread use of these devices in biomedical spectroscopy and molecular imaging. The miniaturization and evolution of integrated circuit technology continues to exemplify a phenomenon known as "Moore's law." The observation made by Intel Corporation founder Gordon Moore in 1965 was that the number of components on the most complex integrated circuit chip would double each year for the next 10 years. Moore's law has come to refer to the continued chip size reduction and exponential decrease in the cost per function that can be achieved on an integrated circuit.

The miniaturization of high-density optical sensor arrays is critical to the development of innovative high-resolution imaging methods at the cellular or molecular scales capable of identifying and characterizing premalignant abnormalities or other early cellular changes. Photonic imaging detectors provide novel solutions for *in vivo* microscopic imaging sensors or microscopic implanted devices with high spatial contrast and temporal resolution.

During the past 10 years there has been an explosion of research in biomedical photonics, resulting in scores of publications, conventions, and manufacturers offering new products in the field. Sensor miniaturization has enabled significant advances in medical imaging technologies over the last 25 years in such areas as magnetic resonance imaging (MRI), computed tomography (CT), nuclear medicine, and optical and ultrasound imaging of diseases. The development of multichannel sensor technologies has led to the development of novel photonic imaging technologies that exploit current knowledge of the genetic and molecular bases of important diseases such as cancer. These molecular biological discoveries have great implications for prevention, detection, and targeted therapy.

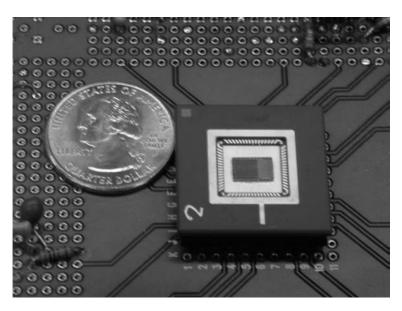

FIGURE 1.7 Modern optical sensor array microchips are fabricated using CMOS technology. Microchip technology has enabled the fabrication of microelectronic circuitries (microchips) and photonic detectors such as PDA, CCD cameras, and CMOS sensor arrays in large numbers at sufficiently low costs to open a mass market and permit the widespread use of these devices in biomedical spectroscopy, molecular imaging, and clinical diagnostics. 1.3.2.3 Nanotechnology

Recently, nanotechnology, which involves research on and development of materials and species at length scales between 1 to 100 nm, has been revolutionizing important areas in biomedical photonics, especially diagnostics and therapy at the molecular and cellular level. The combination of molecular nanotechnology and photonics opens the possibility of detecting and manipulating atoms and molecules using nanodevices that have potential for a wide variety of medical uses at the cellular level.

Today, the amount of research in biomedical science and engineering at the molecular level is growing exponentially because of the availability of new investigative nanotools. These new analytical tools are capable of probing the nanometer world and will make it possible to characterize the chemical and mechanical properties of cells, discover novel phenomena and processes, and provide science with a wide range of tools, materials, devices, and systems with unique characteristics. The marriage of electronics, biomaterials, and photonics is expected to revolutionize many areas of medicine in the 21st century. The futuristic vision of nanorobots moving through bloodstreams armed with antibody-based nanoprobes and nanolaser beams that recognize and kill cancer cells might some day no longer be the "stuff of dream."

The combination of photonics and nanotechnology has already led to a new generation of devices for probing the cell machinery and elucidating intimate life processes occurring at the molecular level previously invisible to human inquiry. Tracking biochemical processes within intracellular environments can now be performed *in vivo* with the use of fluorescent molecular probes (Figure 1.8) and nanosensors (Figure 1.9). With powerful microscopic tools using near-field optics, scientists are now able to explore the biochemical processes and submicroscopic structures of living cells at unprecedented resolutions. It is now possible to develop nanocarriers for targeted delivery of drugs that have their shells conjugated with antibodies for targeting antigens and fluorescent chromophores for *in vivo* tracking.

The possibility of fabricating nanoscale components has recently led to the development of devices and techniques that can measure fundamental parameters at the molecular level. With "optical tweezer" techniques, small particles may be trapped by radiation pressure in the focal volume of a high-intensity, focused beam of light. This technique, also called "optical trapping," may be used to move small cells or subcellular organelles around at will by the use of a guided, focused beam.³⁰ For example, a bead coated

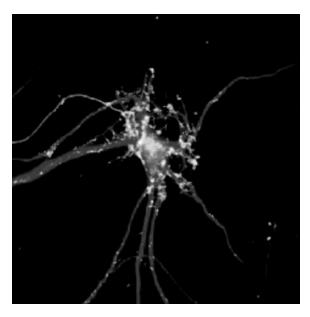

FIGURE 1.8 (Color figure follows p. 28-30.) Biochemical processes in nerve cells can be tracked using green fluorescent protein. Tracking biochemical processes can now be performed with the use of fluorescent probes. For example, there is great interest in understanding the origin and movement of neurotrophic factors such as brain-derived neurotrophic factor (BDNF) between nerve cells. This figure illustrates the use of BDNF tagged with green fluorescent protein to follow synaptic transport from axons to neurons to postsynaptic cells. (From Berman, D.E. and Dudai, Y.K., *Science*, 291, 2417, 2002. With permission.)

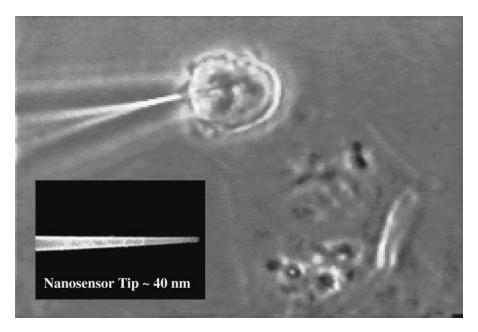

FIGURE 1.9 A fiber-optic nanosensor with antibody probe is used to detect biochemicals in a single cell. The combination of photonics and nanotechnology has led to a new generation of devices for probing the cell machinery and elucidating intimate life processes occurring at the molecular level that were previously invisible to human inquiry. The insert (lower left) shows a scanning electron photograph of a nanofiber with a 40-nm diameter. The small size of the probe allowed manipulation of the nanoprobe at specific locations within a single cell. (Adapted from Vo-Dinh, T. et al., *Nat. Biotechnol.*, 18, 76, 2000.)

with an immobilized, caged bioactive probe could be inserted into a tissue or even a cell and moved around to a strategic location by an optical trapping system. The cage could then be photolyzed by multiphoton uncaging in order to release and activate the bioactive probe.

Optical tweezers can also be used to determine precisely the mechanical properties of single molecules of collagen, an important tissue component and a critical factor in diagnosing cancer and the aging process.³¹ The optical tweezer method uses the momentum of focused laser beams to hold and stretch single collagen molecules bound to polystyrene beads. The collagen molecules are stretched through the beads using the optical laser tweezer system, and the deformation of the bound collagen molecules is measured as the relative displacement of the microbeads, which are examined by optical microscopy. Ingenious optical trapping systems have also been used to measure the force exerted by individual motor proteins.³²

A recent advance in the field of biosensors has been the development of optical nanobiosensors, which have dimensions on the nanometer (nm) size scale. Typical tip diameters of the optical fibers used in these sensors range between 20 and 100 nm. Using these nanobiosensors, it has become possible to probe individual chemical species in specific locations throughout a living cell. Figure 1.9 shows a photograph of a fiber-optic nanoprobe with antibodies targeted to benzopyrene tetrol (BPT) and designed to detect BPT in a single cell.³³ An important advantage of the optical sensing modality is the capability of measuring biological parameters in a noninvasive or minimally invasive manner due to the very small size of the nanoprobe. Following measurements using the nanobiosensor, cells have been shown to survive and undergo mitosis.³⁴

These photonic technologies are just some examples of a new generation of nanophotonic tools that have the potential to drastically change fundamental understanding of the life process. They could ultimately lead to development of new modalities of early diagnostics and medical treatment and prevention beyond the cellular level to that of individual organelles and even DNA, the building block of life.

1.3.3 The Genomics Revolution

James Watson and Francis Crick's publication of the helix structure of DNA in 1953 can be considered the first landmark achievement that launched the Genomics Revolution of the 21st century.³⁵ Almost 50 years after this landmark discovery, the completion of the sequencing of the human genome marked the second major achievement in the area of molecular genetics. The draft of the published sequence encompasses 90% of the human genome's euchromatic portion, which contains the most genes. Figure 1.10 illustrates the scientific progress achieved in genomics and proteomics research since the discovery of the DNA structure.

It is useful to get an overview of this remarkable 21st century achievement in molecular biology, known as the Human Genome Project. This project traces its roots to an initiative in the U.S. Department of Energy (DOE). In 1986, DOE announced its Human Genome Initiative, believing that precise knowledge of a reference human genome sequence would be critical to its missions to pursue a deeper understanding of the potential health and environmental risks posed by energy production and use. Shortly thereafter, DOE and the National Institutes of Health (NIH) teamed up to develop a plan for a joint Human Genome Project (HGP) that officially began in 1990.

From the beginning of the HGP project, photonics technologies provided the critical tools for accelerating the DNA sequencing process. In 1986, Leroy Hood and co-workers described a new technique for DNA sequencing whereby four fluorescent dyes were attached to the DNA instead of using radioactive labels and reading the x-ray films.³⁶ This photonic detection scheme — which allowed the DNA to run down only a single lane and be illuminated by a laser and the result from four fluorescent labels to be read into a computer — has been the workhorse of the sequencing efforts.

In June 2000, scientists announced biology's most spectacular achievement: the generation of a working draft sequence of the entire human genome.³⁷ In constructing the working draft, the 16 genome sequencing centers produced over 22.1 billion bases of raw sequence data, comprising overlapping fragments totaling 3.9 billion bases and providing sevenfold coverage (sequenced seven times) of the human genome. One

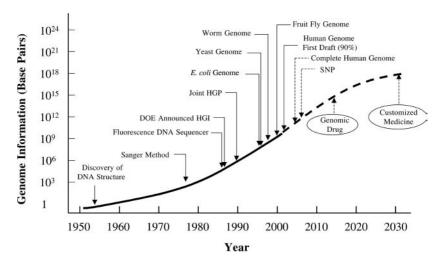

FIGURE 1.10 Advances in the genomics revolution since the discovery of the DNA helix structure have resulted in new information, new approaches, and new technologies for the drug discovery process. Potential applications of this knowledge are numerous and include drug discovery and customized medicine.

of the greatest impacts of knowing the genome sequence is the establishment of an entirely new approach to biomedical research. In the past, researchers studied one gene or a few genes at a time. With whole-genome sequences and new automated, high-throughput technologies, they can address biological and medical problems systematically and on a large scale in a massively parallel manner. They are now able to investigate a large number of genes in a genome, or various gene products in a particular tissue or organ or tumor. They can also study how tens of thousands of genes and proteins work together in interconnected networks to orchestrate the chemistry of life. Specific genes have been pinpointed and associated with numerous diseases and disorders, including breast cancer, muscle disease, deafness, and blindness.

Potential applications of this knowledge are numerous and include drug discovery and customized medicine. Advanced photonics has contributed dramatically to the field of drug discovery in the post-genomic area. Genomics and proteomics present the drug discovery community with a wealth of new potential targets. In the pregenomics area, the basic approach to discovering new drugs mainly involved research efforts focused on individual drug targets. Nonsystematic methods were generally used to find these potential targets. Phenotype analyses were performed by examining the differential expression of some proteins in diseased vs. normal tissue to identify proteins associated with a specific disease process. When a possibly useful compound was successfully synthesized, it was evaluated using time-consuming animal studies and, later, human clinical tests.

The advent of genomics has provided new information, new approaches, and new technologies for the drug discovery process. By using the ability to predict all the possible protein-coding regions in experimental systems, biomedical studies and analyses can be expanded beyond the most abundant and best characterized proteins of the cells to discover new drug targets. Most drugs today are based on about 500 molecular targets; knowledge of the genes involved in diseases, disease pathways, and drug-response sites will lead to the discovery of thousands of new targets. The increasing number of potential targets requires new instrumental approaches for rapid development of new drugs. One area of great interest is the use of high-throughput cell-based assays, which have the potential to provide a fundamental platform, the living cell, to characterize, analyze, and screen a drug target *in situ*.

Combined with high-throughput techniques, fluorescence technologies based on a wide variety of reporter gene assays, ion channel probes and fluorescent probes have provided powerful tools for cell-based assays for drug discovery. An exciting new advance in fluorescent probes for biological studies has been the development of naturally fluorescent proteins for use as fluorescent probes. The jellyfish *Aequorea victoria* produces a naturally fluorescent protein known as green fluorescent protein (GFP). Active

research is under way on the applications of GFP-based assays, which could allow analysis of intracellular signaling pathways using libraries of cell lines engineered to report on key cellular processes.

Another important advance in photonic technologies that has contributed to the dramatic growth of cell-based assays is the development of advanced imaging systems that have the combined capability of high-resolution, high-throughput, and multispectral detection of fluorescent reporters. These reporters allow the development of live cell assays with the ability for *in vivo* sensing of individual biological responses across cell populations, tracking the transport of biological species within intracellular environments, and monitoring multiple responses from the same cell.³⁸

Cellular biosensors³⁹ and extrinsic cellular sensors based on site-specific labeling of recombinant proteins^{40,41} are also important photonic tools recently developed for drug discovery. Advanced photonic techniques using time-resolved and phase-resolved detection, polarization, and lifetime measurements further extend the usefulness of cell-based assays. Novel classes of labels using inorganic fluorophors based on quantum dots or surface-enhanced Raman scattering (SERS) labels provide unique possibilities for multiplex assays.⁴² Today, single-molecule detection techniques using various photonics modalities provide the ultimate tools to elucidate cellular processes at the molecular level.

1.4 Conclusion

As we enter the new millennium, it appears that we are witnessing a new paradigm shift in the contribution of science and technology to the development of human knowledge and the advancement of civilization. In past centuries a discovery in basic science usually led to new technology development. Today, however, technology often creates new devices and instruments that drive scientific discoveries. As we create the tools to peer at the stars, look into the inner world of atoms, or decipher the genetic code of human cells in order to understand and ultimately eliminate the cause of diseases, we are witnessing a shift from a "science-driven" process to a "technology-driven" process in the evolution of human knowledge. Neither science nor technology holds a privileged role in the quest for knowledge. Rather, as the yin and yang of life, science and technology will contribute equally to human development and societal progress.

Biomedical photonics is a relatively new field at the interface of science and technology that has the potential to revolutionize medicine as we know it. The rapid development of laser and imaging technology has yielded powerful tools for the study of disease on all scales, from single molecules to tissue materials and whole organs. These emerging techniques find immediate applications in biological and medical research. For example, laser microscopes permit spectroscopic and force measurements on single protein molecules and laser sources provide access to molecular dynamics and structure to perform "optical biopsy" noninvasively and almost instantaneously, while optical coherence tomography allows visualization of tissue and organs. Using genetic promoters to drive luciferase expression, bioluminescence methods can generate molecular light switches, which serve as functional indicator lights reporting cellular conditions and responses in the living animal. This technique could allow rapid assessment of and response to the effects of antitumor drugs, antibiotics, or antiviral drugs.

Developments in quantum chemistry, molecular genetics, and high-speed computers have created unparalleled capabilities for understanding complex biological systems. Information from the human genome project will make molecular medicine an exciting reality. Current research has indicated that many diseases such as cancer occur as the result of the gradual buildup of genetic changes in single cells. Biomedical photonics can provide tools capable of identifying specific subsets of genes encoded within the human genome that can cause the development of cancer. Photonic techniques are being developed to identify the molecular alterations that distinguish a cancer cell from a normal cell. Such technologies will ultimately aid in characterizing and predicting the pathologic behavior of that cancer cell, as well as the cell's responsiveness to drug treatment.

Biomedical photonics technologies can definitely bring a bright future to biomedical research because they are capable of yielding the critical information bridging molecular structure and physiological function, which is the most important process in understanding, treatment, and prevention of disease. As this handbook explores in the following sections, it is our hope that light is rapidly finding its place as an important diagnostic tool and a powerful weapon in the arsenal of the modern physician.

Introduction 2.1

The electromagnetic spectrum provides a diverse set of photonic tools for probing, manipulating, and interacting with biological systems. A great variety of electromagnetic phenomena are used in biomedicine to detect and treat disease and to advance scientific knowledge. The focus of this chapter is the propagation of "light" in tissues. The main purpose is to provide an introduction to the linear optical properties of human tissues from a conceptual viewpoint, emphasizing how these properties fit into the description of light transport. The term light can have various meanings, but here it is used to refer to the portion of the electromagnetic spectrum with vacuum wavelengths λ_{vac} in the range of 1 μ m to 100 nm (or in the frequency $v = c/\lambda$, 3×10^{14} to 3×10^{15} Hz, where c is the speed of light). This spectral range includes the near infrared (NIR), the visible, and the ultraviolet (UV) A, B, and C bands, and encompasses the so-called therapeutic (or diagnostic) window, which is of great importance in biomedical photonics (Figure 2.1).

As discussed in Chapter 1, the quantum description of light in terms of photons is essential for understanding the exchange of energy and momentum between light and matter and provides the theoretical basis for molecular spectroscopy. The term photonics, however, is used to refer to all electromagnetic wave phenomena, whether or not the quantum nature of light (photon) is a necessary component of its description. There is a parallel with the use of the term *electronics*, which deals with electrical circuit phenomena; in many applications the electric current flowing in a device can be thought of as a

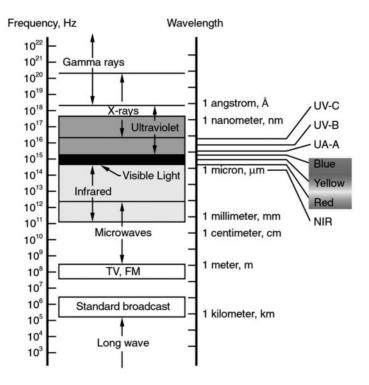

FIGURE 2.1 The electromagnetic spectrum with the region discussed in this chapter expanded on the right. This includes the UV-C (100 to 280 nm), UV-B (280 to 315 nm), and UV-A (315 to 400 nm) bands, the visible region (400 to 760 nm), and a portion of the IR-A band (760 to 1400 nm). The therapeutic window (see Figure 2.16) extends from 600 nm (orange part of the visible) to 1300 nm (IR-A band).

continuous flow of charge, and the quantum nature of the electron is not required for understanding circuit behavior.

In physics, phenomena are often described from either "classical" or "quantum" viewpoints. The term *classical* refers to theories that do not use the concepts of quantum mechanics. In classical theory, light is considered to be an oscillating electromagnetic (EM) field that can have a continuous range of energies. In the quantum model, light waves consist of packets (i.e., "quanta") of energy called photons. Each photon has an energy proportional to the frequency of the EM wave. Quantum theory introduces the idea that light and matter exchange energy as photons, fundamental packets of energy, $E = hv = hc/\lambda$, where h is Planck's constant. The description of light propagation in tissues incorporates both views: a classical picture is used to define the dynamics of light transport mathematically (e.g., to calculate scattering cross sections) and the photon concept is introduced in an *ad hoc* manner when necessary (e.g., to account for molecular transition processes, such as absorption, luminescence, and Raman scattering).

Because multiple scattering effects are important features of light propagation in tissues, the direct application of EM theory to the tissue optics problem is complicated. In place of the direct EM approach, a model known as radiation transport (RT) theory is used that explicitly ignores wave phenomena such as polarization and interference, and instead follows only the transport of light energy in the medium. As will be discussed later, the RT model does, however, implicitly incorporate elements of the classical and quantum descriptions of light. This model is not specific to light and has other important applications in areas such as neutron transport and thermodynamics.

In the electromagnetic description, light consists of oscillating electric and magnetic waves (Figure 2.2). Two important parameters of electromagnetic waves are phase and polarization. The *phase* is a general property of a wave and gives rise to important effects such as interference and diffraction. *Polarization*

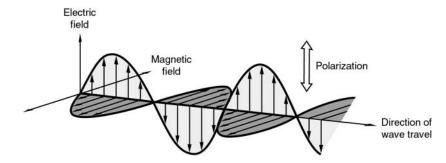

FIGURE 2.2 Schematic diagram of an electromagnetic wave, which consists of the symbiotic oscillations of electric and magnetic fields. The polarization denotes the directions of the electric field vectors in the wave. In the case shown, the polarization is linear and in the vertical direction.

refers to the orientation of the electric field vector of the EM wave. Two waves must have some overlap in their polarizations for interference to occur. In free space, the polarization is perpendicular to the direction of propagation. Since RT theory deals with the transport of light energy, it explicitly ignores the phase and polarization of the EM waves, although it does use wave properties implicitly through the material parameters included in the fundamental equations. The validity of RT theory for strongly scattering optical media has been established empirically, and the theoretical link between RT theory and the fundamental laws of electromagnetism has also been demonstrated; nevertheless, some attempt will be made to distinguish between phenomena that are inherently electromagnetic in nature vs. those that are part of the empirical RT model.

This chapter provides an introduction to fundamental photophysical concepts and basic theoretical models for describing light propagation in biological tissues. We examine in some detail RT theory, including the absorption-dominant and scattering-dominant limits of the problem, and the Monte Carlo method for numerically performing practical transport simulations. The chapter also provides a description of the Kubelka–Munk method. Finally, we provide a representative listing of optical properties of human tissues, including refractive indices, and scattering and absorption coefficients.

2.2 Fundamental Optical Properties

In this section we discuss three photophysical processes that affect light propagation in biological tissue: refraction, scattering, and absorption. These processes can be quantified by the following parameters:

- Index of refraction, $n(\lambda)$
- Scattering cross section, σ_{s}
- Differential scattering cross section, $\frac{d\sigma_s}{d\Omega}$
- Absorption cross section, σ_a

These basic properties, from which the inputs to RT theory are ultimately built, are defined in the following sections. For the purposes of this chapter, it is sufficient to assume that the media considered in this treatment are isotropic systems; this assumption will simplify the description of the fundamental properties while not compromising the essential features of the phenomenology.

2.2.1 Refraction

2.2.1.1 Index of Refraction

The index of refraction is a fundamental property of homogeneous media. This index can also be defined for heterogeneous materials, as will be discussed later in Section 2.3. For a homogeneous medium, the

index of refraction describes its linear optical properties. The general form of the complex index of refraction is

$$\tilde{n}(\lambda) = n(\lambda) - i\alpha(\lambda) . \tag{2.1}$$

where the imaginary part, $\alpha(\lambda)$, is the attenuation and encompasses the attenuation of a wave due to absorption (and scattering if the medium is heterogeneous). The convention is to refer to the real part as the "index of refraction" (as distinct from the "complex index of refraction"):

$$\operatorname{Re}\left[\tilde{n}(\lambda)\right] = n(\lambda). \tag{2.2}$$

The real part of the refractive index is defined in terms of the phase velocity of light in the medium,

$$c_m(\lambda) = \frac{c}{n(\lambda)}, \qquad (2.3)$$

where $c = 2.998 \times 10^8$ m/s is the speed of light in vacuum and $n_{\text{vac}} = 1$. The wavelength of light in the medium λ_m is given in terms of the vacuum wavelength λ as

$$\lambda_m = \frac{\lambda}{n(\lambda)} \,. \tag{2.4}$$

Even though the phase speed and the wavelength of light depend on the refractive index, the wave frequency,

$$v = \frac{c}{\lambda} = \frac{c_m}{\lambda_m},$$

and the size of its photon energy, E = hv, are always the same as in the vacuum. Moreover, although the wavelength in a material is different from its vacuum value, the prevailing convention is to use the quantity λ to refer to the vacuum wavelength. When the actual wavelength in a material is required, this wavelength is denoted by the addition of a subscript (e.g., λ_m).

2.2.1.2 Reflection and Refraction at an Interface

When a light wave propagating in a material with a given refractive index encounters a boundary with a second material with a different index, the path of the light is redirected. If the width of the light beam (or its wavelength) is small compared to the boundary or its curvature, reflection and refractive transmission result. This situation is illustrated in Figure 2.3. The amount of light reflected by and transmitted through a boundary depends on the refractive indices of the two materials, the angle of incidence, and the polarization of the incoming wave. The relation between the angle of incidence and the angle of refraction for the transmitted light is given by Snell's law:

$$\sin \theta_2 = \frac{n_1}{n_2} \sin \theta_1. \tag{2.5}$$

For normal incidence onto a planar boundary, the fraction of the incident energy that is transmitted across the interface is given by

$$T = \frac{4n_1 n_2}{\left(n_1 + n_2\right)^2} \ . \tag{2.6}$$

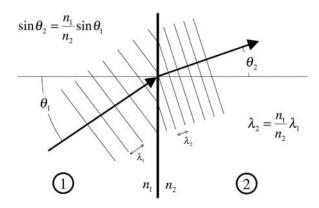

FIGURE 2.3 Light incident on a planar boundary undergoes refraction. The refraction angle θ_2 is given in terms of the angle of incidence θ_1 and the refractive indices, n_1 and n_2 , of the two media. The angle of reflection (not shown) is equal to the angle of incidence.

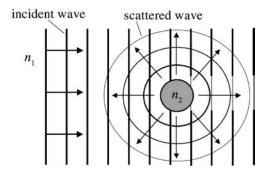

FIGURE 2.4 Light incident on a localized particle embedded in a medium with a different refractive index will be partially scattered.

The fraction of the incident energy that gets reflected is

$$R = 1 - T = \frac{\left(n_1 - n_2\right)^2}{\left(n_1 + n_2\right)^2} \,. \tag{2.7}$$

This reflection from the interface, also known as the Fresnel reflection, is distinct from the diffuse reflectance to be discussed in Section 2.3, which in our context has a subsurface origin. (More general expressions describing transmission, reflection, and refraction phenomena can be found in Reference 2.)

2.2.2 Scattering

2.2.2.1 Scattering at a Localized Inclusion

When the guest material occupies only a localized region within the host material, scattering will occur. For example, a source of scattering in tissues is the mismatch in the refractive indices between subcellular organelles and the surrounding cytoplasm. In this case, some of the incident light is redirected over a range of angles relative to the scattering particle (Figure 2.4).

In biomedical photonics, scattering processes are important in both diagnostic and therapeutic applications:

• *Diagnostic applications*: Scattering depends on the size, morphology, and structure of the components in tissues (e.g., lipid membranes, nuclei, collagen fibers). Variations in these components

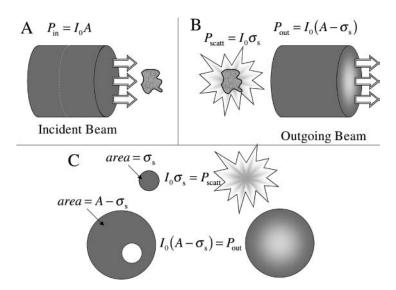

FIGURE 2.5 The scattering cross section expresses the proportionality between the intensity of incident wave and the amount of power scattered from it. (A) Before encountering the scatterer, the beam has a uniform power $P_{in} = I_0 A$ where I_0 is the intensity of the beam and A is the cross-sectional area. (B) After encountering the particle, some of the energy gets scattered out of the beam, and the beam intensity is no longer uniform. (C) The amount of power scattered is equivalent to the power in a piece of the incoming beam with area σ_0 which is the scattering cross section.

due to disease would affect scattering properties, thus providing a means for diagnostic purposes, especially in imaging applications.

• *Therapeutic applications*: Scattering signals can be used to determine optimal light dosimetry (e.g., during laser-based treatment procedures) and provide useful feedback during therapy.

Scattering is most simply described by considering the incident light as a plane wave (i.e., a wave of uniform amplitude in any plane perpendicular to the direction of propagation, at least over a size scale larger than the scattering particle). In principle, given the refractive indices of the two materials and the size and shape of the scatterer, the scattered radiation can be calculated. Scattering is quantified by the scattering cross section. For a monochromatic plane wave that has a given intensity (i.e., power per unit area) I_0 encountering the scattering object, some amount of power P_{scatt} gets spatially redirected (i.e., scattered). The ratio of the power (i.e., energy per second) scattered out of the plane wave to the incident intensity (energy per second per area) is the *scattering cross section*,

$$\sigma_{s}(\hat{\mathbf{s}}) = \frac{P_{\text{scatt}}}{I_{0}}, \qquad (2.8)$$

where $\hat{\mathbf{s}}$ is the propagation direction of the plane wave relative to the scatterer (Figure 2.5). The scattering cross section has units of area and is equivalent to the area that an object would have to "cut out" from the uniform plane wave in order to remove the observed amount of scattered power, P_{scatt} . The concept of cross section is also used for absorption where the power absorbed is proportional to the incident intensity. Note that the cross section is not the projected geometric area of an object as a glass sphere and a steel sphere of the same size will have different cross sections. It is merely a convenient way to quantify the scattering strength of an object.

Scattering depends on the polarization of the incoming wave, but we can consider Equation 2.8 to be an average over orthogonal polarization states. The angular distribution of the scattered radiation is given by the differential cross section (Figure 2.6),

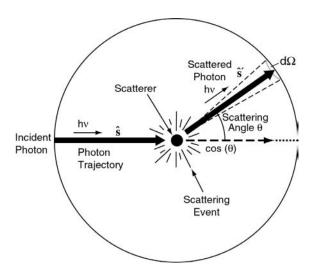

FIGURE 2.6 The differential scattering cross section expresses the angular distribution of the scattered light relative to the incident light. The incident photon travels along the direction \$\mathbf{s}\$ and the scattered photon exits in the \$\mathbf{s}'\$ direction.

$$\frac{d\sigma_{s}}{d\Omega}(\hat{\mathbf{s}},\hat{\mathbf{s}}'),\tag{2.9}$$

where \hat{s}' defines the axis of a cone of solid angle $d\Omega$ originating at the scatterer.

For our purposes, we will assume that the scattering cross section is independent of the relative orientation of the incident light and the scatterer. This is equivalent to assuming that the object is spherically symmetric, a rough but adequate approximation valid within the context of the RT model. Under this approximation, the scattering cross section at a given wavelength is independent of the relative orientation of the particle and incident light,

$$\sigma_{s}(\hat{\mathbf{s}}) = \sigma_{s}, \qquad (2.10)$$

and the differential cross section depends only on the relative orientation of the incident and scattering directions, thus permitting us to write the differential cross section as a function of the cosine of the angle between \hat{s} and \hat{s}' ,

$$\frac{d\sigma_{s}}{d\Omega}(\hat{\mathbf{s}},\hat{\mathbf{s}}') = \frac{d\sigma_{s}}{d\Omega}(\hat{\mathbf{s}}\cdot\hat{\mathbf{s}}'). \tag{2.11}$$

(In a more general context, $\frac{d\sigma_s}{d\Omega}$ depends upon the polarization states of the incoming and outgoing waves, as with σ_{s} .)

A medium containing a uniform distribution of identical scatterers is characterized by the *scattering coefficient*,

$$\mu_{s} = \rho \sigma_{s}, \qquad (2.12)$$

where ρ is the number density of scatterers. The scattering coefficient is essentially the cross-sectional area for scattering per unit volume of medium. The scattering mean free path

$$l_s = \frac{1}{\mu_c} \tag{2.13}$$

represents the average distance a photon travels between consecutive scattering events.

In biological tissues, scattering interactions are often dominant mechanisms affecting light propagation. In practice, scattering is classified into three categories defined by the size of the scattering object relative to the wavelength: (1) the Rayleigh limit, where the size of the scatterer is small compared to the wavelength of the light; (2) the Mie regime, where the size of the scatterer is comparable to the wavelength; and (3) the geometric limit, where the wavelength is much smaller than the scatterer. The Rayleigh and Mie regimes are discussed further in the following sections. The geometric optics limit, where the light–scatterer interaction is described by rays that refract and reflect at the obstacles boundaries, is essentially the case discussed in Section 2.2.1.

2.2.2.2 Rayleigh Limit

Scattering of light by tissue structures much smaller than the photon wavelength involves the so-called *Rayleigh limit*. Those structures include cellular components such as membranes and cell subcompartments (see Figure 2.7A), and extracellular components such as the banded ultrastructure of collagen fibrils. The most important implication of the small size-to-wavelength ratio is that, at any moment in time, the scatter sees only a spatially uniform electric field in the surrounding host. In the classical description (i.e., light as electromagnetic waves, not photons), this condition gives rise to a dipole moment in the scatterer, a slight and spatially simple redistribution of the charges in the scatterer. This dipole moment oscillates in time with the frequency of the incident field and as a consequence gives off dipole radiation. For a spherical particle of radius *a*, the differential cross section in the Rayleigh limit is

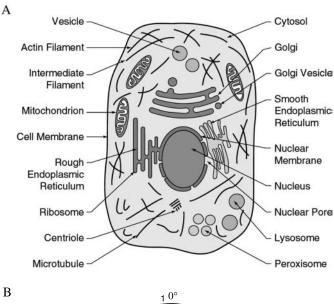

$$\frac{d\sigma_{s}}{d\Omega} = 8\pi^{4} n_{m}^{4} \left(\frac{n_{s}^{2} - n_{m}^{2}}{n_{s}^{2} + 2n_{m}^{2}} \right)^{2} \frac{a^{6}}{\lambda^{4}} \left(1 + \cos^{2}\theta \right), \tag{2.14}$$

where θ is the angle between the direction of the incoming wave and the outgoing direction of interest, and n_m and n_s are the refractive indices of the host medium and the scatterer, respectively (Figure 2.7B). This expression is averaged over polarization states of the incoming and scattered waves, as is appropriate for use in the RT theory.

In the quantum picture, Rayleigh scattering is called "elastic" because the energy of the scattered photon is the same as that of the incident photon. A related process is Raman scattering, which, in contrast, is "inelastic." In the Raman process, the frequencies of scattered photons are shifted from the incident frequency by amounts that are characteristic of molecular transitions, usually between vibrational energy states. The term *inelastic* refers to the fact that the scattered photon either loses energy to (Stokes) or gains energy from (anti-Stokes) the molecule. Raman scattering is extremely weak compared to the elastic Rayleigh scattering. (A rough approximation is 1 Raman-shifted photon for every 106 Rayleigh photons.) Raman scattering is outside the scope of this chapter.

2.2.2.3 Mie Regime

Scattering of light by spherical objects is described by *Mie theory*, which in principle is applicable at any size-to-wavelength ratio. In the intermediate size-to-wavelength ratio range, where the Rayleigh and geometric approximations are not valid, Mie theory is used. Thus this region where the scatterer size and wavelength are comparable is sometimes labled the *Mie regime*. Various cellular structures, such as mitochondria and nuclei (Figure 2.7A), and extracellular components like collagen fibers have sizes on the order of hundreds of nanometers to a few microns, and are comparable in dimension to the photon wavelengths generally used in biomedical applications (0.5 to 1 μ m). Even though these structures are not necessarily spherical, their scattering behavior can be modeled reasonably well by Mie theory applied to spheres of comparable size and refractive index. Because the scatterer is on the order of the wavelength,

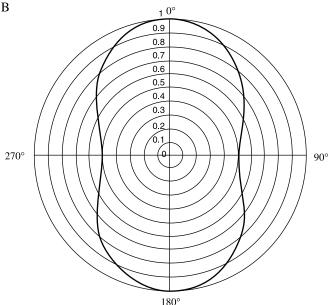

FIGURE 2.7 (A) Cellular structures that act as scatterers in tissue. The organelles themselves scatter light in the Mie regime while the organelle and cellular membranes can act as Rayleigh scatterers. (B) Angular dependence of Rayleigh scattering. The distribution of unpolarized Rayleigh scattered light as a function of angle ($\theta = 0^{\circ}$ is the forward direction).

it experiences a more complex field in the space around it at any moment in time, and thus the motion of charges in the scatterer in response to the field is also more complex. This results in a more complex angular dependence for the scattered light relative to the Rayleigh approximation. There can also be resonances and nulls due to the (classical) constructive and destructive interferences of the fields set up in the scatterer. The exact scattering patterns exhibited by the various biologic structures will of course depend on the detailed shape of the particle. The Mie scattering theory was specifically developed for spherical particles, although the label "Mie regime" is commonly (but loosely) used to refer to scattering from particles of arbitrary shape whose dimensions are on the order of or greater than the wavelength.

As in the Rayleigh limit, the cross section in the Mie regime can be calculated using the classical model, but may be modulated by quantum transitions in the constituent molecules of the scatterer.

2.2.3 Absorption

2.2.3.1 Absorption Processes

Absorption is a process involving the extraction of energy from light by a molecular species. In biomedical photonics, absorption processes are important in diagnostic and therapeutic applications:

- *Diagnostic applications*: Transitions between two energy levels of a molecule that are well defined at specific wavelengths could serve as a spectral fingerprint of the molecule for diagnostic purposes.
- *Therapeutic applications*: Absorption of energy is the primary mechanism that allows light from a laser to produce physical effects on tissue for treatment purposes.

Absorption processes involve an important concept in quantum theory, the *energy level*, which is a quantum state of an atom or molecule. The shift of a species (i.e., a molecule or an atom) from one energy level to another is called a *transition*. A transition of a species from a lower to a higher energy level involves excitation to an excited state and requires absorption of an amount of photon energy, hv, equal to the difference in energy, ΔE , between the two levels:

$$h\mathbf{v} = \Delta E \ . \tag{2.15}$$

A drop from a higher energy level to a lower level is called a decay and is accompanied by a release of energy equal to the difference in energy between the two levels. This release of energy may occur without radiation (by heating the surrounding medium) or may give rise to emission of a photon (e.g., luminescence).

In the quantum picture, photons are absorbed by atoms and molecules in specific transitions, and the photons' energy is used to increase their internal energy states. The regions of the spectrum where this occurs are known as absorption bands; these bands are specific to particular molecular/atomic species. In general, there are three basic types of absorption processes: (1) electronic, (2) vibrational, and (3) rotational. Electronic transitions occur in both atoms and molecules, whereas vibrational and rotational transitions occur only in molecules.

Absorption between Electronic Levels

At equilibrium, a group of molecules has a thermal distribution in the lowest vibrational and rotational levels of the ground state, S_o . When a molecule absorbs excitation energy, it is elevated from S_o to some vibrational level of one of the excited singlet states, S_n , in the manifold $S_1...S_n$. The intensity of the absorption (i.e., fraction of ground-state molecules promoted to the electronic excited state) depends on the intensity of the excitation radiation (i.e., number of photons) and the probability of the transition with photons of the particular energy being used. A term often used to characterize the intensity of an absorption (or an induced emission) band is the oscillator strength, f, which may be defined from the integrated absorption spectrum by the relationship

$$f = 4.315 \times 10^{-9} \int \varepsilon_{\nu} d\nu$$
, (2.16)

where ε_{v} is the molar extinction coefficient at the frequency v.

Oscillator strengths of unity or near unity correspond to strongly allowed transitions, whereas lower values of f are indicative of the smaller transition dipole matrix elements of forbidden transitions. Depending on the types of species, electronic transitions have energies corresponding to photons from the UV through the IR regions of the spectrum.

Absorption Involving Vibrational Levels

Vibrational levels characterize the different states of vibration of the atoms in a molecule. The vibrations in various degrees of freedom are quantized, giving rise to a series of vibrational levels for each vibrational pattern of a molecule. A vibrational transition occurs when a molecule shifts from one vibrational state to another. Typically, vibrational transitions correspond to the energies of photons from the IR.

Absorption Involving Rotational Levels

Rotational levels represent the different states of rotation of a molecule. These quantized energy levels correspond to photon energies from the far IR to submillimeter wavelengths.

The electronic energy levels of molecules are associated with molecular orbitals that describe the distribution of the electrons (i.e., electron clouds) in the molecule. When a molecule undergoes an electronic transition, an electron is transferred from one molecular orbital to another. However, there are cases where the excitation is considered to be localized to a particular bond or groups of atoms. Several types of molecular orbitals are involved in biological compounds: π bonding orbitals, π^* nonbonding orbitals, and n nonbonding (lone-pair) orbitals. The π^* nonbonding orbital is less stable and has a higher energy than the π bonding orbital. An electronic transition involving the transfer of an electron from a π orbital to a π^* orbital is called a $\pi\pi^*$ transition. Alternatively, the transfer of an electron from an n orbital to a π^* orbital is called an $n\pi^*$ transition. In transition metal complexes (e.g., metal porphyrins), the electronic energy levels may also be described by molecular orbitals formed between the metal and ligands. The term *chromophore* refers to the part of the molecule that gives rise to the electronic transition of interest.

The probability of transition between different states or energy levels is governed by complex quantum mechanical rules that depend on the chemical structure, size, and symmetry of the molecules. Some transitions are said to be "allowed," which means that they are very likely to occur, thus giving rise to very strong absorption bands. Others are "forbidden" transitions, which are very unlikely to occur, producing very weak absorption bands.

2.2.3.2 Absorption Cross Section and Coefficient

For a localized absorber, the absorption cross section σ_a can be defined in the same manner as for scattering, i.e.,

$$\sigma_a = \frac{P_{\text{abs}}}{I_0} \,, \tag{2.17}$$

where P_{abs} is the amount of power absorbed out of an initially uniform plane wave of intensity (power per unit area) I_0 . As previously with σ_s , we make the approximation that the cross section is independent of the relative orientation of the impinging light and the absorber. A medium with a uniform distribution of identical absorbing particles can be characterized by the *absorption coefficient*

$$\mu_a = \rho \sigma_a \,, \tag{2.18}$$

where ρ is the number density of absorbers. The reciprocal,

$$l_a = \frac{1}{\mu_a},\tag{2.19}$$

is the *absorption mean free path*, or *absorption length*, and represents the average distance a photon travels before being absorbed. For a medium, the absorption coefficient can be defined by the following relation:

$$dI = -\mu_a I dz , \qquad (2.20)$$

where dI is the differential change of intensity of a collimated light beam traversing an infinitesimal path dz through a homogenous medium with absorption coefficient μ_a . Integrating over a thickness z yields the Beer–Lambert law:

$$I = I_0 \exp\left[-\mu_a z\right],\tag{2.21}$$

which can also be expressed as

$$I = I_0 \exp\left[-\varepsilon_{\lambda} az\right] \tag{2.22}$$

where ε_{λ} is the *molar extension coefficient* [cm² · mol⁻¹] at wavelength λ , a [mol · cm⁻³] is the molar concentration of the absorption species, and z is the thickness [cm]. The molar extension coefficient ε_{λ} (which is equal to μ_{a}/a) is a measure of the "absorbing power" of the species.

A quantity commonly used is the *transmission*, T, defined as the ratio of transmitted intensity I to incident intensity I_0 :

$$T = I/I_0 (2.23)$$

The attenuation, also called absorbance (A) or optical density (OD), of an attenuating medium is given by

$$A = OD = \log_{10}(I_0/I) = -\log_{10}(T).$$
 (2.24)

The variation of ε_{λ} with wavelength constitutes an absorption spectrum. Alternatively, a plot of A vs. wavelength is also another way of presenting the absorption properties.

Once absorbed by a molecular species, the light energy can be dissipated optically by emitting a photon or nonradiatively by exchanging kinetic energy with other internal degrees of freedom of the absorbing species or external species (e.g., "heating" the medium). The quantum description of the absorption and emission processes (e.g., fluorescence, phosphorescence) of molecules is further discussed in Section 28.2 of Chapter 28 of this handbook. The most common situation is a combination of the two processes, where a small amount of the absorbed energy is dissipated nonradiatively and the majority is emitted as a photon in the transition back down to the ground state. This process of emission, known as luminescence, is further broken down into fluorescence (prompt emission from a singlet state) and phosphorescence (delayed emission from a triplet state). In fluorescence the delay between absorption and emission is typically on the order of nanoseconds, whereas in phosphorescence, emission follows much later (milliseconds and longer). As far as photon transport in tissues is concerned, fluorescence from excited singlet states is a much more common phenomenon, although triplet states are often involved in photodynamic therapy.

Under special conditions, the absorption process can also occur by the "simultaneous" extraction of two or more photons. This multiphoton absorption has important application in biomedical optics and is discussed in Chapter 11 of this handbook. Multiphoton absorption is a nonlinear process and is thus beyond the scope of our survey of the linear optical properties that are of primary importance in photon transport. Photons that are emitted in wavelength-changing processes such as fluorescence emission and Raman scattering are considered further in other chapters of this handbook.

2.3 Light Transport in Tissue

As media for light propagation, most human tissues are considered turbid (i.e., "cloudy" or opaque). Turbid tissues are heterogeneous structures and correspondingly have spatial variations in their optical properties. The spatial variation and density of these fluctuations make these tissues strong scatterers of

light. In the absence of absorption, a significant fraction of the photons launched into these tissues are scattered multiple times, giving rise to a diffuse and largely incoherent field of penetrating light. As optical media, these tissues have been successfully modeled as two-component systems: (1) randomly positioned scattering and absorbing particles (2) embedded in a homogeneous continuum. In spite of the complexities of actual tissues, this simple two-component model has proven to give a satisfactory description of optical transport in tissue for many cases of interest. In this section, we examine RT solutions in limiting cases and also discuss Monte Carlo and Kubelka–Munk approaches to the light transport problem. At the end, we discuss some aspects of short-pulse time-resolved propagation.

2.3.1 Preliminaries to Radiation Transport Theory

2.3.1.1 Coherent and Incoherent Light

Light propagating in tissues can be classified into two types: coherent and incoherent. *Coherence* refers to the ability of a light field to maintain a definite (nonrandom) phase relationship in space and time and exhibit stable interference effects. An example of this interference is the speckle pattern produced when coherent light, such as a laser beam, is reflected from a surface. Speckle patterns occur because of the interference of a large number of elementary waves that arises when coherent light is reflected from a rough surface or when coherent light passes through a scattering medium. On the other hand, an *incoherent* source exhibits random phase patterns both temporally and spatially and thus is not capable of exhibiting stable or observable interference effects. An example of an incoherent source is an incandescent light bulb, as in a flashlight: unlike laser light, a flashlight beam reflected off a surface exhibits no speckle patterns. Speckle-related phenomena and measurement methods are discussed in Chapters 3 and 14 of this handbook.

Coherence is often a matter of degree because the same light source may exhibit observable interference effects in some situations and not in others. In the optical regime, coherent sources are necessarily monochromatic, because interferences between light of different wavelengths vary too rapidly to be meaningful. In tissues, light that is scattered multiple times can exhibit coherent and incoherent properties. Within the context of RT theory, the scattered fields are taken to be completely incoherent. This simplification is adequate for much of the phenomena of interest here. However, the scattered fields can also exhibit coherent effects; these are discussed in a later section of this chapter in the context of short-duration light pulses.

The following example illustrates the essential nature of coherence. In electromagnetic theory, the equations are linear in the electric and magnetic field amplitudes. This linear condition implies that the field at a point in a linear medium is the summation (superposition) of the field vectors contributed from each individual light source. For example, consider the total electric field at a point due to two scatterers of light (Figure 2.8),

$$\mathbf{E}_{\text{total}}(\mathbf{r},t) = \mathbf{E}_{1}(\mathbf{r},t) + \mathbf{E}_{2}(\mathbf{r},t), \qquad (2.25)$$

where $\mathbf{E}_1(\mathbf{r},t)$ and $\mathbf{E}_2(\mathbf{r},t)$ are the electric field vectors of the two scattered waves. (To keep things simple, we will ignore the incident field and consider the two scatterers to be the only sources of light in the medium.) To calculate the energy U associated with the scattered light field requires taking the square of its amplitude,

$$U(\mathbf{r}) = \varepsilon \mathbf{E}_{\text{total}}(\mathbf{r}) \cdot \mathbf{E}_{\text{total}}(\mathbf{r}) = \varepsilon \left[\mathbf{E}_{1}^{2}(\mathbf{r}) + \mathbf{E}_{2}^{2}(\mathbf{r}) + 2\mathbf{E}_{1}(\mathbf{r}) \cdot \mathbf{E}_{2}(\mathbf{r}) \right],$$

$$= U_{1}(\mathbf{r}) + U_{2}(\mathbf{r}) + 2\varepsilon \mathbf{E}_{1}(\mathbf{r}) \cdot \mathbf{E}_{2}(\mathbf{r})$$
(2.26)

where ε is the *permittivity* of the medium. (Note that the permittivity ε used in this section is distinct from the molar extension coefficient ε_{λ} defined in Equation 2.22.)

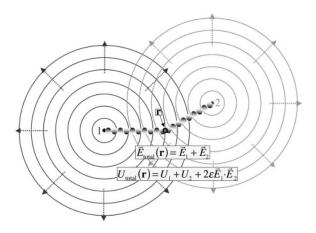

FIGURE 2.8 Superposition of EM waves. The EM field \mathbf{E}_{total} at point \mathbf{r} is the vector sum of the two fields from the respective sources, 1 and 2. The energy U_{total} at point \mathbf{r} due to these two fields includes an interference term to account for constructive or destructive interference.

The energy expressed in Equation 2.26 is not just the addition of the separate energies contributed by the two respective sources but includes a cross term, $2\mathbf{E}_1 \cdot \mathbf{E}_2$, that accounts for the interference of the two sources. If the two electric fields have overlapping polarizations ($|\mathbf{E}_1 \cdot \mathbf{E}_2| > 0$), they can interfere constructively ($\mathbf{E}_1 \cdot \mathbf{E}_2 > 0$) or destructively ($\mathbf{E}_1 \cdot \mathbf{E}_2 < 0$) at point \mathbf{r} . Therefore, the total energy at \mathbf{r} can be greater than or less than the sum of the energies of the individual sources acting alone. Over all of space, however, the constructive and destructive interferences will balance out so that energy is conserved. Consider now the energy averaged over a region of space:

$$U_{\text{avg}} = \varepsilon \overline{\mathbf{E}_{\text{total}} \cdot \mathbf{E}_{\text{total}}} = \varepsilon \left[\overline{\mathbf{E}_{1}^{2}} + \overline{\mathbf{E}_{2}^{2}} + 2 \overline{\mathbf{E}_{1} \cdot \mathbf{E}_{2}} \right]. \tag{2.27}$$

If the region is large enough, the interference contribution to the energy averages away,

$$U_{avg} = \varepsilon \left[\overline{\mathbf{E}_{1}^{2}} + \overline{\mathbf{E}_{2}^{2}} \right] = \overline{U_{1}} + \overline{U_{2}}, \qquad (2.28)$$

and

$$\overline{\mathbf{E}_1 \cdot \mathbf{E}_2} = 0. \tag{2.29}$$

For a greater number of scatterers, the energy at a point can be calculated in the same way, by first adding up the fields due to each scatterer,

$$\mathbf{E}_{total} = \sum_{j=1}^{N} \mathbf{E}_{j} , \qquad (2.30)$$

and then squaring the total,

$$U = \varepsilon \mathbf{E}_{total} \cdot \mathbf{E}_{total} = \varepsilon \sum_{j=1}^{N} \mathbf{E}_{j} \cdot \sum_{j=1}^{N} \mathbf{E}_{j} = \varepsilon \sum_{j=1}^{N} \mathbf{E}_{j}^{2} + \varepsilon \sum_{j=1}^{N} \sum_{\substack{m=1\\ m \neq j}}^{N} \mathbf{E}_{j} \cdot \mathbf{E}_{m}$$

$$= \sum_{j=1}^{N} U_{j} + \varepsilon \sum_{j=1}^{N} \sum_{\substack{m=1\\ m \neq j}}^{N} \mathbf{E}_{j} \cdot \mathbf{E}_{m}$$

$$(2.31)$$

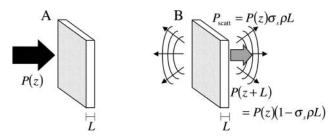

FIGURE 2.9 Multiple scattering. Schematic depiction of the interaction of a planar light beam with a thin slab of scattering material. The material contains ρ scatterers per unit volume, each with cross section σ_s . (A) Before the wave enters the slab, it contains power P(z). (B) After passing through the slab, the power scattered out of the wave is $\sigma_s \rho L$, where L is the thickness of the slab.

The energy involves two types of terms: (1) the energy contributed from each individual source and (2) the interference contributions (which are the manifestation of the coherence of light field). Again, by averaging over a sufficiently large region around the point, the interferences will average to zero:

$$\sum_{j=1}^{N} \sum_{\substack{m=1\\m\neq j}}^{N} \mathbf{E}_{j} \cdot \mathbf{E}_{m} \approx 0.$$
(2.32)

The size of the region necessary for the interferences to become zero depends on how the scatterers are distributed and on the nature of the scattering process. By considering only the spatially averaged energy, the wave nature of the light can be ignored and one need track only the movement of energy through the system. This can be a simpler task because the energies are scalar quantities without phase and polarization. In tissue media, which is modeled as a random collection of identical scattering particles, multiple scattering effects render the field largely incoherent, and the interference terms will be small relative to the average energy. Radiation transport theory will provide the equations that describe how this averaged light energy moves through such media.

2.3.1.2 Multiple Scattering

The systems of interest in this chapter are modeled as distributions of localized scatterers in a uniform background. Multiple scattering is an important phenomenon in these systems. Using a simple model one can illustrate the origin of these effects and their relation between single and multiple scattering. Consider a medium with a uniform distribution of scatterers. Each scatterer has a cross section σ_s , and the number density of scatterers is given by ρ . The medium can be broken up into slabs of thickness, Δz , and the field incident onto the first slab is a plane wave with intensity I_0 (Figure 2.9). The power incident on a local region of the layer with cross-sectional area A is I_0A . The power scattered out of the incident plane wave as it crosses the layer is given by

$$I_{0}\sigma_{s}\rho A\Delta z = I_{0}\mu_{s}A\Delta z = I_{0}\sigma_{s}N_{\text{layer}}, \qquad (2.33)$$

where N_{layer} is the number of scatters encountered in the layer. After passing through the layer, the power remaining in the plane wave is

$$P_{c}(0+\Delta z) = I_{0}A - I_{0}\sigma_{s}\rho A\Delta z = I_{0}A(1-\sigma_{s}\rho\Delta z). \tag{2.34}$$

(When $\sigma_s \rho \Delta z = 1$ for a layer, the effect saturates, so further increases in this quantity beyond unity have no physical effect.) Each successive layer decreases the intensity of the incident field by an addition factor of $(1 - \sigma_s \rho \Delta z)$. If the total number of layers is Γ , the total distance traveled is $L = \Gamma \Delta z$. The power remaining after propagating through this length, L, is

$$P_{c}(L) = I_{0}A(1 - \sigma_{s}\rho\Delta z)^{\Gamma} = I_{0}A(1 - \sigma_{s}\rho\frac{L}{\Gamma})^{\Gamma}. \tag{2.35}$$

As Γ increases, Equation 2.35 converges to an exponential:

$$I_{0}A\left(1-\sigma_{s}\rho\frac{L}{\Gamma}\right)^{\Gamma} \to I_{0}A\exp\left[-\sigma_{s}\rho L\right]. \tag{2.36}$$

Because there is no absorption, the total power in the scattered field given by

$$P_{\text{scatt}}^{\text{total}} = I_c(0)A - I_c(L)A = I_0A(1 - \exp[-\sigma_s\rho L]) = I_0A\left(1 - \exp[-\frac{\sigma_s}{A}N]\right)$$
 (2.37)

where *N* is the total number of scatterers encountered in the medium.

Using the power series expansion for the exponential, the term in parentheses can be written as

$$1 - \exp\left[-\frac{\sigma_{s}}{A}N\right] = -\sum_{m=1}^{\infty} \frac{\left(-\frac{\sigma_{s}}{A}N\right)^{m}}{m!} = \frac{\sigma_{s}}{A}N - \frac{1}{2}\frac{\sigma_{s}^{2}}{A^{2}}N^{2} + \frac{1}{6}\frac{\sigma_{s}^{3}}{A^{3}}N^{3} + \dots$$
 (2.38)

The quantity $\sigma_s \rho L$ is proportional to the number of scatterers encountered along the entire path from 0

to L. Since $\sigma_s \rho L = \frac{\sigma_s}{A} N$ when the quantity $\sigma_s \rho L \ll 1$, the scattered power can be approximated by

$$P_{\text{total}}^{\text{scatt}} \cong NI_0 \sigma_s$$
, (2.39)

and the power is therefore proportional to the number of scatterers. Physically, this is equivalent to saying that the scattered power is entirely due to waves that have scattered only once. The contributions from waves that have scattered more than once are small enough to be safely ignored in this limit. However, when the approximation

$$1 - \exp[-\sigma_{s}\rho L] \approx \sigma_{s}\rho L$$

breaks down, the scattered power has a more complicated nonlinear relationship with the number of scatterers encountered, and thus the power contained in multiply scattered waves is significant. So a criterion for defining a system as a single scattering medium is

$$\sigma_{\rho}L \ll 1, \tag{2.40}$$

or, in terms of the scattering coefficient, as

$$\mu_{L} << 1. \tag{2.41}$$

Even when the cross section is small if the scatterers are sufficiently dense and/or the propagation distance is sufficiently long, multiple-scattering effects can be important. Conversely, particles with large cross sections may not give rise to significant multiple-scattering effects if the concentration of the particles is low or if the path length is short. The significance of the distinction between single- and multiple-scattering processes is that the single-scattering case can be handled in a much more straightforward

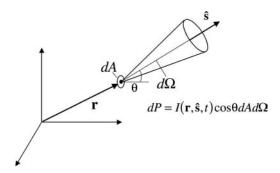

FIGURE 2.10 The light power passing through a surface element da inside a cone of solid angle $d\Omega$ directed at an angle θ to the surface normal n is proportional to the specific intensity $I(\mathbf{r}, \hat{\mathbf{s}}, t)$.

manner. The multiple-scattering effects provide the mechanism for "decohering" the scattered field and ultimately justify the use of RT theory, in which coherence processes are not explicitly taken into account.

2.3.2 The Radiation Transport Model

2.3.2.1 Basic Parameters

The multiple scattering and associated decoherence effects in turbid media effectively suppress the wave nature of light; therefore, instead of tracking light waves, one can track only the average energy they contain. The flow of light energy through the medium is described by RT theory, which explicitly disregards wave interference effects. The fundamental quantity that replaces the electromagnetic field in RT model is the specific intensity, $I(\mathbf{r}, \hat{\mathbf{s}}, t)$. The following relation defines the specific intensity:

$$dP = I(\mathbf{r}, \hat{\mathbf{s}}, t) d\omega da, \qquad (2.42)$$

where dP is the light power at time t and at point \mathbf{r} directed in a cone of solid angle $d\omega$ oriented in the direction defined by the unit vector $\hat{\mathbf{s}}$, from a surface area da normal to $\hat{\mathbf{s}}$ (Figure 2.10). Thus, $I(\mathbf{r}, \hat{\mathbf{s}}, t)$ is the light power per unit area per unit solid angle. Since the energy in a monochromatic light field is proportional to the number of photons the field contains, the specific intensity is representative of the number of photons per second passing through point \mathbf{r} within the solid angle cone.

The medium through which the light energy propagates is characterized by three parameters:

- 1. The absorption coefficient, μ_a
- 2. The scattering coefficient, μ_s
- 3. The scattering "phase" function (SPF), $p(\hat{\mathbf{s}} \cdot \hat{\mathbf{s}}')$

(The function $p(\hat{\mathbf{s}} \cdot \hat{\mathbf{s}}')$ does not have anything to do with the phase of propagating waves; the "phase" label is mainly the legacy of an earlier notation.) The coefficients μ_a and μ_s were defined earlier in Equations 2.18 and 2.12. The attenuation coefficient μ_t combines absorption and scattering effects into a single quantity given as

$$\mu_t = \mu_a + \mu_s \,. \tag{2.43}$$

The total mean free path is defined through the total attenuation coefficient as

$$l_{t} = \frac{1}{\mu_{a} + \mu_{s}} = \frac{1}{\frac{1}{l_{a}} + \frac{1}{l_{s}}}.$$
 (2.44)

In the RT model, the assumption is made that only one type of particle is responsible for both absorption and scattering and thus the number densities of scattering and absorbing particles are the same.

2.3.2.2 Scattering Phase Function

In the RT model, the particles are assumed to be isotropic, and so the scattering phase function, or SPF, is expressed as a function of $\hat{\mathbf{s}} \cdot \hat{\mathbf{s}}' = \cos\theta$. The SPF, $p(\hat{\mathbf{s}} \cdot \hat{\mathbf{s}}')$, describes the fraction of light energy incident on a scatterer from the $\hat{\mathbf{s}}'$ direction that gets scattered in the $\hat{\mathbf{s}}$ direction. (Note that this is a reversal of the earlier convention for $\hat{\mathbf{s}}$ and $\hat{\mathbf{s}}'$ used in Section 2.2.2. Since $\hat{\mathbf{s}} \cdot \hat{\mathbf{s}}' = \hat{\mathbf{s}}' \cdot \hat{\mathbf{s}}$, this change in convention has no bearing on the functional form of the SPF.) SPF can be expressed in terms of the differential scattering cross section,

$$p(\hat{\mathbf{s}} \cdot \hat{\mathbf{s}}') = \frac{4\pi}{\sigma_s + \sigma_a} \frac{d\sigma_s}{d\Omega} (\hat{\mathbf{s}} \cdot \hat{\mathbf{s}}'). \tag{2.45}$$

The integral of the SPF over all the solid angle yields the albedo W_0 ,

$$W_0 = \frac{1}{4\pi} \int_{4\pi} p(\hat{\mathbf{s}} \cdot \hat{\mathbf{s}}') d\Omega' = \frac{\sigma_s}{\sigma_a + \sigma_s},$$

$$= \frac{\mu_s}{\mu_a + \mu_s},$$
(2.46)

which is the fraction of the total cross section that is due to scattering. (It is important to mention here that the choice of normalization for $p(\hat{\mathbf{s}} \cdot \hat{\mathbf{s}}')$ varies among different treatments of RT theory.* To keep the outcomes the same among the different normalization schemes requires modification of one of the terms involving $p(\hat{\mathbf{s}} \cdot \hat{\mathbf{s}}')$ in the RT equations, Equations 2.49 to 2.51, discussed in the next section.)

Another constant of interest is the cosine-weighted average of the scattering, commonly known as the average cosine of scatter:

$$g = \frac{\int_{4\pi} p(\hat{\mathbf{s}} \cdot \hat{\mathbf{s}}') \hat{\mathbf{s}} \cdot \hat{\mathbf{s}}' d\Omega'}{\int_{4\pi} p(\hat{\mathbf{s}} \cdot \hat{\mathbf{s}}') d\Omega'} = \frac{1}{4\pi W_0} \int_{4\pi} p(\hat{\mathbf{s}} \cdot \hat{\mathbf{s}}') \hat{\mathbf{s}} \cdot \hat{\mathbf{s}}' d\Omega'$$
$$= \frac{1}{2W_0} \int_{4\pi} p(\cos\theta) \cos\theta \sin\theta d\theta. \tag{2.47}$$

The parameter g is a measure of scatter retained in the forward direction following a scattering event. For a Rayleigh scatterer, the SPF varies as $1 + \cos^2 \theta = 1 + (\hat{\mathbf{s}} \cdot \hat{\mathbf{s}}')^2$, and its average cosine of scatter, g, is zero. This is because backward and forward scattering are equally likely. A scatterer with g > 0 is more likely to forward-scatter a photon, while a negative g indicates a preference for backward scattering. Most of the scattering processes of interest in tissue optics are in the Mie limit, and the SPF can be difficult to calculate without detailed knowledge of the system. An approximate SPF often used is the Henyey–Greenstein function³ (Figure 2.11):

$$p_{HG}(\cos\theta) = \frac{4\pi\sigma_{s}}{\sigma_{a} + \sigma_{s}} \frac{1 - g^{2}}{\left(1 + g^{2} - 2g\cos\theta\right)^{\frac{3}{2}}}.$$
 (2.48)

^{&#}x27;Investigators in biomedical optics use a variety of different units, notations, and normalization procedures. Despite the different notations, the photophysical phenomena described are similar, and the final results of the derivations are the same.

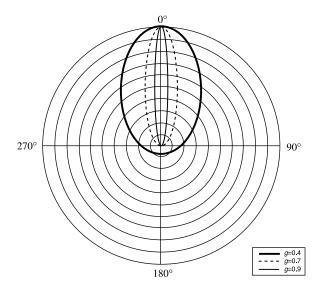

FIGURE 2.11 The angular dependence of the Henyey–Greenstein scattering phase function for g = 0.4, 0.7, and 0.9. Each of the patterns has been normalized to unity. When properly scaled, the maximum value of $p_{HG}(\theta)$ for g = 0.9 is 49 times that of the g = 0.4 case and 10 times that of the g = 0.7 case.

Henyey and Greenstein have developed this expression to describe the angular dependence of light scattering by small particles, which they used to investigate diffuse radiation from interstellar dust clouds in the galaxy.³ This function is convenient to use because it is parameterized by the average cosine of scatter, g. For tissues, g ranges from 0.4 to 0.99. Such values indicate that scattering is strongly forward-peaked. For example, for g = 0.6, almost 90% of the scattered energy is within 90° of the forward (i.e., $\theta = 0$) direction; for g = 0.99, 90% of the energy is scattered to within 5° of the forward direction.

The material constants can be calculated using electromagnetic wave theory, provided the properties of the particles (e.g., shape, size, refractive index, number density) and background medium are known. So even though the light transport in the RT model explicitly ignores the wave nature of light, electromagnetic wave phenomena are implicitly included through these material parameters.

2.3.2.3 Radiation Transport Equation

The fundamental equation describing light propagation in the RT model is the radiation transport equation (also known as the Boltzmann equation), which describes the fundamental dynamics of the specific intensity. Light is effectively treated as a collection of localized, incoherent photons. (Polarization properties can be considered, but we will avoid this complication.) Consider a small packet of light energy defined by its position, $\mathbf{r}(t)$, and direction of propagation $\hat{\mathbf{s}}$. Following along with it over the time interval dt as it propagates in space, the packet loses energy due to absorption and scattering out of $\hat{\mathbf{s}}$, but also gains energy from light scattered into the $\hat{\mathbf{s}}$ -directed packet from other directions and from any local source of the light at $\mathbf{r}(t)$. These processes are quantified by the integro-differential equation known as the radiation transport relation:

$$\frac{1}{c_{m}} \frac{d}{dt} I(\mathbf{r}(t), \hat{\mathbf{s}}, t) = -(\mu_{a} + \mu_{s}) I(\mathbf{r}(t), \hat{\mathbf{s}}, t)
+ \frac{\mu_{a} + \mu_{s}}{4\pi} \int p(\hat{\mathbf{s}} \cdot \hat{\mathbf{s}}') I(\mathbf{r}(t'), \hat{\mathbf{s}}', t) d\Omega' + Q(\mathbf{r}(t), \hat{\mathbf{s}}, t),$$
(2.49)

where c_m is the speed of light in the medium and $Q(\mathbf{r}(t), \hat{\mathbf{s}}, t)$ is the source term. If the coordinate system is fixed to the medium instead of moving with the energy packet, the total time derivative can be reduced

to partial derivatives, $\frac{d}{dt} \rightarrow \frac{\partial}{\partial t} + c\hat{\mathbf{s}} \cdot \vec{\nabla}$, yielding the usual form of the radiation transport equation:

$$\frac{1}{c_{m}} \frac{\partial I(\mathbf{r}, \hat{\mathbf{s}}, t)}{\partial t} = -\hat{\mathbf{s}} \cdot \vec{\nabla} I(\mathbf{r}, \hat{\mathbf{s}}, t) - (\mu_{a} + \mu_{s}) I(\mathbf{r}, \hat{\mathbf{s}}, t)
+ \frac{\mu_{a} + \mu_{s}}{4\pi} \int_{4\pi} p(\hat{\mathbf{s}} \cdot \hat{\mathbf{s}}') I(\mathbf{r}, \hat{\mathbf{s}}', t) d\Omega' + Q(\mathbf{r}, \hat{\mathbf{s}}, t) .$$
(2.50)

In this form, the dynamics can be interpreted through the change in $I(\mathbf{r}, \hat{\mathbf{s}}, t)$ with time. The specific intensity will increase with time if its spatial derivative in the $\hat{\mathbf{s}}$ direction is decreasing — that is, it will "flow" from regions of high intensity to low intensity. The $-(\mu_a + \mu_s) I(\mathbf{r}, \hat{\mathbf{s}}, t)$ term on the right-hand side of Equation 2.50 will always decrease the value of $I(\mathbf{r}, \hat{\mathbf{s}}, t)$, as it accounts for the scattering and absorption losses. The integral term will increase $I(\mathbf{r}, \hat{\mathbf{s}}, t)$ because of scattering from all other directions into the $\hat{\mathbf{s}}$ cone, as will any source of light $Q(\mathbf{r}, \hat{\mathbf{s}}, t)$ at \mathbf{r} . (Note that the integral term will have a different prefactor if an alternate normalization scheme for SPF is chosen, as mentioned in the previous section.)

An important simplification of the RT equation is the steady-state form. The term "steady state" implies

that
$$\frac{\partial I(\mathbf{r}, \hat{\mathbf{s}}, t)}{\partial t} = 0$$
; physically, this means that losses and gains are balanced such that the specific intensity

at any point in the medium does not change with time. The steady-state limit arises out of the time-resolved case when the light source has been switched on and has illuminated the sample long enough for the light levels to reach equilibrium. Strictly, this occurs when the source light has had time to reverberate through the tissue layers (i.e., reflect from each boundary) an infinite number of times. In practice, a large but finite number of reflections are sufficient to reach the steady-state as eventually attenuation and transmission losses render the higher-order reflections negligible. The steady state is applicable to many practical situations, even when the light source is pulsed or modulated. For example, consider a uniform light pulse that is 1 μ s in duration incident from air on a 1-cm-thick sample with an index of refraction of 1.33 with no absorbers or scatterers. One can show that the amount of light energy transmitted through the sample in the steady-state limit can be accounted for to better than one part in a million by just three reverberations of the initial light field through the sample. Over this 1- μ s time interval, light could reverberate through this sample more than 10,000 times. Thus for almost the entire duration of the pulse, the problem could be considered to be in the steady-state limit. The steady-state RT equation in a source-free region is

$$\hat{\mathbf{s}} \cdot \vec{\nabla} I(\mathbf{r}, \hat{\mathbf{s}}) = -(\mu_a + \mu_s)I(\mathbf{r}, \hat{\mathbf{s}}) + \frac{\mu_a + \mu_s}{4\pi} \int_{4\pi} p(\hat{\mathbf{s}} \cdot \hat{\mathbf{s}}')I(\mathbf{r}, \hat{\mathbf{s}}')d\Omega'. \tag{2.51}$$

2.3.3 Analytical Solutions for Limiting Cases

Although conceptually straightforward, the direct analytical solution of the RT equation for many problems of interest is difficult. Most of the complications arise from dealing with the boundaries at tissue interfaces, and geometric aspects of the tissues and light sources. The following discusses some of the important concepts regarding the light distributions and describes limiting cases of the RT model. The discussion will mainly be concerned with light fields propagating in a semi-infinite medium (i.e., cases in which the back wall of the tissue is far enough away that it has no influence on the distribution of light) in order to illustrate some basic properties of the diffuse field in various situations.

2.3.3.1 Incident and Diffuse Light

In the model considered here, the specific intensity is zero until light energy is provided by an external source (e.g., a laser) or an embedded source (e.g., fiber optic). The intensity in the medium can be expressed as

$$I(\mathbf{r},\hat{\mathbf{s}},t) = I_c(\mathbf{r},\hat{\mathbf{s}},t) + I_d(\mathbf{r},\hat{\mathbf{s}},t), \qquad (2.52)$$

where $I_c(\mathbf{r}, \hat{\mathbf{s}}, t)$ represents the unscattered component of the light energy and $I_d(\mathbf{r}, \hat{\mathbf{s}}, t)$ represents the scattered or diffuse component. If the light source is a coherent one, $I_c(\mathbf{r}, \hat{\mathbf{s}}, t)$ is the coherent field in the tissue. Even though coherence has no special implications in the RT model, it provides a convenient means for distinguishing between the field component that only loses energy from scattering, $I_c(\mathbf{r}, \hat{\mathbf{s}}, t)$, and the field component that receives and retains the energy from all orders of scattering, $I_d(\mathbf{r}, \hat{\mathbf{s}}, t)$. The single RT equation can be expressed as two separate equations: one involving only the coherent light,

$$\frac{1}{c_{ss}} \frac{\partial I_c(\mathbf{r}, \hat{\mathbf{s}}, t)}{\partial t} + \hat{\mathbf{s}} \cdot \nabla I_c(\mathbf{r}, \hat{\mathbf{s}}, t) = -(\mu_a + \mu_s) I_c(\mathbf{r}, \hat{\mathbf{s}}, t), \qquad (2.53)$$

and the second involving both light components (coherent and incoherent),

$$\frac{1}{c_{m}} \frac{\partial I_{d}(\mathbf{r},\hat{\mathbf{s}},t)}{\partial t} + \hat{\mathbf{s}} \cdot \nabla I_{d}(\mathbf{r},\hat{\mathbf{s}},t) =$$

$$- (\mu_{a} + \mu_{s}) I_{d}(\mathbf{r},\hat{\mathbf{s}},t)$$

$$+ \frac{\mu_{a} + \mu_{s}}{4\pi} \int_{4\pi} p(\hat{\mathbf{s}},\hat{\mathbf{s}}') I_{d}(\mathbf{r},\hat{\mathbf{s}}',t) d\Omega'$$

$$+ \frac{\mu_{a} + \mu_{s}}{4\pi} \int_{4\pi} p(\hat{\mathbf{s}},\hat{\mathbf{s}}') I_{c}(\mathbf{r},\hat{\mathbf{s}}',t) d\Omega' .$$
(2.54)

The last term in Equation 2.54 can be written as a source term for the diffuse component equation,

$$Q_{c}(\mathbf{r},\hat{\mathbf{s}},t) = \frac{\mu_{a} + \mu_{s}}{4\pi} \int_{4\pi} p(\hat{\mathbf{s}},\hat{\mathbf{s}}') I_{c}(\mathbf{r},\hat{\mathbf{s}}',t) d\Omega'.$$
 (2.55)

If the incident field is a plane wave, the coherent field solution to Equation 2.51 takes the form of the Beer–Lambert law (as shown earlier in Equation 2.21). For example, a planar source of intensity I_0 launched into a semi-infinite medium normal to its surface ($\hat{\mathbf{s}}_1 = \hat{z}$ and z is the depth into the tissue) takes the form

$$I_{c}(z,t) = f(c_{m}t - z)I_{c}(0)\exp[-(\mu_{a} + \mu_{s})z]$$

$$= I_{0}(1 - R^{2})f(c_{m}t - z)\exp[-(\mu_{a} + \mu_{s})z],$$
(2.56)

where $f(c_m t - z)$ is a positive definite, differentiable function describing the time envelope of the light pulse, valid for z > 0 and t > 0. In the steady state, the plane wave solution is simply

$$I_c(z) = I_0(1 - R^2) \exp[-(\mu_a + \mu_s)z].$$
 (2.57)

Note that the intensity of a plane wave relates to the specific intensity as

$$I(z,t) = \int I(\mathbf{r},\hat{\mathbf{s}},t)\delta(\hat{\mathbf{s}}-\hat{z})d\Omega.$$
 (2.58)

The behavior of the coherent field is straightforward in most cases, and its main role in tissue optics is to serve as a source for the diffuse field. The study of light transport in tissues means tracking the distribution of the diffuse field since in most situations it is the penetrating component of the light. Thus the determination of the specific intensity of the diffuse field I_d is the principal goal. The diffuse light gives rise to important phenomena such as diffuse reflectance, which arises from the subsurface scattering of light. A portion of the light launched into tissue will be scattered back across the surface as it is redirected by multiple scattering events. This light is thus distinct from surface reflections and is largely incoherent as its source is the subsurface diffuse field. This diffusely "reflected" light contains information about the bulk of the medium because it has collectively sampled an extended volume of the tissue. Changes in the diffuse reflectance over time can be used to track the dynamics of certain absorbing species in tissue, such as oxygenated hemoglobin. (Note that in other contexts "diffuse reflectance" also refers to reflection from a rough surface or interface.)

To introduce some of the important aspects of the diffuse and coherent light, we will examine approximate solutions for the two limiting cases — $\mu_a >> \mu_s$ (absorption-dominant limit) and $\mu_s >> \mu_a$ (scattering-dominant limit). We will also briefly discuss Monte Carlo calculations and the propagation of short pulses of light.

2.3.3.2 Absorption-Dominant Limit

In the case where absorption of light is the dominant process, the light does not penetrate the tissue deeply enough for significant scattering to occur, and the diffuse field will remain small compared to the coherent one. Using Equation 2.54, one can find an approximate solution for I_d by considering only the contributions of singly scattered light from the coherent field, encompassed in the term

$$\frac{\mu_a + \mu_s}{4\pi} \int_{4\pi} p(\hat{\mathbf{s}}, \hat{\mathbf{s}}') I_c(\mathbf{r}, \hat{\mathbf{s}}') d\Omega'$$

and ignoring the contributions of rescattered light, from the term

$$\frac{\mu_a + \mu_s}{4\pi} \int_{4\pi} p(\hat{\mathbf{s}}, \hat{\mathbf{s}}') I_d(\mathbf{r}, \hat{\mathbf{s}}') d\Omega'.$$

In the steady state, using this single-scattering approximation, Equation 2.54 becomes

$$\hat{\mathbf{s}} \cdot \vec{\nabla} I_d(\mathbf{r}, \hat{\mathbf{s}}) = -(\mu_a + \mu_s) I_d(\mathbf{r}, \hat{\mathbf{s}}) + \frac{\mu_a + \mu_s}{4\pi} \int_{4\pi} p(\hat{\mathbf{s}}, \hat{\mathbf{s}}') I_c(\mathbf{r}, \hat{\mathbf{s}}') d\Omega'. \tag{2.59}$$

The transport equation along a straight-line path of length s parallel to the direction \hat{s} is

$$\frac{d}{ds}I_d(\mathbf{r},\hat{\mathbf{s}}) = -(\mu_a + \mu_s)I_d(\mathbf{r},\hat{\mathbf{s}}) + \frac{\mu_a + \mu_s}{4\pi} \int_{4\pi} p(\hat{\mathbf{s}},\hat{\mathbf{s}}')I_c(\mathbf{r},\hat{\mathbf{s}}')d\Omega', \qquad (2.60)$$

where **r** points to the path that begins at the point \mathbf{r}_0 . This is a differential equation of the type $\frac{dy}{ds} + P(s)y = Q(s)$, which has the general solution

$$y(s) = Ce^{-\int_{s_0}^{s} P(w)dw} + e^{-\int_{s_0}^{s} P(w)dw} \int_{s_0}^{s} e^{-\int_{s_0}^{s'} P(v)dv} Q(s')ds', \qquad (2.61)$$

where C is a constant determined by the boundary conditions. Integrating along the path from 0 to s, the diffuse field is

$$I_{d}(s,\hat{s}) = C \exp[-\mu_{t}s] + \exp[-\mu_{t}s] \frac{\mu_{t}}{4\pi} \int_{0}^{s} \exp[\mu_{t}s_{1}] \int_{4\pi} p(\hat{s},\hat{s}') I_{c}(\mathbf{r}_{1},\hat{s}') d\Omega' ds_{1}. \tag{2.62}$$

Now we take the surface of the scattering medium to be at the plane $\mathbf{r} \cdot \hat{z} = 0$, which includes the point \mathbf{r}_0 (s = 0), and assume that the coherent light in the medium is a plane wave traveling in the \hat{z} direction:

$$I_{c}(\mathbf{r},\hat{\mathbf{s}}) = I_{0} \exp\left[-\mu_{t}(\mathbf{r} - \mathbf{r}_{0}) \cdot \hat{z}\right] \delta(\hat{\mathbf{s}} - \hat{z}). \tag{2.63}$$

The solution is then

$$\begin{split} I_{d}(s,\hat{\mathbf{s}}) &= C \exp\left[-\mu_{t}s\right] + \exp\left[-\mu_{t}s\right] \frac{\mu_{t}}{4\pi} \int_{0}^{s} \exp\left[\mu_{t}s_{1}\right] \int_{4\pi} p(\hat{\mathbf{s}},\hat{\mathbf{s}}') I_{c}(\mathbf{r}_{1},\hat{\mathbf{s}}') d\Omega' ds_{1} \\ &= C \exp\left[-\mu_{t}s\right] + \exp\left[-\mu_{t}s\right] \frac{\mu_{t}I_{0}}{4\pi} p(\hat{\mathbf{s}}\cdot\hat{\mathbf{z}}) \int_{0}^{s} \exp\left[\mu_{t}s_{1}(1-\cos\theta)\right] ds_{1} \\ &= C \exp\left[-\mu_{t}s\right] + \frac{I_{0}p(\cos\theta)}{4\pi} \frac{\exp\left[-\mu_{t}s\cos\theta\right] - \exp\left[-\mu_{t}s\right]}{1-\cos\theta}, \end{split} \tag{2.64}$$

except for $\hat{\mathbf{s}} = \hat{z} (\cos \theta = 1)$, where it is

$$= C \exp[-\mu_t z] + \frac{I_0 p(1)}{4\pi} \mu_t z \exp[-\mu_t z]. \tag{2.65}$$

Along the path from 0 to s, only the forward-scattered energy from the plane wave can contribute. Thus, the calculated value of I_d is only the forward-directed portion ($0 \le \theta < \pi/2$) of total diffuse field. So I_d of Equations 2.64 and 2.65 is now denoted $I_d^{(+)}$. With the nature of the solution properly interpreted, the constant of integration is simple to determine. The forward-directed diffuse field vanishes at the front surface (because there is nothing behind it to scatter into it), so C = 0. The forward diffuse field is then

$$I_d^{(+)}(s,\hat{s}) = I_0 \frac{p(\cos\theta)}{4\pi} \frac{\exp[-\mu_t s \cos\theta] - \exp[-\mu_t s]}{1 - \cos\theta} \left(0 < \theta < \frac{\pi}{2}\right), \tag{2.66}$$

and

$$I_d^{(+)}(z,\hat{z}) = I_0 \frac{p(1)}{4\pi} \mu_t z \exp[-\mu_t z] (\theta = 0).$$
 (2.67)

To solve for the diffuse field in the backscatter directions, $I_d^{(-)}$, the path must extend for the distance from s to the back wall of the sample, s_b . Only the plane wave components ahead of $I_d^{(-)}(s)$ (i.e., further along the path than the depth s) can scatter in the backward direction and contribute to the $\pi/2 < \theta < \pi$ portion of the diffuse field. At the end of the path, the sample will be assumed to be sufficiently thick such that back wall effects (reflections) will not contribute to the diffuse fields. The general solution of Equation 2.61 now becomes

$$y(s) = Ce^{-\int_{s}^{s_{b}} P(s')ds'} + e^{-\int_{s}^{s_{b}} P(s')ds'} \int_{s}^{s_{b}} e^{-\int_{s'}^{s_{b}} P(s'')ds''} Q(s')ds', \qquad (2.68)$$

and $I_d^{(-)}$ is

$$I_{d}^{(-)}(s,\hat{\mathbf{s}}) = C \exp\left[-\mu_{t}(s_{b} - s)\right]$$

$$+ I_{0} \frac{p(\cos\theta)}{4\pi} \frac{\exp\left[-\mu_{t}s|\cos\theta\right] - \exp\left[-\mu_{t}s_{b}(1+|\cos\theta|) + \mu_{t}s\right]}{1+|\cos\theta|}$$

$$(2.69)$$

for $\pi/2 < \theta \le \pi$, and for this range of angles using $\cos \theta = -|\cos \theta|$. In the limit that $s_b >> s$ and $\mu_t s_b >> 1$, $I_d^{(-)}$ becomes

$$I_d^{(-)}(s,\hat{s}) = I_0 \frac{p(\cos\theta)}{4\pi} \frac{\exp[-\mu_t s|\cos\theta|]}{1+|\cos\theta|}.$$
 (2.70)

Substituting the Henyey–Greenstein SPF for $p(\cos\theta)$, the total diffuse field as a function of depth $z = s\cos\theta$ (Figure 2.12) is

$$I_{d}(z,\cos\theta) = I_{0} \frac{\mu_{s}}{\mu_{t}} \begin{cases} \frac{1-g^{2}}{\left(1+g^{2}-2g\cos\theta\right)^{\frac{3}{2}}} \frac{\exp\left[-\mu_{t}z\right] - \exp\left[-\mu_{t}z/\cos\theta\right]}{1-\cos\theta} & 0 < \theta < \frac{\pi}{2} \\ \frac{1-g^{2}}{\left(1-g\right)^{3}} \mu_{t}z \exp\left[-\mu_{t}z\right] & \theta = 0 \\ \frac{1-g^{2}}{\left(1+g^{2}-2g\cos\theta\right)^{\frac{3}{2}}} \frac{\exp\left[-\mu_{t}z\right]}{1+\left|\cos\theta\right|} & \frac{\pi}{2} < \theta < \pi \end{cases}$$
(2.71)

These fields are maximized at depths of

$$z_{max} = \begin{cases} -\frac{1}{\mu_t} \frac{\cos\theta \ln[\cos\theta]}{1 - \cos\theta} & 0 < \theta < \frac{\pi}{2} \\ \frac{1}{\mu_t} & \theta = 0 \\ 0 & \frac{\pi}{2} < \theta < \pi \end{cases}$$
 (2.72)

With the Henyey–Greenstein SPF, one can see that the small diffuse field approximation may be violated for the forward fields when g is close to 1. For example, at g = 0.8, in the $\theta = 0$ case

$$\frac{1-g^2}{(1-g)^3} = 45$$

and for g = 0.95

$$\frac{1-g^2}{(1-g)^3} = 780.$$

Thus the degree of anisotrophy of the scattering should be taken into consideration before invoking the small albedo limit for a given problem.

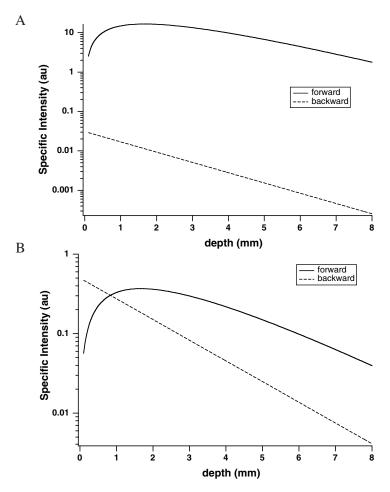

FIGURE 2.12. The forward $(\theta = 0^{\circ})$ and backscattered $(\theta = 180^{\circ})$ diffuse light in the absorption-dominant limit $(\mu_a >> \mu_s)$ for $\mu_t \cong \mu_a = 0.6$ mm⁻¹. (A) g = 0.8 and (B) g = 0.0 (isotropic scattering).

2.3.3.3 Scattering-Dominant Limit: the "Diffusion Approximation"

When the absorption is sufficiently low to permit significant penetration of light into the tissue, scattering is the dominant transport process. This scattering-dominant limit, known as the *diffusion limit*, is important because photons are able to move through the tissue, although the strong scattering disperses the light in a random fashion. In the diffusion process, the particles (in our case photons) moving through a medium do so in a series of steps of random length and direction (i.e., random walk). Each step begins with a scattering event and is equally likely to be taken in any direction. This isotropic scattering is described by the reduced scattering coefficient μ'_s , which is related to the previously defined anisotropic scattering parameters as follows:

$$\mu_s' = (1 - g)\mu_s. \tag{2.73}$$

In an average sense, this relationship equates the number of anisotropic scattering steps, given by m = 1/1 - g, with one isotropic scattering event. For example, in a medium characterized by g = 0.75, it takes an average of four scattering events for a population of photons to disperse isotropically. In tissues, one encounters values of g from 0.4 to >0.99, which results in isotropic dispersion of photons after as few as

2 steps to over 100 steps. The photons can also be absorbed as they propagate, and the absorption properties of the medium are encompassed by the usual absorption coefficient, μ_a .

When the number of photons undergoing the random walk is large, the density of photons can be described as a continuous function in space whose dynamics are described by the diffusion equation. In the diffusion limit, the properties of the medium are contained in the diffusion constant,

$$D = \frac{c_m}{3(\mu_a + (1 - g)\mu_s)},$$
 (2.74)

which has dimensions of length squared over time. The quantity

$$\mu_t' \equiv \mu_a + (1 - g)\mu_s \tag{2.75}$$

is called the transfer attenuation of the medium. The diffusion coefficient can also be written as

$$D = \frac{1}{3} c_m l_t' \,, \tag{2.76}$$

where $l'_t = 1/\mu'_t$ is the effective mean free path. The diffusion coefficient enters into the solutions for I_d in factors that describe the width of the diffuse photon distribution in space. For the examples shown below, the "widths" of the photon distributions are proportional to \sqrt{D} .

Diffusion Equation

When the scattering processes are dominant, the angular dependence of the specific intensity is well approximated by the first-order expansion in the unit vector $\hat{\mathbf{s}}$,

$$I_d(\mathbf{r}, \hat{\mathbf{s}}, t) \cong \frac{1}{4\pi} \Phi_d(\mathbf{r}, t) + \frac{3}{4\pi} F_d(\mathbf{r}, t) \hat{\mathbf{s}}_f \cdot \hat{\mathbf{s}} , \qquad (2.77)$$

where

$$\Phi_d(\mathbf{r},t) = \int_{4\pi} I_d(\mathbf{r},\hat{\mathbf{s}},t) d\Omega$$
 (2.78)

is the total intensity at point r (also called the *fluence rate*), and

$$\mathbf{F}_{d}(\mathbf{r},t) = F_{d}(\mathbf{r},t)\hat{\mathbf{s}}_{f} = \int_{A\pi} I_{d}(\mathbf{r},\hat{\mathbf{s}},t)\hat{\mathbf{s}}d\Omega$$
 (2.79)

is the net intensity vector. The total intensity can also be written as $\Phi_d(\mathbf{r},t) = h v c_m \eta_d(\mathbf{r},t)$, where $\eta_d(\mathbf{r},t)$ is the photon density. Similarly, the net intensity vector is proportional to the photon current density, $J(\mathbf{r},t) = c_m F_d(\mathbf{r},t)$. Integrating all the terms in the RT equation over the entire 4π of solid angle results in a new relation expressed in terms of $\Phi_d(\mathbf{r},t)$ and $F_d(\mathbf{r},t)$:

$$\frac{1}{c_m} \frac{\partial}{\partial t} \Phi_d(\mathbf{r}, t) + \vec{\nabla} \cdot \mathbf{F}_d(\mathbf{r}, t) = -\mu_a \Phi_d(\mathbf{r}, t) + Q_c + Q_s, \qquad (2.80)$$

where Q_c and Q_s represent source terms due to the coherent field and local sources. This equation gives us an expression of the divergence of \mathbf{F}_d in terms of the total intensity $\mathbf{\Phi}_d$.

The essential step in obtaining Equation 2.80 from Equation 2.54 is the calculation of the integral over the SPF:

$$\frac{\mu_{a} + \mu_{s}}{4\pi} \iint_{4\pi} p(\hat{\mathbf{s}}, \hat{\mathbf{s}}') I_{d}(\mathbf{r}, \hat{\mathbf{s}}', t) d\Omega' d\Omega =
\frac{\mu_{a} + \mu_{s}}{4\pi} \int_{4\pi} \left[\int_{4\pi} p(\hat{\mathbf{s}}, \hat{\mathbf{s}}') d\Omega \right] I_{d}(\mathbf{r}, \hat{\mathbf{s}}', t) d\Omega' =
\mu_{s} \int_{4\pi} I_{d}(\mathbf{r}, \hat{\mathbf{s}}', t) d\Omega' = \mu_{s} \Phi_{d}(\mathbf{r}, t) .$$
(2.81)

This term then cancels out the scattering loss contribution on the right-hand side of the original RT equation (Equation 2.54). The next step is to define a second relation between \mathbf{F}_d and $\mathbf{\Phi}_d$, and to use this new relation to eliminate \mathbf{F}_d . The lowest-order approximation is obtained by using Fick's law,

$$c_{m}\mathbf{F}_{d}(\mathbf{r},t) = -D\vec{\nabla}\mathbf{\Phi}_{d}(\mathbf{r},t). \tag{2.82}$$

Fick's law asserts that the net photon current is proportional to the gradient of the photon density, or, in other words, when the photon density varies in space, there is a net flow of photons from high density to low density regions along the path of steepest descent. Substituting Equation 2.82 into Equation 2.80 yields the diffusion equation:

$$\frac{\partial}{\partial t} \Phi_d(\mathbf{r}, t) = D \nabla^2 \Phi_d(\mathbf{r}, t) - \mu_a c_m \Phi_d(\mathbf{r}, t) + Q_c + Q_s. \tag{2.83}$$

A higher-order approximation for the diffusion problem can be derived from the RT equation in which the constants D, μ'_{tr} , and g arise naturally in the process. However, the resulting relation, known as the telegrapher's equation, has not been found to offer any significant advantages over the diffusion equation in tissue optics.⁴

Analytical solutions to the diffusion equation in practical situations can be quite complicated due to the finite sizes of the tissues and the related boundary effects. In the following section, we will examine solutions in some specific, ideal cases in order to demonstrate the nature of diffuse fields. The idealized results given below can often be used as starting points for the more complex situations that occur in solving practical problems.

Time-Dependent Solutions

In the following situation, time-dependent solutions of Equation 2.83 are given for the case in which material boundaries are far enough away to be neglected. A source is used to inject light at t = 0 but is removed immediately after and for all later times $(Q_oQ_s = 0, t > 0)$.

Following an injection of N photons into the medium at point \mathbf{r}_0 , the solution of Equation 2.83 for t > 0 takes the form

$$\Phi_{d}(\mathbf{r},t) = h v c_{m} \frac{N \exp(-\mu_{a} c_{m} t)}{(4\pi D t)^{\frac{3}{2}}} \exp\left(-\frac{r^{2}}{4D t}\right), \tag{2.84}$$

where $|r = \mathbf{r} - \mathbf{r}_0|$ (Figure 2.13). The spatial distribution of the light is Gaussian, with a time-varying 1/e radius of $r_{1/e} = \sqrt{4Dt}$. The numerator of the first factor, $N \exp(-\mu_a c_m t)$, contains the total number of photons that exist at time t, which is ever decreasing in time because of absorption. The denominator can be considered to be a volumetric normalization factor because it contains the factor $r_{1/e}^3 = \left(4Dt\right)^{3/2}$ is thus proportional to the volume of the sphere of radius $r_{1/e}$. At any time, and almost 90% of the photons will lie within the sphere of radius $r_{1/e}$. The photon density itself falls to half of its maximum inside of $r_{1/e}$:

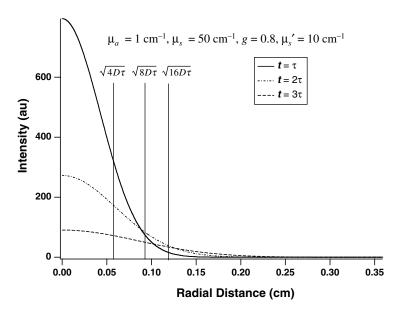

FIGURE 2.13 The photon density in the time-dependent diffusion process due to the point injection of photons at t = 0. The three curves represent the solution for time $t = \tau$, $t = 2\tau$, and $t = 4\tau$.

$$r_{1/2} = 2\sqrt{\ln 2}\sqrt{Dt} = 1.67\sqrt{Dt}$$
 (2.85)

Toward the center of the distribution, the local photon density is decreasing with time, while farther out, the density is increasing with time. The boundary between the two regions (growth boundary) occurs at the radius:

$$r_g = \sqrt{6Dt \left(1 + \frac{2}{3}\mu_a c_m t\right)}. \tag{2.86}$$

For $r = |\mathbf{r} - \mathbf{r}_0| < r_g$, the photon density is decreasing with time, while for $r > r_g$ the photon density is increasing with time. This radius defines the boundary between the sphere from which energy is escaping and the surrounding region that sees a net increase in energy with time.

Similar solutions are available for other source geometries. For a line source of photons injected at t = 0, the solution is

$$hvc_{m} \frac{N \exp(-\mu_{a}c_{m}t)}{4\pi Dt} \exp\left(-\frac{\left(\rho - \rho_{0}\right)^{2}}{4Dt}\right), \tag{2.87}$$

where $\rho - \rho_0$ is the perpendicular distance from the source line to a point in the medium and N now represents the number of photons emitted per unit of length. Here, the distribution has cylindrical symmetry, and 63% of the energy is within the cylinder of radius $\rho_{1/e} = \sqrt{4Dt}$. The boundary between increasing and decreasing density occurs at

$$\rho_g = \sqrt{4Dt \left(1 + \mu_a c_m t\right)} \,. \tag{2.88}$$

For a planar source the solution is

$$hvc_m \frac{N \exp(-\mu_a c_m t)}{(4\pi D t)^{1/2}} \exp\left(-\frac{(z-z_0)^2}{4D t}\right),$$
 (2.89)

where N is now interpreted as the number of photons injected per unit area, and $z - z_0$ is the distance from the observation point to the plane. The boundary between increasing and decreasing density is planar and occurs at a distance of

$$z_{g} = \sqrt{2Dt(1 + 2\mu_{a}c_{m}t)}$$
 (2.90)

in both directions normal to the source plane.

Steady-State Solutions

In the steady-state regime in a source free region, the diffusion equation becomes

$$\nabla^2 \Phi_d(\mathbf{r}) - \kappa_d^2 \Phi_d(\mathbf{r}) = 0, \qquad (2.91)$$

where

$$\frac{1}{\kappa_d} = \sqrt{\frac{D}{\mu_a c_m}} = \sqrt{\frac{1}{3\mu_a (\mu_a + (1 - g)\mu_s)}}$$
 (2.92)

is the diffusion length. A point source of light at r = 0, injecting photons at a rate to maintain the steady state, has a photon density away from the source of

$$\frac{\Phi_d(\mathbf{r})}{h\nu c_m} = \frac{N\kappa_d^2}{4\pi} \frac{\exp[-\kappa_d r]}{r}.$$
 (2.93)

In this case about 25% of the photons are inside the sphere of radius $1/\kappa_d$. A sphere of radius $4/\kappa_d$ contains 90% of the photons (see Figure 2.14).

For a line source the photon density is

$$\frac{\Phi_d(\mathbf{r})}{h\nu c_m} = \frac{N\kappa_d^2}{2\pi} K_0(\kappa_d \rho), \qquad (2.94)$$

where $K_0(\kappa_d \rho)$ is the zero-order-modified Bessel function of the second kind. For $\kappa_d \rho << 1$,

$$K_0(\kappa_d \rho) \sim \ln \frac{1}{\kappa_d \rho}$$
,

while, for large $\kappa_d \rho$,

$$K_0(\kappa_d \rho) \sim \frac{\exp[-\kappa_d \rho]}{\sqrt{\kappa_d \rho}}$$
.

A cylinder of radius $1/\kappa_d$ contains 44% of the photons and a cylinder of radius 3.2/ κ_d holds 90%. For a planar source, we have

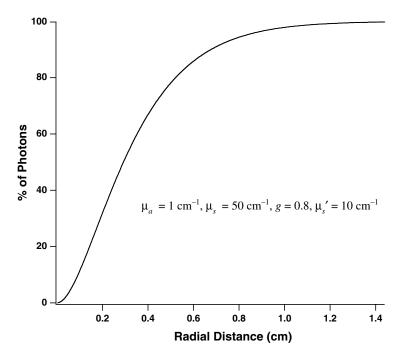

FIGURE 2.14 The percentage of photons inside a spherical volume, plotted as a function of the radius of the sphere, for the point source solution of the steady-state diffusion problem.

$$\Phi_d(\mathbf{r}) = \frac{N\kappa_d}{2} \exp\left[-\kappa_d |z|\right]. \tag{2.95}$$

Here, 63% of the photons are within $1/\kappa_d$ of either side of the plane, and 90% are within $2.3/\kappa_d$. Technically, these three solutions are the Green's functions for the steady-state diffusion equation

$$D\nabla^{2}\Phi_{d}^{G}(\mathbf{r},\mathbf{r}') - \mu_{a}c_{m}\Phi_{d}^{G}(\mathbf{r},\mathbf{r}') = -\delta(\mathbf{r} - \mathbf{r}')$$
(2.96)

for the various geometries (spherical, cylindrical, and planar). Because of their link to the Dirac delta function, they are considered distributions (i.e., generalized functions) as opposed to ordinary point functions. These solutions (Equations 2.93 through 2.95) can be used within the context of Green's theorem to solve problems involving finite sources and known boundary conditions.

2.3.4 Numerical Approach: Monte Carlo Simulations

Many problems of practical interest often involve a variety of light sources, multiple tissue types, and complex geometries. Analytical solutions for realistic scenarios are complicated at best, if even possible. These more realistic cases are instead solved with numerical techniques. For RT problems, the most widely used approach is the Monte Carlo (MC) method. The term *Monte Carlo* refers to a broad class of methods that employ random numbers in the course of solving a problem. Among the first large-scale applications of MC methods were RT problems involving neutron transport; thus, the MC approach is well suited to problems involving light transport in tissue because they are based on the same underlying framework of RT theory. The algorithms for implementing the basic elements of an MC simulation are straightforward. The technique thus possesses a great deal of flexibility and is widely applicable to practical transport problems. The MC approach can be used for any albedo and SPE.

The name refers to Monte Carlo, Monaco, where the primary attractions are casinos that offer games of chance. The random behavior in games of chance is similar to how MC simulation selects variable

values at random to simulate a model. When one rolls a die, one knows that a number from 1 to 6 will come up, but not which number for any particular roll. The same phenomenon occurs with photon trajectories propagating inside tissues, which exhibit an uncertain value for any particular time or event (e.g., scattering, absorption). The simulation is based on the random walks that photons make as they travel through tissue, chosen by statistically sampling the probability distributions for step size and angular deflection per scattering event. As the number of photons grows, the net distribution of all the photon paths yields an increasingly accurate approximation to the RT problem.

In an MC approach to photon transport, single photons are traced through the sample step by step, and the distribution of light in the system is built from these single-photon trajectories. The parameters of each step (length, direction, "weight," etc.) are calculated using functions whose arguments are random numbers. As the number of photons in the simulation grows toward infinity, the MC prediction for the light distribution approaches an exact solution of the RT equation. The actual number of photons necessary for a realistic result (i.e., a good statistical sample) depends on the specifics of the simulation and which quantities one desires to determine. As few as 3000 may be adequate for determining diffuse reflectance from a sample, while more than 100,000 may be required for a complex three-dimensional simulation.⁵

As an example of how step parameters are calculated by this method, we will illustrate how the step size is determined. The exponential decrease in intensity with depth as expressed in Beer's law,

$$\frac{I(L)}{I_0} = p_L = \exp[-(\mu_a + \mu_s)L], \qquad (2.97)$$

can be interpreted in the MC context as the probability p_L ($0 \le p_L \le 1$) that a photon will propagate a distance L without being scattered or absorbed. This relation is then inverted to express L in terms of the probability,

$$L = -\frac{\ln p}{\mu_a + \mu_s} \,, \tag{2.98}$$

and the probability is then treated as a random number. For each step, an L is calculated by randomly selecting a number p from a uniform distribution

$$f(p) = \begin{cases} 1 & 0$$

The expectation value (i.e., average) of $\ln p$ over the distribution $\underline{f}(p)$ is -1; so, as the number of random samplings grows, the resulting mean free path will converge to $\overline{L} = 1/\mu_a + \mu_s$, as one would expect.

Monte Carlo methods have been used for various transport processes as well as for emission in tissues. For example, modeling laser-induced fluorescence involves an expression for the fraction of fluorescence emitted per unit depth that escapes from the medium. Accurate expressions for fluence rate and escape function for the one-dimensional case based upon MC simulation results have been reported.⁶

2.3.5 Kubelka-Munk Model

For optically inhomogeneous media, the expression for quantitative analysis can be derived from an equation developed for optical studies on surfaces with diffuse reflectance.⁷ Schuster first conceived the continuum model and derived the basic differential equations for diffuse scattering materials to describe the behavior in a foggy atmosphere of radiation from a star.⁸ Schuster's model described two diffuse fluxes traveling in opposite directions through the gas, contributing backscattered flux to each other. Kubelka and Munk further improved the model conceived by Schuster and derived differential equations similar to those developed by Schuster except for the emission terms.⁹ Later, Kubelka developed a set of useful equations that provided the foundations for many quantitative studies of absorption, scattering, and

luminescence processes in diffuse scattering media. These equations are often known as the Kubelka–Munk (K–M) equations:¹⁰

$$-di/dx = -(S+K)i + Sj, (2.99)$$

$$dj/dx = -(S+K)j + Si, (2.100)$$

where i is the intensity of light propagating inside the sample in the forward (transmitted) direction, j is the intensity of light propagating in the backscattered direction, S is the scatter coefficient per unit thickness, K is the absorption coefficient per unit thickness, and x is the distance from the nonilluminated side.

The K–M equations simply describe the fact that the light beam traveling in the transmitted direction (i) decreases in intensity due to the absorption (K) and scattering (S) processes, and gains intensity from the scattering process that occurs in the beam coming from the other direction (i).

The basic assumptions in the K–M model are that the sample is a planar, homogeneous, and ideal diffuser illuminated on one side with diffuse monochromatic light. This model also assumes that the reflection and absorption processes occur at infinitesimal distances and are constant over the area under illumination and over the thickness of the sample. It is also implicitly assumed in the one-dimensional approximation of the K–M model that the reflected light beam is normal to the sample surface.

The general solutions in i and j for the K–M equations are given by

$$i = A \sinh bSx - B \cosh bSx, \tag{2.101}$$

$$j = (aA - bB)\sinh bSx - (aB - bA)\cosh bSx, \tag{2.102}$$

where

$$a = 1 + K/S (2.103)$$

$$b = (a^2 - 1)^{1/2}. (2.104)$$

The arbitrary constants A and B can be eliminated using the following conditions:

$$i = I_0 T$$
; $j = 0$ for $x = 0$ (2.105)

$$i = I_0$$
; $j = I_0 R$ for $x = X$. (2.106)

The transmittance T and reflectance R are then given by

$$T = b(a \sinh bSX + b \cosh bSX)^{-1},$$
 (2.107)

$$R = \sinh bSX(a \sinh bSX + b \cosh bSX)^{-1}, \tag{2.108}$$

where *X* is the thickness of the sample.

The solution for *T* and *R* can be used to determine the coefficient *SX*.

For a scattering medium that does not absorb light (i.e., when K = 0) the transmission T and reflectance R become

$$T_0 = 1(SX + 1)^{-1}, (2.109)$$

$$R_0 = SX(SX+1)^{-1}. (2.110)$$

The value of SX can be determined using the above equations. In general T_0 can be derived from measurement of the absorbance $A_0 = \log 1/T_0$.

There has been a great interest in using the K–M model for investigating optical properties of diffuse media. 11-29 A simple modification of the two-flux K–M model for the solution of one-dimensional

problems to the theory of radiation transfer in biological tissues and media was reported. The results were compared with the exact solution and experimental data for the substantiation of the applicability of the model to the problems of noninvasive laser diagnostics in medicine. A method utilizing the K–M theory was developed to allow the quantification of tissue reflectance spectra to study *in vivo* kinetic changes in the oxygen saturation of hemoglobin and myoglobin. The K–M model was used for investigating quantitative optical biopsy of tissue *ex vivo*. Later models use four fluxes that, in addition to the diffuse forward and backward fluxes, also involve collimated forward and backward fluxes. Multipleflux models provide data in good agreement with experimental results; however, the applicability of the K–M models is limited to simple slab geometries.

2.3.6 Time-Resolved Propagation of Light Pulses

When a light pulse is launched into a slab of tissue, the light that exits the sample can be broken into coherent and incoherent fields, as discussed previously. However, in contrast to the approximate RT model, some of the multiply scattered light retains phase coherence with the unscattered portion. In the forward direction, the interference of the coherent scatter and the unscattered light will effectively alter the refractive index of the medium. The coherent light is also called the "ballistic" component because it follows a straight path through the tissue. In the backscatter direction, there will be coherent components due to reflections from tissue boundaries and scattering. The remaining light will be diffuse. In the forward direction, the first part of the diffuse component to emerge consists of "snake" photons, so called because their paths approximate a straight line as they forwardscatter through the medium. If the detector used to observe the exiting light has sufficient time resolution, these photons can be isolated from the later-arriving components, consisting of a cloud of photons that have followed winding and varied paths through the slab.

The ballistic photons are the first to exit the tissue, and their mostly predictable paths (usually straight lines, although refraction may occur in multilayered samples) make them useful for absorption mapping and tomographic imaging (see Figure 2.15). The snake photons can also be used for mapping and tomography because their paths are nearly straight. Snake photons have the advantage over ballistic photons in scattering-dominant regimes because the ballistic component is more strongly attenuated as the tissue thickness increases. Most of the remaining multiple-scattering photons take random paths through the tissue; these paths can only be characterized statistically. Any information regarding local variations in the tissue (e.g., embedded tumors) carried by these later photons is dispersed and may be diluted in the cloud of diffuse light.

The specific conditions under which an experimental technique is considered time resolved depends upon the application. For example, if the aim is to be able to separate the ballistic, snake and diffuse components in a through-transmission experiment across a 1-cm sample, then the pulse width of light should be very short, typically on the order of ps (10^{-12} s) or less.

2.3.6.1 Effective Index of Refraction

Since some portion of the scattered field, even if multiply scattered, can maintain phase coherence with the initial field, the coherent portion of the scattered field will interfere with the original unscattered light. This interference manifests itself as a phase shift, and hence a time delay for time-resolved pulses. This implies that the speed of light in the medium, and hence the effective index of refraction, is affected by the scatterers. For a slab of tissue with no embedded scatterers, the time a photon takes to traverse the tissue is

$$\tau_0 = \frac{n_m}{c} L , \qquad (2.111)$$

where L is the width of the tissue sample and n_m is the index of refraction for the medium. When scatterers are present, the time of propagation becomes

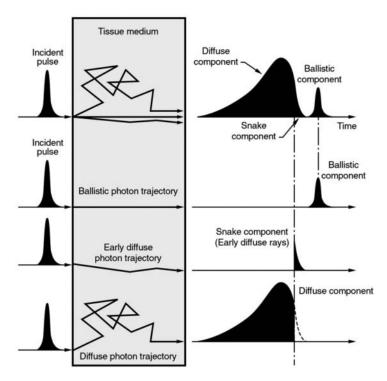

FIGURE 2.15 Paths of ballistic, snake, and diffusion photons propagating through tissue. For a short pulse of light transmitted through tissue, the ballistic component emerges first, followed by the diffuse (multiply scattered) component. The early part of the diffuse component is known as the "snake" component because the paths of these photons approximate straight lines through the tissue.

$$\tau_0 = \frac{n_{\text{eff}}}{c} L , \qquad (2.112)$$

where n_{eff} is the *effective refractive index* of the two-component medium. The question then is how to calculate n_{eff} . A commonly used approximation is to compute the effective index of refraction as the volume-weighted average of its constituents. For our two-component medium, the effective index is then

$$n_{\text{eff}} = (1 - V)n_m + Vn_{\text{sc}}, \qquad (2.113)$$

where V is the volume fraction of the scatterers embedded in the medium. This can also be written as

$$n_{\text{eff}} = n_m (1 + V\delta), \qquad (2.114)$$

where $n_{sc}/n_m = 1 + \delta$ and δ is the fractional contrast between the two indices. This volume-weighted approximation, however, does not take into account the coherent interference effects of the scattered field on the unscattered field. This interference will delay (or advance) the light over the medium alone, and is consistent with the volume-weighted approach only in limiting cases. However, the volume-weighted average approach is likely an adequate approximation in many cases of interest.

There are several theoretical formulations of the problem of defining the speed of ballistic transport across a multiply scattering medium. One such relation is that of Waterman and Truell,³⁰ who extended the earlier results of Foldy and Lax. The interference of the coherent scatter and the incident field gives rise to the following relation for the effective index of refraction of the medium:

$$n_{eff}^{2} = n_{m}^{2} \left(1 + \frac{\rho \lambda^{2}}{2\pi n_{m}^{2}} f(0) \right)^{2} - \left(\frac{\rho \lambda^{2}}{2\pi n_{m}^{2}} f(\pi) \right)^{2}, \qquad (2.115)$$

where $f(\theta)$ is the scattering amplitude and is related to the differential cross section as

$$\left| f(\mathbf{\theta}) \right|^2 = \frac{d\mathbf{\sigma}}{d\Omega} (\mathbf{\theta}). \tag{2.116}$$

For Rayleigh scatterers, using $|f(\theta)| = |f(\pi)|$ and Equation 2.14, the relation yields

$$n_{eff}^{2} = n_{m}^{2} \left(1 + \frac{\rho \lambda^{2}}{\pi n_{m}^{2}} f(0) \right)$$

$$= n_{m}^{2} \left(1 + 3V \frac{n_{sc}^{2} - n_{m}^{2}}{n_{sc}^{2} + 2n_{m}^{2}} \right), \tag{2.117}$$

where $V = \rho 4/3\pi a^3$ is the volume fraction of scatterers in the medium. Taking the square root,

$$n_{\text{eff}} = n_m \sqrt{1 + 2V\delta \frac{1 + \delta/2}{1 + 2\delta/3 + \delta^2/3}}$$
 (2.118)

For small $V\delta$, this can be approximated to lowest order in δ ,

$$n_{\text{eff}} = n_m (1 + V\delta), \qquad (2.119)$$

which is equivalent to the volume-weighted result. This result is essentially the single-scattering approximation to the problem, as it is linear in the volume fraction (and hence in the number) of scatterers. The question is then how well the approximate relation performs over realistic ranges of δ and V. Refractive indices for tissue constituents range from 1.33 (water) to above 1.6 (melanin particles), so 0.2 could be considered a relatively large value for δ . A comparison of Equation 2.114 with Equation 2.118 for a volume fraction of 25% shows the two expressions to be the same to better than 1% for δ of up to 0.36. At a volume fraction of 10%, the approximation is good to 1% for δ up to 0.6. For Rayleigh scatterers, using reasonable values for V and δ , the volume-weighted approach can be accurate to at least the 1% level, if not better.

Another issue for pulse propagation is dispersion, the change in the pulse shape for the ballistic component. In this case, the notion of a single velocity is somewhat ill defined. As many as five different velocities (e.g., phase, group, signal, energy, etc.) have been defined for pulse transmission through dispersive media. We will consider two of these: phase velocity and group velocity. Phase velocity is defined as

$$c_m(\mathbf{v}) = \frac{c_0}{n(\mathbf{v})} \tag{2.120}$$

and is the speed points of constant phase (e.g., the crests of the wave) for each individual wavelength component in the pulse. This can also be written as $1/(k_m/\omega)$, where $\omega = 2\pi v$ and $k_m = 2\pi/\lambda_m$. The speed of the envelope can be difficult to define because it changes shape in the material. A reasonable approximation to the speed of the pulse envelope is given by the group velocity, which is defined as

$$c_m^{\rm gr} = \frac{1}{dk_{\cdot \cdot \cdot}/d\omega} \tag{2.121}$$

$$= \frac{c_0}{n(\lambda)} \frac{1}{1 - \frac{\lambda}{n(\lambda)} \frac{d}{d\lambda} n(\lambda)}.$$
 (2.122)

One can use this relation to define the group index of refraction,

$$n_g(\lambda) = n(\lambda) \left(1 - \frac{\lambda}{n(\lambda)} \frac{d}{d\lambda} n(\lambda) \right).$$
 (2.123)

Variations in absorption and scattering in a material will give rise to index of refraction changes as they are fundamentally linked by causality. For cases where $n(\lambda)$ is known as a function of wavelength, the group index may be a more accurate estimate of the pulse speed for pulses whose dominant wavelength component is λ .

2.4 Tissue Properties

2.4.1 Refractive Indices

The refractive index for a medium determines the speed of light in the medium, and changes in the refractive index, either continuous or abrupt (i.e., at a boundary), give rise to scattering, refraction, and reflection. Since tissues are heterogeneous in composition, one may need to know the refractive indices for the various tissue constituents (e.g., to calculate scattering properties) or an "averaged" value for the tissue as a whole (e.g., the time delay of ballistic photons). The effective refractive index of a tissue is often approximated as the volume-weighted average of the values of its constituents, a reasonable estimate in many cases (see the discussion in Section 2.3.6.1).

Water makes up a significant portion of most tissues, and its index (n = 1.33) represents the minimum value for fluids and soft-tissue constituents. Among the other soft-tissue components, melanin particles, found mostly in the epidermal layer of the skin (see Section 2.4.3.2 below), are at the high end of the refractive index scale, with reported values above 1.6. Indices of refraction for whole tissues themselves — including parts of the brain, aorta, lung, stomach, kidney, and bladder — fall in the range of 1.36 to 1.40. Extracellular fluids and intracellular cytoplasm fall in the range of 1.35 to 1.38. The index of refraction for fatty tissues is around 1.45. The membranes that enclose cells and subcellular organelles are composed largely of lipids, and the index mismatch between the cytoplasm and these lipid structures is the origin of much of the scattering in cellular tissues. For hard tissues, the index for tooth enamel has been measured as 1.62 within the visible spectrum. Specific values for various bones in the body are not widely reported. The refractive indices of various tissues and tissue components are listed in Table 2.1.

2.4.2 Scattering Properties

As discussed previously, scattering occurs where there is a spatial variation in the refractive index, either continuous or abrupt (e.g., due to localized particles). In cellular media, the important scatterers are the subcellular organelles. The size range exhibited by these organelles includes the wavelengths of the therapeutic window, as their dimensions run from <100 nm to 6 μ m. As scatterers, most of these structures fall in the Mie regime, exhibiting highly anisotropic forward-directed scattering patterns.

The mitochondria, the site of respiration and energy production in cells, are the dominant scatterers among the organelles. These structures are roughly cylindrical and vary in size depending on cell type, with characteristic dimensions of 0.5 to 2 μ m. The mitochondria, in addition to being enclosed in a lipid

membrane, also have lipid folds running inside them. This structure gives these organelles a high optical contrast to the surrounding cytoplasm and produces the observed strong scattering effects.

The largest of the cellular organelles is the cell nucleus, with a diameter in the 4- to 6-µm range. The endoplasmic reticulum and Golgi apparatus are some of the larger organelles. These two organelles also pinch off small submicron vesicles (spherical membrane-enclosed containers) that transport their various molecular products through the cell. These smaller vesicle-type organelles include lysosomes and perioxisomes that are 0.25 to 0.5 µm in diameter.

The cells vary in shape and size among the different tissue types with dimensions of a few microns and larger. An isolated cell can be a strong scatterer, but within a tissue the scattering is largely subcellular in origin. In skin, melaninosomes are important scattering structures ranging in size from 100 nm to $2 \mu m$. These species contain melanin particles, which are strung together as beads. (Melanin is discussed further in Section 2.4.3.2.)

In blood, the disk-shaped red cells (erythrocytes) are the strongest scatterers. The erythrocyte disk is \sim 2 μ m thick with a diameter of 7 to 9 μ m. The scattering properties of blood are dependent on the hematocrit (volume fraction of red cells) and its degree of agglomeration.

Support tissues, consisting of cells and extracellular proteins such as elastin and collagen, provide mechanical strength and durability. The scattering properties of these tissues arise from the small-scale inhomogeneities and the large-scale variations in the structures they form. The characteristic sizes of the small-scale variations are subwavelength, and the scattering is of the Rayleigh type. For example, collagen fibrils have a banded structure that produces Rayleigh scattering and has a periodicity of 70 nm, on the order of 10 times smaller than the wavelengths in the diagnostic window.³¹ The scattering coefficients (μ_s) and average cosines of scatter (g) for various tissues are given in Table 2.2.

2.4.3 Absorption Properties

2.4.3.1 The Therapeutic Window

The ability of light to penetrate tissues depends on how strongly the tissues absorb light. Within the spectral range known as the therapeutic window (or diagnostic window), most tissues are sufficiently weak absorbers to permit significant penetration of light. This window extends from 600 to 1300 nm, from the orange region of the visible spectrum into the NIR. At the short-wavelength end, the window is bound by the absorption of hemoglobin, in both its oxygenated and deoxygenated forms. The absorption of oxygenated hemoglobin increases approximately two orders of magnitude as the wavelength shortens in the region around 600 nm. At shorter wavelengths many more absorbing biomolecules become important, including DNA and the amino acids tryptophan and tyrosine. At the IR end of the window, penetration is limited by the absorption properties of water. Within the therapeutic window, scattering is dominant over absorption, and so the propagating light becomes diffuse, although

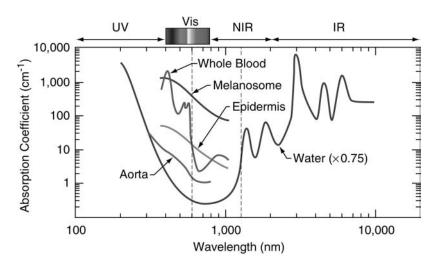

FIGURE 2.16 (Color figure follows p. 28-30.) The "therapeutic window" (region between the dashed lines) in tissue, which runs from 600 to 1400 nm, and the spectra of several important absorbers in this range.

not necessarily entering into the diffusion limit. Figure 2.16 shows a diagram of the therapeutic window of tissue. The absorption properties of various components of tissues are discussed below.

2.4.3.2 Absorption Properties of Tissue Components

Absorption in tissues is a function of molecular composition. Figure 2.17 shows the chemical structures of some molecules of biological and biomedical interest. Molecules absorb photons when the photon's energy matches an interval between internal energy states, and the transition between quantum states obeys the selection rules for the species. At the short-wavelength (higher photon energy) end of the spectrum, these transitions are electronic. Some of the important absorbers in the UV include DNA, the aromatic amino acids (tryptophan and tyrosine), proteins, melanins, and porphyrins (which include hemoglobin, myoglobin, vitamin B12, and cytochrome c) (Figure 2.17B). Figure 2.18 shows the absorption spectra of Fe(III) cytochrome c at various pH values from 6.8 to 1.7.33

Nucleic acids. DNA has an absorption peak at 258 nm ($\varepsilon = 6.6 \times 10^3$ cm² · mol⁻¹), but its absorption falls four orders of magnitude as the wavelength increases to 300 nm, and it has no significant activity in the visible and NIR. Figure 2.19 shows the absorption spectrum of DNA from *Escherichia coli* in the native form at 25°C (solid curve) and as an enzymic digest of nucleotides (dashed curve).³² RNA exhibits similar absorption properties, having a maximum absorption at 258 nm ($\varepsilon = 14.9 \times 10^3$ cm² · mol⁻¹). The absorption of nucleic acids arise from $n - \pi^*$ and $\pi - \pi^*$ transitions. The absorption spectra of the constituent purine and pyrimidine bases occur between 200 and 300 nm. The absorption maxima (λ_{max}) and extinction coefficients (ε) of several purine and pyrimidine bases and their derivatives are shown in Table 2.3.

Amino acids and proteins. A number of amino acid side chains — including His, Arg, Glu, Gln, Asn, and Asp — have transitions around 210 nm. These transitions cannot usually be observed in proteins because they are overlapped by the much stronger absorption bands associated with amide backbone groups, which have strong absorption around 230 nm. The amino acids tryptophan, tyrosine, and phenylalanine contain an aromatic ring, which distinguishes them from the other amino acids. They are strong absorbers for $\lambda < 300$ nm and have local peaks in the 260- to 280-nm range and even larger peaks at shorter wavelengths (Figure 2.20).³³ The useful UV range for proteins is at wavelengths longer than 230 nm, where absorption bands from the aromatic side chains of phenylamine ($\lambda_{max} = 257$ nm; $\varepsilon = 0.2 \times 10^{-3}$ cm² · mol⁻¹), tryptophan ($\lambda_{max} = 280$ nm; $\varepsilon = 5.6 \times 10^3$ cm² · mol⁻¹), and tyrosine ($\lambda_{max} = 274$ nm; $\varepsilon = 1.4 \times 10^3$ cm² · mol⁻¹)³⁴ occur (Figure 2.20A). Because tryptophan has the most intense absorbance, it is often used as the basis for protein concentration measurements. Chemical modification of tryptophan

FIGURE 2.17 Chemical structures of various species of biological interest.

or tyrosine can alter their absorption spectra. NADH absorbs at 340 nm ($\varepsilon = 6.2 \times 10^6 \cdot \text{mol}^{-1}$) and at 260 nm ($\varepsilon = 14 \times 10^6 \cdot \text{mol}^{-1}$), while NAD absorbs only at 260 nm ($\varepsilon = 18 \times 10^6 \cdot \text{mol}^{-1}$). Measurements of NADH absorption can be used to monitor a reaction occurring in biological fluids and tissues. Figure 2.20B shows the absorption spectra of other constituents in biological tissues.

Skin. The skin covers the entire surface of our bodies and protects internal organs from the harsh elements of the environment; it is usually described as consisting of three layers. The outer layer is the epidermis. Below is the dermis, which is made up of skin appendages such as hair follicles and sweat glands, surrounded by fibrous supporting tissue and collagen. Finally, the underlying layer, called the subcutaneous tissue, contains fat-producing cells and fibrous tissue. The outermost part of the epidermis is the corneal layer, consisting of millions of dead skin cells, which are shed and continuously replaced by living cells (epidermal keratinocytes) that originate from the basal layer. Melanocytes, which are among the basal cells of the epidermis, produce melanin, the protective pigment responsible for skin color. Melanocytes are stimulated by sunlight and therefore produce melanin to protect the skin against harmful UV radiation.

(B) Absorption spectra of various constituents in tissue.

Melanins. Melanins are a group of polymers that provide for pigmentation and are the dominant chromophores in the skin.³⁵ In most people the absorption of epidermis is usually dominated by melanin absorption. Melanin is a polymer built by condensation of tyrosine molecules and has a broad absorption spectrum exhibiting stronger absorption at shorter wavelengths. Melanin is found in the melanosome, a membranous particle whose internal membranes are studded with many melanin granules, particulates of about 10 to 30 nm in size. In the visible range (400 to 700 nm), melanin exhibits strong absorption, which decreases at longer wavelengths.

Blood and hemoglobin. Knowledge about the optical properties μ_a , μ_s , and g of human blood plays an important role for many diagnostic and therapeutic applications in laser medicine and medical diagnostics. Hemoglobin is a constituent in biological tissue that exhibits several absorption bands. Hemoglobin molecules within the red blood cells (erythrocytes) carry 97% of the oxygen in the blood, while the remaining 3% is dissolved in the plasma. Each hemoglobin molecule contains four iron-containing heme groups as well as the protein globin. Oxygen atoms easily bind to the iron, causing the hemoglobin to assume different structures. Hemoglobin in the oxygenated state is referred to as oxyhemoglobin (HbO₂); in the reduced state, it is called deoxyhemoglobin (Hb). If the hemoglobin molecule is bound to carbon monoxide, then it becomes carboxyhemoglobin (HbCO). The porphyrin ring system is mainly responsible for the color in heme protein. This relatively large molecular system has a high degree of electron delocalization, which results in a decrease in the energy required for a transition to occur. As a result, the absorption of porphyrin occurs in the visible range. For example, the absorption spectrum of Fe(III) hemoprotein exhibits several bands at 400, 500, 530, 590, 625, and 1000 nm.³⁴

The absorption spectrum of hemoglobin changes when binding occurs. Oxygenated hemoglobin is a strong absorber up to 600 nm; then its absorption drops off very steeply, by almost two orders of magnitude, and remains low. The absorption of deoxygenated hemoglobin, however, does not drop dramatically; it stays relatively high, although it decreases with increasing wavelengths. The isobestic point where the two spectra intersect occurs at about 800 nm. ³⁶ The optical properties of blood depend strongly on physiological parameters such as oxygen saturation, osmolarity, flow conditions, and hematocrit.

The integrating sphere technique and inverse MC simulations were applied to measure μ_a , μ_s , and g of circulating human blood.³⁷ At 633 nm the optical properties of human blood with a hematocrit of 10% and an oxygen saturation of 98% were found to be 2.10 ± 0.02 cm⁻¹ for μ_a , 773 \pm 0.5 cm⁻¹ for μ_s , and 0.994 \pm 0.001 for the g factor. An increase of the hematocrit up to 50% led to a linear increase of absorption and reduced scattering. Variations in osmolarity and wall shear rate led to changes of all three parameters, while variations in the oxygen saturation led only to a significant change in the absorption coefficient. Spectra of all three parameters were measured in the wavelength range of 400 to 2500 nm for oxygenated and deoxygenated blood; the results showed that blood absorption follows the absorption behavior of hemoglobin and water. Figure 2.21 shows the extinction coefficient of hemoglobin.³⁶

Chance and co-workers employed time-resolved spectroscopy to measure photon path lengths and thereby determine hemoglobin concentration in tissue.³⁸ Although deoxyhemoglobin and melanin are strong absorbers inside the diagnostic window, their relatively low concentrations in tissues explain why they do not significantly affect transmission processes. However, when light strikes a blood vessel, it encounters the full strong absorption of whole blood.

Water. At the NIR end of the window, the dominant absorber is water because of transitions between its vibrational energy states. The absorption of water in the spectral range of 700 to 1100 nm is shown in Figure 2.22. Note that even within the water transmission window (UV to 930 nm) where the absorption of water is rather low, water still contributes significantly to the overall attenuation of tissue because its concentration is very high in biological tissue.

Skull. The skull has been studied in the therapeutic window, and its absorption is quite low (0.02 to 0.05 mm⁻¹) compared with that of soft tissue.³⁹

2.5 Conclusion

This chapter emphasizes the basic physics of light propagation in tissues with the goal of providing a fundamental framework for more in-depth study. The discussions are aimed at providing an introduction to and description of basic concepts and equations related to photon transport in biological tissues. The following chapters give detailed treatments of the wide range of phenomena that fall within the broad umbrella of biomedical photonics. A further description of specific theoretical methods for image reconstruction such as diffraction tomography is provided in Chapter 4. Various light phenomena in tissue are described in Chapter 3. Experimental techniques and clinical applications of light transport are described in Chapters 21, 22, and 33.

2.6 Summary

Across the spectrum, a great variety of electromagnetic phenomena are used in biomedicine to detect and treat disease, and to advance scientific knowledge. In principle, the propagation of light in tissue can be described using fundamental electromagnetic theory; however, the direct application of EM wave theory in tissue optics is not simple because of the complexity of tissue as a host medium for light propagation. Instead, the problem can be simplified by ignoring wave phenomena such as polarization and interferences, and particle properties such as inelastic collisions. This model, known as the *radiation transport (RT) theory*, is a general description of the flow of energy or particles in a system.

Several properties provide the basis on which the inputs to RT theory are built:

Index of refraction, $n(\lambda)$ Scattering cross section, σ_s Differential scattering cross section, $d\sigma_s/d\Omega$ Absorption cross section, σ_a

• The *index of refraction* is a fundamental property of homogeneous media. The real part of the refractive index, $n(\lambda)$, can be defined in terms of the phase velocity of light in the medium,

$$c_m(\lambda) = \frac{c}{n(\lambda)}$$
.

- Refractive index mismatches on a macroscopic scale (e.g., between soft tissue and bones, skin, and skull) give rise to refraction. On the other hand, refractive index mismatches at microscopic scales (e.g., cell membrane boundaries, organelles) give rise to scattering of light in biological tissue.
- The ratio of the power scattered out of a plane wave to the incident intensity is the *scattering cross section*,

$$\sigma_s(\hat{\mathbf{s}}) = \frac{P_{scatt}}{I_0} ,$$

where $\hat{\mathbf{s}}$ is the propagation direction of the plane wave relative to the scatterer.

• The scattering coefficient μ_s [cm⁻¹] can be expressed in terms of particle density ρ [cm⁻³] and scattering cross section σ_s [cm²] as

$$\mu_s = \rho \sigma_s$$
.

- Scattering of light by tissue structures much smaller than the photon wavelength involves the socalled *Rayleigh limit*. Those structures include many components of the cell such as membranes, cell subcompartments, etc. The Rayleigh scattered light is equally distributed among the forward and rearward hemispheres, with peaks in the forward and backward directions.
- Scattering of light by spherical objects is described by *Mie theory*, which in principle is applicable at any size-to-wavelength ratio. In the intermediate size-to-wavelength range, where the Rayleigh and geometric approximations are not valid, Mie theory is used. Thus this region where the scatterer size and wavelength are comparable is sometimes labeled the *Mie regime*. Various cellular structures and extracellular components have sizes from hundreds of nanometers to a few microns and are comparable in dimension to the photon wavelengths of the therapeutic window. Even though these structures are not necessarily spherical, their scattering behavior can be modeled reasonably well by Mie theory applied to spheres of comparable size and refractive index. The scattering from tissue in this regime is strongly peaked in the forward direction.
- Absorption processes involve an important concept in quantum theory, the *energy level*, which is
 a quantum state of an atom and molecule. The energy of a particular level is determined relative
 to the ground level, or lowest possible energy level (zero energy). The shift of a species (e.g.,
 molecule or atom) from one energy level to another is called a *transition*. A transition of a species
 from a lower to a higher energy level involves excitation to an excited state and requires absorption
 of an amount of photon energy, hv, equal to the difference in energy, ΔE, between the two levels:

$$hv = \Delta E$$
.

• For a localized absorber, the *absorption cross section* σ_a can be defined in the same manner as for scattering:

$$\sigma_a = \frac{P_{abs}}{I_0} ,$$

where P_{abs} is the amount of power absorbed out of an initially uniform plane wave of intensity (power per unit area) I_0 .

• The absorption coefficient μ_a [cm⁻¹] can be defined in terms of particle density ρ [cm⁻³] and absorption cross section σ_a [cm²]

$$\mu_a = \rho \sigma_a$$
.

• The fundamental equation that describes light propagation in the RT model is the *radiation transport* (RT) *equation*, which describes the fundamental dynamics of the specific intensity. The steady-state RT equation in a source-free region is

$$\hat{\mathbf{s}} \cdot \nabla I(\mathbf{r}, \hat{\mathbf{s}}) = -(\mu_a + \mu_s)I(\mathbf{r}, \hat{\mathbf{s}}) + \frac{\mu_a + \mu_s}{4\pi} \int_{4\pi} p(\hat{\mathbf{s}} \cdot \hat{\mathbf{s}}')I(\mathbf{r}, \hat{\mathbf{s}}')d\Omega',$$

where $I(\mathbf{r}, \hat{\mathbf{s}}, t)$ is the specific intensity [light power per unit area per unit solid angle] at point \mathbf{r} directed in a cone of solid angle oriented in the direction defined by the unit vector $\hat{\mathbf{s}}$.

• The scattering phase function (SPF), $p(\hat{\mathbf{s}} \cdot \hat{\mathbf{s}}')$, describes the fraction of light energy incident on a scatterer from the $\hat{\mathbf{s}}'$ direction that is scattered out into the $\hat{\mathbf{s}}$ direction.

- Although conceptually straightforward, the direct analytical solution of the RT equation for many
 problems of interest is difficult. Most of the complications arise from dealing with the boundaries
 at tissue interfaces and geometric aspects of the tissues and light sources. The RT equation can be
 solved using analytical approaches based on deterministic approximations. Two common analytical approaches involve the diffusion approximation and the Kubelka–Munk model. In the numerical
 approach, the Monte Carlo method is often used to calculate photon transport through tissue.
- The ability of light to penetrate tissues depends on how strongly the tissues absorb light. Within the spectral range known as the *therapeutic window* (also called the *diagnostic window*), most tissues are sufficiently weak absorbers to permit significant penetration of light. This window extends from 600 to 1300 nm, from the orange region of the visible spectrum into the N/R.

3.1 Introduction

Two large classes of biological media can be considered with regard to light interactions with biological tissues and fluids: (1) strongly scattering (opaque) like skin, brain, vessel walls, eye sclera, blood, and lymph and (2) weakly scattering (transparent) like cornea, crystalline lens, vitreous humor, and aqueous humor of the front chamber of eye. ¹⁻⁷ Light interactions with tissues of the first class can be described in the model of multiple scattering of scalar or vector waves in a randomly nonuniform absorbing medium. For tissues of the second class, interactions can be described in the model of single (or low-step) scattering of an ordered isotropic or anisotropic medium with closely packed scatterers with absorbing centers.

The transparency of tissues reaches its maximum in the near-infrared (NIR), which is associated with the fact that living tissues do not contain strong intrinsic chromophores that would absorb radiation within this spectral range. ^{1–7} Light penetrates into a tissue over several centimeters, which is important for the transillumination of thick human organs (brain, breast, etc.). However, tissues are characterized by strong scattering of NIR radiation, which prevents obtaining clear images of localized inhomogeneities arising in tissues due to various pathologies, e.g., tumor formation, local increase in blood volume caused by a hemorrhage, or the growth of microvessels. Therefore, special attention in optical tomography and spectroscopy is focused on the development of methods for the selection of image-carrying

photons or detection of photons providing the information concerning optical parameters of the scattering medium.

Methods of noninvasive optical diagnosis and spectroscopy of tissues are concerned with two radiation regimes: continuous wave (CW) and time-resolved.¹⁻⁷ The time-resolved interactions are realized by means of exposure of a tissue to short laser pulses and subsequent recording of scattered broadened pulses (time-domain method) or by irradiation with modulated light and recording the depth of modulation of scattered light intensity and the corresponding phase shift at modulation frequencies (frequency-domain or phase method). The time-resolved regimes are based on the excitation of the photon-density wave spectrum in a strongly scattering medium, which can be described in the framework of the nonstationary radiation transfer theory (RTT). The CW regime is described by the stationary RTT.

Many optical medical technologies employ laser radiation and fiber optics; therefore, light coherence is very important for the analysis of the interaction of light with tissues and cell ensembles.^{2–5,7–12} This problem can be considered in terms of the loss of coherence due to the scattering of light in a randomly nonuniform medium with multiple scattering or the change in the statistics of speckles in the scattered field. The coherence of light is of fundamental importance for the selection of photons that have experienced no or a small number of scattering events, as well as for the generation of speckle-modulated fields from scattering phase objects with single and multiple scattering. Such approaches are important for coherent tomography, diffractometry, holography, photon-correlation spectroscopy, laser Doppler anemometry, and speckle interferometry of tissues and biological flows. The use of optical sources with a short coherence length opens up new opportunities in coherent interferometry and tomography of tissues, organs, and blood flows.

The vector nature of light waves is important for light–tissue interaction because, in a scattering medium, it is manifested as polarization ability of an initially unpolarized incident light or the change in the character of polarization state of an initially polarized light propagating in a medium. Similar to coherence properties of a light beam reflected from or transmitted through a biological object, polarization properties of light can be employed as a selector of photons coming from different depths in an object.^{3,5,7}

Quasi-elastic light scattering (QELS) as applied to monitoring of dynamic systems (chaotic or directed movements of tissue components or cells) is based mainly on the correlation or spectral analysis of the temporal fluctuations of the scattered light intensity.^{3,5,7-10} QELS spectroscopy (also known as light-beating spectroscopy or correlation spectroscopy) is widely used for various biomedical applications, particularly for blood or lymph flow measurement and cataract diagnostics. Diffusion wave spectroscopy (DWS) is available for the study of optically thick tissue when multiple scattering prevails and photon migration (diffusion) within tissue is important for the character of intensity fluctuations.

Raman scattering is the basis for Raman vibrational spectroscopy. It is a great tool to study the structure and dynamic function of biological molecules and has been used extensively for monitoring and diagnosis of diseases such as cataracts, artherosclerotic lesions in coronary arteries, precancerous and cancerous lesions in human soft tissues, and bone and teeth pathologies.^{13–15}

Light-induced fluorescence is also a powerful noninvasive method for tissue pathology recognition and monitoring.^{7,17–19} Autofluorescence, fluorescence of introduced markers, and time-resolved, laserscan, and multiphoton fluorescence have been used to study human tissues and cells *in situ*.

Light-induced thermal effects on tissue are important for diagnostics, therapy, and surgery.^{5,7,12,20–25} The optothermal spectroscopy, based on detecting time-dependent heat generation induced in a tissue by pulsed- or intensity-modulated optical radiation, is widely used in biomedicine. Among optothermal methods, optoacoustic (OA) and photoacoustic (PA) techniques are of great importance. They allow one to estimate tissue optical, thermal, and acoustic properties that depend on peculiarities of tissue structure.

For thermal phototherapy and surgery, much higher light intensities are used. Controllable temperature rise and thermal or thermomechanical damage (coagulation, vaporization, vacuolization, pyrolysis, ablation) of a tissue are important in that case. 12,21-25

Diagnostic Window

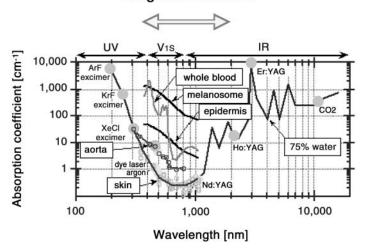

FIGURE 3.1 Water, some tissues (aorta, skin), and tissue component (whole blood, melanosome, epidermis) absorption spectra. Wavelengths of lasers widely used in laser therapy and surgery are also shown (ArF, KrF, and XeCl excimer lasers; dye laser; argon laser; solid-state Nd: YAG, Ho:YAG, and Er:YAG lasers). 3.2 Light Interactions with a Strongly Scattering Tissue

3.2.1 Continuous Wave (CW) Light

Biological tissues are optically inhomogeneous and absorbing media whose average refractive index is higher than that of air. This is responsible for the partial reflection of the radiation at the tissue—air interface (Fresnel reflection), while the remaining part penetrates the tissue. Multiple scattering and absorption are responsible for light beam broadening and eventual decay as it travels through a tissue, whereas bulk scattering is a major cause of the dispersion of a large fraction of radiation in the backward direction. Cellular organelles such as mitochondria are the main scatterers in various tissues. 1-7

Absorbed light is converted to heat or radiated in the form of fluorescence; it is also consumed in photobiochemical reactions. The absorption spectrum depends on the type of predominant absorption centers and water content of tissues (see Figure 3.1). Absolute values of absorption coefficients for typical tissues lie in the range of 10^{-2} to 10^4 cm⁻¹.¹⁻⁷ In the ultraviolet (UV) and infrared (IR) ($\lambda \ge 2 \mu m$) spectral regions, light is readily absorbed, which accounts for the small contribution of scattering and inability of radiation to penetrate deep into tissues (only across one or more cell layers). In the wavelength range of 600 to 1600 nm, scattering prevails over absorption; the intensity of the reflected radiation increases to 35 to 70% of the total incident light (due to backscattering).

Light interaction with multilayer and multicomponent tissues is a very complicated process (see Figure 3.2). For example, for skin, the horny layer (stratum corneum) reflects about 5 to 7% of the incident light. A collimated light beam is transformed to a diffuse one by microscopic inhomogeneities at the air–horny layer interface. A major part of the reflected light results from backscattering in different skin layers (stratum corneum, epidermis, dermis, blood, and fat). The absorption of diffuse light by skin pigments is a measure of bilirubin and melanin content and hemoglobin saturation with oxygen. These characteristics are widely used in the diagnosis of various diseases. Certain phototherapeutic and diagnostic modalities take advantage of ready transdermal penetration of visible and NIR light inside the body in the wavelength region corresponding to the so-called therapeutic or diagnostic window (600 to 1600 nm).

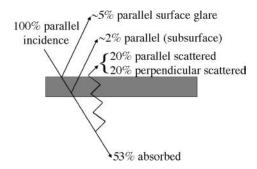

FIGURE 3.2 Simplified two-layer scattering and absorption model of skin at linear polarized incident light. (From Jacques, S.L. et al., *Proc. SPIE*, 4001, 94, 2000. With permission.)

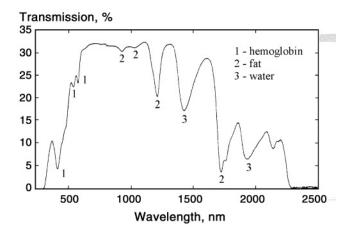

FIGURE 3.3 Transmission spectrum of a 3-mm-thick slab of female breast tissue. A spectrometer with an integrating sphere was used. The contributions of absorption bands of the tissue components (hemoglobin = 1, fat = 2, and water = 3) are indicated. (From Marks, F.A., *Proc. SPIE*, 1641, 227, 1992. With permission.)

Another example of heterogeneous multicomponent tissue is a female breast. The absorption bands of hemoglobin, fat, and water are clearly seen in the *in vitro* measured spectrum of a 3-mm slab of breast tissue presented in Figure 3.3.²⁷ There is a wide window between 700 and 1100 nm, and narrow ones at about 1300 and 1600 nm where the lowest percentage of light is attenuated.

A collimated (laser) beam is attenuated in a tissue layer of thickness *d* in accordance to the exponential law (Beer–Lambert law):

$$I(d) = (1 - R_{\rm E}) I_0 \exp(-\mu_{\rm E} d),$$
 (3.1)

where I(d) is the intensity of transmitted light measured using a distant photodetector with a small aperture (on-line or collimated transmittance), W/cm²; R_F is the coefficient of Fresnel reflection; at the normal beam incidence, $R_F = [(n-1)/(n+1)]^2$; n is the relative mean refractive index of tissue and surrounding media; I_0 is the incident light intensity, W/cm²; $\mu_t = \mu_a + \mu_s$ is the extinction coefficient (interaction or total attenuation coefficient), 1/cm; μ_a is the absorption coefficient, 1/cm; μ_s is the scattering coefficient, 1/cm. The mean free path length between two interactions is denoted by

$$l_{\rm ph} = \mu_{\rm r}^{-1}. \tag{3.2}$$

To analyze light propagation under multiple scattering conditions, it is assumed that absorbing and scattering centers are uniformly distributed across the tissue. Visible and NIR radiation is normally subject to anisotropic scattering characterized by a well-apparent direction of a scattered photon.

A sufficiently strict mathematical description of CW light propagation in a scattering medium is possible in the framework of the stationary RTT. This theory is valid for an ensemble of scatterers located far from one another and has been successfully used to work out some practical aspects of tissue optics. The main stationary equation of RTT for monochromatic light has the form:¹⁻⁷

$$\frac{\partial I(\bar{r},\bar{s})}{\partial s} = -\mu_t I(\bar{r},\bar{s}) + \frac{\mu_s}{4\pi} \int 4\pi I(\bar{r},\bar{s}') p(\bar{s},\bar{s}') d\Omega', \tag{3.3}$$

where $I(\bar{r}, \bar{s})$ is the radiance (or specific intensity) – average power flux density at a point \bar{r} in the given direction \bar{s} , (W/cm²sr); $p(\bar{s}, \bar{s}')$ is the scattering phase function, 1/sr; and $d\Omega$ is the unit solid angle about the direction \bar{s}' , sr. It is assumed that no radiation sources are inside the medium.

To characterize the relation of scattering and absorption properties of a tissue, a parameter such as albedo is usually introduced $\Lambda = \mu_s/\mu_r$. The albedo ranges from zero for a completely absorbing medium to unity for a completely scattering medium.

The phase function $p(\bar{s}, \bar{s}')$ describes the scattering properties of the medium and is in fact the probability density function for scattering in the direction \bar{s}' of a photon traveling in the direction \bar{s} ; in other words, it characterizes an elementary scattering act. If scattering is symmetric relative to the direction of the incident wave, then the phase function depends only on the scattering angle θ (angle between directions \bar{s} and \bar{s}'), i.e., in practice, the phase function is usually well approximated with the aid of the postulated Henyey–Greenstein function:^{1–7}

$$p(\bar{s},\bar{s}') = p(\theta) = \frac{1}{4\pi} \cdot \frac{1 - g^2}{\left(1 + g^2 - 2g\cos\theta\right)^{3/2}},$$
 (3.4)

where g is the scattering anisotropy parameter (mean cosine of the scattering angle θ). The value of g varies in the range from 0 to 1: g = 0 corresponds to isotropic (Rayleigh) scattering and g = 1 to total forward scattering (Mie scattering at large particles).^{28–31}

The integro-differential equation (Equation 3.1) is frequently simplified by representing the solution in the form of spherical harmonics. Such simplification leads to a system of $(N+1)^2$ connected differential partial derivative equations known as the P_N approximation. This system is reducible to a single differential equation of order (N+1). For example, four connected differential equations reducible to a single diffusion-type equation are necessary for N=1.¹⁻⁷ The photon diffusion coefficient, cm²/c,

$$D = c/3(\mu_s' + \mu_a), \tag{3.5}$$

and the reduced (transport) scattering coefficient, 1/cm,

$$\mathbf{u}_{s}' = (1 - g)\mathbf{u}_{s} \tag{3.6}$$

are the major parameters of the diffusion equation; here c is the velocity of light in the medium.

The transport mean free path (MFP) of a photon (cm) is defined as

$$lt = (\mu_s' + \mu_a)^{-1}. (3.7)$$

It is worthwhile to note that the transport mean free path in a medium with anisotropic single scattering significantly exceeds the mean free path in a medium with isotropic single scattering $l_t >> l_{\rm ph}$. The transport MFP l_t is the distance over which the photon loses its initial direction.

3.2.2 Polarized Light

It is a common belief that the randomness of tissue structure results in fast depolarization of light propagating in tissues; therefore, polarization effects are usually ignored. However, in certain tissues (transparent tissues such as eye tissues, cellular monolayers, mucous membrane, superficial skin layers, etc.) the degree of polarization of transmitted or reflected light remains measurable even when the tissue has considerable thickness. In such a situation, the information about the structure of tissues and cell ensembles can be extracted from the registered depolarization degree of initially polarized light, the polarization state transformation, or appearance of a polarized component in the scattered light. 3,5,7,26,31–36 With regard to practical implications, polarization techniques are believed to give rise to simplified schemes of optical medical tomography compared with time-resolved methods and also provide additional information about the structure of tissues.

Polarization refers to the pattern described by the electric field vector as a function of time at a fixed point in space. When the electric field vector oscillates in a single fixed plane all along the beam, the light is said to be linearly polarized. This linearly polarized wave can be resolved into components parallel E_{\parallel} and perpendicular E_{\perp} to the scattering plane. If the plane of the electric field rotates, the light is said to be elliptically polarized, because the electric field vector traces out an ellipse at a fixed point in space as a function of time. If the ellipse happens to be a circle, the light is said to be circularly polarized. The connection between phase and polarization can be understood as follows: circularly polarized light consists of equal amounts of linear, mutually orthogonal polarized components where they oscillate exactly 90° out of phase. In general, light of arbitrary elliptical polarization consists of unequal amplitudes of linearly polarized components and the electric fields for the two polarizations oscillate at the same frequency but have some constant phase difference.

Light of arbitrary polarization can be represented by four numbers known as the Stokes parameters: I, Q, U, and V refers to the intensity of the light; the parameters Q, U, and V represent the extent of horizontal liner, 45° linear, and circular polarization, respectively. In terms of the electric field components, the Stokes parameters are given by

$$I = \langle E_{\parallel} E_{\parallel}^{*} + E_{\perp} E_{\perp}^{*} \rangle,$$

$$Q = \langle E_{\parallel} E_{\parallel}^{*} - E_{\perp} E_{\perp}^{*} \rangle,$$

$$U = \langle E_{\parallel} E_{\perp} + E_{\perp} E_{\parallel}^{*} \rangle,$$

$$V = \langle E_{\parallel} E_{\perp}^{*} - E_{\perp} E_{\parallel}^{*} \rangle,$$
(3.8)

and the irradiance or intensity of light by

$$I^2 = Q^2 + U^2 + V^2. (3.9)$$

The polarization state of the scattered light in the far zone is described by the Stokes vector connected with the Stokes vector of the incident light

$$\vec{I}_s = M \cdot \vec{I}_i, \qquad (3.10)$$

where M is the normalized 4×4 scattering matrix (intensity or Mueller's matrix):

$$M = \begin{bmatrix} M_{11} & M_{12} & M_{13} & M_{14} \\ M_{21} & M_{22} & M_{23} & M_{24} \\ M_{31} & M_{32} & M_{33} & M_{34} \\ M_{41} & M_{42} & M_{43} & M_{44} \end{bmatrix},$$
(3.11)

and \vec{I}_i is the Stokes vector of incident light:

$$\vec{I}_{i,s} = \begin{bmatrix} I_{i,s} \\ Q_{i,s} \\ U_{i,s} \\ V_{i,s} \end{bmatrix}.$$
 (3.12)

The degree of linear polarization of scattered light is defined as

$$P_{L} = (I_{\parallel} - I_{\perp})/(I_{\parallel} + I_{\perp}) = [Q_{s}^{2} + U_{s}^{2}]^{1/2}/I_{s}, \tag{3.13}$$

and that of circular polarization as

$$P_C = V_s / I_s. ag{3.14}$$

Elements of the light scattering matrix (LSM) depend on the scattering angle θ , the wavelength, and geometrical and optical parameters of the scatterers. There are only 7 independent elements (of 16) in the scattering matrix of a single particle with fixed orientation and nine relations that connect the others together. For scattering by a collection of randomly oriented scatterers, there are ten independent parameters.

 M_{11} is what is measured when the incident light is unpolarized, the scattering angle dependence of which is the phase function of the scattered light. It provides only a fraction of the information theoretically available from scattering experiments. M_{11} is much less sensitive to chirality and long-range structure than some of the other matrix elements. M_{11} refers to a degree of linear polarization of the scattered light; M_{22} displays the ratio of depolarized light to the total scattered light (a good measure of scatterers' nonsphericity); M_{34} displays the transformation of 45° obliquely polarized incident light to circularly polarized scattered light (uniquely characteristic for different biological systems); the difference between M_{33} and M_{44} is a good measure of scatterers' nonsphericity.

If a particle is small with respect to the wavelength of the incident light, its scattering can be described as if it were a single dipole. The so-called Rayleigh theory is applicable under the condition that $m(2\pi a/\lambda) << 1$, where m is the relative refractive index of the scatterers, $(2\pi a/\lambda)$ is the size parameter, a is the radius of the particle, and λ is the wavelength of the incident light in a medium.³¹ For the NIR light and typical biological scatterers with a refractive index referring to the ground matter m=1.05 to 1.1, the maximum particle radius is about 12 to 14 nm for the Rayleigh theory to remain valid. For this theory the scattered irradiance is inversely proportional to λ^4 and increases because a^6 : the angular distribution of the scattered light is isotropic.

The Rayleigh-Gans or Rayleigh-Debye theory addresses the problem of calculating the scattering by a special class of arbitrary shaped particles. It requires |m-1| << 1 and $(2\pi a'/\lambda) |m-1| << 1$, where a' is the largest dimension of the particle.³² These conditions mean that the electric field inside the particle must be close to that of the incident field and the particle can be viewed as a collection of independent dipoles exposed to the same incident field. A biological cell might be modeled as a sphere of cytoplasm with a higher refractive index ($\bar{n} = 1.37$) relative to that of the surrounding water medium ($\bar{n} = 1.35$); then m = 1.015 and, for the NIR light, this theory will be valid for the particle dimension up to a' = 850 to 950 nm. This approximation has been applied extensively to calculations of light scattering from suspensions of bacteria.³² It can be applicable for describing light scattering from cell components (mitochondria, lysosomes, peroxisomes, etc.) in tissues due to their small dimensions and refraction.

For the description of the region near the forward direction scattering caused by large particles (of order of 10 µm), the Fraunhofer diffraction approximation is useful.³² According to this theory the scattered light has the same polarization as that of the incident light and the scatter pattern is independent of the refractive index of the object. For the small scattering angles, Fraunhofer diffraction approximation can accurately represent the change in irradiance as a function of particle size. That is why this approach is applicable in laser flow cytometry. The structures of the biological cell such as cell membrane, nuclear texture, and granules in the cytoplasm can be represented by variations in optical density.

Mie or Lorenz–Mie scattering theory is an exact solution of Maxwell's electromagnetic field equations for a homogeneous sphere.^{31,32} In the general case, light scattered at a particle becomes elliptically polarized. For spherically symmetric particles of an optically inactive material, the Mueller scattering matrix is given by³¹

$$M = \begin{vmatrix} M_{11} & M_{12} & 0 & 0 \\ M_{12} & M_{11} & 0 & 0 \\ 0 & 0 & M_{33} & M_{34} \\ 0 & 0 & -M_{34} & M_{33} \end{vmatrix}.$$
(3.15)

Mie theory has been extended to arbitrary coated spheres and to arbitrary cylinders.³² In Mie theory the electromagnetic fields of the incident, internal, and scattered waves are each expanded in a series.³² A linear transformation can be made between the fields in each of the regions. This approach can also be used for nonspherical objects such as spheroids. The linear transformation is called the transition matrix (T-matrix), which for spherical particles is diagonal.

For a system of small, spatially uncorrelated particles, the degree of linear (i = L) and circular (i = C) polarization in the far region of the initially polarized (linearly or circularly) light transmitted through a layer of thickness d is defined by the relation³⁴

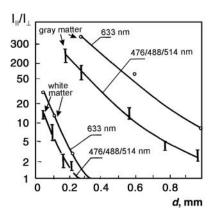

$$P_{i} \cong \frac{2d}{l_{s}} \sinh(l_{s}/\xi_{i}) \cdot \exp(-d/\xi_{i}), \qquad (3.16)$$

where $l_s = l/\mu_s$ is the scattering length; $\xi_i = (\zeta \cdot l_s/3)^{0.5}$ is the characteristic depolarization length for a layer of scatterers, $d >> \xi_i$, $\zeta_L = l_s/[\ln(10/7)]$, $\zeta_C = l_s/(\ln 2)$.

As can be seen from Equation 3.16, the characteristic depolarization length for linearly polarized light in tissues that can be represented as ensembles of Rayleigh particles is approximately 1.4 times greater than the corresponding depolarization length for circularly polarized light. One can employ Equation 3.16 to assess the depolarization of light propagating through an ensemble of large-scale spherical particles whose sizes are comparable with the wavelength of incident light (Mie scattering). For this purpose, one should replace l_s by the transport length $l_t \cong 1/\mu_s'$ and take into account the dependence on the size of scatterers in ζ_L and ζ_C . With the growth in the size of scatterers, the ratio ξ_L/ζ_C changes. It decreases from ~1.4 down to ~0.5 as $2\pi a/\lambda$ increases from 0 up to ~4, where a is the size of scatterers and λ is the wavelength of the light in the medium, and remains virtually constant at the level of 0.5 when $2\pi a/\lambda$ grows from ~4 to 15.

The Mueller matrix for the backscattering geometry was obtained by solving a radiative transfer equation with appropriate boundary conditions. ³³ Analysis of this matrix structure showed that its form coincides with the single scattering matrix for optically active spherical scatterers. Thus, different tissues or the same tissues in various pathological or functional states should display different responses to the probing with linearly and circularly polarized light. This effect can be employed in optical medical tomography and for determining optical and spectroscopic parameters of tissues. As follows from Equation 3.16, the depolarization length in tissues should be close to the mean transport path length l_t of a photon because this length characterizes the distance within which the direction of light propagation and, consequently, the polarization plane of linearly polarized light, become totally random after many sequential scattering events.

Since the length l_t is determined by the parameter g characterizing the anisotropy of scattering, the depolarization length should also substantially depend on this parameter. Indeed, the experimental data of Bicout et al.³⁴ demonstrate that the depolarization length l_p of linearly polarized light, which is defined as the length within which the ratio I_{\parallel}/I_{\perp} decreases to 2, displays such a dependence. The ratio mentioned above varied from 300 to 1, depending on the thickness of a sample and the type of a tissue (see Figure 3.4). These measurements were performed within a narrow solid angle ($\sim 10^{-4}$ sr) in the direction of the

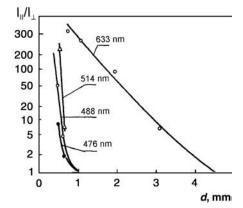

FIGURE 3.4 Tissue polarization properties. Dependence of the depolarization degree $(I_{\parallel}/I_{\perp})$ of laser radiation (He-Ne laser, $\lambda = 633$ nm and Ar laser, $\lambda = 476/488/514$ nm) on the penetration depth (d) for brain tissue (gray and white matter) and whole blood (low hematocrit). Measurements were performed within a small solid angle (10^{-4} sr) along the axis of a laser beam 1 mm in diameter. A strong influence of fluorescence was seen for blood irradiated by Ar laser.

incident laser beam. The values of l_p considerably differed for white substance of brain and a tissue of cerebral cortex: 0.23 and 1.3 mm for $\lambda = 633$ nm, respectively. Whole blood is characterized by a considerable depolarization length (about 4 mm) at $\lambda = 633$ nm; this is indicative of dependence on the parameter g, whose value for blood exceeds the values of this parameter for tissues of many other types and can be estimated as 0.982 to 0.999.^{5,7,10}

In contrast to depolarization, the attenuation of collimated light is determined by the total attenuation coefficient μ_t (see Equation 3.1). For many tissues, μ_t is much greater than μ_s' . Therefore, in certain situations, it is impossible to detect pure ballistic photons (photons that do not experience scattering), but forwardscattered photons retain their initial polarization and can be used for imaging purpose. Ostermeyer et al.³⁶ experimentally demonstrated that laser radiation retains linear polarization on the level of $P_L \leq 0.1$ within 2.5 l_r . Specifically, for skin irradiated in the red and NIR ranges, $\mu_a \cong 0.4$ cm⁻¹, $\mu_s' \cong 20$ cm⁻¹, and $l_t \cong 0.48$ mm.

Consequently, light propagating in skin can retain linear polarization within the length of about 1.2 mm. Such an optical path in a tissue corresponds to a delay time on the order of 5.3 ps, which provides an opportunity to produce polarization images of macro-inhomogeneities in a tissue with a spatial resolution equivalent to the spatial resolution that can be achieved with the selection of photons by means of more sophisticated time-resolved techniques. In addition, polarization imaging makes it possible to eliminate specular reflection from the surface of a tissue (see Figure 3.2), which allows one to apply this technique for the imaging of microvessels in facile skin.³ Polarization images can see skin subsurface textural changes and allow one to erase melanin from the image.²⁶

Polarization imaging is a new direction in tissue optics.^{5,7,26,33} The registration of two-dimensional polarization patterns for the backscattering of a polarized incident narrow laser beam is the base for this technique. Major informative images can be received using the backscattering Mueller matrix approach. To determine each of the 16 experimental matrix elements, a total of 16 images should be taken at various combinations of input and output polarization states.

3.2.3 Short Light Pulses

When probing the plane-parallel layer of a scattering medium with an ultrashort light pulse, the transmitted pulse consists of a ballistic (coherent) component, a group of photons having zigzag trajectories, and a highly intensive diffuse component (see Figure 3.5a).^{1–7,17,23,37} Both unscattered photons and photons undergoing forward-directed, single-step scattering contribute to the intensity of the ballistic component (comprised by photons traveling straight along the light beam). This component (not shown in Figure

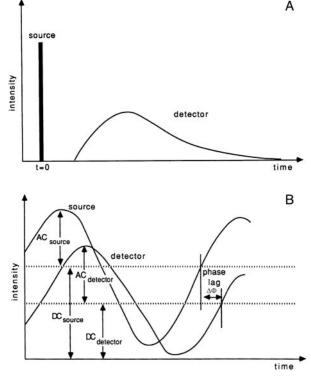

FIGURE 3.5 Schematic representation of the time evolution of the light intensity measured in response to a very narrow light pulse (A) and a sinusoidally intensity-modulated light (B) transversing an arbitrary distance in a scattering and absorbing medium. (From Fishkin, J.B. and Gratton, E., *J. Opt, Soc. Am. A*, 10, 127, 1993. With permission.)

3.5a) is subject to exponential attenuation with increasing sample thickness. This accounts for the limited utility of ballistic photons for practical diagnostic purposes in medicine.

The group of snake photons with zigzag trajectories includes photons that experienced only a few collisions each. They propagate along trajectories, which only slightly deviate from the direction of the incident beam and form the first-arriving part of the diffuse component. These photons carry information about the optical properties of the random medium.

The diffuse component is very broad and intense because it contains the bulk of incident photons after they have participated in many scattering acts and therefore migrate in different directions and have different path lengths. Moreover, the diffuse component carries information about the optical properties of the scattering medium, and its deformation may reflect the presence of local inhomogeneities in the medium. The resolution obtained by this method at a high light-gathering power is much lower than in the method measuring straight-passing photons. Two principal probing schemes are conceivable — one recording transmitted photons and the other taking advantage of their backscattering.

The time-dependent reflectance is defined as^{38,39}

$$R(r_{sd},t) = \frac{z_0}{(4\pi D)^{3/2}} t^{-5/2} \exp\left(-\frac{r_{sd}^2 + z_0^2}{2Dt}\right) \exp\left(-\mu_a ct\right), \tag{3.17}$$

where t is the time; $z_0 = (\mu_s')^{-1}$, and D is the photon diffusion coefficient, cm²/c (see Equation 3.5).

An important advantage of the pulse method is its applicability to *in vivo* study due to the possibility of the separate evaluation of μ_a and μ_s' using a single measurement in the backscattering or transillumination regimes.

3.2.4 Diffuse Photon-Density Waves

When probing the plane-parallel layer of a scattering medium with an intensity modulated light, the modulation depth of scattered light intensity $m_U \equiv \mathrm{AC}_{\mathrm{detector}}/\mathrm{DC}_{\mathrm{detector}}$ (see Figure 3.5B) and the corresponding phase shift relative to the incident light modulation phase $\Delta\Phi$ (phase lag) can be measured. ^{1-7,40} In applications to tissue spectroscopy and tomography compared with pulse measurements, this method is simpler and more reliable in terms of data interpretation and noise immunity. These happen because amplitude modulation is measured at low peak powers, slow rise time; therefore, smaller bandwidths than the pulse measurements are needed. The current measuring schemes are based on heterodyning of optical and transformed signals. ⁴⁰

The development of the theory underlying this method resulted in the discovery of a new type of wave: photon-density waves or progressively decaying waves of intensity. $^{1-7,40-42}$ Microscopically, individual photons make random migrations in a scattering medium, but collectively they form a photon-density wave at a modulation frequency ω that moves away from a radiation source (see Figure 3.5B). Photon-density waves possess typical wave properties, e.g., they undergo refraction, diffraction, interference, dispersion, and attenuation.

In strongly scattering media with weak absorption far from the walls and a source or a receiver of radiation, the light distribution may be regarded as a decaying diffusion process described by the time-dependent diffusion equation for photon density. For a point light source with harmonic intensity modulation at frequency $\omega = 2\pi v$ placed at the point $\bar{r} = 0$, an alternating component (AC) of intensity is a going-away spherical wave with its center at the point $\bar{r} = 0$, which oscillates at a modulation frequency with modulation depth

$$m_U(\bar{r}, \omega) = m_I \exp(\bar{r} \sqrt{D/c\mu_a}) \exp(-\bar{r} \sqrt{\omega/2D}),$$
 (3.18)

and undergoes a phase shift relative to the phase value at point $\bar{r} = 0$ equal to

$$\Delta\Phi(\bar{r},\omega) = \bar{r}(\omega/2D)^{0.5}, \qquad (3.19)$$

where m_I is the intensity modulation depth of the incident light, $D = c/3(\mu_s' + \mu_a)$. The length of a photon-density wave, Λ_{Φ} , and its phase velocity, V_{Φ} , are defined by

$$\Lambda_{\Phi}^2 = 8\pi^2 D/\omega \quad \text{and} \quad V_{\Phi}^2 = 2D\omega. \tag{3.20}$$

Measuring $m_U(\bar{r},\omega)$, $\Delta\Phi(\bar{r},\omega)$ allows one to determine the transport scattering coefficient μ_s and the absorption coefficient μ_a separately and to evaluate the spatial distribution of these parameters.

Keeping medical applications in mind, we can easily estimate that, for $\omega/2\pi = 500$ MHz, $\mu_s' = 15$ cm⁻¹, $\mu_a = 0.035$ cm⁻¹, and $c = (3 \times 10^{10}/1.33)$ cm/s, the wavelength is $\Lambda_{\Phi} \cong 5.0$ cm and the phase velocity is $V_{\Phi} \cong 1.77 \times 10^9$ cm/s.

3.3 Optothermal Interactions

3.3.1 Temperature Rise and Tissue Damage

When photons traveling in tissue are absorbed, heat is generated. The generated heat, described by the heat source term S at a point \mathbf{r} , is proportional to the fluence rate of light $\phi(\mathbf{r})$ (mW/cm²) and absorption coefficient $\mu_a(\mathbf{r})$ in this point^{3,21–23,43}

$$S(\mathbf{r}) = \mu_a(\mathbf{r})\phi(\mathbf{r}). \tag{3.21}$$

The traditional bioheat equation originated from the energy balance describes the change in tissue temperature over time at point \mathbf{r} in the tissue:

$$\rho \tilde{n} \frac{\partial T(\mathbf{r},t)}{\partial t} = \nabla \left[k_m \nabla T(\mathbf{r},t) \right] + S(\mathbf{r}) + \rho c w \left(T_a - T_v \right), \qquad (3.22)$$

where ρ is the tissue density (g/cm³), c is the tissue specific heat (mJ/g·°C), $T(\mathbf{r},t)$ is the tissue temperature (°C) at time t, k_m is the thermal conductivity (mW/cm·°C), $S(\mathbf{r})$ is the heat source term (mW/cm³), w is the tissue perfusion rate (g/cm³·s), T_a is the inlet arterial temperature (°C), and T_v is the outlet venous temperature (°C) — all at point $S(\mathbf{r})$ in the tissue. In this equation convection, radiation, vaporization, and metabolic heat effects are not accounted for because of their negligible effect in many practical cases. The source term is assumed to be stationary over the time interval of heating. The first term to the right of the equation describes any heat conduction (typically away from point \mathbf{r}), and the source term accounts for heat generation due to photon absorption. In most cases of light (laser)—tissue interaction, the heat transfer caused by perfusion (last term) is negligible.

Initial and boundary conditions must be accounted for in order to solve this equation. The initial condition is the tissue temperature at t = 0 and the boundary conditions depend on tissue structure and geometry of light heating. Methods of solving the bioheat equation can be found in References 3 and 21 through 24.

Damage to a tissue results when it is exposed to a high temperature for a long time period.^{3,21–24,43} The damage function is expressed in terms of an Arrhenius integral:

$$\Omega(\tau) = \ln\left(\frac{C(0)}{C(\tau)}\right) = A \int_0^{\tau} e^{-\frac{E_a}{RT(t)}} dt , \qquad (3.23)$$

where τ is the total heating time (s); C(0) is the original concentration of undamaged tissue; $C(\tau)$ is the remaining concentration of undamaged tissue after time τ ; A is an empirically determined constant (s⁻¹); E_a is an empirically determined activation energy barrier (J/mol); R is the universal gas constant (8.32 J/mol·K); and T is the absolute temperature (K).

In noninvasive optical diagnostic and some photochemical applications of light one must keep the tissue below the damaging temperature, so-called the critical temperature $T_{\rm crit}$. This temperature is defined as the temperature where the damage accumulation rate, $d\Omega/dt$, is equal to 1.0:⁴³

$$T_{\text{crit}} = \frac{E_a}{R \ln(A)}.$$
 (3.24)

The constants A and E_a can be calculated on the basis of experimental data when tissue is exposed to a constant temperature.²² For example, for pig skin, $A = 3.1 \times 10^{98}$ and $E_a = 6.28 \times 10^5$, which gives $T_{\text{crit}} = 59.7^{\circ}\text{C}$.

With CW light sources, due to the increase in temperature difference between the irradiation and the surrounding tissue, conduction of heat away from the light absorption point and into surrounding tissue increases. Depending on the light energy, large tissue volumes may be damaged or loss of heat at the target tissue component may be expected. For pulsed light, little heat is usually lost during the pulse duration because light absorption is a fast process while heat conduction is relatively slow; therefore, more precise tissue damage is possible.

The following forms of irreversible tissue damage are expected as tissue temperature rises past T_{crit} : coagulation (denaturization of cellular and tissue proteins) is the basis for tissue welding; vaporization (tissue dehydration and vapor bubble formation [vacuolization], $T \ge 100$ °C) is the basis for tissue

mechanical destruction; pyrolysis ($T \ge 350$ to 450°C). Vaporization, vacuolization, and pyrolysis combine to produce thermal ablation — the basis of laser surgical tissue removal.

The disadvantage of thermal ablation with CW light sources is undesirable damage to surrounding tissue via its coagulation. Pulsed light can deliver sufficient energy in each pulse to ablate tissue, but in a short enough time that the tissue is removed before any heat is transferred to the surrounding tissue. To achieve precise tissue cutting, lasers with a very short penetration depth, like excimer ArF laser, are used (see Figure 3.1).

As condensed matter, tissue can show any of noncoherent or coherent effects at laser irradiation.⁴⁴ Linear noncoherent effects exist within a wide area of pulse duration and intensities; for long pulses of 1 s the intensity should not exceed 10 W/cm²; for shorter pulses of 10^{-9} s the intensity can be up to 10^{9} W/cm². Multiphoton processes may exist at relatively low pulse duration (10^{-9} to 10^{-12} s) at intensities of 10^{9} to 10^{12} W/cm² and rather low light energies, not higher than 0.1 J/cm². The linear and nonlinear coherent effects may be induced only by a very short pulse with time duration comparable with relaxation time of biological molecules, $\tau \le 10^{-13}$.

3.3.2 Optothermal and Optoacoustic Effects

The time-dependent heat generated in a tissue via interaction with pulsed or intensity-modulated optical radiation is known as optothermal (OT) effect.^{5,20,45} Such interaction also induces a number of thermoelastic effects; in a tissue in particular, it causes generation of acoustic waves. Detection of acoustic waves is the basis for optoacoustic (or photoacoustic) methods. The informative features of this method allow one to estimate tissue thermal, optical, and acoustical properties that depend on tissue structure peculiarities. Two main modes can be used for excitation of tissue thermal response: (1) a pulse of light excites the sample and the signal is detected in the time domain with a fast detector attached to a wide-band amplifier (signal averaging and gating techniques are used to increase the signal-to-noise ratio) or (2) an intensity-modulated light source, a low-frequency transducer, and phase-sensitive detection for noise suppression are provided.

In every case the thermal waves generated by the heat release result in several effects that have given rise to various techniques: optoacoustics (OA) or photoacoustics (PA), optothermal radiometry (OTR) or photothermal radiometry (PTR), photorefractive techniques, etc.^{5,20,45} (see Figure 3.6).

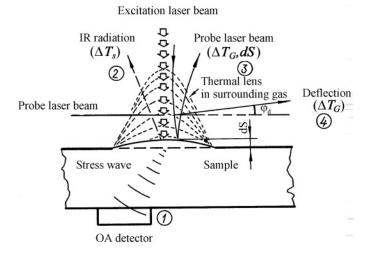

FIGURE 3.6 Schematic representation of some optothermal techniques in application to tissue study. $\Delta T_s =$ temperature change of a sample; dS = thermoelastic deformation; $\varphi_d =$ deflection angle of a probe laser beam; 1 = OA technique; 2 = OTR technique; 3 = thermal lens technique; 4 = deflection technique. (From Tuchin, V.V., Laser and Fiber Optics in Biomedical Science, Saratov University Press, Saratov, Russian Federation, 1998. With permission.)

The term optoacoustics (OA) refers primarily to the time-resolved technique utilizing pulsed lasers and measuring profiles of pressure in tissue; photoacoustics (PA) describes primarily spectroscopic experiments with CW modulated light and a PA cell.

When a laser beam falls down to the sample surface and the wavelength is tuned to an absorption line of the tissue component of interest, the optical energy is absorbed by the target component and most of the energy transforms to heat. The time-dependent heating leads to all of the earlier mentioned thermal and thermoelastic effects. In OA or PA techniques, a microphone or piezoelectric transducer in acoustic contact with the sample is used as a detector to measure the amplitude or phase of the resultant acoustic wave. In OTR technique, distant IR detectors and array cameras are employed for the sample surface temperature estimation and its imaging. The intensity of the signals obtained with any of the OT or OA techniques depends on the amount of energy absorbed and transformed into heat and on thermoelastic properties of the sample and its surrounding. When nonradiative relaxation is the main process in a light beam decay, and extinction is not very high, $\mu_a d << 1$ (d is the length of a cylinder within the sample occupied by a pulse laser beam), the absorbed pulse energy induces the local temperature rise defined by

$$\Delta T \cong E\mu_a d/C_p V\rho, \qquad (3.25)$$

where C_P is the specific heat capacity for a constant pressure; $V = \pi w^2 d$ is the illuminated volume; w is the laser beam radius; ρ is the medium density. Assuming an adiabatic expanding of illuminated volume on heat with a constant pressure, one can calculate the change of the volume ΔV . This expansion induces a wave propagating in the radial direction with the sound speed, v_a . The corresponding change of pressure Δp is proportional to the amplitude of mechanical oscillations:

$$\Delta p \sim (f_a/w)(\beta v_a/C_p) E \mu_a, \qquad (3.26)$$

where β is the coefficient of volumetric expansion and f_a is the frequency of the acoustic wave.

Equations 3.25 and 3.26 provide the basis for various OT and OA techniques. The information about the absorption coefficient μ_a at the definite wavelength can be received from direct measurements of the temperature change ΔT (optical calorimetry), volume change ΔV (optogeometric technique), or pressure change Δp (OA and PA techniques). For a highly scattering tissue, measurements of the stress-wave profile and amplitude should be combined with measurements of the total diffuse reflectance in order to extract absorption and scattering coefficients of the sample separately. The absorption coefficient in a turbid medium can be estimated from the acoustic transient profile only if the subsurface irradiance is known.

For turbid media irradiated with a wide laser beam (>0.1 mm), the effect of backscattering causes a higher subsurface fluence rate compared with the incident laser fluence.⁵ Therefore, the *z*-axial light distribution in tissue and the corresponding stress distribution have a complex profile with a maximum at a subsurface layer. However, when the heating process is much faster than the medium expansion, the stress amplitude adjacent to the irradiated surface, $\delta p(0)$, and the stress exponential tail into the depth of tissue sample, $\delta p(z)$, can be determined.⁴⁶ The stress is confined temporarily during laser heat deposition when the laser pulse duration is much shorter than the time of stress propagation across the light penetration depth in the tissue sample. Such conditions of temporal pressure confinement in the volume of irradiated tissue allow for the most efficient pressure generation.

The pulse laser heating of a tissue causes its temperature perturbations and corresponding modulation of its own thermal (infrared) radiation. This is the basis for pulse optothermal radiometry (OTR). 5,20,46,47 The maximum of intensity of thermal radiation of living objects falls at the wavelength range close to 10 μ m. A detailed analysis of OTR signal formation requires knowledge on the internal temperature distribution within the tissue sample, tissue thermal diffusivity, and its absorption coefficients at the excitation μ_a and emission μ_a' (10 μ m) wavelengths. Conversely, knowledge of some of the mentioned parameters allows one signal to reconstruct, for example, the depth distribution of μ_a on the basis of measured OTR. 47

The surface radiometric signal $S_r(t)$ at any time t is the sum of the contributions from all depths in the tissue at time t. The radiation from deeper depths is attenuated by the infrared absorption of the sample before reaching the detector. Because the initial surface temperature is known, the temperature distribution into the sample depth can be extracted from $S_r(t)$ measurement.

OTR, OA, and PA transient techniques provide a convenient means for *in vitro* or even *in vivo* and *in situ* monitoring of human skin properties (optical absorption, thermal properties, water content) and surface concentrations of topically applied substances (drugs and sunscreen diffusion). The main difficulty of the PA method in the case of *in vivo* measurements is the requirement for a closed sample cell that can guide the acoustic signal efficiently from sample to microphone. The use of pulsed OA and OTR techniques is more appropriate for *in vivo* and *in situ* measurements.

3.4 Refractive Index and Controlling of Light Interactions with Tissues

Refractive index in tissues is of great importance for light–tissue interaction. Most tissues have refractive indices for visible light in the 1.335 to 1.62 range (e.g., 1.55 in the stratum corneum, 1.62 in the enamel, and 1.386 at the lens surface).^{5,48} It is worthwhile to note that *in vitro* and *in vivo* measured values of refractive indices may differ significantly. For example, the refractive index in rat mesenteric tissue *in vitro* was found to be 1.52 compared to only 1.38 *in vivo*. This difference can be accounted for by the decreased refractivity of ground matter n_0 due to impaired hydration.

The mean refractive index \overline{n} of a tissue is defined by the refractive indices of its scattering centers material n_c and ground matter n_0 .

$$\overline{n} = c_s n_s + (1 - c_s) n_0, \qquad (3.27)$$

where c_s is the volume fraction of the scatterers.

The $n_s/n_0 \equiv m$ ratio determines the scattering coefficient. For example, in a simple monodisperse model of scattering dielectric spheres:⁴⁹

$$\mu'_{s} = 3.28\pi a^{2} \rho_{s} (2\pi a/\lambda)^{0.37} (m-1)^{2.09},$$
(3.28)

where a is the sphere radius and ρ_s is the volume density of the spheres. Equation 3.28 is valid for noninteracting Mie scatterers, g > 0.9; $5 < 2\pi a/\lambda < 50$; 1 < m < 1.1.

It follows from Equation 3.28 that even a 5% change in the refractive index of the ground matter $(n_0 = 1.35 \rightarrow 1.42)$, when that of the scattering centers is $n_s = 1.47$, will cause a sevenfold decrease of μ_s '. Therefore, matching the refractive index of the scatterers and ground material allows one to reduce tissue scattering considerably. This phenomenon is very useful for improving measurement conditions for optical tomograpy and for obtaining more precise spectroscopic information from the depth of a tissue.

Optical parameters of a tissue, in particular refractive index, are known to depend on water content. The refractive index of water over a broad wavelength range of 0.2 to 200 μ m has been reported.⁴⁸ The following relation was shown to be valid for the visible and NIR wavelength range (λ in nm):⁵⁰

$$n_{\text{H,O}} = 1.3199 + 6878/\lambda^2 - 1.132 \times 10^9/\lambda^4 + 1.11 \times 10^{14}/\lambda^6.$$
 (3.29)

For different parts of a biological cell, values of refractive index in the NIR can be estimated as follows: extracellular fluid, $\bar{n}=1.35$ to 1.36; cytoplasm, 1.360 to 1.375; cell membrane, 1.46; nucleus, 1.38 to 1.41; mitochondria and organelles, 1.38 to 1.41; melanin, 1.6 to 1.7.5,51 Scattering arises from a mismatch in refractive index of the components that make up the cell. When cells are surrounded by other cells or tissue structures of similar index, certain organelles become the important scatterers for tissues. For

instance, the nucleus is a significant scatterer because it is often the largest organelle in the cell and its size increases relative to the rest of the cell throughout neoplastic progression.

Mitochondria (500 to 1500 nm in diameter), lysosomes (500 nm), and peroxisomes (500 nm) are very important scatterers whose size relative to the wavelength of light suggests that they must provide a significant contribution to the backscattering. Melanin granular, traditionally thought of as an absorber, must be considered an important scatterer because of its size and high refractive index.⁵¹ Structures consisting of membrane layers such as the endoplasmic reticulum or Golgi apparatus may prove significant because they contain index fluctuations of high spatial frequency and amplitude. Besides cell components, tissue fibrous structures such as collagen and elastin must be considered important scatterers.

Refractivity measurements in a number of strongly scattering tissues at 633 nm performed with a fiber-optic refractometer have shown that fatty tissue has the largest refractive index (1.455) followed by kidney (1.418), muscular tissue (1.410), and then blood and spleen (1.400).⁵² The lowest refractive indices were found in lungs and liver (1.380 and 1.368, respectively). There is a tendency to decreasing refractive indices with increasing light wavelength from 390 to 700 nm (for example, for bovine muscle in the limits of 1.42 to 1.39).

It is possible to achieve a marked impairment of scattering by matching the refractive indices of scattering centers and ground matter by means of intratissue administration of the appropriate chemical agents. Experimental optical clearing in human sclera in the visible wavelength range induced by administration of verografin, trazograph, glucose, propylene glycol, polyethylene glycol, and other solutions has been described. ^{5,7,53–57} Osmotic phenomena appear to be involved when optical properties of tissues are modulated by sugar, alcohol, glycerol, and electrolyte solutions.

Experimental studies on optical clearing of normal and pathological skin and its components (epidermis and dermis) and the management of reflectance and transmittance spectra using glycerol, glycerol–water solutions, glucose, sunscreen creams, cosmetic lotions, gels, and pharmaceutical products have been carried out.^{5,7}

A marked clearing effect through rat⁵⁵ and human⁵⁶ skin and the rabbit sclera⁷ occurred for an *in vivo* tissue within a few minutes of topical application or intratissue injection of glycerol, glucose, verografin, or trazograph. *In vivo* reflectance spectra of the human skin at inter-skin injection of 40% glucose are shown in Figure 3.7. Skin is well protected for penetration of any agent by the stratum corneum, and

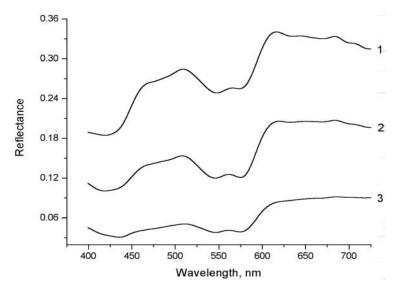

FIGURE 3.7 Reflectance spectra measured before (1) and at 23 min (2) and 60 min (3) after interskin injection of 0.1 ml of 40% glucose into internal side of the forearm of the male volunteer. (From Tuchin, V.V. et al., *J. Tech. Phys. Lett.*, 27(6), 489, 2001. With permission.)

reflectance of the skin is defined mostly by dermis; therefore, the intradermis injection was applied. The fiber-optic photodiode array spectrometer providing about 0.9-mm-deep measurements was used.

The concept that index matching could improve the optical penetration depth of whole blood is proved experimentally in *in vitro* studies using optical coherence tomography.^{58,59} For example, for whole blood twice diluted by saline, adding 6.5% of glycerol increases the optical penetration up to 117%; optical clearing up to 150% was achieved mostly due to refractive index matching for the high-molecular-weight dextran.⁵⁹

3.5 Fluorescence

3.5.1 Fundamentals and Methods

Fluorescence arises upon light absorption and is related to an electronic transition from the excited state to the ground state of a molecule. In the case of thin samples, e.g., cell monolayers or biopsies with a few micrometers in diameter, fluorescence intensity I_F is proportional to the concentration c and the fluorescence quantum yield η of the absorbing molecules. In scattering media, the path lengths of scattered and unscattered photons within the sample are different, and should be accounted for. However, in rather homogeneous thin samples, the linearity between I_F , c, and η is still fulfilled.

At excitation biological objects by ultraviolet light ($\lambda \le 300$ nm), fluorescence of proteins as well as of nucleic acids can be observed. Fluorescence quantum yields of all nucleic acid constituents, however, are around 10^{-4} to 10^{-5} , corresponding to lifetimes of the excited states in the picosecond time range. Autofluorescence (AF) of proteins is associated with amino acids such as tryptophan, tyrosin, and phenylalanine with absorption maxima at 280, 275, and 257 nm, respectively, and emission maxima between 280 nm (phenylalanine) and 350 nm (tryptophan). Usually the protein spectrum is dominated by tryptophan. Fluorescence from collagen or elastin using excitation between 300 and 400 nm shows broad emission bands between 400 and 600 nm with maxima around 400, 430, and 460 nm. In particular, fluorescence of collagen and elastin can be used to distinguish various types of tissues, e.g., epithelial and connective tissue. $^{17,18,60-63}$

The reduced form of coenzyme nicotinamide adenine dinucleotide (NADH) is excited selectively in a wavelength range between 330 and 370 nm. NADH is most concentrated within mitochondria where it is oxidized within the respiratory chain located within the inner mitochondrial membrane and its fluorescence is an appropriate parameter for detection of ischemic or neoplastic tissues. Fluorescence of free and protein-bound NADH has been shown to be sensitive on oxygen concentration. Flavin mononucleotide (FMN) and dinucleotide (FAD) with excitation maxima around 380 and 450 nm have also been reported to contribute to intrinsic cellular fluorescence.

Porphyrin molecules, e.g., protoporphyrin, coproporphyrin, uroporphyrin, or hematoporphyrin, occur within the pathway of biosynthesis of hemoglobin, myoglobin, and cytochromes. Abnormalities in heme synthesis, occurring in the cases of porphyrias and some hemolytic diseases, may enhance the porphyrin level within tissues considerably. Several bacteria, e.g., *Propionibacterium acnes* or bacteria within dental caries lesions, accumulate considerable amounts of protoporphyrin. Therefore, acne or caries detection based on measurements of intrinsic fluorescence appears to be a promising method.

At present, various exogenous fluorescing dyes can be applied for probing cell anatomy and cell physiology.⁶⁰ In humans, such dyes as fluorescein and indocyanine green are in use for fluorescence angiography or blood volume determination. Fluorescence spectra often give detailed information on fluorescent molecules, their conformation, binding sites, and interaction within cells and tissues. Fluorescence intensity can be measured as a function of the emission wavelength or of the excitation wavelength. The fluorescence emission spectrum $I_F(\lambda)$ is specific for any fluorophore and is commonly used in fluorescence diagnostics.

For many biomedical applications, an optical multichannel analyzer (OMA; a diode array or a CCD camera) as a detector of emission radiation is preferable because spectra can be recorded very rapidly and repeatedly with sequences in the millisecond range. Fluorescence spectrometers for *in vivo* diagnostics

are commonly based on fiber optic systems.⁷ The excitation light of a lamp or a laser is guided to the tissue (e.g., some specific organ) via fiber using appropriate optical filters. Fluorescence spectra are usually measured via the same fiber or via a second fiber or fiber bundle in close proximity to the excitation fiber.

Now available are various comprehensive and powerful fluorescence spectroscopies, such as microspectrofluorimetry, polarization anisotropy, time-resolved with pulse excitation and frequency domain, timegated, total internal reflection fluorescence spectroscopy and microscopy, fluorescence resonant energy transfer method, confocal laser scanning microscopy, and their combinations. These methods allow one to provide:⁶⁰

- Three-dimensional topography of specimens measured in the reflection mode for morphological studies of biological samples
- · High-resolution microscopy measured in the transmission mode
- · Three-dimensional fluorescence detection of cellular structures and fluorescence bleaching kinetics
- · Time-resolved fluorescence kinetics
- · Studies of motions of cellular structures
- · Time-gated imaging in order to select specific fluorescent molecules or molecular interactions
- · Fluorescence lifetime imaging
- · Spectrally resolved imaging

Principles of optical clinical chemistry based on measuring of changes of fluorescence intensity, wavelength, polarization anisotropy, and lifetime are described in Lakowicz. ¹⁸ Various fluorescence techniques of selective oxygen sensing and blood glucose and blood gases detection are available. ¹⁸

3.5.2 Multiphoton Fluorescence

A new direction in laser spectroscopy of biological objects involves multiphoton (two- or three-photon) fluorescence scanning microscopy, which makes it possible to image functional states of an object or, in combination with autocorrelation analysis of the fluorescence signal, determine the intercellular motility in small volumes. The two-photon technique employs ballistic and scattered photons at the wavelength of the second harmonic of the incident radiation coming to a wide-aperture photodetector exactly from the focal area of the excitation beam. A unique advantage of two-photon microscopy is the possibility of investigating three-dimensional distributions of chromophores excited with ultraviolet radiation in thick samples.

Such an investigation becomes possible because chromophores can be excited (e.g., at the wavelength of 350 nm) with laser radiation whose wavelength falls within the range (700 nm) where a tissue has a high transparency. This radiation can reach deeply lying layers and produces less damage in tissues. Fluorescence emission in this case occurs in the visible range (>400 nm) and emerges from a tissue comparatively easily and reaches a photodetector, which registers only the legitimate signal from the focal volume without any extraneous background. Investigations of tissues and cells by means of two-photon microscopy are characterized by the following typical parameters of laser systems: the wavelength ranges from 700 to 960 nm, the pulse duration is on the order of 150 fs, the pulse repetition rate is 76 to 80 MHz, and the mean power is less than 10 mW. Such parameters can be achieved with mode-locked dye lasers pumped by an Nd:YAG laser or with titanium sapphire lasers pumped by an argon laser. Diodepumped solid-state lasers also hold much promise for the purposes of two-photon microscopy.

3.6 Vibrational Energy States Excitation

Mid-infrared (MIR) and Raman spectroscopies use light-excited vibrational energy states in molecules to obtain information about the molecular composition, molecular structures, and molecular interactions in a sample. $^{13-16,64}$ In MIR spectroscopy infrared light from a broad band source (usually 2.5 to 25 μ m

or 4000 to 400 cm⁻¹) is directly absorbed to excite the molecules to higher vibrational states. In a Raman scattering event, light is inelastically scattered by a molecule when a small amount of energy is transferred from the photon to the molecule (or vice versa). This leads to excitation of the molecule, usually from its lowest vibrational energy level in the electronic ground state to a higher vibrational state. The energy difference between the incident and scattered photon is expressed in a wavenumber shift (cm⁻¹). Some vibrations can be excited by Raman and MIR processes; others can only be excited by a Raman scattering or by MIR absorption. Both techniques enable recording of high-quality spectra in relatively short acquisition times (30 to 60 s).

The MIR and Raman spectroscopy techniques are successfully applied in various areas of clinical studies, such as cancerous tissue examination, the mineralization process of bone and teeth tissue monitoring, glucose sensing in blood, noninvasive diagnosis of skin lesions on benign or malignant cells, and monitoring of treatments and topically applied substances (e.g., drugs, cosmetics, moisturizers, etc.) in skin. ^{13–16,64}

Raman spectroscopy is widely used in biological studies, ranging from studies of purified biological compounds to investigations at the level of single cells. At present, combinations of spectroscopic techniques such as MIR and Raman with microscopic imaging techniques are explored to map molecular distributions at specific vibrational frequencies on samples to locally characterize tissues or cells.⁶⁴ Chemical imaging will become more and more important in clinical diagnosis.

3.7 Light Interaction with Eye Tissues

Healthy tissues of the anterior of the human eye chamber, e.g., the cornea and lens, are highly transparent for visible light due to their ordered structure and the absence of strongly absorbing chromophors. Scattering is an important feature of light propagation in eye tissues. The size of the scatterers and the distance between them are smaller than or comparable with the wavelength of visible light; the relative refractive index of the scattering matter is equally small (soft particles). Typical eye tissue models are long, round dielectric cylinders (corneal and scleral collagen fibers) or spherical particles (lens protein structures) having refractive index n_s and orderly (transparent cornea and lens) or quasi-orderly (sclera, opaque lens) distributed in the isotropic base matter with refractive index $n_0 < n_s$. Light scattering analysis in eye tissues often is possible using a single-scattering model owing to the small scattering cross section (soft particles).

In case of disordered (randomly distributed) scatterers, the resultant field intensity is the total intensity of fields scattered by individual scatterers (fibril or particles). For ordered scatterers, fields, rather than intensities, should be summed to take into account effects of interference arising in the presence of the near order of scatterers. In the integral form, the scattering indicatrix for symmetric scattering of particles with pair correlation is described by the expression:

$$I(\theta) = I_0(\theta) \left\{ 1 + \rho_s \int_0^{\infty} [g(r) - 1] \exp[i(\bar{s}' - \bar{s})\bar{r}] d^3r \right\} = I_0(\theta) F_{\text{int}}, \qquad (3.30)$$

where $I_0(\theta)$ is the scattering indicatrix of an isolated scatterer; θ is the scattering angle; ρ_s is the mean density of scatterers; g(r) is the radial distribution function of scattering centers (local to average density ratio for scattering centers, for noninteracting centers $g(r) \to 1$); \bar{s} and \bar{s} are unit vectors for incident and scattered waves, respectively; \bar{r} is the radius-vector and d^3r is the volume of a scatterer; and $F_{\rm int}$ takes into account the effects of interference.

Equation 3.30 is valid for a monodisperse system of scatterers and can be used provided a scattering indicatrix for a single particle $I_0(\theta)$ is available from computations based on the Mie theory and corresponding approximate relations.

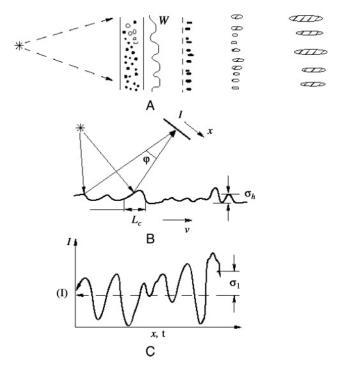

FIGURE 3.8 Formation and propagation of speckles (A), observation of speckles (B), and intensity modulation (C).

3.8 Formation of Speckles

Speckle structures are produced as a result of interference of a large number of elementary waves with random phases that arise when coherent light is reflected from a rough surface or when coherent light passes through a scattering medium.^{3,7,65–67} Generally, there are two types of speckles: subjective speckles that are produced in the image space of an optical system (including an eye) and objective speckles, formed in a free space and usually observed on a screen placed at a certain distance from an object. Because the majority of tissues are optically nonuniform, irradiation of such objects with coherent light always gives rise to the appearance of speckle structures, which distort the results of measurements and, consequently, should be eliminated in some way, or provide new information concerning the structure and the motion of a tissue and its components.

Figure 3.8 schematically illustrates the principles of the formation and propagation of speckles. The average size of a speckle in the far-field zone is estimated as

$$d_{av} \sim \lambda/\varphi,$$
 (3.31)

where λ is the wavelength and ϕ is the angle of observation.

Displacement of the observation point over a screen (x) or the scanning of a laser beam over an object with a certain velocity ν (or an equivalent motion of the object itself with respect to the laser beam) under conditions when the observation point remains stationary gives rise to spatial or temporal fluctuations of the intensity of the scattered field. These fluctuations are characterized by the mean value of the intensity $\langle I \rangle$ and the standard deviation σ_I (see Figure 3.8B). The object itself is characterized by the standard deviation σ_h of the altitudes (depths) of inhomogeneities and the correlation length L_c of these inhomogeneities (random relief).

Because many tissues and cells are phase objects, the propagation of coherent beams in tissues can be described within the framework of the model of a random phase screen. Ideal conditions for formation of speckles, when completely developed speckles arise, can be formulated as: coherent light irradiates a

diffusive surface (or a transparency) characterized by Gaussian variations of optical length $\Delta L = \Delta(nh)$ and standard deviation of relief variations, $\sigma_L >> \lambda$; the coherence length of light and the sizes of the scattering area considerably exceed the differences in optical paths due to the surface relief, and many scattering centers contribute to the resulting speckle pattern.

Statistical properties of speckles can be divided into statistics of the first and second orders. Statistics of the first order describes the properties of speckle fields at each point. Such a description usually employs the intensity probability density distribution function p(I) and the contrast

$$V_I = \sigma_I / \langle I \rangle, \qquad \sigma_I^2 = \langle I^2 \rangle - \langle I \rangle^2,$$
 (3.32)

where $\langle I \rangle$ and σ_I^2 are the mean intensity and the variance of the intensity fluctuations, respectively. In certain cases, statistical moments of higher orders are employed.

For ideal conditions, when the complex amplitude of scattered light has Gaussian statistics, the contrast is $V_I = 1$ (developed speckles), and the intensity probability distribution is represented by a negative exponential function:

$$p(I) = \langle I \rangle^{-1} \exp\{-I/\langle I \rangle\}. \tag{3.33}$$

Thus, the most probable intensity value in the corresponding speckle pattern is equal to zero, i.e., destructive interference occurs with the highest probability.

Partially developed speckle fields are characterized by a contrast $V_I < 1$. The contrast may be lower due to a uniform coherent or incoherent background added to the speckle field. For phase objects with $\sigma_{\phi}^2 >> 1$ and a small number of scatterers $N = w/L_{\phi}$ contributing to the field at a certain point in the observation plane, the contrast of the speckle pattern is greater than unity. The statistics of the speckle field in this case is non-Gaussian and nonuniform (i.e., the statistic parameters depend on the observation angle).

The specific features of the diffraction of focused laser beams from moving phase screens underlie speckle methods of structure diagnostics and monitoring of motion parameters of tissue, blood, and lymph.

Statistics of the second order shows how fast the intensity changes from point to point in the speckle pattern, i.e., characterizes the size and the distribution of speckle sizes in the pattern. Statistics of the second order is usually described in terms of the autocorrelation function of intensity fluctuations:

$$g_2(\Delta \xi) = \langle I(\xi + \Delta \xi)I(\xi)\rangle, \tag{3.34}$$

and its Fourier transform, representing the power spectrum of a random process; $\xi \equiv x$ or t is the spatial or temporal variable; and $\Delta \xi$ is the change in variable. Angular brackets $\langle \ \rangle$ in Equation 3.34 stand for the averaging over an ensemble or over time.

In the elementary case, when reflected light in developed speckle structures retains linear polarization, intensity distribution at the output of a dual-beam interferometer can be written as⁵

$$I(r,t) = I_r(r) + I_s(r) + 2[I_r(r)I_s(r)]^{1/2} |\gamma_{11}(\Delta t)| \cos \{\Delta \Phi_I(r) + \Delta \Psi_I(r) + \Delta \Phi_I(t)\},$$
(3.35)

where $I_r(r)$ and $I_s(r)$ are intensity distributions of the reference and signal fields, respectively; r is the transverse spatial coordinate; $\gamma_{11}(\Delta t)$ is the degree of temporal coherence of light; $\Delta \Psi_I(r)$ is the deterministic phase difference of the interfering waves; $\Delta \Psi_I(r) = \Psi_{Ir}(r) - \Phi_{Is}(r)$ is the random phase difference; and $\Delta \Phi_I(t)$ is the time-dependent phase difference related to the motion of an object.

In the absence of speckle modulation, the deterministic phase difference $\Delta \Psi(r)$ governs the formation of regular interference fringes. On the average, the output signal of a speckle interferometer reaches its

maximum when the interfering fields are phase-matched ($\Delta\Psi(r)$ = const within the aperture of the detector), focused laser beams are used (speckles with maximum sizes are produced), and a detector with a maximum area is employed.

3.9 Dynamic Light Scattering

3.9.1 Quasi-Elastic Light Scattering

Quasi-elastic light scattering (QELS) spectroscopy, photon-correlation spectroscopy, spectroscopy of intensity fluctuations, and Doppler spectroscopy are synonymous terms associated with the dynamic scattering of light, which underlies a noninvasive method for studying the dynamics of particles on a comparatively large timescale. The implementation of the single-scattering mode and the use of coherent light sources are of fundamental importance in this case. The spatial scale of testing a colloid structure (an ensemble of biological particles) is determined by the inverse of the wave vector $|\bar{s}|$

$$|\bar{s}| = (4\pi n/\lambda_0)\sin(\theta/2), \tag{3.36}$$

where n is the refractive index and θ is the angle of scattering. With allowance for self-beating due to the photomixing of the electric components of the scattered field, the intensity autocorrelation function (AF) can be measured $g_2(\tau) = \langle I(t) I(t+\tau) \rangle$. For Gaussian statistics, this AF is related to the first-order AF by the Siegert formula:

$$g_2(\tau) = A \left[1 + \beta_{sb} \left| g_1(\tau) \right|^2 \right], \tag{3.37}$$

where τ is the delay time; $A = \langle i \rangle^2$ is the square of the mean value of the photocurrent, or the base line of the AF; β_{sb} is the parameter of self-beating efficiency, $\beta_{sb} \approx 1$; and $g_1(\tau) = \exp(-\Gamma_T \tau)$ is the normalized AF of the optical field for a monodisperse system of Brownian particles, $\Gamma = |\bar{s}|^2 D_T$ is the relaxation parameter and $D_T = k_B T/6\pi \eta r_h$ is the coefficient of translation diffusion, k_B is the Boltzmann constant, T is the absolute temperature, η is the absolute viscosity of the medium, and r_h is the hydrodynamic radius of a particle. Many biological systems are characterized by a bimodal distribution of diffusion coefficients, when fast diffusion (D_{Tf}) can be separated from slow diffusion (D_{Ts}) related to the aggregation of particles. The goal of QELS spectroscopy is to reconstruct the distribution of scattering particles in sizes, which is necessary for the diagnosis or monitoring of a disease.

Description of the principles and characteristics of the homodyne and heterodyne photon-correlation spectrometers, the so-called laser Doppler anemometers (LDAs), differential LDA schemes, and laser Doppler microscopes (LDMs) and review of medical applications, mainly the investigation of eye tissues (cataract diagnosis), investigation of hemodynamics in isolated vessels (vessels of eye fundus or any other vessels) with the use of fiber-optic catheters, and blood microcirculation in tissues can be found in References 5, 7, and 10.

3.9.2 Diffusion Wave Spectroscopy

Diffusion wave spectroscopy (DWS) is a new class of technique in the field of dynamic light scattering related to the investigation of the dynamics of particles within very short time intervals. 5–8,41,68,69 A fundamental difference of this method from QELS is that it is applicable to the case of dense media with multiple scattering, which is critical for tissues. In contrast to the case of single scattering, the AF of the field $g_1(\tau)$ is sensitive to the motion of a particle on the length scale on the order of $[L/l_t]^{-1/2}$, which is generally much less than λ , because $L >> l_t$ (L is the total mean photon path length and l_t is the transport length of a photon, $l_t \approx 1/\mu'_s$). Thus, DWS AFs decay much faster than AFs employed in QELS.

Experimental implementation of DWS is very simple. A measuring system should provide irradiation of an object under study by a CW laser beam and measurement of intensity fluctuations of the scattered radiation within a single speckle with the use of a single-mode receiving fiber, photomultiplier, photon-counting system, and a fast digital correlator working in a nanosecond range. The possibilities of the DWS technique for medical applications have been demonstrated for blood flow monitoring in the human forearm. The AF slope is the indicative parameter for determination of blood flow velocity. The normalized AF of field fluctuations can be represented in terms of two components related to the Brownian and directed motion of scatterers (erythrocytes):

$$g_1(\tau) \approx \exp\left\{-2\left[\tau/\tau_B + (\tau/\tau_s)^2\right]L/l_t\right\},$$
 (3.38)

where $\tau_B^{-1} \equiv \Gamma_T$ is defined in Equation 3.31, $\tau_S^{-1} \cong 0.18G_V |\bar{s}| l_t$ characterizes the directed flow, and G_V is the gradient of the flow rate. It allows one to express the slope of the AF in terms of the diffusion coefficient (characterizes blood microcirculation) and the gradient of the directed velocity of blood.

4.1 Introduction

The potential of optical tomography as a new diagnostic tool has stimulated considerable interest in the last 10 years.¹⁻⁴ Although limited to about the first 5 cm of the body, the technique offers several advantages often not available in established imaging modalities, such as ultrasound, x-ray computed tomography, and magnetic resonance imaging.^{5,6} These benefits include nonionizing radiation, relatively inexpensive instrumentation, and the potential for functional (i.e., spectroscopic) imaging of optical tissue properties. In functional imaging, light at specific wavelengths can be used to excite specific biological molecules of interest, such as NAD, NADH, tryptophan, and hemoglobin, in order to provide real-time, *in vivo* information on the functional status of tissues and organs (e.g., pH, tissue oxygenation, glucose, dysplasia, tumor, etc.). Luminescence techniques based on bioluminescence allow monitoring gene expression *in vivo* in animals for drug discovery investigations.

The use of light for diagnostics of deep tissue still presents great challenges. Electromagnetic radiation in the UV and visible wavelength range is strongly absorbed by biological species in tissue. Due to absorption by tissue chromophores, the intensity of light decreases rapidly as it penetrates deep inside tissue. At all wavelengths, scattering of light occurs strongly in tissue; however, in the near-infrared "optical window," where hemoglobin absorbs weakly (600 to 900 nm), multiple scattering in tissue dominates absorption, and penetration can be substantial, sometimes reaching 5 cm or more.

As light propagates in an optically dense medium such as tissue, it rapidly loses its coherence and, as a result, light intensity (or photon flux density or radiance) is usually the observable quantity. To a reasonable approximation, the radiance can be shown to obey a diffusion equation, which, when the

source is modulated, reduces to a Helmholtz equation with a complex wave number. With a harmonically modulated source, the radiance oscillates in space and in time; this oscillation is termed a diffuse photon density wave (DPDW). Such waves, although highly damped, are diffracted and scattered by optical inhomogeneities within the tissue. A number of authors have reported theoretical and experimental investigations of these waves.^{7–28}

This chapter describes several approaches to optical tomography based on theoretical models of light propagation and scattering in tissue. We examine in some detail three optical tomography algorithms. The first employs Fourier methods to reconstruct an image from time-harmonic DPDW data recorded at one modulation frequency. This method can be regarded as a generalization of diffraction tomography developed originally for acoustical imaging. The second and third algorithms are iterative and attempt to minimize an error norm in the frequency and time domains, respectively. An overview is also given of other algorithmic approaches that have appeared in the literature in the last decade. Experimental techniques, instrumentation, and clinical applications of optical tomography are described in Chapters 9 (lifetime-based imaging), 21 (functional imaging with diffusing light), 22 (photon migration spectroscopy frequency-domain techniques), and 33 (near-infrared fluorescence imaging and spectroscopy in random media and tissues) of this handbook.

Here, we focus on imaging algorithms for reconstructing spatial maps of optical properties of tissue by exploiting models of the interaction of light with tissue. Two basic measurement methodologies are used for imaging: (1) frequency-domain methods that employ harmonically modulated photon density-waves, and phase-resolved detection, which measures the phase shift of the photon density waves, 17,18,20,21,23,29-45 and (2) "time-resolved" methods that use pulsed excitation and gated detection to examine the response of tissue to a short pulse of incident light. 46-60 Figure 4.1 shows a schematic diagram of the phase-resolved and time-resolved techniques. "Continuous-wave" imaging methods, which employ steady-state illumination, may also be classified as frequency-domain, since these correspond to the zero frequency limit. 61,62

The simplest time-resolved imaging method exploits the fact that the first-arrival photons propagate along paths that have not deviated significantly from the line joining the source and receiver. Such photons are referred to as "ballistic photons." Photons that are scattered, predominantly in the forward direction, are sometimes referred to as "snake-like photons," as illustrated in Figure 4.2. In the case of ballistic photons, scattering is neglected, and conventional tomographic algorithms based on straight-line propagation are, in principle, applicable. Because of the need for ultrafast laser pulses for excitation

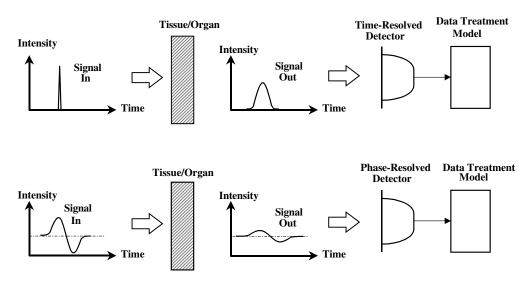

FIGURE 4.1 Schematic diagram of the time-resolved (top) and phase-resolved (bottom) techniques.

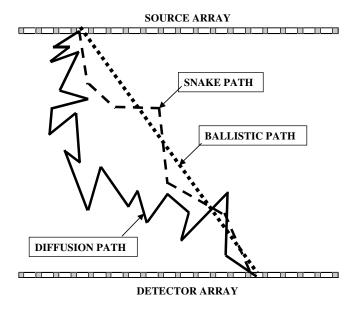

FIGURE 4.2 Schematic diagram of various photon trajectories through tissue medium.

(femtosecond and picosecond time frames⁶³), the very precise timing used to gate the first-arrival photons is technically challenging. In this regard, harmonic modulation of an intensity source is less demanding. Moreover, beyond a few centimeters, the relative number of ballistic photons becomes exceedingly small, so that ballistic measurements rapidly become signal-to-noise limited.

Frequency domain methods offer better signal-to-noise performance because more photons are available for measurement, and synchronous detection using phase-resolved measurements can be employed to enhance the signal. In time-resolved methods, the "boxcar" or a pulse-averaging scheme is often used to improve the signal-to-noise ratio. Modern time-resolved methods typically examine the entire transient response (rather than merely the ballistic photons) and attempt to fit this response to a model based, for example, on the time-dependent diffusion equation. In this manner, scattered photons are also accounted for, and time-domain methods that employ rapid averaging of the transient signals can achieve signal-to-noise ratios competitive with frequency-domain methods. In this chapter, we describe in detail two frequency-domain imaging algorithms, followed by a time-domain imaging algorithm applicable to time-resolved measurements.

We focus on two particular formulations of the inverse problem: analytical and iterative. Here, the term "inverse problem" refers to the task of deriving the spatial distribution of optical tissue properties from the detected scattered photons. The analytical approaches are noniterative, although we distinguish them from linear inversion schemes that are purely numerical, i.e., methods that solve a linear system of equations directly. These analytical approaches have largely been inspired by diffraction tomography (DT), which, in its conventional formulation, is a wave-equation-based inversion scheme.^{64–67} In particular, DT provides an explicit solution to a linearized integral equation using Fourier inversion methods.

Traditional DT begins with the Helmholtz equation with a real wave number, but our starting point is the diffusion equation; the latter reduces to a Helmholtz equation with a complex wave number when the source is harmonically modulated. In this case, the required generalization of diffraction tomography resembles a Fourier-Laplace inversion. Markel and Schotland⁴⁴ have formulated the problem in this way, which requires an analytic continuation of the data in the Fourier domain. We describe a related approach that provides an explicit inversion formula,³⁶ as does Markel and Schotland's method, but does not invoke an inverse Laplace transform and more explicitly defines the process of analytic continuation.

Another category of algorithms attempts to minimize iteratively a global error norm that quantifies the difference between measured and predicted data. Typically, the error norm is the mean-square error,

although other norms are possible. The predicted observations are computed using a forward solution to the transport problem, but the choice of forward algorithm (e.g., finite element, finite difference, or an integral equation solution) is not relevant for our purposes, although speed and accuracy are obviously desirable traits.

Iterative approaches are computationally expensive but have some advantages over analytical solutions. For example, analytical solutions, or Fourier methods, are necessarily based on a linearization procedure, which requires a weak-scattering assumption. Nonlinear iterative algorithms need make no such assumption because these methods iterate a forward algorithm, which, in principle, need not be subject to approximations. The forward algorithm can be designed to deal with voids and complicated boundaries, as well as arbitrary source and detector-array geometries. The forward algorithm may, for example, solve the full integro-differential transport equation, rather than the diffusion equation, which is generally the starting point for DT-based methods.

In investigating iterative algorithms, we emphasize the importance of the adjoint method in computing the functional gradient (or Fréchet derivative) of the error norm. The numerical evaluation of this gradient is generally the most demanding part of the computation, but the adjoint method renders this computation vastly more efficient than a "brute force" gradient evaluation based, for example, on finite differences. In the second algorithm described, we show how the adjoint method can be applied directly to the integro-differential transport equation, rather than to the diffusion equation, which is the more common approach.

4.2 Photon Transport in Tissue

In this section, we review some of the basic equations obeyed by photon density waves and describe some of their properties. Most imaging algorithms begin with an equation derived from the Boltzmann transport equation, whose time-dependent form is given by^{68,69}

$$\frac{1}{c} \frac{\partial \psi(\mathbf{r}, t, \mathbf{s})}{\partial t} + \mathbf{s} \cdot \nabla \psi(\mathbf{r}, t, \mathbf{s}) + \sigma_t(\mathbf{r}) \psi(\mathbf{r}, t, \mathbf{s}) = \sigma_s(\mathbf{r}) \int \psi(\mathbf{r}, t, \mathbf{s}') f(\mathbf{s} \cdot \mathbf{s}') d^2 \mathbf{s}' + q(\mathbf{r}, t, \mathbf{s}), \qquad (4.1)$$

where $\psi(\mathbf{r},t,\mathbf{s})$ is the time-dependent radiance (or photon flux density) in the direction \mathbf{s} at the point \mathbf{r} ; c is the velocity of light in the medium and $\sigma_t(\mathbf{r}) = \sigma_s(\mathbf{r}) + \sigma_a(\mathbf{r})$, where $\sigma_s(\mathbf{r})$ and $\sigma_a(\mathbf{r})$ are the spatially dependent scattering and absorption cross sections; $f(\mathbf{s} \cdot \mathbf{s}')$ is the phase function that denotes the probability of an incident photon from direction \mathbf{s} being scattered into the direction \mathbf{s}' ; and $q(\mathbf{r},t,\mathbf{s})$ is the source flux.

The diffusion approximation results on performing a spherical harmonic expansion of the radiance in Equation 4.1 and retaining the lowest-order nontrivial terms in the expansion. Defining the photon density as

$$\psi(\mathbf{r},t) = \int \psi(\mathbf{r},t,s)d^2s, \qquad (4.2)$$

the diffusion approximation can be shown to give⁶⁸

$$\frac{1}{c} \frac{\partial \psi(\mathbf{r},t)}{\partial t} - \nabla \cdot \left[D(\mathbf{r}) \nabla \psi(\mathbf{r},t) \right] + \sigma_a(\mathbf{r}) \psi(\mathbf{r},t) = Q(\mathbf{r},t), \qquad (4.3)$$

where $D(\mathbf{r}) = 1/3[\sigma_a(\mathbf{r}) + \sigma_s'(\mathbf{r})]$ is the diffusion coefficient; $\sigma_s'(\mathbf{r}) = (1 - g) \sigma_s(\mathbf{r})$ is the reduced scattering coefficient; g is the mean cosine of the scattering angle; and $Q(\mathbf{r},t)$ is the source density function. If we now assume that the sources in Equations 4.1 and 4.3 are harmonically modulated at frequency ω so that $q(\mathbf{r},t,s) = q(\mathbf{r},s) \exp(-i\omega t)$ and $Q(\mathbf{r},t) = Q(\mathbf{r}) \exp(-i\omega t)$, then, writing $\psi(\mathbf{r},t,s) = \psi(\mathbf{r},s) \exp(-i\omega t)$, Equation 4.1 becomes

$$s \cdot \nabla \psi(r,s) + \left[\sigma_{t}(r) - \frac{i\omega}{c}\right] \psi(r,s) = \sigma_{s}(r) \int \psi(r,s') f(s \cdot s') d^{2}s' + q(r,s), \tag{4.4}$$

and, writing $\psi(\mathbf{r},t) = \psi(\mathbf{r}) \exp(-i\omega t)$, Equation 4.3 reduces to

$$\nabla \cdot \left[D(\mathbf{r}) \nabla \psi(\mathbf{r}) \right] + \left[\frac{i\omega}{c} - \sigma_a(\mathbf{r}) \right] \psi(\mathbf{r}) = -Q(\mathbf{r}). \tag{4.5}$$

Note that the radiance $\psi(r,s)$ in Equation 4.4 and the photon density $\psi(r)$ in Equation 4.5 are now complex quantities, since in-phase and quadrature components of the signals can be measured, corresponding to the real and imaginary parts of $\psi(r,s)$ and $\psi(r)$.

Now write $D(\mathbf{r}) = D_0 + D_1(\mathbf{r})$ and $\sigma_a(\mathbf{r}) = \sigma_0 + \sigma_1(\mathbf{r})$, where $D_1(\mathbf{r})$ and $\sigma_1(\mathbf{r})$ will denote perturbations assumed to be small compared to the background values D_0 and σ_0 if the equations are ultimately to be linearized. Then, substituting into Equation 4.5 gives

$$\nabla^2 \psi(\mathbf{r}) + k_0^2 \psi(\mathbf{r}) = -\frac{1}{D_0} \nabla \cdot \left[D_1(\mathbf{r}) \nabla \psi(\mathbf{r}) \right] + \frac{\sigma_1(\mathbf{r})}{D_0} - S(\mathbf{r}) , \qquad (4.6)$$

where $S(\mathbf{r}) = Q(\mathbf{r})/D_0$ and the wave number is given by

$$k_0 = \left[\frac{i\omega}{cD_0} - \frac{\sigma_0}{D_0}\right]^{1/2} \tag{4.7}$$

By definition, the wavelength and the phase velocity of the photon density wave $\psi(\mathbf{r})$ are given, respectively, by $^{11}\lambda=2\pi/k_r$ and $v_p=\omega/k_p$, where k_r is the real part of Equation 4.7. The "skin depth," or depth to which the photon density falls to e^{-1} of its incident value, is given by $\delta=1/k_i$ where k_i is the imaginary part of Equation 4.7. If, for example, we choose a modulation frequency such that $\omega>>\sigma_a c$, then Equation 4.7 simplifies to $k_0=\sqrt{i\omega/cD_0}=(1+i)\sqrt{\omega/2cD_0}$, in which case $\lambda=2\pi\sqrt{2cD_0/\omega}$, $v_p=\sqrt{2cD_0/\omega}$, and $\delta=\sqrt{2cD_0/\omega}$.

4.3 Optical Diffusion Tomography

4.3.1 Classes of Inversion Algorithms

The reconstruction of an image of optical properties requires the solution to an inverse problem. One can classify inversion algorithms as one of three types:

- 1. Algorithms based on linear numerical inversion methods
- 2. Algorithms based on Fourier-based inversion methods
- 3. Algorithms based on nonlinear iterative methods

The starting point for the first two methods is typically the diffusion equation, which is then transformed to an integral equation via Green's theorem (known as the Lippmann-Schwinger equation), linearized to first order in the inhomogeneity (the Born approximation), and then solved. In the first class of algorithms, a process of discretization converts the integral equation into a system of linear equations, which are then numerically solved using some type of regularized inversion scheme. Examples of this approach are singular-value decomposition and various iterative procedures such as an algebraic reconstruction technique or a conjugate gradient algorithm using, for example, a Tikhonov regularization procedure. ^{29,33,42,70}

In the second class of algorithms, one solves the linearized integral equation using Fourier methods. Diffraction tomography falls into this class; in this case, the integral equation is manipulated into a form

from which the Fourier transform of the unknown optical inhomogeneity can be recovered. An inverse Fourier transform then yields the image. An aesthetically pleasing feature of Fourier-based methods is that they sometimes yield explicit inversion formulas, although the derivation of these formulas generally requires that the source and detection surfaces have simple geometries, such as lines or circles for 2-D problems and planes or spheres for 3-D problems.^{66,71}

These inversion formulas are computationally efficient because the inversion has been performed analytically, whereas a purely numerical solution requires the equivalent of the inversion of a large matrix. Although numerical inversion algorithms allow greater freedom in formulating regularization schemes, regularization is still possible in Fourier-based methods, usually in the form of a low-pass, spatial-frequency filter. This filter attenuates the higher spatial-frequency components to reduce noise sensitivity.

Imaging algorithms in the third category are based on nonlinear optimization techniques, in which a global error norm, such as the mean-square error, is iteratively minimized. This method is the most general because, in principle, no approximations need be made for the benefit of analytical tractability. Here, the unknown inhomogeneity is sought that best predicts the data, subject perhaps to additional *a priori* constraints. At each iteration, the forward solution is computed on the basis of the current estimate of the unknown inhomogeneity and compared to the measurements. Normally, gradient descent methods are employed to minimize the mean-square error, although other approaches, such as simulated annealing or evolution algorithms, ⁷² are possible.

Gaudette and coworkers⁴² recently conducted a comprehensive review of the first class of algorithms, linear numerical schemes. In this chapter, we shall focus on the second and third classes of algorithms, Fourier methods and nonlinear iterative methods. We will discuss examples of each of these approaches from our research to illustrate both techniques.

4.3.2 Analytical and Quasi-Analytical Methods

In the category of Fourier-based methods we include diffraction-tomography methods, as well as back-projection and angular spectrum techniques.

Inspired by x-ray tomography, several algorithms based on the concept of filtering and back-projection have been proposed. Walker et al.⁷³ proposed a particularly simple back-projection algorithm in which the data, after filtering, are back-projected along the straight lines joining each source and detector. Colak et al.³¹ conducted a comprehensive investigation of back-projection methods using different filtering schemes. Such methods are rapid and robust but do not take into account the diffraction or scattering of the photon density waves.

By use of an angular spectrum decomposition of the scattered waves, Li et al.²¹ and Durduran et al.⁷⁴ examined other algorithms that rigorously take into account DPDW diffraction. This approach is well suited for data acquisition over planar geometries because a spatial Fourier transform is performed over a plane (or line in 2-D imaging). The angular spectrum analysis decomposes the DPDW field into spatial frequency components, each of which propagates in different directions and attenuates at different rates. This method is particularly convenient for examining how spatial resolution changes with depth. The authors used the angular spectrum formulation to develop a quasi-analytical reconstruction algorithm based on filtering and back-propagation of the DPDW field.

A closely related approach developed by a number of authors begins by linearizing the Green's integral and then employing a plane-wave expansion of the Green's function.^{39,75} This is a first step toward a conventional diffraction tomography formulation, except that in this case, the problem is complicated by the complex wave number. Along these lines, Matson^{32,37,45} developed a projection slice theorem that relates the Fourier transform of the data to that of the object. However, the theorem in the form presented is not suitable for reconstructing the object directly via Fourier inversion because the complex wave number gives rise to complex spatial-frequency variables.

Norton and Vo-Dinh³⁶ showed how an explicit solution can be derived by a process of analytical continuation that makes the spatial-frequency variables real, after which a conventional inverse Fourier

transform can be performed to reconstruct the object. This approach is described in more detail below. A method somewhat related to that of Norton and Vo-Dinh was developed by Markel and Schotland,⁴⁴ who obtained a solution to the Born integral equation based on a Fourier-Laplace inversion scheme. Their solution also implies analytically continued data. Other authors have also developed formal solutions for continuous-wave imaging (i.e., in the zero frequency limit) based on a Laplace-transform inversion.^{61,62} Finally, Chen et al.³⁸ developed an approximate explicit solution by using a stationary-phase approximation to the Green's integral.

4.3.3 Nonlinear Iterative Methods

Nonlinear iterative approaches attempt to find the inhomogeneity that best predicts the data. 40,57,76,77 In these algorithms, regularization schemes are relatively easy to implement — for example, by attaching a penalty function to the error functional, which can be designed to emphasize objects that are smooth or have minimum norm or maximum entropy. Also, *a priori* constraints can be enforced at each iteration. Formulating the method in a maximum-likelihood or a Bayesian framework allows noise statistics to be taken explicitly into account. 78,79 Typically, the image is decomposed into pixels, each of which is described by one or more parameters, such as the diffusion or absorption coefficient at that point. A pixel basis is not necessary, however; other parameterizations are possible, such as the shape of the anomaly. 43,80

An essential ingredient in most of these schemes is the computation of the functional gradient (or Fréchet derivative) of the mean-square error. A brute-force approach to evaluating the gradient could be performed by computing finite differences. That is, if N unknowns were characterizing the inhomogeneity (e.g., N pixels in the image), then a minimum of N forward problems would be required to compute the N derivatives using finite differences. With the adjoint method, only two forward problems need to be solved: one forward problem and its adjoint. In computing the functional gradient using the adjoint method, most published algorithms have employed the adjoint of the diffusion equation. However, Norton and Dorn employe the adjoint of the integro-differential transport equation, which is generally a more accurate model of DPDW propagation and scattering. We examine this method below in a simple example of a continuous-wave inverse problem for reconstructing the pixels of the scattering coefficient in a 2-D object. We also show how this approach can be applied to transient data.

4.4 Algorithms for Imaging

4.4.1 An Explicit Solution Based on Diffraction Tomography

We present in this section an analytical solution to the inverse diffusion problem using the methods of diffraction tomography.³⁶ As noted, DT is a wave-equation-based inversion procedure whose starting point is a Helmholtz equation with a real wave number. As we shall see, however, the complex wave number in the Helmholtz equation (Equation 4.7) that arises from the diffusion equation can be dealt with by analytical continuation of the data in the Fourier domain; then, the conventional DT methodology can be applied.

For simplicity, we assume that the frequency ω is large compared to $\mu_a c$; although this assumption is not necessary, it simplifies the algebra. In this case, Equation 4.7 becomes simply $k_0 = \sqrt{i\omega/cD_0}$. We also assume that scattering dominates absorption, so that the parameter to be imaged is the diffusion coefficient $D(\mathbf{r})$ or, equivalently, the perturbation $D_1(\mathbf{r})$. Then Equation 4.6 reduces to

$$\nabla^2 \psi(\mathbf{r}) + k_0^2 \psi(\mathbf{r}) = -\frac{1}{D_0} \nabla \cdot \left[D_1(\mathbf{r}) \nabla \psi(\mathbf{r}) \right] - S(\mathbf{r}). \tag{4.8}$$

Equation 4.8 can be converted to an integral equation using standard techniques, giving

$$\psi(\mathbf{r}) = \psi_i(\mathbf{r}) + \frac{1}{D_i} \int \nabla \cdot \left[D_1(\mathbf{r}') \nabla \psi(\mathbf{r}') \right] g(\mathbf{r}|\mathbf{r}') d^3 \mathbf{r}', \qquad (4.9)$$

where g(r|r') is a Green's function and

$$\psi_i(\mathbf{r}) = \int S(\mathbf{r}')g(\mathbf{r}|\mathbf{r}')d^3\mathbf{r}$$
 (4.10)

is the incident field. The Green's function is defined by

$$\nabla^2 g(\boldsymbol{r}|\boldsymbol{r'}) + k_0^2 g(\boldsymbol{r}|\boldsymbol{r'}) = -\delta(\boldsymbol{r} - \boldsymbol{r'}).$$

If the source can be approximated as a point at \mathbf{r}_s then letting $S(\mathbf{r}) = \delta(\mathbf{r} - \mathbf{r}_s)$, Equation 4.10 reduces to $\psi_i(\mathbf{r}) = g(\mathbf{r} \mid \mathbf{r}_s)$. In the Born approximation, the scattered field, represented by the integral on the right-hand side of Equation 4.9, is assumed to be much smaller than the incident field, $\psi_i(\mathbf{r})$. Then, to the first-order approximation in the inhomogeneity $D_1(\mathbf{r})$, we replace $\psi(\mathbf{r})$ by $\psi_i(\mathbf{r})$ in the integrand of Equation 4.9. Defining the scattered field by $\psi_s = \psi - \psi_i$ and setting $\mathbf{r} = \mathbf{r}_d$ in Equation 4.9, where \mathbf{r}_d is the detection point, we obtain

$$\Psi_s(\mathbf{r}_s, \mathbf{r}_d) = \frac{1}{D_0} \int \nabla \cdot \left[D_1(\mathbf{r}) \nabla g(\mathbf{r}_s | \mathbf{r}) \right] g(\mathbf{r}_d | \mathbf{r}) d^3 \mathbf{r} . \tag{4.11}$$

Here, we have substituted $\psi_i(\mathbf{r}) = g(\mathbf{r} \mid \mathbf{r}_s) = g(\mathbf{r}_s \mid \mathbf{r})$ in the integrand of Equation 4.9. Abbreviating $g_s = g(\mathbf{r}_d \mid \mathbf{r})$ and $g_d = g(\mathbf{r}_d \mid \mathbf{r})$, this integral can be rewritten using an integration by parts with the aid of the identity $\nabla \cdot [D_1 \nabla g_s] g_d = \nabla \cdot [D_1 g_d \nabla g_s] - D_1 \nabla g_d \cdot \nabla g_s$. When this is substituted into Equation 4.11, the volume integral of $\nabla \cdot [D_1 g_d \nabla g_s]$ can be converted to a surface integral over the domain of integration with the aid of the divergence theorem. This integral will vanish, since we can define $D_1(\mathbf{r}) = 0$ on this surface. Then Equation 4.11 becomes

$$\Psi_s(\mathbf{r}_s, \mathbf{r}_d) = -\frac{1}{D_0} \int D_1(\mathbf{r}) \nabla g(\mathbf{r}_s | \mathbf{r}) \cdot \nabla g(\mathbf{r}_d | \mathbf{r}) d^3 \mathbf{r} . \qquad (4.12)$$

For simplicity, at this point we consider a 2-D problem, although the theory can be readily generalized to 3-D. We then write $\mathbf{r} = (x,z)$, with all quantities assumed to be independent of the third dimension, y. For brevity we will refer to the sources as "points" lying along a line array, but for a true 2-D problem each "point" source is really a line source in the direction y. A similar statement can be made for the "point" detectors.

Consider now the 2-D geometry shown in Figure 4.3, in which the source point is confined to a line with coordinates $\mathbf{r}_s = (x_s, 0)$ and the detector point is confined to a line with coordinates $\mathbf{r}_d = (x_d, L)$ parallel to, and at a distance L from, the source line. We now employ the following plane-wave expansions of the 2-D Green's functions:

$$g(\mathbf{r}|\mathbf{r}_s) = \frac{i}{4\pi} \int_{-\infty}^{\infty} \frac{dk_x}{\gamma} \exp[ik_x(x - x_s)] \exp(i\gamma z)$$
 (4.13a)

$$g(\mathbf{r}|\mathbf{r}_d) = \frac{i}{4\pi} \int_{-\infty}^{\infty} \frac{dk_x}{\gamma} \exp\left[ik_x(x - x_d)\right] \exp\left[i\gamma(L - z)\right], \tag{4.13b}$$

where

$$\gamma = \sqrt{k_0^2 - k_x^2} \ . \tag{4.13c}$$

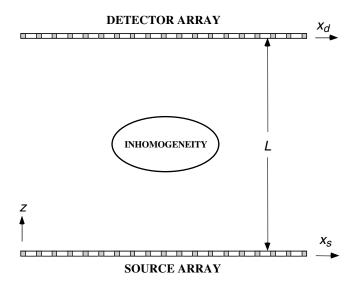

FIGURE 4.3 Simplified 2-D geometry of source-detector system. The source point is confined to a line with coordinates $\mathbf{r}_t = (x_o 0)$ and the detector point is confined to a line with coordinates $\mathbf{r}_d = (x_d L)$. See text for discussion.

We now compute the 2-D Fourier transform of Equation 4.12 with respect to x_s and x_d , that is,

$$\tilde{\Psi}_s(k_s, k_d) = \int \int_{-\infty}^{\infty} \Psi_s(r_s, r_d) \exp[i(k_d x_d + k_s x_s)] dx_s dx_d$$
(4.14)

Equations 4.13a and 4.13b are substituted into Equation 4.12 and the result into Equation 4.14. After interchanging the orders of integration and some manipulation, we obtain

$$\tilde{\Psi}_{s}(k_{s}, k_{d}) = C(k_{s}, k_{d}) \int_{0}^{L_{x}} dx \int_{0}^{L_{z}} dz \ D_{1}(x, z) \exp[i(k_{s} + k_{d})x + i(\gamma_{s} - \gamma_{d})z], \tag{4.15}$$

where $\gamma_s \equiv \sqrt{k_o^2 - k_s^2}$ and $\gamma_d \equiv \sqrt{k_o^2 - k_d^2}$

$$C(k_s, k_d) = -\frac{1}{4D_0} \frac{k_s k_d - \gamma_s \gamma_d}{\gamma_s \gamma_d} \exp[i \gamma_d L]$$
(4.16)

Note that in Equation 4.15 we have limited the nonzero domain of $D_1(x,z)$ to the rectangular regions $0 < x < L_x$ and $0 < z < L_z$. Note also that Equation 4.15 is in the form of a 2-D Fourier transform of the inhomogeneity $D_1(x,z)$, which can be written

$$\tilde{\Psi}_{s}(k_{s}, k_{d}) = C(k_{s}, k_{d}) \int_{0}^{L_{x}} dx \int_{0}^{L_{z}} dz D_{1}(x, z) \exp[i(k_{x}x + k_{z}z)], \qquad (4.17)$$

with transform variables defined by

$$k_{x} \equiv k_{c} + k_{d}, \tag{4.18a}$$

$$k_z \equiv \gamma_s - \gamma_d = \sqrt{k_0^2 - k_s^2} - \sqrt{k_0^2 - k_d^2}$$
 (4.18b)

For Equation 4.17 to assume the form of an ordinary 2-D Fourier transform, the transform variables k_x and k_z must be real; however, as written, k_z in Equation 4.18b is complex, because $k_0^2 = i\omega/cD_0$. To

invert Equation 4.17, we perform an analytical continuation of k_s and k_d into their respective complex planes in such a way as to make k_x and k_z real; then, an ordinary inverse Fourier transform of Equation 4.17 will yield the reconstruction of $D_1(x,z)$, denoted $\hat{D}_1(x,z)$:

$$\hat{D}_{1}(x,z) = \frac{1}{(2\pi)^{2}} \int \int_{-\infty}^{\infty} \frac{\tilde{\Psi}_{s}(k_{s},k_{d})}{C(k_{s},k_{d})} \exp[-i(k_{x}x + k_{z}z)] dk_{x} dk_{z} . \tag{4.19}$$

The transform variables k_x and k_z in Equation 4.18 can be made real using the following change of variables:

$$k_s \equiv k_0 \sin(p - q + iv), \qquad (4.20a)$$

$$k_d \equiv k_0 \sin(p + q + iv), \qquad (4.20b)$$

where p, q, and v are new variables. Recalling that $k_0 \equiv \sqrt{i\omega/cD_0} = (1+i)\sqrt{\omega/2cD_0}$, substituting Equations 4.20a and 4.20b into Equation 4.18 and employing trigonometric identities, gives

$$k_x = \sqrt{2\omega/cD_0} (1+i)\sin(p+i\nu)\cos q, \qquad (4.21a)$$

$$k_z = \sqrt{2\omega/cD_0} (1+i)\sin(p+i\nu)\sin q. \qquad (4.21b)$$

We now choose the variables p and v such that the imaginary part of $(1 + i) \sin(p + iv)$ vanishes. This gives the relation

$$tan p = -tan v.$$
(4.22)

With this condition, Equations 4.21a and 4.21b become purely real. Employing Equation 4.22 to eliminate ν in Equations 4.21a and 4.21b, we obtain

$$k_x = f(p)\cos q, \qquad (4.23a)$$

$$k_z = f(p)\sin q, (4.23b)$$

where $f(p) \equiv \sqrt{2\omega/cD_0} \sin 2p/\sqrt{\cos 2p}$.

Note that by forcing k_x and k_z to be real in Equation 4.19, we have made k_s and k_d complex. The implications of this will be explained shortly. In evaluating Equation 4.19, it is convenient to change the variables of integration from (k_x,k_x) to (p,q) since, in the integrand of Equation 4.19,

$$\tilde{\Psi}_s(k_s, k_d) = \tilde{\Psi}_s[k_s(p,q), k_d(p,q)] \equiv \tilde{\Psi}_s(p,q),$$

and similarly,

$$C(k_s, k_d) = C[k_s(p,q), k_d(p,q)] \equiv C(p,q)$$
,

where the relations $k_s(p,q)$ and $k_d(p,q)$ are defined through Equations 4.21 and 4.22. From Equation 4.23, the entire Fourier plane $-\infty < k_x < \infty$ and $-\infty < k_z < \infty$ maps into the domain $0 \le p < \pi/4$ and $0 \le q < 2\pi$. Then, on changing variables to (p,q), Equation 4.19 becomes

$$\hat{D}_{1}(x,z) = \frac{1}{(2\pi)^{2}} \int_{0}^{\pi/4} dp \, J(p) A(p) \int_{0}^{2\pi} dq \, \frac{\tilde{\Psi}_{s}(k_{s}, k_{d})}{C(k_{s}, k_{d})} \exp[-if(p)(x \cos q + \sin q)], \qquad (4.24)$$

where J(p) is the Jacobian of the transformation from (k_x,k_x) to (p,q), which can be shown to be $J(p)=(2\omega/cD_0)$ $(1+\cos^22p)\sin 2p/\cos^22p$ and A(p) has been inserted to serve as a spectral apodization function, or lowpass filter, that forces the integrand to zero for large p. The simplest choice for A(p) is A(p)=1 for $p < p_{max}$ and A(p)=0 for $p > p_{max}$. The function A(p) is necessary to compensate for any exponential growth in the analytically continued data $\tilde{\Psi}_s(k_s,k_d)$ caused by noise. The lowpass filter A(p) may be regarded as a form of regularization.

We conclude by discussing how measurements can be analytically continued. This is, in principle, performed by substituting the complex variables (k_s,k_d) , defined by Equations 4.20 and 4.22, into the Fourier relation (Equation 4.14) and performing the integration. This will in general give rise to growing exponentials in the factor $\exp[i(k_d,x_d+k_d,x_d)]$, which, in the absence of noise, will be compensated for by the dying exponentials in the data $\tilde{\Psi}_s(k_s,k_d)$. If we limit the domain of integration in Equation 4.14 (which will always be the case for finite-length source and detector arrays), the integral (Equation 4.14) will remain bounded. In this process, however, noise in the data will be amplified relative to the signal, which is a reflection of the ill-conditioning of the inverse problem. As noted, the purpose of the function A(p) in Equation 4.24 is to reduce this noise at the expense of some loss of resolution.

To summarize, given the measurements $\psi_s(r_s, r_d)$, the reconstruction procedure requires the following steps. First, the modified Fourier transform of $\psi_s(r_s, r_d)$, defined by Equation 4.14, is evaluated using the complex transform variables k_s and k_d as defined by Equations 4.20 and 4.22. This result is then substituted into Equation 4.24 to obtain the image. Figure 4.4 shows a simulated reconstruction of two point inhomogeneities with no noise, 2% noise, and 5% noise added to the simulated data. Further details on the approach described in this section, with further discussion of the simulation, can be found in Reference 36.

4.4.2 Nonlinear Iterative Algorithm: Frequency Domain Data

The nonlinear iterative approach involves attempting to find a set of parameters that best predicts the data. For simplicity, we assume that scattering dominates absorption (i.e., $\sigma_s >> \sigma_a$), so that the scattering cross section $\sigma_s(\mathbf{r})$ is the parameter of interest. Then the transport equation (Equation 4.4) becomes

$$s \cdot \nabla \psi(r,s) + \left[\sigma_s(r) - \frac{i\omega}{c}\right] \psi(r,s) = \sigma_s(r) \int \psi(r,s') f(s \cdot s') d^2 s' + q(r,s). \tag{4.25}$$

The adjoint equation to Equation 4.25 is

$$-s \cdot \nabla \psi^{+}(\boldsymbol{r}, s) + \left[\sigma_{s}(\boldsymbol{r}) - \frac{i\omega}{c}\right] \psi^{+}(\boldsymbol{r}, s) = \sigma_{s}(\boldsymbol{r}) \int \psi^{+}(\boldsymbol{r}, s') f(s \cdot s') d^{2}s' + q^{+}(\boldsymbol{r}, s), \qquad (4.26)$$

where the adjoint flux $\psi^+(r,s)$ is defined as the solution to Equation 4.26 given the adjoint source $q^+(r,s)$, which will be defined. Equations 4.25 and 4.26 can be abbreviated as

$$L\{\psi\} = q \tag{4.27}$$

and

$$L^{+} \{ \psi^{+} \} = q^{+}, \tag{4.28}$$

where L and L^+ are the linear forward and adjoint operators defined by Equations 4.25 and 4.26. One can then show that 87

$$\iiint \Psi L^{+} \{ \Psi^{+} \} d^{3} \mathbf{r} \ d^{2} \mathbf{s} = \iiint \Psi^{+} L \{ \Psi \} d^{3} \mathbf{r} \ d^{2} \mathbf{s}. \tag{4.29}$$

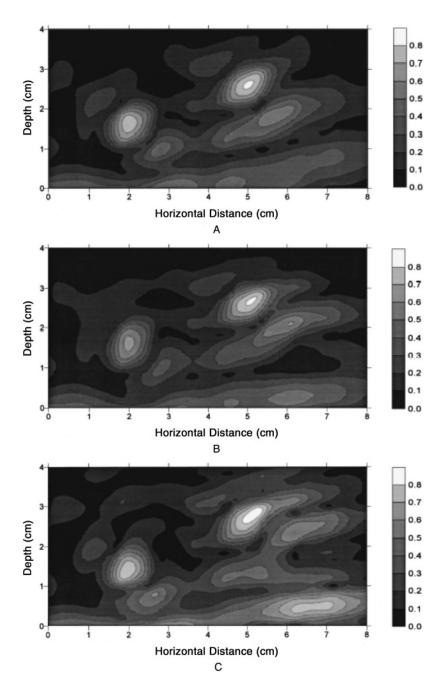

FIGURE 4.4 Simulated reconstruction of two-point inhomogeneities using theoretical algorithms with (A) no noise, (B) 2% noise, and (C) 5% noise added to the simulated data. (From Norton, S.J. and Vo-Dinh, J., *Opt. Soc. Am.*, A15, 2670, 1998. With permission.)

We define the error norm expressing the difference between the predicted flux, $\psi(r,s)$, and the observed flux, $\psi^{(obs)}(r,s)$, as

$$E = \frac{1}{2} \int \int D(r,s) |\psi(r,s) - \psi^{(obs)}(r,s)|^2 d^2r d^2s , \qquad (4.30)$$

where $D(\mathbf{r},\mathbf{s})$ is a function that restricts the domain (\mathbf{r},\mathbf{s}) to "detector space"; we refer to $D(\mathbf{r},\mathbf{s})$ as the detector response function. For example, suppose we have N point detectors at \mathbf{r}_i , i = 1, ..., N.

Further, suppose that each detector has an angular response $R_i(s)$ at point r_i . Then

$$D(\mathbf{r},\mathbf{s}) = \sum_{i=1}^{N} R_{i}(\mathbf{s}) \delta^{(3)}(\mathbf{r} - \mathbf{r}_{i}), \qquad (4.31)$$

where $\delta^{(3)}(\mathbf{r})$ is the 3-D Dirac delta function. Substitution of Equation 4.31 into Equation 4.30 gives the error norm

$$E = \frac{1}{2} \sum_{i=1}^{N} \int d^2 s \, R_j(s) \left| \psi(\mathbf{r}_j, s) - \psi^{(obs)}(\mathbf{r}_j, s) \right|^2. \tag{4.32}$$

Our objective is to find the scattering cross section $\sigma_s(r)$ that minimizes E.

Now a small variation $\delta \sigma_s(\mathbf{r})$ in the cross section $\sigma_s(\mathbf{r})$ will give rise to a variation $\delta \psi(\mathbf{r},\mathbf{s})$ in the flux and a corresponding variation δE in the error E defined by Equation 4.30:

$$\delta E = \text{Re} \iint D(\psi - \psi^{(obs)}) * \delta \psi d^3 r d^2 s, \qquad (4.33)$$

where Re means real part and * denotes the complex conjugate. The corresponding variation in the transport equation (Equation 4.27) will be

$$\delta L\{\psi\} + L\{\delta\psi\} = \delta q, \qquad (4.34)$$

because L is a linear operator. Normally, the source q is fixed, so that $\delta q = 0$ and Equation 4.34 gives

$$L\{\delta\psi\} = -\delta L\{\psi\}. \tag{4.35}$$

We wish to eliminate the unknown flux variation, $\delta \psi$, from Equation 4.33 with the aid of Equation 4.35 to express δE explicitly in terms of the operator variation δL , which, in turn, can be related to the variation in the scattering cross section, $\delta \sigma_s$ through Equation 4.25, as we show next.

To accomplish this, define the adjoint source $q^+ \equiv D(\psi - \psi^{(obs)})^*$ so that Equation 4.28 becomes

$$L^{+}\left\{\psi^{+}\right\} \equiv D\left(\psi - \psi^{(obs)}\right)^{*}. \tag{4.36}$$

Substituting Equation 4.36 into Equation 4.33 and using Equation 4.29 gives

$$\delta E = \operatorname{Re} \int \int \delta \psi L^{+} \left\{ \psi^{+} \right\} d^{3} \boldsymbol{r} \, d^{2} \boldsymbol{s} = \operatorname{Re} \int \int \psi^{+} L \left\{ \delta \psi \right\} d^{3} \boldsymbol{r} \, d^{2} \boldsymbol{s} \,. \tag{4.37}$$

Substituting Equation 4.35 into the second integral finally results in

$$\delta E = -\text{Re} \iint \psi^{+} \delta L \{\psi\} d^{3}r d^{2}s. \qquad (4.38)$$

Now, variation of the linear transport operator L defined in Equation 4.25 gives

$$\delta L\{\psi\} = \delta \sigma_s \psi - \delta \sigma_s \int \psi f \, d^2 s' \,. \tag{4.39}$$

Substituting Equation 4.39 into Equation 4.38 and interchanging orders of integration gives

$$\delta E = \int \left[\nabla_s E(\mathbf{r}) \right] \delta \sigma_s(\mathbf{r}) d^3 \mathbf{r} , \qquad (4.40)$$

where

$$\nabla_{s} E(\mathbf{r}) \equiv \operatorname{Re} \int \int \psi^{+}(\mathbf{r}, \mathbf{s}) \left[\psi(\mathbf{r}, \mathbf{s}) - \int \psi(\mathbf{r}, \mathbf{s}') f(\mathbf{s} \cdot \mathbf{s}') d^{2} \mathbf{s}' \right] d^{2} \mathbf{s} . \tag{4.41}$$

Here, $\nabla_s E(\mathbf{r})$ is the functional gradient (or Fréchet derivative) of the mean-square error, E, computed with respect to the scattering cross section $\sigma_s(\mathbf{r})$. Equation 4.40 may be regarded as the continuous-space analogue of a directional derivative, where the integral is analogous to a dot product between the functional gradient, $\nabla_s E(\mathbf{r})$, and the infinite-dimensional "vector" $\delta \sigma_s(\mathbf{r})$. If $\sigma_s(\mathbf{r})$ depends on a finite number of discrete parameters, Equation 4.40 reduces to the usual finite-dimensional gradient, as shown below. Equation 4.41 may also be interpreted as the mean-square error "sensitivity" in the sense that it tells us how sensitive a change in the error functional, E, is to a change in $\sigma_s(\mathbf{r})$ at the point \mathbf{r} .

Once the functional gradient has been computed, any convenient gradient descent algorithm may be employed to drive the error norm (Equation 4.32) to a minimum. Examples of descent algorithms are the method of steepest descent, the conjugate-gradient method, or various quasi-Newton methods.^{88,89} The point is that any of these descent algorithms requires the gradient, which traditionally has been the most expensive part of the computation. For example, the conjugate-gradient algorithm updates the previous estimate of $\sigma_s(r)$, denoted $\sigma_s^{(n-1)}(r)$, as follows:^{88,89}

$$\sigma_{\cdot}^{(n)}(\mathbf{r}) = \sigma_{\cdot}^{(n-1)}(\mathbf{r}) + \alpha_{\cdot \cdot \cdot} f_{\cdot \cdot}(\mathbf{r})$$

where

$$f_{n}(\mathbf{r}) = -\nabla_{n}^{(n-1)}E(\mathbf{r}) + \beta_{n}f_{n-1}(\mathbf{r})$$

In the latter equation, the gradient $\nabla_s^{(n-1)}E(\mathbf{r})$ is computed on the basis of the estimate $\sigma_s^{(n-1)}(\mathbf{r})$, and α_n and β_n are step-size parameters updated at each iteration, with the initial condition $\beta_0 \equiv 0$.

4.4.2.1 Finite Number of Parameters

The finite-dimensional case can also be treated using the preceding results. Suppose, for example, that we represent the spatially varying cross section $\sigma_s(\mathbf{r})$ using a finite number of pixels at the points \mathbf{r}_p , p = 1, ..., P More generally, we can expand $\sigma_s(\mathbf{r})$ in a set of P basis functions, as follows:

$$\sigma_{s}(\mathbf{r};\mathbf{a}) = \sum_{p=1}^{p} a_{p} \varphi_{p}(\mathbf{r}), \tag{4.42}$$

where $\mathbf{a} = \{a_1, \dots, a_p\}$ is a set of coefficients to be determined. The variation $\delta \sigma_s(\mathbf{r})$ can then be written

$$\delta\sigma_{s}(r;a) = \sum_{p=1}^{p} \varphi_{p}(r) \delta a_{p}. \qquad (4.43)$$

Substituting Equation 4.43 into Equation 4.40 gives

$$\delta E = \sum_{p=1}^{p} \left[\int \left[\nabla_{s} E(\mathbf{r}) \right] \varphi_{p}(\mathbf{r}) d^{3} \mathbf{r} \right] \delta a_{p}$$
(4.44)

However,

$$\delta E = \sum_{p=1}^{p} \frac{\partial E}{\partial a_p} \delta a_p \tag{4.45}$$

Comparing Equations 4.44 and 4.45, we obtain the components of the finite-dimensional gradient of the norm *E*:

$$\frac{\partial E}{\partial a_p} = \int \left[\nabla_s E(\mathbf{r}) \right] \varphi_p(\mathbf{r}) d^3 \mathbf{r}$$
 (4.46)

where $\nabla_s E(\mathbf{r})$ is defined by Equation 4.41.

4.4.2.2 Adding a Regularization Term

In general, the inverse transport problem is ill posed, and consequently ill conditioned, because of the diffuse nature of the photon migration in tissue; thus, a regularization scheme is needed to stabilize the inversion in the presence of noisy data. One approach involves adding a penalty term to the error norm (Equation 4.30) designed, for example, to penalize large variations in the unknown $\sigma_s(\mathbf{r})$ or to emphasize smoother solutions. Regularization of this kind not only helps mitigate ill-conditioning but also serves to force uniqueness in an under-determined problem. Equation 4.30 is then modified to read

$$E = \frac{1}{2} \iiint D \left| \Psi - \Psi^{(obs)} \right|^2 d^3 r d^2 s + \frac{1}{2} \lambda \int C(\sigma_s) d^3 r, \qquad (4.47)$$

where $C(\sigma_s)$ is a penalty function and λ is a parameter that controls the relative weighting of the two terms in Equation 4.47. Possible choices of $C(\sigma_s)$ are

$$C(\sigma_s) = \sigma_s(r)^2, \tag{4.48a}$$

$$C(\sigma_s) = \nabla \sigma_s(r) \cdot \nabla \sigma_s(r), \tag{4.48b}$$

$$C(\sigma_s) = -\sigma_s(r) \ln \sigma_s(r). \tag{4.48c}$$

Working through the same derivation as above and letting $\nabla_s E(\mathbf{r})$ denote the Fréchet derivative defined by Equation 4.41, the augmented norm (Equation 4.47) gives the following new Fréchet derivatives corresponding, respectively, to the preceding three penalty functions:

$$\nabla_{s}^{(1)}E(\mathbf{r}) = \nabla_{s}E(\mathbf{r}) + \lambda\sigma_{s}(\mathbf{r}), \tag{4.49a}$$

$$\nabla_{\mathbf{r}}^{(2)}E(\mathbf{r}) = \nabla_{\mathbf{r}}E(\mathbf{r}) - \lambda \nabla^{2}\sigma_{\mathbf{r}}(\mathbf{r}), \tag{4.49b}$$

$$\nabla_{\varsigma}^{(3)} E(\mathbf{r}) = \nabla_{\varsigma} E(\mathbf{r}) + \lambda \left[1 - \ln \sigma_{\varsigma}(\mathbf{r}) \right]. \tag{4.49c}$$

4.4.2.3 Example: Two-Dimensional Imaging of a Scattering Cross Section

To illustrate how the preceding theory can be implemented, consider a simple 2-D continuous wave (steady-state) imaging problem. We divide a square imaging domain into $N \times N$ square pixels, each with an unknown scattering cross section denoted by σ_{mn} , with m, n = 1, ..., N. We wish to determine the N^2 unknowns σ_{mn} based on scattering observations on the boundary of the square domain. We consider a very simple discrete transport model for purposes of illustration; in this model, a photon incident on a pixel can be scattered in just four directions — up, down, left, and right — where each direction is described, respectively, by the unit vectors s_1 , s_2 , s_3 , s_4 . Denote the photon flux moving in the direction s_i in pixel (m,n) by $\psi_{mn}(s_i)$. This flux then obeys the following discrete transport equation:

$$\mathbf{s}_{i} \cdot \nabla_{d} \Psi_{mn} \left(\mathbf{s}_{i} \right) + \sigma_{mn} \Psi_{mn} \left(\mathbf{s}_{i} \right) = \sigma_{mn} \sum_{i=1}^{4} f \left(\mathbf{s}_{i} \cdot \mathbf{s}_{j} \right) \Psi_{mn} \left(\mathbf{s}_{j} \right) + q_{mn} \left(\mathbf{s}_{i} \right)$$

$$(4.50)$$

for i=1,...,4. This is the discretized version of Equation 4.25 in the zero-frequency limit ($\omega=0$). Here ∇_d is a difference operator defined below, $f(s_i \cdot s_j)$ is a known scattering law, and $q_{mn}(s_i)$ is a source term, also assumed known. If we assume that the pixels are of unit dimensions ($\Delta x = \Delta y = 1$), then we have for the four directions:

$$\begin{split} & \boldsymbol{s}_{1} \cdot \nabla_{d} \boldsymbol{\psi}_{mn} (\boldsymbol{s}_{1}) = \boldsymbol{\psi}_{mn} (\boldsymbol{s}_{1}) - \boldsymbol{\psi}_{m-1,n} (\boldsymbol{s}_{1}) \\ & \boldsymbol{s}_{2} \cdot \nabla_{d} \boldsymbol{\psi}_{mn} (\boldsymbol{s}_{2}) = \boldsymbol{\psi}_{mn} (\boldsymbol{s}_{2}) - \boldsymbol{\psi}_{m+1,n} (\boldsymbol{s}_{2}) \\ & \boldsymbol{s}_{3} \cdot \nabla_{d} \boldsymbol{\psi}_{mn} (\boldsymbol{s}_{3}) = \boldsymbol{\psi}_{mn} (\boldsymbol{s}_{3}) - \boldsymbol{\psi}_{m,n-1} (\boldsymbol{s}_{3}) \\ & \boldsymbol{s}_{4} \cdot \nabla_{d} \boldsymbol{\psi}_{mn} (\boldsymbol{s}_{4}) = \boldsymbol{\psi}_{mn} (\boldsymbol{s}_{4}) - \boldsymbol{\psi}_{m,n+1} (\boldsymbol{s}_{4}) \end{split}$$

This is a reasonable approximation to the spatial derivatives, assuming that the flux is slowly varying on the scale of a pixel. More realistic transport models obviously exist but can be treated similarly. The forward problem can be defined as the task of computing the fluxes $\psi_{mn}(s_i)$, given the set $\{\sigma_{mn}\}$; a simple forward algorithm can be devised by iterating Equation 4.50. Our objective is to minimize the following mean-square error with respect to $\{\sigma_{mn}\}$:

$$E = \frac{1}{2} \sum_{m,n=1}^{N} \sum_{i=1}^{4} D_{mn}(\mathbf{s}_{i}) \left[\Psi_{mn}(\mathbf{s}_{i}) - \Psi_{mn}^{(obs)}(\mathbf{s}_{i}) \right]^{2},$$
 (4.51)

in which the detector response function is defined by $D_{mn}(\mathbf{s}_i) \equiv 1$ for the observed flux on the boundary of the domain, and $D_{mn}(\mathbf{s}_i) \equiv 0$ otherwise.

We wish to show in this section how, using the adjoint method, we can compute the partial derivatives of the mean-square error $\partial E/\partial \sigma_{mn}$ in terms of known quantities. Defining for brevity $F_{ij} \equiv f(s_i \cdot s_j) - \delta_{ij}$, where δ_{ij} is the Kronecker delta, we can write Equation 4.50 in the more compact form

$$s_i \cdot \nabla_d \Psi_{mn}(s_i) - \sigma_{mn} \sum_{j=1}^4 F_{ij} \Psi_{mn}(s_j) = q_{mn}(s_i).$$
 (4.52)

The adjoint of Equation 4.52 is

$$-\mathbf{s}_{i} \cdot \nabla_{d}^{+} \psi_{mn}^{+}(\mathbf{s}_{i}) - \sigma_{mn} \sum_{i=1}^{4} F_{ij} \psi_{mn}^{+}(\mathbf{s}_{j}) = q_{mn}^{+}(\mathbf{s}_{i}), \tag{4.53}$$

where the adjoint source, $q_{mn}^+(s_i)$, is to be defined, and

$$\begin{split} & s_{1} \cdot \nabla_{d}^{+} \psi_{mn}^{+} (s_{1}) = \psi_{mn}^{+} (s_{1}) - \psi_{m+1,n}^{+} (s_{1}), \\ & s_{2} \cdot \nabla_{d}^{+} \psi_{mn}^{+} (s_{2}) = \psi_{mn}^{+} (s_{2}) - \psi_{m-1,n}^{+} (s_{2}), \\ & s_{3} \cdot \nabla_{d}^{+} \psi_{mn}^{+} (s_{3}) = \psi_{mn}^{+} (s_{3}) - \psi_{m,n+1}^{+} (s_{3}), \\ & s_{4} \cdot \nabla_{d}^{+} \psi_{mn}^{+} (s_{4}) = \psi_{mn}^{+} (s_{4}) - \psi_{m,n-1}^{+} (s_{4}). \end{split}$$

If we abbreviate Equations 4.52 and 4.53 by

$$L_{mn}\left\{\psi_{mn}(s_i)\right\} = q_{mn}(s_i),$$

$$L_{mn}^{+}\left\{\psi_{mn}^{+}(s_i)\right\} = q_{mn}^{+}(s_i),$$

then the adjoint relation analogous to Equation 4.29 is

$$\sum_{m,n=1}^{N} \sum_{i=1}^{4} \Psi_{mn}(s_{i}) L_{mn}^{+} \left\{ \Psi_{mn}^{+}(s_{i}) \right\} = \sum_{m,n=1}^{N} \sum_{i=1}^{4} \Psi_{mn}^{+}(s_{i}) L_{mn} \left\{ \Psi_{mn}(s_{i}) \right\}.$$

We now define the adjoint source as

$$q_{mn}^{+}(\boldsymbol{s}_{i}) \equiv D_{mn}(\boldsymbol{s}_{i}) \left[\boldsymbol{\Psi}_{mn}(\boldsymbol{s}_{i}) - \boldsymbol{\Psi}_{mn}^{(obs)}(\boldsymbol{s}_{i}) \right]$$

If we follow the same procedure as described in the previous section, we obtain the following simple result for the derivatives of the mean-square error:

$$\frac{\partial E}{\partial \sigma_{pq}} = \sum_{i=1}^{4} \sum_{j=1}^{4} F_{ij} \Psi_{pq}^{+}(\boldsymbol{s}_{i}) \Psi_{pq}(\boldsymbol{s}_{j}), \tag{4.54}$$

where $\psi_{pq}(\mathbf{s}_i)$ and $\psi^+_{pq}(\mathbf{s}_i)$ are the solutions to Equations 4.52 and 4.53 computed on the basis of the current estimate of $\{\sigma_{mn}\}$. A simulation was performed by Norton⁸³ using these formulas to reconstruct a 64-pixel-square region with the scattering law $f(\mathbf{s}_i \cdot \mathbf{s}_i) = 0.1$ for $i \neq j$ and $f(\mathbf{s}_i \cdot \mathbf{s}_i) = 0.7$.

These formulas can be easily generalized to account for multiple sources and multiple modulation frequencies. If the modulation frequencies can be made sufficiently high so that the DPDW "skin depth" δ is comparable to the size of the region of interest, then multifrequency data can be shown to improve the conditioning of the inverse problem.⁹⁰

4.4.3 Nonlinear Iterative Algorithm: Time-Resolved Data

As noted, when recording transient data, it is not advantageous to restrict ourselves to the relatively small number of first-arrival photons. Arridge and coworkers, ^{58,60,91} for example, have advocated measurement of the first few moments of the temporal response (e.g., the first moment being the mean arrival time); these measurements can then be employed in an iterative descent algorithm to minimize an appropriate error norm, similar to the scheme described earlier in this chapter. In this section, we

describe a time-domain iterative algorithm designed to minimize an error norm that weights the entire transient waveform. For simplicity, we assume that the diffusion approximation holds, in which case the photon flux density, $\psi(r,t)$, obeys the time-dependent diffusion equation given by Equation 4.3:

$$\frac{1}{c} \frac{\partial \psi(\mathbf{r},t)}{\partial t} - \nabla \cdot \left[D(\mathbf{r}) \nabla \psi(\mathbf{r},t) \right] + \sigma_a(\mathbf{r}) \psi(\mathbf{r},t) = Q(\mathbf{r},t), \qquad (4.55)$$

subject to the initial condition $\psi(r,0) = 0$. Although we employ the diffusion model (Equation 4.55) to illustrate our procedure, a similar time-domain treatment can be carried out with the time-dependent transport equation as a starting point.⁸⁵

Suppose the region of interest is illuminated by a light pulse, which diffuses through the tissue and is detected at N point detectors at $\mathbf{r}, j = 1, ..., N$; the pulse is observed over the interval of time [0,T] and the observations are denoted by $\mathbf{\psi}^{(obs)}(\mathbf{r}_j,t)$. The optical parameters, $D(\mathbf{r})$ and $\sigma_a(\mathbf{r})$, that minimize the time-integrated mean-square error are then sought:

$$E = \frac{1}{2} \sum_{j=1}^{N} \int_{0}^{T} w_{j}(t) \left[\psi(\mathbf{r}_{j}, t) - \psi^{(obj)}(\mathbf{r}_{j}, t) \right]^{2} dt .$$
 (4.56)

Here, the integration is over the observation interval T, and $w_j(t)$ is an arbitrary temporal weighting function. To compute the Fréchet derivative of Equation 4.56, we employ the adjoint diffusion equation, given by

$$-\frac{1}{c}\frac{\partial \psi^{+}(\mathbf{r},t)}{\partial t} - \nabla \cdot \left[D(\mathbf{r})\nabla \psi^{+}(\mathbf{r},t)\right] + \sigma_{a}(\mathbf{r})\psi^{+}(\mathbf{r},t) = Q^{+}(\mathbf{r},t), \qquad (4.57)$$

where the adjoint source is defined by

$$Q^{+}(\boldsymbol{r},t) = \sum_{j=1}^{N} w_{j}(t) \left[\psi(\boldsymbol{r}_{j},t) - \psi^{(obs)}(\boldsymbol{r}_{j},t) \right] \delta(\boldsymbol{r} - \boldsymbol{r}_{j}). \tag{4.58}$$

We require that the adjoint field obey the terminal condition $\psi^+(\mathbf{r},T) = 0$. The reason for this will become apparent shortly. We now vary Equation 4.56, giving

$$\delta E = \sum_{j=1}^{N} \int_{0}^{T} w_{j}(t) \left[\psi(\mathbf{r}_{j}, t) - \psi^{(obs)}(\mathbf{r}_{j}, t) \right] \delta \psi(\mathbf{r}_{j}, t) dt.$$
 (4.59)

In view of the definition (Equation 4.58) of the adjoint source, we can write Equation 4.59 as

$$\delta E = \int d^3 \mathbf{r} \int_0^T dt \, Q^+(\mathbf{r}, t) \delta \psi(\mathbf{r}, t), \tag{4.60}$$

where the volume integral includes the spatial domain of interest. Next, substituting the left-hand side of Equation 4.57 into Equation 4.60 and integrating by parts, once with respect to time and twice with respect to space,⁸¹ we obtain

$$\delta E = \int d^3 r \int_0^T dt \left\{ \frac{1}{c} \frac{\partial \delta \psi(\mathbf{r}, t)}{\partial t} - \nabla \cdot \left[D(\mathbf{r}) \nabla \delta \psi(\mathbf{r}, t) \right] + \sigma_a(\mathbf{r}) \delta \psi(\mathbf{r}, t) \right\} \psi^+(\mathbf{r}, t) . \tag{4.61}$$

When integrating by parts with respect to time, we find that the integrated part vanishes on account of the initial condition $\delta \psi(\mathbf{r},0) = 0$ and the terminal condition $\psi^+(\mathbf{r},T) = 0$. Similarly, we assume that appropriate homogeneous boundary conditions hold on the surface of the domain of integration, which ensures that the boundary terms vanish when integrating by parts with respect to space. Next, we vary Equation 4.55 to obtain

$$\frac{1}{c} \frac{\partial \delta \psi(\mathbf{r},t)}{\partial t} - \nabla \cdot \left[\delta D(\mathbf{r}) \nabla \psi(\mathbf{r},t) \right] - \nabla \cdot \left[D(\mathbf{r}) \nabla \delta \psi(\mathbf{r},t) \right] + \delta \sigma_a(\mathbf{r}) \psi(\mathbf{r},t) + \sigma_a(\mathbf{r}) \delta \psi(\mathbf{r},t) = 0$$

or

$$\frac{1}{c} \frac{\partial \delta \psi(\mathbf{r},t)}{\partial t} - \nabla \cdot \left[D(\mathbf{r}) \nabla \delta \psi(\mathbf{r},t) \right] + \sigma_a(\mathbf{r}) \delta \psi(\mathbf{r},t) = \nabla \cdot \left[\delta D(\mathbf{r}) \nabla \psi(\mathbf{r},t) \right] - \delta \sigma_a(\mathbf{r}) \psi(\mathbf{r},t) .$$

Substituting this into Equation 4.61 gives

$$\delta E = \int d^3 r \int_0^T dt \Big\{ \nabla \cdot \Big[\delta D(\mathbf{r}) \nabla \psi(\mathbf{r}, t) \Big] - \delta \sigma_a(\mathbf{r}) \psi(\mathbf{r}, t) \Big\} \psi^+(\mathbf{r}, t)$$

The first term can be integrated once more by parts with respect to r to yield

$$\begin{split} \delta E &= -\int d^3 r \int_0^T dt \, \nabla \psi(\mathbf{r}, t) \cdot \nabla \psi^+(\mathbf{r}, t) \delta D(\mathbf{r}) - \int d^3 r \int_0^T dt \, \psi(\mathbf{r}, t) \psi^+(\mathbf{r}, t) \delta \sigma_a(\mathbf{r}) \\ &= \int d^3 r \, \nabla_D E(\mathbf{r}) \delta D(\mathbf{r}) + \int d^3 r \, \nabla_a E(\mathbf{r}) \delta \sigma_a(\mathbf{r}), \end{split}$$

where the Fréchet derivatives for $D(\mathbf{r})$ and $\sigma_a(\mathbf{r})$ are, respectively,

$$\nabla_{D}E(\mathbf{r}) = -\int_{0}^{T} dt \, \nabla \psi(\mathbf{r}, t) \cdot \nabla \psi^{+}(\mathbf{r}, t), \tag{4.62}$$

$$\nabla_a E(\mathbf{r}) = -\int_0^T dt \, \psi(\mathbf{r}, t) \psi^+(\mathbf{r}, t). \tag{4.63}$$

When these functional derivatives are used to update the parameters $D(\mathbf{r})$ and $\sigma_a(\mathbf{r})$ in a descent algorithm of one's choice, the time-integrated error functional (Equation 4.56) can be driven to a minimum. In a manner similar to that of the previous section, a penalty term can also be added to Equation 4.56 to regularize the solution.

As noted, the time-dependent residual in Equation 4.56 can be appropriately weighted through the selection of the weighting function $w_j(t)$ to control the signal-to-noise ratio. Arridge⁶⁸ argues that employing the logarithm of $\Psi^{(obs)}(\mathbf{r},t)$ may be advantageous. The above approach can be carried out in the latter case as well, after the field Equations 4.55 and 4.57 are modified by substituting $\Psi(\mathbf{r},t) = \exp[\gamma(\mathbf{r},t)]$, which defines new field equations in $\gamma(\mathbf{r},t)$. After this logarithmic transformation, the Fréchet derivatives of $D(\mathbf{r})$ and $\sigma_a(\mathbf{r})$ can be derived in the same way as above. The interesting question of what constitutes sufficient data to reconstruct $D(\mathbf{r})$ and $\sigma_a(\mathbf{r})$ simultaneously is beyond the scope of our discussion, but has been discussed by Arridge.⁹²

4.5 Conclusion

This chapter has examined in some detail three optical tomography algorithms. The first of these employs Fourier methods to reconstruct an image from time-harmonic DPDW data recorded at one modulation

frequency. This approach may be regarded as a modification of conventional diffraction tomography. The other algorithms employ a gradient descent algorithm to minimize a global error norm measuring the difference between recorded and predicted data. This approach is very general and can accommodate either time- or frequency-domain measurements.

Whether the algorithm is iterative or Fourier-based, the inverse problem will inevitably be ill conditioned because of the diffuse nature of the multiply scattered light or, equivalently, because of the smoothing effect of the forward transport operator. This implies that any inversion procedure that attempts to "undo" this smoothing will amplify noise in the data and will, as a result, require some form of regularization to mitigate the noise amplification. A variety of such schemes exists, but the price paid for regularization is some loss of spatial resolution. In this regard, it is important to note that resolution is ultimately noise-limited, since the resolution typically achieved is well beyond the "diffraction limit" — that is, less than the wavelength of a photon density wave. Moreover, the size of the region probed may sometimes be less than a single DPDW wavelength, implying operation well within the near field.

In addition to reviewing two fundamental methods of image reconstruction (diffraction tomography and the iterative minimization of an error norm), we have tried to provide a representative sampling of the literature in this area. A more comprehensive review of time- and frequency-domain techniques was given recently by Arridge.⁶⁸ We have not referenced many papers that have addressed related but more specialized topics, such as forward algorithms, more accurate photon transport models, fluorescence imaging and spectroscopic methods, effects of boundaries and unusual measurement geometries, and clinical studies. Also, in the interests of space, we have, with a few exceptions, emphasized references in archival journals rather than conference proceedings, although a great deal of work has been published in the latter (particularly the SPIE proceedings²). The number of research papers in optical tomography has grown rapidly in the last 10 years, and one has every reason to expect that continued technical and algorithmic progress will ultimately yield systems of significant clinical value.

5.1 Introduction

The progress made in various fields of science and technology, especially in the development of technical and instrumental tools, has always led, is now leading, and will undoubtedly continue to lead to new, useful, and sometimes revolutionary applications in medicine. As medicine penetrates to ever deeper organizational levels (cellular and molecular) in the human organism (levels that are closely similar in all living creatures), it evolves into biomedicine and becomes more closely connected with all the life sciences. Figure 5.1 depicts the "biomedical tools tree," illustrating the applications of various tools and methods in biomedicine, from its origin in the Middle Ages to genetic engineering at present and into the future. Biomedical photonics, the subject of this volume, embraces a wide range of laser light applications in biomedical diagnostics at various levels of the organism, in therapy, and, finally, in surgery. In many applications laser light is exceptionally efficient and well matched to present-day advanced technology and to the human body — the object of all these applications.

The human body is a uniquely organized functional system including biomolecular, cellular, and tissue structures measuring from a fraction of a nanometer to a few meters, i.e., ranging over ten orders of magnitude. Figure 5.2 illustrates the spatial spectrum of various human structures, from individual atoms and molecules to organs and the body as a whole. The entirety of this spectrum is as yet unknown (except for its extreme sections), but one can assume that it features a fractal dependence like that of the cardiovascular system. Throughout this huge range of sizes, the mutual interaction of all the structures is integrated and matched.

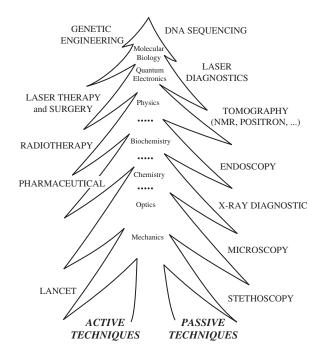

FIGURE 5.1 Biomedical "tools tree."

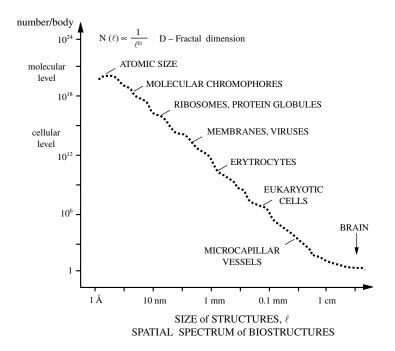

FIGURE 5.2 Presumable spatial spectral distribution of nonhomogeneities in biotissue.

Researchers in one of the major avenues of research in modern technology, namely, nanotechnology, are endeavoring to create nanostructures the size of a molecule and organize their interaction. Naturally, nanotechnology here is faced with enormous difficulties associated with the organization of an addressable mode of interaction of nanoelements with one another and with trying to create a highly organized conglomerate of nanostructures such as a molecular computer, a robot, etc. This problem seems more

involved than the development of the nanostructures themselves. Yet, in living organisms, from a cell to the human being, this problem is solved quite easily and efficiently, probably owing to their adequate hierarchic organization. Perhaps this fact explains why laser light proves an effective diagnostic, therapeutic, and surgical means at all organizational levels of the human body: biomolecules, cells, organs, and the body as a whole. The capabilities of lasers here seem inexhaustible.

Coherent laser light can be localized within a region measuring a few fractions of a micron so that it can irradiate intracellular structures, and nonlocalized to cover a region a few meters in size, with its coherence remaining unimpaired. Laser light supplies energy in a noncontact manner, i.e., without the need to use electrodes that cause mechanical damage to biostructures. Of special value is the possibility of conveying light via the optical information window of man, i.e., the human eye.

Laser light is monochromatic and can be made to have any wavelength, i.e., the supply of laser-light energy is spectral-selective, and so its action on biomolecules can be as selective as are their absorption or light-action spectra. Laser light can supply energy of any magnitude necessary, and its irradiation intensity can be varied over a wide range (from a few mW/cm² to 10¹¹ W/cm²) by varying the energy and duration of the laser pulse (from a few femtoseconds to a few seconds, minutes, and more).

The combination of these unique capabilities, absent in any other type of radiation, makes the laser a universal and efficient biomedical tool.^{2–5}

5.2 Laser-Biomatter Interaction

Laser light interacts with living matter at various biological organization levels: (1) the biomolecule, (2) subcellular structures, (3) cells, (4) biotissues, (5) organs, and (6) the whole organism. All these structures fall within different sections of the spatial spectrum (Figure 5.2).

All types of laser-biomatter interaction can be categorized as (1) resonance processes, involving the absorption of laser light and the resultant excitation of biomolecules, and (2) nonresonance processes, involving the scattering of laser light by molecular vibrations or by refractive index irregularities in the biotissues exposed or its reflection from boundaries between media differing in refractive index (interfaces).

When a biomolecule absorbs laser light, the expenditure of the excitation energy can follow various pathways, depending on the type of excitation (electronic or vibrational) of the molecules, its surroundings, and radiation intensity (Figure 5.3). Some absorbed energy degrades to heat in a radiationless manner (for example, vibrational excitation by IR light degrades to heat in a picosecond timescale) and some of it may be transferred to the neighboring molecules. The electronically excited molecules may take part in chemical reactions or they may be raised to higher quantum states, provided the light intensity is high enough (ultraviolet pulses), and then be involved in photochemical processes. Almost all these excitation pathways are now successfully utilized in laser biomedicine: in laser fluorescence diagnostics, laser photodynamic therapy, laser phototherapy, and laser thermal surgery. The sum of the quantum yields attained in particular channels is equal to unity. Depending on the conditions of irradiation and the state of the medium, the quantum yield in any desired channel can be varied with a view to improving the efficiency of its utilization.

Laser radiation parameters (wavelength, spectral bandwidth, intensity, duration) can be varied over very wide limits, thus making it possible to implement various types of light-biomatter interaction (linear and nonlinear, single- and multiple-photon, coherent and noncoherent, thermal and nonthermal, etc.). Thus one can induce various effects in biotissues (photochemical modification, thermal destruction, explosive ablation, optical breakdown, shock pressure waves, photodisruption, etc.), as illustrated in Figure 5.4.

Figure 5.5 illustrates various nonresonant light-scattering processes occurring at a molecular and a macroscopic level. In addition to Raman light scattering by molecular vibrations, important biomedical applications are the processes of scattering light by macroscopic particles that increase the photon pathway in the exposed biotissue and give rise to a Doppler light-frequency shift by moving particles (Doppler flowmetry),⁶ and the gradient (dipole) force due to the transfer of photon momentum $h\omega/c$) to the scattering particle (the physical basis of optical tweezers⁷).

FIGURE 5.5 Effects of nonresonant scattering interaction of laser light with biotissue.

When considering the interaction between laser radiation and biotissues, one should take into account (and possibly use) the inhomogeneous character of the various biological, chemical, and physical (optical, acoustical, electrical, etc.) properties of tissues. The characteristic size of these inhomogeneities varies over very wide limits, from the size of individual molecules to that of blood cells and organs (Figure 5.2).

The spatial inhomogeneity of the optical characteristics of biotissue (specifically its absorption characteristics) leads to a nonuniform distribution of the heat released as a result of absorbing pulsed laser radiation. The following three characteristic times are important in this case: τ_p — the laser pulse duration; $\tau_c = a/v_s$ — the time it takes for sound to propagate with a velocity of v_s beyond an inhomogeneity of size a, i.e., the relaxation time of the pressure resulting from the pulsed local heating; and $\tau_{hd} = a^2k\chi$ — the time it takes for heat to propagate by diffusion beyond the inhomogeneity (k is a numerical coefficient depending on the shape of the inhomogeneity and χ is the thermal diffusitivity), i.e., the relaxation time of pulsed heating. Figure 5.6 shows regions of enhanced pressure, ΔP (pressure confinement), and enhanced temperature, ΔT (temperature confinement), in the case of microsphere of radius R (R = a, k = 27) for pulses differing in duration. Both these effects are important in the irradiation of real biotissues, and should not only be taken into consideration, but also be used to advantage.

5.3 Laser Biomedical Macrodiagnostics

All laser biomedical diagnostic techniques can conveniently be subdivided into two classes: (1) macrodiagnostics of various objects (tomography, topography, detection of pulsation, blood flow measurements, etc.) and (2) micro(spectro)diagnostics at a molecular level. Macrodiagnostic techniques are discussed below, and microdiagnostic techniques are discussed in the following section.

Some biomedically oriented macrodiagnostic techniques are already well developed and are used in clinics. One may cite as an example the Doppler flowmetry of blood flow in microcapillary blood vessels, based on the Doppler frequency shift of the light backscattered by moving particles. This principle is at the root of a whole class of instruments used for biomedical and other purposes. Of interest are the capabilities of laser light combined with laser-beam scanning in topographic studies of the human body, remote sensing of heartbeats, etc. In principle, all these methods may give rise to a new approach to the intelligent characterization of the human body, including the dynamics of the processes occurring

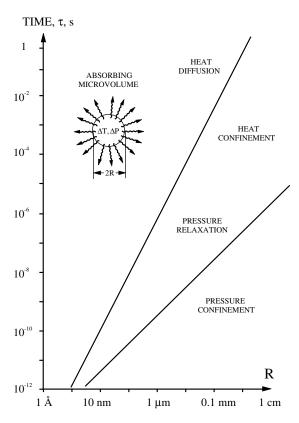

FIGURE 5.6 Regions of homogeneous heating, local heating without local rise of pressure, and local heating and local rise of pressure.

there (blood flows, breathing, heartbeats, etc.) and their interplay. The combination of laser-optical and computer technologies will prove useful here, with the latter including CD ROM recording and storage of physiological data on individual patients in various periods of their life, various stages of illness, and so on.

But the central problem is the development of methods for laser diagnostics of inhomogeneities (tomography) in biotissue, which is an absorbent and highly scattering medium, and therefore a very difficult object for optical techniques. The tomography of biotissue is important for medical diagnostics, laser therapy, and surgery. To choose the optimal regime and correct laser irradiation dose, it is necessary to know the light absorption and scattering values of the tissue. Moreover, it is important to know the spatial distribution of the light absorption and scattering inhomogeneities over the area being irradiated. For example, determination of the location, size, and depth of tissue injuries, blood vessels, inclusions, pigments, etc. is of real importance.

Diagnostic methods for light absorption inhomogeneities in turbid media are widely discussed in the literature: these methods include photon migration,⁸ time-resolved photon migration,^{9–12} optical coherence tomography,^{13–15} and others. The optical properties of tissue can be measured by such methods.^{16,17} They prove most effective in transparent media and are mainly sensitive to refractive index inhomogeneities. The most exciting results have been obtained by using optical coherence tomography¹⁵ for eye diagnostic purposes. Here, the lateral and longitudinal spatial resolution (in tissue depth) is limited to the wavelength of light, i.e., to a size much smaller than that of cells.

One of the promising techniques for measuring absorption inhomogeneities in turbid media is the optoacoustic method. It is based on the excitation of thermal or acoustic waves (thermooptical excitation) through absorption of time-modulated or space-modulated laser radiation (see, for example, References

18 through 20). The excitation of acoustic waves (optoacoustic signals) occurs as a result of transient nonuniform thermal expansion of the exposed area. The advantage of the optoacoustic method is the direct dependence of the amplitude of the excited wave on the light-absorption coefficient. Light-absorption measurements by means of time-resolved laser optoacoustic tomography can be taken in real time. Therefore, this method may prove useful in medical diagnostics.

Optical catheters are now successfully used for medical diagnostic purposes. The development of microminiature photonic spectral sensors and the advancement of nanotechnology will lead to the creation of self-contained, intelligent optical sensors. These sensors will be inserted in a controlled way into the human body via all the channels available, especially the highly branched system of blood vessels, transmitting information not only via the optical fiber but also by radio channels. This approach is fairly promising because it is based on the rapid progress of semiconductor microlasers operating within various spectral regions at very low power.

5.4 Spectral Biomedical Microdiagnostics

Spectral diagnostics at a molecular level makes use of a wide variety of laser spectroscopy methods (see, for example, References 16 and 17) to obtain extremely important information on tissue properties (spectral and time resolution, sensitivity, selectivity, and spatial resolution). The following discussion lists the most important performance characteristics of opticospectral diagnostics. The order of discussion is rather arbitrary because in actual application there is usually the need for a combination of several of these capabilities. For example, high sensitivity is a key parameter with any method.

5.4.1 Spectral Resolution

The well-developed laser spectroscopy techniques²¹ are capable of practically any required spectral resolution, from a few megahertz to a few nanometers. But in medical diagnostics, which almost always is concerned with species in condensed media, spectral resolution is usually limited because of their relatively wide absorption and fluorescence spectral bands. A moderately high spectral resolution of a few nanometers is quite sufficient for the spectroscopy of physiologically important chemical species in biotissues, for example, in the measurements of natural endogeneous molecules in blood and tissues (O₂ concentration, pH level, glucose concentration, etc.). The noninvasive photonic spectral technique is an almost ideal, noninvasive way to monitor a number of important physiological parameters. One can anticipate the development of photonic spectral instruments for personal use, as well as "diagnostics cafés" (similar to Internet cafés) for online measurement of the patient's physiological parameters, saving the patient the time and expense of a clinic visit.

A higher spectral resolution is necessary to analyze the molecular composition of the gas-phase products of metabolism (breathing test) and, on this basis, to diagnose certain diseases and to conduct drug and alcohol tests. Recent progress in the development of semiconductor quantum-cascade lasers operating in the IR range at room temperature^{22,23} has opened up exciting possibilities for developing photonic tools for diagnosing gaseous media in medical practice, as well as photonic tools for private use.

5.4.2 Time Resolution

The development of short- and ultrashort-pulse lasers has led to the improvement of time resolution from a few nanoseconds to a few picoseconds and then to a few femtoseconds. Ultrafast laser spectroscopy methods have contributed greatly to understanding fundamental processes in biological systems (see References 24 and 25). The list of intrinsically fast processes in biological systems is very long, including energy and electron transport in photosynthesis and reaction centers, and proton transfer and isomerization in the vision pigment and bacterial membranes. The biomedical diagnostic capabilities of present-day, simple solid-state femtosecond lasers²⁶ are practically unlimited. The main avenue of inquiry here is the search for biomolecular characteristics that require a high time resolution to be determined.

Femtosecond spectroscopy of the primary photochemical processes (femtochemistry²⁷) is likely to provide insight into the primary chemical processes involving the most important biomolecules (DNA, RNA, proteins) and will be an open field for many investigations in the years to come.

5.4.3 Sensitivity

Laser spectroscopic techniques possess an ultrahigh sensitivity, and today they enable one to detect individual atoms (laser resonance photoionization spectroscopy²⁸) and molecules (fluorescence spectroscopy with laser excitation²⁹).

The detection of single atoms is of interest in determining trace elements in biological specimens. For example, the resonance photoionization method has been used to measure trace amounts of aluminum in blood. ³⁰ Existing analysis techniques — the present-day mass spectrometric techniques, for example — meet practically all the requirements. Highly sensitive methods of detecting trace elements are important for understanding the pathways of microelements in the environment, food products, and human body.

Single molecules can be detected directly in condensed media (*in situ*), especially when combined with laser confocal microscopy, which allows one to irradiate a small volume containing a small number of fluorescing molecules, even a single such molecule.^{31,32} In the case of two-photon microscopy, laser radiation can be made to scan a three-dimensional space, an especially convenient capability in studies at the cellular and intracellular levels.³³ Molecules with low fluorescence yield can be detected through use of chemical labeling with specially selected fluorescent molecular dyes; this method is promising for detecting nucleotides in DNA sequencing.³⁴

5.4.4 Selectivity

The wide and frequently overlapping absorption and fluorescence spectral bands of biomolecules materially limit the selectivity of all spectral methods for biomolecules in their native condensed medium. Therefore, when a higher selectivity is required, one should combine spectral methods with other (nonoptical spectroscopy) methods.

The chemical labeling of nucleotides with fluorescent dye molecules in DNA sequencing³⁴ is an effective method for improving detection selectivity because the excitation spectra of the nucleotides coincide for all practical purposes. The preliminary chromatographic separation of a mixture of biomolecules, followed by the spectral-selective detection of their laser-induced fluorescence, is an effective method for improving selectivity at a very high sensitivity.

The fluorescence spectra of molecules may coincide, but the difference in fluorescence decay time between them makes it possible to use time-gating detection of the fluorescence of the desired molecule. Such a time selection substantially improves the contrast, especially in the fluorescent imaging of biotissues. ¹⁶ Where the time selection technique is applicable, it can be used *in vivo* and *in situ*, i.e., in actual human diagnostics. ¹⁶

Combining various selection methods with opticospectral selection techniques substantially extends the field of application of laser optical methods.

5.4.5 Spatial Resolution

Laser methods are applicable practically across the whole of the spatial spectrum range of biostructures presented in Figure 5.2. The two-dimensional (2D) lateral resolution is simplest to achieve. In the range down to a fraction of a micron, various optical microscopic techniques whose capabilities have been substantially extended with the advent of lasers, particularly scanning confocal microscopy.³⁵ Femtosecond laser pulses cause the two-photon excitation of the fluorescing molecules of interest without causing any photodamage to them. When the femtosecond pulses are focused with a microscope, the excitation of the molecules occurs predominantly at the focal point of the microscope; this forms the basis of three-dimensional, two-photon microscopy.^{33,36–38} All these methods in principle are capable of

ensuring a spatial resolution of up to a fraction of the optical wavelength, which is sufficient for studying intracellular structures.

The next steps forward are investigations with spatial resolutions from a few tens to a few hundred nanometers. Such resolutions are quite realizable by use of scanning near-field optical microscopy (SNOM).^{39–41} SNOM methods can be used only for 2D imaging because they are capable only of spatial resolution of the surface of biostructures.

Of much interest is the development of methods to obtain direct information on the molecular structure of individual biomolecules, especially DNA and proteins. Solving this challenging biophotonics problem can lead to the development of tabletop DNA sequencers and ultramicroscopy tools for uncrystallizable protein. Such a possibility has arisen⁴² with the advent of modern femtosecond lasers capable of producing coherent light pulses in the x-ray region of the spectrum. 43,44

5.5 Laser Therapy

The existing methods of laser therapy can be subdivided into two classes: (1) low-intensity laser therapy techniques and (2) photodynamic laser therapy techniques.

Low-intensity laser therapy is based on the excitation of endogenous chromophores in biotissues that absorb radiation in certain visible and near-IR spectral bands. This method requires monochromatic light of relatively low intensity (a few fractions of a W/cm²) that causes no average heating of the exposed biotissue. The difference between laser and nonlaser (light-emitting diode, or LED) light sources is in their depth of coherence, l_{coh} , determined by the light spectrum width $\Delta v(\text{cm}^{-1}): l_{\text{coh}} \approx 1/(\Delta v)$. Figure 5.7 illustrates the difference between the coherence volumes of the exposed biotissue.

In the coherence volume, as a result of random interference in the course of the scattering of light, a spatially nonuniform light intensity distribution (speckles)⁴⁵ is formed, which causes a spatially nonuniform deposition of the absorbed light energy. This, in turn, leads to a spatially nonuniform distribution of the photobiochemical reaction rates and local temperature variations. Although the primary mechanisms of the phototherapeutic effect are still to be understood,⁴⁶ the effectiveness of treatment by low-intensity laser therapy has been proved by numerous clinical trials conducted in a number of countries.⁴⁷ What is important is that existing semiconductor lasers and LEDs are compact, reliable, and cheap, which makes for widespread use not only at clinics, but also in private practice.

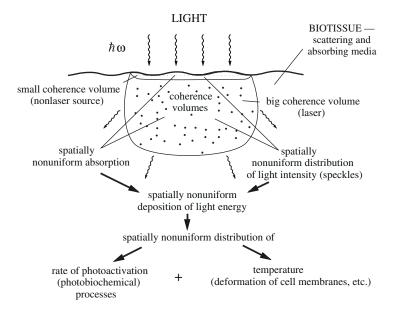

FIGURE 5.7 Coherence volumes for irradiation of biotissue by monochromatic optical beam.

Photodynamic therapy is based on various types of photochemical reactions involving endogenous chromophores. In this field, the existing lasers will be replaced by solid-state lasers pumped by an array of laser diodes. The progress of high-power semiconductor lasers in the blue range of the spectrum is so rapid that they will also be used in clinical setups convenient to operate.

The development of photothermotherapy — a potential method based on the microlocal biotissue transient heating effect due to the nonradiative relaxation of the absorbed laser radiation in the tissue — seems quite feasible. This method would involve a nondestructive local transient being heated by short-pulse laser radiation.⁴⁹ At least three mechanisms are responsible for the transient local heating of biotissue exposed to laser radiation.

First, it is well known that when a chromophore absorbs a photon, some excitation energy relaxes in a radiationless manner, and this leads to an increase in the temperature of the chromophore and its immediate surroundings. This was observed to occur, for example, during excitation of the heme in hemoglobin and in hemoglobin itself.⁴⁸ Following the absorption of a visible photon, the heme temperature rose to 500 K. The transfer of vibrational energy to the immediate surroundings caused a rapid cooling (within 2 to 20 ps). For this reason, the effect of local heating of chromophores is important on a picosecond time scale and perhaps may play some part in biomolecular processes.

The second mechanism relates to the nonuniform spatial distribution of the laser radiation intensity. For example, when coherent light propagates through an optically inhomogeneous, scattering biotissue, random interferences in the tissue inevitably give rise to speckle structures, 45 with irregularities characteristically measuring up to $\lambda/2$. If the given effect — for example, local heating — is shorter than the correlation time of the speckle pattern fluctuations (which depends on the internal motions in the exposed medium), this speckle-like distribution of laser intensity distribution will be fairly substantial and perhaps play some role in low-intensity laser therapy.

Third, the absorption coefficient of the tissue at a certain radiation wavelength varies over sufficiently wide limits throughout the tissue volume. A simple example is the enhanced absorption of hemoglobin in blood that is distributed over the bulk of the tissue by vessels with a great variety of diameters and lengths (fractal structure with a dimension of D=2.7). The spatial variations of the tissue absorption are especially great in the visible and near-IR regions of the spectrum, but are smoothed out in the UV and IR regions because of the strong absorption by all organic molecules in the UV region and by water in the IR region. The magnitude of the local transient temperature rise is not very high, although it is much higher than that of time- and volume-averaged heating.⁴⁹ The gradient of the local temperature rise can be very high (Figure 5.8), for example, $\partial T/\partial r \sim 10^6$ degrees/cm.⁴⁹ This possible effect can play a role for thin biological structures (such as membranes).

Of course, stronger transient heating causes photothermal damage. This effect can also be used for photothermal therapy, for example, by means of photothermal sensitizers (metallo derivatives of porphyrines and porphyrinoid compounds, etc.). In that case, it will be possible to cause selective photothermal damage to macromolecules or subcelluar organelles to treat tumors.⁵⁰ Because the spatial spectrum of absorption inhomogeneities in biotissues is very wide (Figure 5.2), properly selecting the duration and wavelength of the laser pulses used can cause the local transient heating of the desired micro- and macrostructures in the exposed biotissue.

Pulsed heating of the targeted kinds of microvolumes in biotissues with laser pulses of certain wavelengths, durations, and intensities will open up entirely new possibilities for photothermotherapy. This is because the local transient overheating of microvolumes may be substantial ($\Delta T = 1$ to 100°C), while the time- and space-averaged macroscopic heating of the entire irradiated region is much lower. Also, by varying the laser radiation wavelength, one can affect the pulsed heating of the desired biologically important microvolumes, the relationship between the locally absorbing regions, and the wavelength. Locally measured pulsed heating of targeted microvolumes will have a material effect on biochemical processes, and so will form the basis for new therapeutic techniques based in principle on the use of tunable, ultrashort laser pulses. However, the actual types of therapy can only be determined through experimental investigations into local absorption regions, the nature and size of those tissues, and the

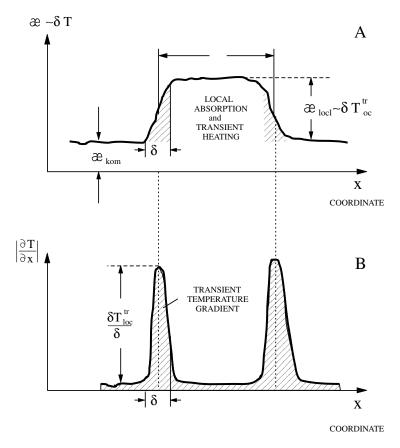

FIGURE 5.8 Spatial temperature gradient (A) produced at the boundary of a local absorption microvolume in the case of energy deposition by short laser pulses (B).

characteristics of pulsed overheating and temperature gradients produced. All this should be the aim of special systematic studies in the near future.

5.6 Laser Surgery

Laser surgery uses three types of laser-biotissue interactions, which require different laser radiation parameters and so are carried out by means of entirely different types of lasers. These three types of interaction are arbitrarily referred to as photocoagulation, photoablation, and photodisruption. In fact, each of these modes of interaction comprises a fairly complex sequence of processes that are the subject of special investigations.

When a biotissue is exposed to a continuous wave (CW) radiation that it absorbs well, the tissue temperature rises, and that temperature increase causes, consecutively, enzymes to denature and membranes to loosen (40 to 45°C), coagulation and necrosis (60°C), drying out (100°C), carbonization (150°C), and, finally, pyrolysis and vaporization (above 300°C). This process is usually associated with photocoagulation, for it is important in stopping profuse bleeding when performing surgical operations on blood-containing organs. Here lies the advantage of the photocoagulative laser surgery technique over the standard surgical methods. The shortcoming of this technique is the thermal injury caused to adjacent biotissue regions as a result of heat conduction, which can transfer heat a few millimeters over tens of seconds (Figure 5.6).

By using pulsed laser radiation of certain wavelength, one can selectively heat local, restricted areas with elevated absorption (this is achieved when operating in the heat confinement region of Figure 5.6). This selective photothermolysis technique is at the root of precise microsurgery.⁵¹ The effect of local laser heating of spatially nonuniform (granulated) biotissues has long been discussed in connection with the problem of pulsed-laser-induced retinal injuries.⁵² This raises the following important question: What is the maximum temperature to which biotissues can be heated without risking destruction? It is essential that this temperature be tied to irradiation time. With traditional heating methods, short-term heating conditions are difficult to realize, but laser radiation makes it possible to deposit energy in a small tissue volume that cools rapidly as a result of thermal diffusion. It therefore becomes possible to study the limits of permissible local tissue overheating during time periods from 10⁻³ to 10⁻¹² s for the previously discussed nondestructive photothermotherapy. This obviously will be the subject of future studies.

Also, high-power pulsed laser radiation can help effect the pulsed ablation (expositive evaporation) of the surface of soft and hard biotissues.⁵³ This process occurs in the pressure confinement region of Figure 5.6, where heating is strong enough and is accompanied by a substantial pulsed pressure rise. The mechanism and conditions of the laser ablation of various materials, including biotissues, are discussed in Reference 54.

The main phenomena experimentally observed to occur in the process of pulsed laser ablation of biological tissues are (1) the presence of a threshold incident pulse energy fluence for ablation, (2) the formation of shock waves, (3) the gasdynamic sputtering of the ablation products with supersonic velocities, and (4) the dependence of the ablation efficiency and threshold energy fluence on the attenuation coefficient of the tissue. These phenomena can, in principle, be explained within the framework of any of the mechanisms mentioned above: photochemical,⁵³ photothermal,⁵⁴ or photomechanical⁵⁵ mechanisms. The relationship between the contributions from each of these mechanisms for particular irradiation conditions and types of tissue is presented in References 56 and 57.

With the photochemical pulsed ablation mechanism, the laser energy absorbed by the tissue biomolecules excites electronic states in biopolymers (proteins) that lie above the dissociation and ionization limits of these molecules. The direct dissociation of molecular bonds, or their mediate dissociation through reactions with ions or radicals formed from highly excited electronic states, leads to splitting of long polymer chains into short fragments. The numerous bond breaks cause pressure to rise materially inside the irradiated tissue, which causes the molecular fragments to escape from the tissue. The threshold dissociation and ionization energies $\hbar\omega_{d,i}$ range between approximately 6 and 8 eV. The corresponding laser wavelengths fall within the UV region of the spectrum. Therefore, any appreciable quantum yields of photochemical reactions in proteins and other biopolymers can be expected only at irradiation wavelengths λ shorter than 200 nm.⁵⁸ The role of photochemical processes in the ablation of biotissues by pulses with a wavelength of $\lambda > 250$ nm can be considered negligible.

The necessary condition for photothermal explosion is to make the tissue substance in the irradiated tissue volume go to an overheated metastable state within a time interval shorter than that required for heat to diffuse from this volume, with the temperature of the tissue rising high enough for an intense formation within the tissue of gas-phase bubbles in a fluctuating manner. Within the framework of this model, the pulsed laser ablation process can be subdivided into three stages: optophysical, thermophysical, and gasdynamic.⁵⁹

During the first stage, the laser radiation is absorbed by the tissue, and subsequently, the excitation energy is converted into heat. Depending on the wavelength of the laser radiation, the absorbing chromophores in the tissue are either biomolecules (mainly proteins) or water. In both cases, water serves as a reservoir for the thermal energy into which the laser-radiation energy is converted. As the irradiated tissue volume is heated so that the tissue temperature rises above the threshold value, the optophysical stage of the ablation processes comes to an end. The second stage, thermophysical ablation, consists in the formation of gas-phase bubbles in the overheated tissue volume. The process is accompanied by the rise of pressure in this volume and the resultant shock wave propagates over the heated tissue layer faster than the metastable overheated liquid phase is formed. The thermophysical stage is followed by the gasdynamic stage. During this last stage of the pulsed laser ablation process,

the overheated tissue volume is ejected, and the ablation products undergo gasdynamic sputtering with supersonic velocities.

The experimental magnitudes of the energy fluence threshold for laser ablation are a factor 5 to 12 lower than the energy fluence required for heating the biotissue to the boiling point. This paradox may be explained by the spatially nonuniform heating of the biotissue by the laser pulse. At wavelengths shorter than 1.4 μ m, laser radiation can be absorbed by microchromophore centers in the tissue, whose volume is materially smaller than the volume of the total irradiated tissue. The explosive boiling of such overheated microcenters and the ensuing mechanical removal of the entire irradiated tissue bulk sharply reduces the volume energy density E_{thr} necessary for the ablation process to occur.⁵⁹

Another approach to explaining the experimentally observed pulsed laser ablation parameters is by assuming the action of a photomechanical stress mechanism. To understand this mechanism, let us compare the pressures produced in the heated tissue volume by a long and a short laser pulse. We will compare the pulse duration τ_p with the characteristic hydrodynamic expansion time of the heated tissue. ⁵⁶ Let the pulse duration τ_p be long enough in comparison with the time $\tau_{\rm exp}$ so that it is equal to the time it takes for sound to propagate to the depth of light penetration into the tissue (pressure confinement region in Figure 5.6).

In this case, while a given tissue layer is heated by the laser pulse, the increased pressure (compression) pulse resulting from the thermal expansion of the irradiated tissue propagates over the irradiated tissue volume, followed by a negative-pressure depression pulse. Thus, the pressure rise in the irradiated tissue volume due to the gradual heating of the tissue is compensated for by the depression produced behind the sound wavefront. Esenaliev et al.⁶⁰ have carried out quantitative studies of the absolute pressure values of the acoustical and shock waves generated and propagating in a biotissue under pulsed ($\tau_p = 50 \text{ ns}$) UV ($\lambda = 308 \text{ nm}$) laser irradiation (below and above the ablation threshold). These authors found that powerful (several hundred bars of pressure) acoustic compression and depression short pulses were generated in the biotissue.

The spatially nonuniform heating of biotissues by laser radiation gives rise to local overheated microregions in which microexplosions are induced.^{57,59} This phenomenon explains quite naturally the presence of vapor and microparticles in the ejected products, as well as the low laser energy fluence marking the ablation threshold. The specific energy deposition at the ablation threshold may be approximately an order of magnitude lower than that necessary to heat the tissue uniformly up to the explosive evaporation temperature.⁵⁷ This is evidence that only 10% of the bulk of the tissue suffers evaporation at the ablation threshold; the rest of the ejected mass is in the form of microparticles. The local overheating of microregions may result from the spatial variation of the absorbed energy due to the nonuniformity of the absorptivity of the absorbing medium and the laser energy fluence.^{61,62}

To effect explosive ablation of absorbing biotissues, pulsed lasers whose pulse duration is much shorter than the time it takes for heat to be withdrawn from the exposed zone are used. The laser ablation process enables one to perform precision surgical operations only where the necessary light penetration depth is shallow enough. For example, the radiation produced by the ArF excimer laser at a wavelength of 193 nm can penetrate the optically transparent cornea to a depth of only a few microns, because proteins strongly absorb radiation in the region of 200 nm.

However, progress made in the field of ultrashort-pulse lasers, especially solid-state femtosecond lasers, has made it possible to perform precision surgical operations on biotissues featuring a low linear absorption at the laser radiation wavelength. This achievement is possible because of the high intensity of focused laser pulses, which results in the multiple-photon absorption (Figure 5.3) usually observed in the form of "optical breakdown."⁶³ In this case, plasma generation, shock-wave formation, and disruption take place, followed by the ejection of the heated biotissue region. What is important is that at a high radiation intensity the multiple-photon absorption coefficient is much higher than its linear absorption counterpart, so that the threshold energy fluence here drops to a few fractions of a J/cm², compared with 10 to 100 J/cm² in the case of nanosecond-pulse irradiation at the same wavelength.

Thus, moderate requirements for femtosecond lasers are quite acceptable today because they can operate at high pulse repetition frequency and good efficiency. Moreover, the possibility of pumping such

lasers by radiation from a laser diode array makes them fairly reliable and suitable for use in clinical practice. One can anticipate considerable progress in this area of precision laser surgery, and not only in corneal corrective surgery.

Apart from direct medical applications, laser surgery can also be made very effective at the cellular level by focusing the laser radiation used (microirradiation).⁶⁴ It seems possible to increase the extent of localization of laser radiation so as to concentrate it within a submicron-size region by simultaneously employing near-field optics and femtosecond-pulse techniques. Optical fiber nanotips can be used for this purpose. Two important facts will be utilized here. First, the multiple-photon absorption of radiation in biotissues is much higher than in the transparent material of the optical nanotip, and so the delivery of the necessary laser-pulse energy fluence can be ensured. Second, the distance to which heat can be transferred in the course of a subpicosecond time is no more than 1 nm (Figure 5.6). One can foresee the development along these lines of femtosecond nanolocal "molecular laser surgery."

5.7 Conclusion

Concluding this brief analysis of some future trends in laser and photonics biomedicine, which is a supplement to my review of 15 years ago,⁶⁵ I clearly see the rapid development and fruitfulness of this field of laser application. In terms of its speed of development and usefulness, this field can probably only be compared with laser fiber science and telecommunications technology. Both of these areas will have a great impact on the further development of human society. Incidentally, when the laser first appeared, neither of these fields was considered a potentially serious application — one more example of how subjective and unreliable all sorts of predictions can be, even in science and technology.

This chapter presents an overview of the basic instrumentation used in photonic applications. The chapter is intended to provide an introduction to the basic setups, apparatus, and system components for readers from other research fields who wish to become further acquainted with biomedical photonics. Only basic devices and components are described in this chapter. More advanced instrumentation and specialized systems for specific applications are described in detail in Chapters 7 through 9 of this handbook.

6.1 Basic Spectrometer

The detection and analysis of the optical signal require a spectrophotometer. This instrument is commercially available from many manufacturers, or it may be built using standard components. For routine analytical work, it is more convenient to use an available commercial instrument. For research investigations and special applications, it is sometimes necessary to build an apparatus to specific performance requirements.

6.1.1 Basic Apparatus

This section describes how various basic components can be combined to develop instrumental setups for different types of spectroscopic measurements. The common feature of spectroscopic measurements is that that they all measure spectroscopic properties related to the molecular composition and structure of biochemical species in the sample of interest. There are several types of spectroscopic measurements: absorption, scattering (elastic and inelastic), and emission. A typical spectroscopic experiment that allows us to analyze complex biological systems is conceptually simple. Light at a certain wavelength λ (or frequency $\nu = c/\lambda$) is used to irradiate a sample of interest. This process is called "excitation." Then some of the properties of the light that emerges from the sample are measured and analyzed.

Some properties deal with the fraction of the incident radiation absorbed by the sample; the techniques involved are called absorption spectroscopy, e.g., ultraviolet (UV), visible, and infrared (IR) absorption

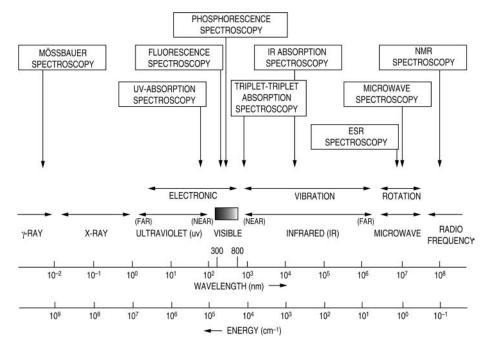

FIGURE 6.1 Various types of spectroscopies and related spectral ranges in the electromagnetic spectrum.

techniques. Other properties are related to the incident radiation dissipated and reflected back from the samples (elastic scattering techniques). Alternatively, one can measure the light emitted and scattered by the sample, processes that occur at wavelengths different from the excitation wavelength; the techniques involved are fluorescence, phosphorescence, and inelastic scattering (Raman scattering). Other specialized techniques can be used to detect specific properties of the emitted light, such as its degree of polarization and decay times.

The range of wavelengths used in various types of molecular spectroscopy to study biological molecules is quite extensive (Figure 6.1). Table 6.1 summarizes the different types of molecular spectroscopy and the associated wavelength ranges of the electromagnetic radiation.

A basic spectrophotometer generally consists of the following components:

- 1. An excitation light source
- 2. Dispersive devices (optical filters, monochromators, or polychromators)
- 3. A sample (usually in a compartment with a sample holder)
- 4. A photometric detector (equipped with a read-out device)

Successful application of photonic methods requires considerable attention to experimental details and a good understanding of the instrumentation. The recorded spectra (absorption, emission, or excitation) represent the photon emission rate or power recorded at each wavelength, over a wavelength interval determined by the slit widths, and dispersion of the monochromator. There are many manufacturers of spectrometers, each offering several models with different performance characteristics and different options. Basic instrument components are also commercially available. An investigator may assemble off-the-shelf components for his or her particular applications. The basic components can be adapted to design the instrument for each type of spectroscopic measurement.

6.1.2 Instrument for Absorption Measurements

Figure 6.2A shows a schematic arrangement of a typical instrument setup for absorption measurements. The collimated output of a light source is focused on the entrance slit of an excitation monochromator

TABLE 6.1 Spectroscopic Techniques for Biological and Biomedical Applications

Spectral Region*	Wavelength* (cm)	Energy* (kcal mol ⁻¹)	Techniques	Properties
γ-Ray	10-11	3×10^{8}	Mössbauer	Nucleus properties
X-ray	10-8	3×10^{5}	X-ray diffraction/scattering	Molecular structure
UV	10^{-5}	3×10^{2}	UV absorption	Electronic states
Visible	6×10^{-5}	5×10^{3}	Visible absorption	Electronic states
			Luminescence	Electronic states
Infrared	10^{-3}	3×10^{0}	IR absorption	Molecular vibrations
			IR emission	Electronic states
Microwave	10^{-1}	3×10^{-2}	Microwave	Rotations of molecules
	10^{0}	10^{-3}	Electron paramagnetic resonance	Nuclear spin
Radio-frequency	10	3×10^{-4}	Nuclear magnetic resonance	Nuclear spin

^{*}Approximate values

for wavelength scanning. The output of the excitation monochromator is directed to the sample inside the sample compartment. The light transmitted by the sample is collected through appropriate optics and focused onto a detector. This simple instrumental setup is often used in a single-beam absorption spectrometer. Double-beam instruments include a reference beam, which is used to correct spectral fluctuations in the lamp automatically in order to reduce electronic drift and lamp warm-up periods.

6.1.3 Instrument for Scattering Measurements

The elastic scattering (ES) technique involves detection of the backscattering of a broadband light source irradiating the sample of interest. Figure 6.2B shows a typical instrument setup that can be used for elastic scattering measurements. A spectrometer records the backscattered light at various wavelengths and produces a spectrum that is dependent on sample structure, as well as chromophore constituents. In general, the sample is illuminated with the excitation light, which is selected with a dispersive element and then directed to a specific point location (e.g., via an optical fiber) of the sample. The scattered light is measured at the same wavelength as the excitation wavelength.

With inelastic scattering measurements, one measures the scattered light from the sample in a spectral region different from the excitation wavelength. In this case, the basic setup is similar to the ES setup but has an additional dispersive element to analyze the scattering emission from the samples (Figure 6.2C).

6.1.4 Instrument for Emission Measurements

Figure 6.2D shows a schematic arrangement of a typical spectrometer for emission (e.g., fluorescence, phosphorescence) measurements. The excitation light source is usually a laser or high-intensity xenon arc lamp. The collimated output of the light source is focused on the entrance slit of an excitation monochromator whose output is directed to the sample. When a laser is used as the excitation source, the excitation monochromator is not required. The emission from the sample is collected through appropriate optics and focused onto the entrance slit of an emission monochromator. The excitation beam and the emission beam are usually focused at right angles for minimum interference from scattered light.

There are three basic classes of spectrophotometers: filter instruments, monochromator instruments, and multichannel devices. The first type of device uses optical filters, whereas the latter two systems use prisms or gratings as dispersive elements. The more expensive grating spectrometers are more versatile than filter instruments and can be used for either applied or basic studies.

Selection of an instrument appropriate to specific needs requires careful examination of many factors, including cost. The three major features to consider are the intensity of the excitation light source, the resolution and throughput of the monochromators, and the sensitivity of the detector. Although it is desirable to have an intense excitation light source, the cost-benefit ratio should be taken into consideration.

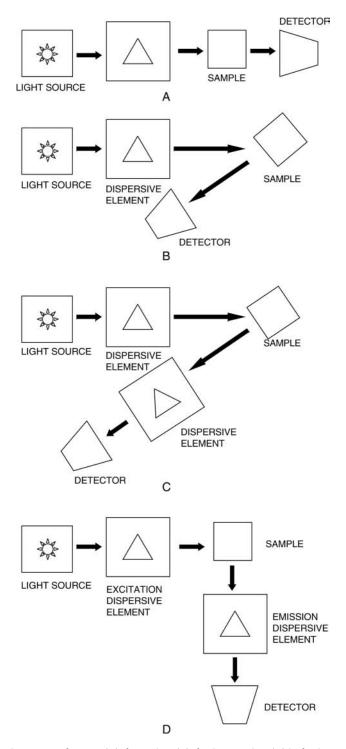

FIGURE 6.2 Various instrumental setups: (A) absorption; (B) elastic scattering; (C) inelastic scattering; (D) emission.

For most fluorescence measurements at room temperatures, the spatial resolution need not be excessively high because the bandwidths of fluorescence spectra are usually larger than 5 nm. A monochromator with low spectral dispersion, however, would allow use of larger slit widths and consequently provide for higher radiance throughput. On the other hand, IR absorption and Raman instruments require very high spectral resolution (1 nm or less) in order to resolve the much narrower vibrational bands spectrally.

The spectrometer used for phosphorescence measurements is essentially the same as that used for fluorescence measurements. The only additional equipment required is a phosphoroscope attachment for isolating the long-lived phosphorescence from shorter-lived emissions (fluorescence, excitation scattered light). Frequently, a fluorescence spectrometer (fluorimeter) can be modified easily or equipped with a phosphoroscope to perform measurements.

The sensitivity of the spectrometer is strongly dependent on the choice of the detector, such as the photomultiplier (PM) tube or the charge-coupled device (CCD). The relative sensitivity of the PM tube or CCD can be found in data sheets from the manufacturer.

In addition to these factors, the choice of a spectrometer also depends on other features that are more difficult to characterize, such as the reliability of electronic components, the repeatability and accuracy of scanning mechanisms, and the stray-light rejection ability of the monochromators.

A cost-benefit evaluation must be made in the choice between a single-beam and a double-beam spectrometer. In the more expensive double-beam instruments, spectral fluctuations in lamp output are automatically corrected, reducing electronic drift and lamp warm-up periods. However, the performance of a single-beam instrument is adequate for most applications.

6.2 Instrumental Components: General Considerations

6.2.1 Excitation Light Sources

UV light is generally used for excitation in many spectroscopic measurements. These UV sources may be classified into two categories, namely, line or continuum type, and can be used in a continuous wave (CW) mode or in a pulsed mode. The line sources provide sharp spectral lines, whereas continuum sources exhibit a broadband emission.

6.2.1.1 High-Pressure Arc Lamps

High-pressure arc lamps are the most commonly used radiation sources. These lamps produce an intense quasi-continuum radiation ranging from the UV (<200 nm) to the near-infrared (NIR) (>1000 nm) with only a few broad bands at approximately 450 to 500 nm. The lamps consist of two tungsten electrodes in a quartz envelope containing gases under high pressure, for example, xenon (Xe), mercury, an Xe—mercury mixture. Lamps of this type are commercially available in a wide range of input power from a few watts to several kilowatts.

The high-pressure mercury arc lamp is similar to the high-pressure Xe lamp in appearance and performance. The spectral output of mercury lamps is of a line type, whereas that of the Xe lamps is of a continuum type. If excitation can be carried out at only one wavelength or a few fixed wavelengths of the mercury emission lines, the mercury lamp is probably the most effective radiation source. The Xe lamp, however, is more commonly used because it provides a smoother spectral profile more suitable for conducting excitation spectra measurements.

The Xe arc lamp is the most versatile light source for steady-state spectrometers and has found widespread use. This lamp provides a relatively continuous light output from 250 to 700 nm. Xe arc lamps emit a continuum of light as a result of the recombination of electrons with the ionized Xe atoms. Complete separation of the electrons from the atoms yields the continuous emission. These lamps are available with an ellipsoidal reflector as part of the lamp. Parabolic reflectors in some commercially available Xe lamps collect a large solid angle of light and provide a collimated output.

The operation of high-pressure arc lamps requires special care and handling, such as reduction of the excitation stray light with a good monochromator, use of a highly regulated DC power supply, and

removal of the heat generated by the lamp output in the IR range. A warm-up period is also necessary to minimize arc wandering, because of a tendency for the arc to change its location inside the lamp envelope during the first half hour of operation. This arc wandering effect may cause sudden variations in the observed intensity, especially when the image of the arc is focused into a small slit aperture.

Extreme care should be exercised when inspecting high-pressure arc lamps. They may explode when dropped or bumped because they are filled with gases at high pressures (~5 atm at ambient temperature and 20 to 30 atm at operating temperature conditions). It is recommended that special leather gloves, safety glasses, and protective headgear be used whenever the lamp housing is opened. One should not look directly at an operating Xe lamp; the extreme brightness will damage the retina, and the UV light can damage the cornea. With some older lamps, proper ventilation or use of deozonators is required to remove the ozone produced by the UV radiation of the lamp. Nowadays, many available Xe lamps are considered ozone-free because their operation does not generate ozone in the surrounding environment.

6.2.1.2 Low-Pressure Vapor Lamps

Low- (or medium-) pressure mercury vapor lamps are often used as line sources. They are simple to use, require little power, and offer intense UV radiation concentrated in a few lines (e.g., 253.7 nm, 365.0/265.5/366.3 nm multiplet). The mercury vapor lamps are widely used in simple filter-type spectrometers because of their low cost, intense emission characteristics, and good stability. The lamps do not need a complex power supply system and provide excellent reference light sources for calibration of spectrometers.

6.2.1.3 Incandescent Lamps

The tungsten filament incandescent lamp is the simplest continuum source. This type of incandescent lamp exhibits a smooth, continuous spectral profile determined by the blackbody radiation characteristics given by Planck's equation:

$$S_{\lambda} = \frac{5.8967\lambda^{-5}E_{\lambda}}{\exp(14388/\lambda T)^{-1}}$$

where S_{λ} is the spectral radiance $(W - \text{cm}^{-2} - \text{sr}^{-1} - \text{nm}^{-1})$, λ is the wavelength (nm), T is the temperature (K), and E_{λ} is the spectral emissivity of the filament material (dimensionless).

Since incandescent lamps usually have low UV output, they are seldom used as excitation sources, especially for luminescence measurements where samples absorb the UV. Their smooth spectral profile, however, makes them very suitable for intensity calibration procedures.

Standard incandescent lamps with calibration data provided by the National Institute of Standards and Technology (NIST) are readily available commercially. Intensity calibration data are available for the spectral range from 250 nm to 2.5 μ m.

6.2.1.4 Solid-State Light Sources

Light-emitting diodes (LEDs) are solid-state light sources that provide output over a wide range of wavelengths. These devices require little power and generate little heat. One can use a few LEDs to cover a spectral range from 400 to 700 nm. LEDs are practical light sources for many low-power photonic applications and can be amplitude-modulated up to hundreds of megahertz. Another type of solid-state light source is the solid-state laser, described in the next section.

6.2.1.5 Lasers

Although conventional light sources have primarily been used for absorption analyses, lasers are increasingly used in luminescence and Raman measurements. The advantages offered by lasers as excitation sources include the following:

- 1. Monochromaticity
- 2. High degree of collimation

- 3. High intensity
- 4. Phase coherence
- 5. Short pulse duration (with pulsed lasers)
- 6. Polarized radiation

Selection of laser excitation sources is determined by the wavelengths that can be matched to the absorption band of the compounds to be analyzed in order to take advantage of maximum absorption. If time-resolved measurements are performed, the pulse width of the laser is an important factor to consider. The intensity of a laser is very high at (or even near) the laser emission lines and, therefore, often interferes with the lower intensity of the emission or scattering signal being measured. A number of devices, such as a spike filter or a single monochromator, may be used to reject the Rayleigh scattered light. Notch filters, which consist of crystalline arrays of polystyrene spheres, exhibit very high efficiency rejection of laser lines.

Many publications have described the principle and applications of lasers in detail.¹⁻⁶ Some general properties of various types of lasers are detailed in the following section.

6.2.1.5.1 General Properties of Lasers

The laser process is a stimulated emission following population inversion between different electronic levels of an active medium. Laser operation occurs inside a resonant optical cavity filled with an active medium that can be a gas, solid crystal, semiconductor, or dye solution.

Some lasers are operated in the CW mode; others are pulsed. There are several methods for producing very short pulses. The simplest is to induce a population inversion for only short periods of time using pulsed electrical discharges. Other pulsing methods include Q-switching, cavity dumping, and mode locking. The Q-switching method consists of first decreasing the reflectivity or the quality, Q, of the laser cavity and then suddenly switching the Q value back to a relatively high value. Active Q-switching can be done by shutter devices, such as an electro-optic Kerr cell,⁶ a Pockels cell (a device that provides a modulation linearly proportional to the applied electric field), or simply a rotating mirror.

Passive Q-switching uses a saturated absorber such as gas or a dye. Cavity dumping is a pulse-forming technique for laser materials having excited-state lifetimes too short for Q-switching operation. Another method that produces subnanosecond pulses is the mode-locking technique. This technique involves locking the phase of the electromagnetic longitudinal modes inside the cavity. The repetition rate of mode-locked pulses, determined by the speed of light and twice the length of the optical cavity, is too high for phosphorescence measurements. For a 1-m cavity, the time interval between two pulses is 6.6 ns. Even with a cavity design based on a folded-path mirror with a total length up to 10^3 m, the laser still produces pulses at 5.5-µs intervals.

6.2.1.5.2 Gas Lasers

The active medium of a gas laser is either an atomic (e.g., helium–neon), molecular (e.g., carbon dioxide, hydrogen cyanide, rare gas halide, water vapor), or ionized (e.g., argon, krypton, xenon, helium–cadmium, helium–selenium) gas. Output powers of CW gas lasers range from milliwatts to kilowatts. Peak powers of pulsed gas lasers can reach several megawatts.

A compact, low-power gas laser often used for alignment and for calibration is the helium—neon laser. The output of this laser ranges from less than a milliwatt to several tens of milliwatts at 632.8 nm. Certain lasers also emit at 1152 nm.

Two commonly used gas lasers are the argon ion laser and the krypton ion laser. These rare gas lasers emit a series of lines from the near-UV to the IR region and have CW output ranging from tens of milliwatts to tens of watts. An ion laser that uses a metal vapor as the active medium is the helium–cadmium laser. It provides a CW output in the milliwatt range in the blue or UV regions. A CW gas laser with high power (up to several hundred watts) at 10 μ m is the carbon dioxide laser.

A very practical and widely used laser is the nitrogen laser. It operates only in the pulsed mode. This laser produces subnanosecond to tens-of-nanosecond pulses in the near-UV region (337 nm). The energy per pulse ranges from a few microjoules to a few joules.

TABLE 6.2 Types and Spectral Characteristics of CW and Pulsed Commercial Gas Lasers

Active Medium	Output Wavelength (nm)	CW Gas Laser	Pulsed Gas Laser
Active Medium	(11111)	Lasei	Lasei
Argon	330-514	X	X
Argon fluoride	193		X
Argon-krypton	450-1,090	X	
Barium	1,500		X
Carbon dioxide	9,000-11,000	X	X
Carbon monoxide	5,000-7,000	X	X
Copper	510.5 - 578.2		X
Deuterium cyanide	$190 \times 10^3 - 195 \times 10^3$	X	
Deuterium fluoride	3,600-4,000	X	X
Fluoride	624–780		X
Gold	627.8		X
Helium-cadmium	325 - 442 - 441	X	
Helium-neon	632.8 - 1,152 - 3,391	X	
Helium-selenium	460-653	X	
Helium-xenon	3,805	X	X
Hydrogen cyanide	$311 \times 10^3 - 337 \times 10^3$	X	X
Hydrogen fluoride	2,600-3,000	X	X
Krypton	330-790	X	X
Lead			X
Methanol	118.8×10^{3}	X	X
Methyl fluoride	$190 \times 10^3 - 596 \times 10^3$	X	X
Nitrogen	337		X
Water	$(18 - 78 - 118) \times 10^3$	X	X
Xenon bromide	282		X
Xenon chloride	318		X
Xenon fluoride	351 - 353 - 354		X

Pulsed output in the UV region is also obtained with excimer lasers, in which the active medium is an excimer, a molecule that is stable only in the excited state and dissociates immediately after it emits light (e.g., krypton fluoride, xenon fluoride, xenon chloride, or argon fluoride).

In chemical lasers, the active medium, such as hydrogen fluoride or deuterium fluoride, is produced by a chemical reaction induced by electrical discharges. Table 6.2 summarizes various characteristics of several CW and pulsed gas lasers.

6.2.1.5.3 Solid-State Lasers

Solid-state lasers can be the pulsed type, such as the chromium-doped ruby laser with principal output at 694 nm, or the CW type, such as the YAG (yttrium aluminum garnet) laser, with principal output at 1064 nm. Solid-state lasers are pumped optically. Optical pumping of pulsed lasers is usually achieved with an Xe flash tube. Pulsed outputs range from tenths of a joule to tens of joules. The repetition rate of these pulsed lasers is relatively low (0.1 Hz to tens of hertz). The CW YAG laser is generally used in the pulsed mode following mode-locking, cavity-dumping, or Q-switching operations. The CW output of YAG lasers is between a tenth of a watt and several watts.

Other solid-state lasers include glass lasers that operate only in a pulsed mode like the ruby lasers, and the F-center lasers, which provide a tunable CW output in the 2000- to 3000-nm spectral range.

6.2.1.5.4 Semiconductor Lasers

One important family of semiconductor lasers is diode lasers. In a semiconductor diode laser, the front and back surfaces of the diode form the resonant cavity that generates light emission when electrons and holes recombine at the p-n junction. When driven by a low current, the diode emits incoherent light. Above an input current threshold, the diode begins to emit coherent laser light. The small size of semiconductor lasers allows efficient packaging. They can be operated on battery power and therefore are useful

for remote operation. High-power diode lasers are generally not tunable; however, many wavelengths of interest are available for medical applications. One type of diode laser has a tunable output: the lead salt type. The other type has a fixed-wavelength output: the gallium arsenide (GaAs) or gallium-aluminum (GaAl) type. The lead salt lasers emit at 2000 to 3000 nm and are used for high-resolution spectroscopy in the IR region. GaAs and GaAl lasers are usually employed in communications utilizing fiber-optic cables or in information processing. Diode lasers can be amplitude modulated to several gigahertz. Titanium-sapphire lasers, which typically produce 100-fs pulses, are often used for ultrafast measurements or multiphoton excitation.

6.2.1.5.5 Tunable Dye Lasers

A dye laser consists of an organic dye solution optically pumped by a light source (flash lamp, nitrogen laser, or ion laser). Dye lasers offer many properties that make them close to ideal light sources. Dye lasers can be tuned across a large spectral range from the UV to the NIR with a series of different dyes. The type of output desired and the absorption properties of the dye determine the choice of the pump source. Pulsed sources usually provide peak powers at levels sufficiently high for laser action in most dyes when the energy per pulse is low.

6.2.1.5.6 Tunable Lasers with Optical Parametric Oscillators

Optical parametric oscillators (OPO) have extended the laser radiation from visible to the IR and have opened a new area for spectroscopists. With OPO systems, no changing of dye solutions is needed. In a process similar to harmonic generation, the operation of an OPO is based on the nonlinear response of a medium to a driving field (the pump laser beam) to convert photons of one wavelength to photons of other, longer wavelengths. Specifically, in the so-called parametric process, a nonlinear medium (usually a crystal) converts the high-energy photon (the pump wave) into two lower-energy photons (the signal and idler waves).

The exact wavelengths of the signal and idler are determined by the angle of the pump wave vector relative to the crystal axis. Energy can be transferred efficiently to the parametric waves if all three waves (pump, signal, idler) are traveling at the same velocity. Under most circumstances, the variation of index of refraction with crystal angle and wavelength allows this "phase matching" condition to be met only for a single set of wavelengths for a given crystal angle and pump wavelength. Thus as the crystal rotates, different wavelengths of light are produced.⁷

When the crystal is contained in a resonant cavity, feedback causes gain in the parametric waves in a process similar to buildup in a laser cavity. Thus, light output at the resonated wavelength (and the simultaneously produced other parametric wavelength) occurs. The cavity can be singly resonant at either the signal or idler wavelength, or it can be doubly resonant at both wavelengths.

6.2.2 Optical Fibers and Dispersive Devices

6.2.2.1 Optical Filters

The simplest dispersive element is the optical filter, which can be used when variation of the excitation or emission wavelength is not needed. In this case the filter is simply a single-wavelength selector device. Filters may be used to select the excitation light (excitation filters) or remove the scattered excitation light from the emission (emission filters). It is often desirable to use optical filters in addition to monochromators. In general, excitation filters with a narrow spectral bandpass are used to provide selectivity and should be able to withstand high-intensity light and, in some cases, high temperatures. Conversely, emission filters usually have a broad bandpass and are generally employed to provide maximum light throughput.

Filters may be classified into three main categories: neutral, cutoff, and bandpass. Neutral density filters, which have a nearly constant transmission over a wide spectral range, are generally used to attenuate the light equally at all wavelengths. For example, one can use neutral density filters to strongly decrease luminescence signals and intense excitation light, or to adjust or match the intensity of two signals.

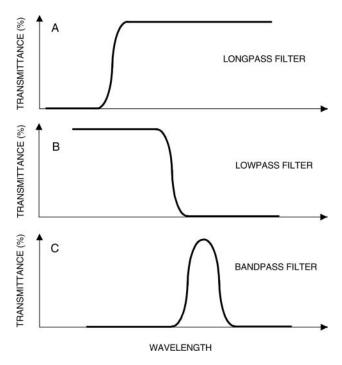

FIGURE 6.3 Schematic diagram of transmission curves of various types of filters: (A) longpass filter; (B) lowpass filter; (C) bandpass filter and notch filter.

Cutoff filters, which have a sharp transmission cutoff, are generally used to remove undesired radiation, such as stray light or second-order diffraction light. Longpass (or highpass) filters are often used to reject scattered light from the excitation and to transmit the emission of interest (e.g., fluorescence). Similarly, shortpass (or lowpass) filters are used to transmit light at the shorter wavelengths and remove light occurring at wavelengths longer than the spectral range of interest. Notch filters are used to remove light within a specific bandwidth of interest. They are often used to remove the interfering laser excitation light from the emission light (e.g., Raman or fluorescence).

Bandpass filters generally serve to isolate a particular spectral region of interest for excitation or detection. Great care should be taken in the selection of bandpass filters to avoid the possibility of emission from the filter itself. When illuminated with UV light, some filters exhibit luminescence that can interfere with the sample emission. For this reason, it is usually desirable to position the filter farther away from the sample, rather than close to it. Figure 6.3 shows schematic diagrams of transmission curves for various types of filters: longpass (A), shortpass (B), and bandpass filters (C). Figure 6.4 depicts typical transmission curves of holographic and dielectric notch filters.

Filters can also be classified according to their operating principle: absorption, interference, or bire-fringence. Absorption filters include neutral density, cutoff, and wide bandpass filters. They may be fashioned from a variety of materials, including colored glass, gelatin, chemical solution, gas, sapphire, and alkali–halide materials. Colored glass filters are the most practical and least expensive. The spectral characteristics of the coloring inorganic species determine the transmission properties of the filters. Gelatin containing a dye is also used in absorption filters. Gelatin filters are thermally less stable than glass filters and should be used only as emission filters. Optical cells filled with a specific chemical solution or gas may be used as filters in special cases, but they are not convenient for general use.

Interference filters are generally of the narrow bandpass (10 nm) or broadband (50 to 80 nm) type. Carefully controlled thicknesses of vacuum-deposited layers of dielectric and metallic layers are arranged so that light outside the spectral bandpass is eliminated by destructive interference, whereas light within the bandpass is transmitted by constructive interference. Some interference filters have linearly variable

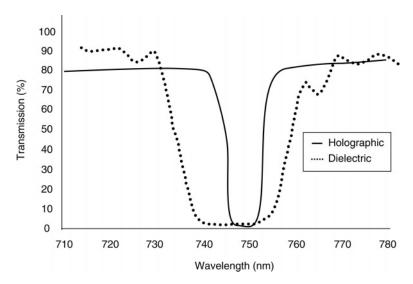

FIGURE 6.4 Typical transmission curves of holographic and dielectric notch filters.

transmittance across the substrate; because these filters are angle sensitive, great care should be taken when mounting them in an optical system. Interference filters, which transmit typically 30% of the intensity in the UV and 60% in the visible range, are generally used as excitation filters because of their narrow bandpass (from 50 to 1 nm). Heat from the excitation light beam is usually not a problem because radiation that is not transmitted is rejected by reflection. Interference filters covering a broad spectral range from the UV to the IR are commercially available from many suppliers.

Dichroic filters are substrates coated with thin films to produce the desired transmission and reflection properties across the spectral range of interest. They are often used as color filters (both additive and subtractive) or as devices designed to transmit light at certain wavelengths and reflect light at other wavelength ranges. Dichroic filters are angle sensitive, so care should be taken to mount them properly in optical systems.

Birefringence filters, which are constructed with polarizers and retardation plates, may be used in polarization measurements. These filters are generally made of stretched polymer films, the absorption properties of which determine the characteristics of the filters. They usually have a bandwidth similar to that of interference filters.

6.2.2.2 Monochromators

Continuous wavelength selection is performed with monochromators, used to disperse polychromatic or white light into the various colors. The performance specifications of a monochromator are characterized by the spectral dispersion, the efficiency, and the stray light levels. The spectral dispersion is usually expressed in nanometers per millimeter; the slit width is expressed in millimeters. Low stray light and high efficiency are desired qualities in selecting a monochromator. The two types of monochromators are prism and grating monochromators.

6.2.2.2.1 Prism Monochromators

In prism monochromators, light dispersion is due to the change of the refractive index of the prism material with the wavelength of the incident light. The angular dispersion D is given by

$$D = \frac{d\theta}{d\lambda} = \frac{dn}{d\lambda} \frac{d\theta}{dn},$$
 (6.1)

where θ is the angular deviation, n is the refractive index of the prism materials, and λ is the wavelength of the light source.

Prism monochromators usually produce less stray light than grating devices and are free from overlap from multiple orders, but they are less convenient to use than grating monochromators because of their nonlinear scanning dispersion.

6.2.2.2.2 Grating Monochromators

Most spectrometers are now equipped with monochromators having diffraction gratings. Gratings comprise a large number of lines, or grooves, ruled on a highly polished surface. The density and shape of these grooves determine the characteristics of a grating. Energy throughput and resolution increase with increasing number of grooves per millimeter. The width of a groove should be approximately equal to the wavelength of the light to be dispersed. The shape of the groove should be such that the maximum amount of light at a given wavelength is concentrated at only one specific angle for each order. The design and construction of the grating also determine the other properties of the monochromator, for example, reflectivity (or radiance throughout) and stray light rejection.

The general diffraction grating formula is given by

$$\sin\theta + \sin\theta' = k\frac{\lambda}{d} = kn\lambda , \qquad (6.2)$$

where θ is the angle of incidence, n is the number of grooves per unit length, d is the groove spacing, and k is the dispersion order (see Figure 6.5A).

As shown in this formula, the grating disperses light because θ' is dependent on λ . A spectrum is obtained for each value of k. As a consequence, gratings also produce second- and higher-order dispersions that may overlap the lower-order emission of interest. One simple procedure to overcome this problem is to place a cutoff filter at the exit slit of the grating monochromator so that only one order is transmitted. The first-order dispersion (k = 1), which produces the highest throughput, is generally used for emission measurements. Higher orders, however, result in higher resolution. At the zero order (k = 0), there is no dispersion because all wavelengths are reflected at the same angle.

Most gratings used in modern spectrometers are of the reflection type ($\theta = \theta'$). In this case, the observation is in the direction of illumination (Littrow configuration). The grating formula then becomes

$$\sin \theta = k \frac{\lambda}{d} \,. \tag{6.3}$$

This relation shows that a spectral scan, which is linear with respect to the wavelength λ , can easily be produced with a simple sine-bar mechanism.

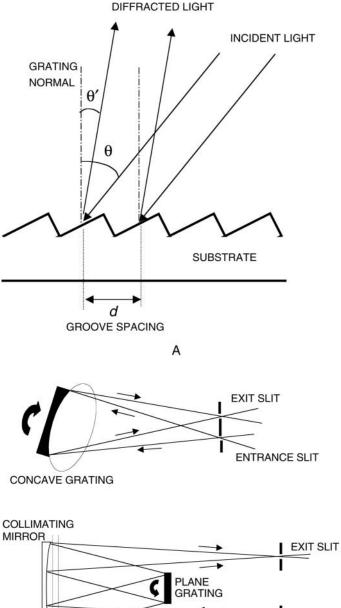

The scanning mechanisms of almost all commercial grating monochromators are readily made linear with respect to wavelength. If one prefers to record a spectrum on a linear wave-number (cm⁻¹) scale, a mechanical device that generates a reciprocal function may be attached to the monochromator. This latter device is available commercially, but it is used mostly in Raman spectrometers.

Three interrelated factors — spectral dispersion, resolving power, and throughput — should be considered in optimizing the conditions for a given experimental situation. The spectral dispersion, D_s , is defined by

$$D_{S} = \frac{d\lambda}{dl} = \frac{1}{l_{f}} \frac{d\Phi^{-1}}{d\lambda} = \frac{1}{l_{f}} = d',$$
 (6.4)

where d' is the distance measured across the slit, l_f is the focal length of the lens or mirror, Φ is the angle of deviation (or diffraction), and $d\Phi/d\lambda$ is the rate of change of Φ with wavelength.

This equation indicates that a constant spectral dispersion and resolution are readily provided when the slit width d is kept constant. No elaborate slit program is required (as in prism monochromators) to keep the spectral resolution constant over a spectral scan.

PLANE GRATING

ENTRANCE SLIT

FIGURE 6.5 (A) The grating rule (θ = angle of incidence; θ' = angle of diffraction; d = groove spacing) and (B) optical configuration of planar grating and concave grating.

The resolving power R, which denotes the ability of a grating monochromator to separate adjacent emission lines, is defined by

$$R = \frac{\lambda}{\Delta \lambda} = \frac{w}{\lambda} \left(\sin \theta + \sin \theta' \right), \tag{6.5}$$

where w is the width of the grating.

By combining Equations 6.2 and 6.5, one obtains (for k = 1)

$$R = wn. (6.6)$$

This relation shows that the resolving power is directly proportional to the grating dimension (width) and to the groove density. For example, a grating with 1200 grooves/mm and 100-mm width would have a resolving power *R* given by

$$R = wn = 100 \times 1200 = 120,000. \tag{6.7}$$

The spectral bandpass B_S is given by

$$B_S = \frac{d'}{I_f D_S} \,. \tag{6.8}$$

This relation indicates that a smaller slit width would yield a smaller bandpass and provide better resolution. Larger slit widths, however, yield increased signal levels and therefore higher signal-to-noise (S/N) values.

The transmission efficiency of a grating is dependent on the wavelength and on the design of the grating. Two other factors that should be taken into consideration in selecting a grating are the blaze and the blaze angle. The blaze angle is the angle at which the grooves are ruled in the grating surface, and the blaze is the wavelength at which the maximum efficiency of the grating is concentrated. In general, one selects an excitation monochromator with high efficiency in the UV range and an emission monochromator with high efficiency in the visible spectral range. For example, a grating blazed at 300 nm may be chosen for excitation, whereas a grating blazed at 500 nm may be used for emission because the fluorescence of most organic compounds occurs between 400 and 600 nm. Use of gratings with an improper blaze angle may be a source of low sensitivity for many compounds.

In many monochromators, gratings with different blazes can be snapped into and out of the grating mount. Grating monochromators are now more widely used than prism monochromators because of their higher resolution. These monochromators are convenient to use because they produce a spectral dispersion that is linear with respect to wavelength.

The light throughput for various standard gratings varies between 50 and 90% and increases with groove density. For conventionally ruled gratings, this density has a practical limit above which it may produce substantial stray light and "ghosts." Ghosts are spurious spectral lines caused by periodic imperfections in the gratings. Stray light is defined as any light that passes through the monochromator outside the monochromator bandpass. For Raman measurements (and in some degree fluorescence measurements) that involve very low signal levels in the presence of an intense excitation source, the stray light level of the monochromator is perhaps the most critical parameter.

The advent of lasers and holography in the early 1960s made possible the production of holographic gratings with high throughput and low stray light. Monochromators may have planar or concave gratings. Planar gratings are usually produced mechanically and may contain imperfections in some of the grooves.

Concave gratings are usually produced by holographic and photoresist methods. Because they are produced optically, holographic gratings have fewer imperfections than mechanically produced (i.e., ruled) gratings. As a result of their optical configuration, a concave grating functions as the diffracting and the focusing element, resulting in one instead of three reflecting surfaces (Figure 6.5B). Fewer reflecting surfaces generally result in increased efficiency.

6.2.2.3 Tunable Filters

Tunable filters are special types of dispersive devices. These devices, such as acousto-optic tunable filters (AOTFs) and liquid crystal tunable filters (LCTFs), allow the investigator rapidly to record an image at various wavelengths. An AOTF is a solid-state optical bandpass filter that can be tuned to various wavelengths within microseconds by varying the frequency of the acoustic wave propagating through the medium. The solid-state nature of the AOTF provides a high-throughput (90% diffraction efficiency) dispersive element with no moving parts, thus increasing the ruggedness of the instrumentation.

AOTF devices consist of a piezoelectric transducer bonded to a birefringent crystal. The transducer is exited by a radio frequency (rf) (50 to 200 MHz) and generates acoustic waves in a birefringent crystal. Those waves establish a periodic modulation of the index of refraction via the elasto-optic effect. Under proper conditions, the AOTF will diffract part of the incident light within a narrow frequency range. Only light that enters the crystal so that its angle to the normal of the face of the crystal is within a certain range can be diffracted by the Bragg grating.

In a non-collinear AOTF, the diffracted beam is separated from the undiffracted beam by a diffraction angle. The undiffracted beam exits the crystal at an angle equal to the incident light beam, while the diffracted beam exits the AOTF at a small angle with respect to the original beam. A detector can be placed at a distance so that the diffracted light can be monitored while the undiffracted light does not irradiate the detector. In addition, when the incident beam is linearly polarized and aligned with the crystal axis, the polarization of the diffracted beam is rotated 90° with respect to the undiffracted beam. This can provide a second means to separate the diffracted and undiffracted beams.

LCTFs use electrically controlled liquid crystal elements that transmit a certain wavelength band while being relatively opaque to others. The LCTF is based on a Lyot filter, a device constructed of a number of static optical stages, each consisting of a birefringence retarder (quartz for LCTFs) sandwiched between two parallel polarizers. A stack of stages function together to pass a single narrow wavelength band. Tunability is provided by the partial alignment of the liquid crystals along an applied electric field between the polarizers; the stronger the field, the more the alignment and the greater the increase in retardance. Tuning times for randomly accessing wavelengths depend on the liquid crystal material used and the number of stages in the filter. At the moment, commercial devices use nematic components that result in tuning times of approximately 50 to 75 ms.

The operating principles of AOTFs and LCTFs and their use in imaging are described in detail in Chapter 8 of this handbook.

6.2.3 Optical Fibers

Optical fibers and waveguides are described in detail in Chapter 7 of this handbook. This section briefly mentions only the basic and salient features of optical fibers. A widely used component that provides an optical link between a spectroscopic instrument and a remotely located sample is the optical fiber. The rapid growth of fiber optic sensing has paralleled the commercial availability of low-attenuation optical fibers. In many applications, the optical fibers comprise a core made with an optically transparent material (e.g., glass, quartz, or polymer) with a certain refractive index, n_1 , surrounded by a cladding made with another material (e.g., quartz or plastic) having another refractive index, n_2 . Light transmission is based on total internal reflection as depicted in Figure 6.6. Light rays that impinge on the core—cladding interface at an angle equal to or greater than the critical angle θ_c , as determined by Snell's law, can be transmitted along the fiber by total internal reflection. Accordingly, an important fiber characteristic, the half acceptance angle β_c , is given by the equation:

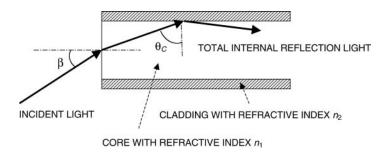

FIGURE 6.6 Total internal reflection in an optical fiber.

$$\sin\beta = \left(n_1^2 - n_2^2\right)^{1/2} / n_0,$$

where n_0 is the refractive index of the medium in which the end of the fiber resides.

Low attenuation over desired spectral regions and a large β value are desirable fiber characteristics. Fibers with large values of β permit the coupling of a large amount of excitation radiation from the source at the incident end of the fiber and the efficient collection of fluorescence signal at the sensing end of the fiber.

Optical fibers can be used to transmit the excitation light to a sample and transmit the signal (reflected or scattered light) from the sample to the detector. Several possible optical fiber configurations can perform these measurements: single-fiber system, bifurcated fiber system, and dual-fiber system (Figure 6.7). In Figure 6.7A, a single fiber is used to transmit the excitation beam from a light source to the sample and transmit the emission from the sample to the detector. A dichroic filter is used to transmit the light at the excitation wavelength and reflect light at the emission wavelength. In Figure 6.7B, a bifurcated fiber is used, one end transmitting the excitation light to the sample, and the other end transmitting the sample emission light to the detector. In Figure 6.7C, two separate parallel fibers are used, one fiber transmitting excitation light and the other transmitting the emission light. In Figure 6.7D, two perpendicular fibers are used. The angle between the fibers can be varied and optimized in order to optimize the overlap of the excitation and detection volumes and to minimize scattered light.

6.2.4 Polarizers

Light can be described as consisting of two transverse electric and magnetic fields that are perpendicular to the direction of light propagation and to each other. The direction of the electric vector is used to describe the polarization of light. Most incoherent light sources consist of a large number of atomic and molecular emitters. The rays from such sources, which have electric fields with no preferred orientation, are called unpolarized. On the other hand, if a light beam (e.g., from a laser) consists of rays where the electric field vectors are oriented preferentially in the same direction, the beam is said to be linearly polarized.

Polarizers transmit light that has its electric vector aligned with the polarization axis, and block light that is rotated 90°. A commonly used device is the Glan–Thompson polarizer. This device consists of a calcite prism, a birefringent material, where the refractive index is different along each optical axis of the crystal. In general, the polarization characteristics of a crystal are determined by the crystal structure and electron bonding. Calcite is widely used as a polarizing material because of its excellent transmission well into the UV range and large difference in the two index-of-refraction values. Glan–Thompson polarizers exhibit high extension coefficients (near 10⁶) and high acceptance angle (10 to 15°).

Other types of polarizers include film polarizers composed of materials that absorb light polarized in one direction more strongly than light of the orthogonal polarization. These are thin films of a stretched polymer (e.g., polyvinyl alcohol) that transmit the light polarized in one direction and absorb the light polarized in another direction. The film sheets are stretched to orient and align the molecules. Polarizer

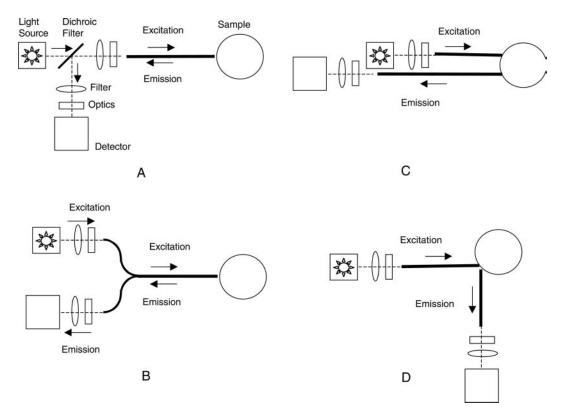

FIGURE 6.7 Various configurations using optical fibers: (A) single-fiber system; (B) bifurcated-fiber system; (C) parallel dual-fiber system; (D) dual-fiber system.

films are not suitable for use with intense light beams (e.g., lasers) because they absorb light and therefore can be easily damaged. Other types of polarizers, such as the Wollaston polarizers and Rochon prism polarizers, split the unpolarized light into two beams, which then must be spatially selected.

6.2.5 Detectors

Selection of a suitable detector is one of the most critical steps in the development of a spectrometer. Detectors for electromagnetic radiation can be classified into photoemissive, semiconductor, and thermal types. Photoemissive detectors are generally used in optical measurements. These devices include PM tubes, photodiodes, and imaging tubes. The PM tubes are the most commonly used because they are the most sensitive detectors for the visible and near-UV regions. There are two types of detectors, single-channel detectors and multichannel. Multichannel detectors include one-dimensional and two-dimensional detector arrays. Traditionally, spectroscopy has involved using a scanning monochromator and a single-element detector (e.g., photodiode, PM). With monochromators, only one spectral resolution element, or channel, can be monitored at a time. Detectors that permit the recording of the entire spectrum simultaneously, thus providing the multiplex advantage, are known as multichannel detectors. With multichannel systems, a complete spectrum can be recorded in the same time it takes to record one wavelength point with a scanning system.

6.2.5.1 Single-Channel Detectors

6.2.5.1.1 Photomultipliers

PMs are widely used for their high spectral sensitivity, wide operating range, low cost, and relatively simple electronics. A PM coupled with a monochromator is the simplest and most commonly used

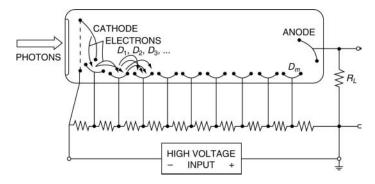

FIGURE 6.8 Schematic diagram of a photomultiplier tube (D_i , dynode i; R_I , load resistor).

single-channel spectrometer. The spectral resolution and the sensitivity of the spectrometer are strongly dependent on the characteristics of the monochromator and the PM tube. Modern holographic gratings generally offer excellent stray light rejection.

The PM is a vacuum tube containing a highly sensitive surface, the photocathode, generally made of a metal oxide. The PM tube operates as a current source. The intensity of the current output is proportional to the intensity of the light striking the photocathode, which is a thin film of metal on the inside of the PM window. Figure 6.8 is a schematic diagram of a PM tube. The photons cause electrons to be ejected from the photocathode surface as the result of the photoelectric effect. The photocathode is held at a high negative potential, typically -1000 to -2000 V. The photoelectrons then cascade down the dynode chain in increasing numbers as a result of secondary emission, which occurs at each dynode surface.

Each dynode is an electrode coated with a material that emits several secondary electrons for each incoming electron. The electrons are accelerated down the dynode chain by a potential on the order of 100 V between two consecutive dynodes. The secondary electrons ejected from the first dynode are then accelerated onto the next dynode, where they induce further emission of secondary electrons. The secondary emission occurring at every successive dynode stage can provide an overall internal amplification factor of up to 10⁸. The total number of dynodes is usually between 7 and 12, and the total high voltage between the first and last dynode is commonly between 0.7 and 1.5 kV. The total current collected at the anode is proportional to the incoming photon flux and is linear over many orders of magnitude.

The photocathode materials and the transmission characteristics of the window materials determine the spectral response of the photocathode. Only a photon with an energy greater than the work function of the cathode material results in the release of a photoelectron from the cathode. Photocathode material determines the long-wavelength cutoff, and the window material determines the short-wavelength cutoff. Figure 6.9 depicts examples of some typical cathode sensitivity responses.

The PM is equivalent to a current power supply, since all secondary electrons ejected from the dynodes are replaced from the power supply via the dynode resistor chain. The number of dynodes determines the amplification gain of the PMT, and the gain per dynode stage is determined by the interdynode potential. The values of the dynode resistors are selected so that the current through the dynode resistor chain is about 100 times the maximum anode current. This design ensures that the anode potential remains constant during measurement. The manufacturers provide designs of typical dynode circuitry.

One limiting factor of the PM is the dark current that may be due to leakage current (imperfect insulation), ionization of residual gases inside the tube by electrons, and thermionic emission from the cathode or the dynodes. Proper preparation of PM connections significantly reduces the dark current in PM tubes. Figure 6.10 shows the five most common dynode configurations. The PM response time depends basically on the number of dynode stages and the dynode configurations; the line-focused configuration generally exhibits the fastest time response (<3 ns). In general, the capacitance between the anode and other electrodes determines the rise time of the PM tube.

Cooling the PM tube reduces the thermionic component of the dark current. With phototubes having GaAs cathodes, cooling produces a falloff in sensitivity in the red region but increases the sensitivity over

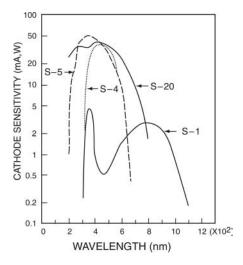

FIGURE 6.9 Examples of spectral responses curves of photomultipliers.

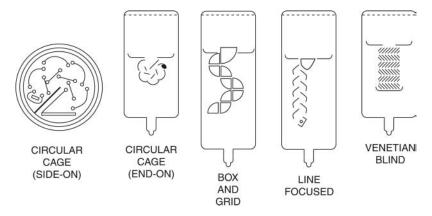

FIGURE 6.10 Typical dynode configurations of photomultipliers.

the rest of the visible spectrum. PMs require various accessories such as housing assemblies, power supplies, current stabilization devices, and magnetic shielding. Cooling equipment is usually optional. Many suppliers of PM tubes also provide the accessories and frequently offer the complete detection system in one package.

Microchannel plates (MCPs) are special PM tubes that contain numerous holes, microchannels (instead of a dynode chain), which are lined with the secondary emissive dynode material. In an MCP, the electrons are amplified as they drop down the voltage gradient across the MCP. MCP devices have very fast time responses and are used in the most demanding high-speed, time-resolved measurements.

6.2.5.1.2 Photodiode and Avalanche Photodiode

A simple detector is a diode, a semiconductor device that produces, as a result of the absorption of photons, a photovoltage or free carriers that support the conduction of photocurrent. Photodiodes (PDs) are used for the detection of optical communication signals and for the conversion of optical power to electrical power. However, the lack of high amplification limits their usefulness for high-sensitivity measurements.

An avalanche photodiode (APD) is a PD that uses avalanche breakdown to achieve internal multiplication of photocurrent. The APD is usually a silicon-based semiconductor containing a pn junction consisting of a positively doped p region and a negatively doped p region sandwiching an area of neutral charge termed the depletion region. These diodes provide gain by the generation of electron-hole (e-h)

pairs from an energetic electron that creates an "avalanche" of electrons in the substrate. Photons entering the diode first pass through the silicon dioxide layer and then through the *n* and *p* layers before entering the depletion region, where they excite free electrons and holes, which then migrate to the cathode and anode, respectively.

When a semiconductor diode has a reverse bias (voltage) applied, and the crystal junction between the p and n layers is illuminated, then a current will flow in proportion to the number of photons incident upon the junction. Avalanche diodes are very similar in design to the silicon p-i-n diode; however, the depletion layer in an APD is relatively thin, resulting in a very steep localized electrical field across the narrow junction. In operation, very high reverse-bias voltages (up to 2500 V) are applied across the device. As the bias voltage is increased, electrons generated in the p layer continue to increase in energy as they undergo multiple collisions with the crystalline silicon lattice. This "avalanche" of electrons eventually results in electron multiplication analogous to the process occurring in one of the dynodes of a PM tube.

APDs are capable of modest gain (500 to 1000) but exhibit substantial dark current, which increases markedly as the bias voltage is increased. They are compact and immune to magnetic fields, require low currents, are difficult to overload, and have a high quantum efficiency that can reach 90%. Usually, APDs are run with a reverse bias that is less than the breakdown value. In this mode, they have a gain of 200 to 300, which is too low for photon counting. However, APDs operated in the Geiger mode (with a reverse bias slightly greater than the breakdown value) can give similar gains to those of a PM, around 10^6 , and can be used for single-photon counting of low-level signals. The development of APDs as high-performance photodetectors is currently an active field of research.

6.2.5.1.3 Hybrid Detectors

Hybrid PM (HPM) tubes and hybrid PDs (HPDs) are devices that have the potential for use in single-photon counting applications. These devices have a photocathode similar to that of conventional PM tubes. Following the absorption of a photon, an electron may be emitted from the photocathode. However, unlike in PM tubes, the photoelectrons are amplified in a solid-state structure by an avalanche process, resulting in an electrical pulse. In an HPD, the electron is accelerated in a strong electric field toward a silicon sensor, which represents the anode. The electron is stopped in the depleted silicon, where a large number of e–h pairs are created, depending on its kinetic energy (10 to 20 keV).

6.2.5.2 Multichannel Detectors

A well-known example of a multichannel detector is the photographic plate. Other multichannel detectors include the diode array, the CCD, or the charge-injection device. In multichannel spectrometers, the detector is placed at the focal plane of a polychromator, which is a monochromator with the exit slit removed. As a result, the entire emission dispersed at all wavelengths within the polychromator is detected simultaneously. The simultaneous detection of all of the dispersed emission using n spectral resolution elements reduces the measurement time by a factor of n in the case of a signal-to-noise-limited measurement, or improves the S/N ratio by a factor of n in the case of a time-limited measurement.

6.2.5.2.1 Vidicons

The vidicon is a device used in the 1970s that is essentially a television-type device comprising an array of microscopic photosensitive diode junctions grown upon a single-silicon-crystal wafer. These diode junctions form individual microelements used to detect simultaneously the radiation dispersed by the polychromator. Prior to detection, each diode is charged to a preset reversed-bias potential by a fast-scanning electron beam. The electromagnetic radiation that strikes the diode causes depletion of the charge in each diode. A current proportional to the incident radiation recharges the diode to the preset potential when the electron beam scans again, thus providing information on the intensity of the incident light that has struck the diode. Consequently, an almost instantaneous recording of the spectral intensity at each diode is generated in the computer memory of the vidicon detector. Vidicons are capable of integrating radiation intensity over multiple scanning cycles because of their charge storage capabilities.

Sensitivity can be further enhanced by incorporating an image-intensification section in front of the vidicon to yield a silicon intensified target vidicon.

6.2.5.2.2 Photodiode Array

Another multichannel detector is the photodiode array (PDA), which also utilizes PDs as detection elements. Recording the signal is performed with direct on-chip circuitry rather than with a scanning electron beam. The electronic switches needed to read from individual PDs are built right onto the chip. One diode is read at a time, and the analog signal read out through each electronic switch correlates with the amount of light intensity impinging on the PD. Most multichannel PDAs are silicon based, operating from 180 to 1100 nm. PDA systems with InGaAs detectors can be used in the NIR spectral range (800 to 1700 nm). Signal amplification is achieved by a microchannel plate image intensifier. Gated detection down to 5-ns time resolution can be performed with the intensified diode array.

6.2.5.2.3 Charge-Coupled Device

More recently, multichannel devices such as CCDs are increasingly used as a result of their high quantum yield, two-dimensional imaging capability, and very low dark current. CCDs represent a great advance in detector instrumentation from the UV to NIR spectral range. They are very widely used because of their two-dimensionality and unique combination of sensitivity, speed, low noise, ruggedness, and durability in a relatively compact package. Because of their widespread use in spectroscopy, this section provides a detailed description of the operating principle of CCDs and the instrumental factors involved in the selection of CCDs for specific applications.

CCDs are one- or two-dimensional arrays of silicon PDs with metal-oxide semiconductor architectures. The detector arrays consist of individual detector elements, called pixels, which are defined by capacitors, called gates. These capacitors are charged by electrons generated by the light impinging onto the CCD. Silicon exhibits an energy gap of 1.14 eV. Incoming photons with energy greater than this can excite valence electrons into the conduction band, thus creating e-h pairs. The average lifetime for these carriers is $100 \,\mu s$. After this time, the e-h pair will recombine. Photons with energy of from 1.14 to 5 eV generate single e-h pairs. Photons with energy of >5 eV produce multiple pairs. A 10-eV photon will produce three e-h pairs, on average, for every incident photon. Soft x-ray photons can generate thousands of signal electrons, making it possible for a CCD to detect single photons. For use as an IR imager, a CCD must be made of another material, like germanium (band gap $0.55 \, eV$).

The current sources (e–h pairs) produced are localized in small areas, an array of capacitors, called pixels. Common two-dimensional CCD chips have 512×512 or 1024×1024 pixels. The charge accumulates in proportion to the light intensity impinging onto the pixel. A CCD sensor provides only one serial output: the readout register through which each capacitor can be discharged (each pixel can be read). A differential voltage is applied across each gate to perform charge transfer. The photogenerated charge is moved to the readout register by a series of parallel shifts, sequentially transferring charge from one pixel to the next within a column, until the charge finally collects in the readout register.

The charge from a row of pixels can be binned before readout to improve the S/N value. Furthermore, the dark count of CCDs is very low, especially when the detector is cooled. A CCD array can accumulate charge generated by photoelectrons almost noiselessly. However, CCD noise is produced in the act of commutating the charge out to a charge detector. Readout noise also tends to increase with increasing readout speeds; typically, the best CCD camera systems currently available give around five electrons of readout noise per pixel.

CCDs have several structures, including front-illuminated, back-illuminated, and open-electrode structures (Figure 6.11). In front-illuminated CCDs, incident photons have to penetrate a polysilicon electrode before reaching the depletion region. In back-illuminated or back-thinned CCDs, the substrate is polished and thinned to remove most of the bulk silicon substrate. Because illumination occurs from the back, the polysilicon on the front does not affect the quantum efficiency (QE) of the detector. CCDs are currently the detectors with the highest QEs. Typically, a CCD array has a QE of around 40%, but back-thinning can increase the QE to around 80% at 600 nm. Back-thinned CCDs are usually coated

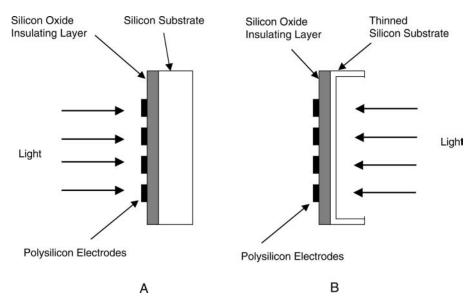

FIGURE 6.11 Structure of front-illuminated (A) and back-illuminated (B) CCDs.

with an antireflection material for enhanced response in the UV or the NIR region. Often reflections from boundaries of the back-thinned devices form constructive and destructive interference patterns, referred to as the "etaloning effect." The etaloning effect often causes an undesired oscillation superimposed on the spectrum at wavelengths longer than 650 nm.

The transmittance of the electrode depends on its thickness. Because the polysilicon electrode material does not transmit at below 400 nm, some versions of front-illuminated UV CCDs have the detector coated with a phosphor, which converts UV radiation to green light. These UV CCDs can provide a 10 to 15% QE response in the 120- to 450-nm spectral range. The coating is selected so that it does not degrade the visible and NIR response of the detector. In open-electrode CCDs, the central area of the electrode is etched to expose the underlying photosensitive silicon. These types of CCDs exhibit QEs of 30% or greater in the UV.

Cooling CCDs is important because the operating temperature of the detector determines the dark-current noise. In general, the dark-current level is reduced 50% for every 9°C drop in temperature. Two common cooling methods are liquid-nitrogen cooling and thermoelectric cooling using multistage Peltier devices. Liquid-nitrogen cooling provides the lowest operating temperatures, achieving typical dark-current levels of one to three electrons per pixel per hour at –133°C. Four-stage thermoelectrically cooled CCDs have typical operating temperatures of –73°C with typical noise levels of one to two electrons per pixel per minute. Thermoelectric cooling systems are often a good choice because they can offer good performance, approaching that of liquid-nitrogen-cooled systems, and provide the convenience of uninterrupted operation. Research spectrometers generally require cooled CCDs to detect low-level signals, but conventional consumer-application CCDs are uncooled because of the high light levels and the very low bit depth of the analyzing electronics.

CCDs are often used as steady-state detectors. Because they have relatively slow time response, an intensifier stage with fast gating capability is used for time-resolved measurements. Intensified charge-coupled devices (ICCDs) can have nanosecond gate times.

Selection of CCDs is based on the spectral range of interest, resolution, and expected optical signal level. No single system can satisfy all of the possible spectral and S/N requirements in spectroscopy. The user should carefully analyze needs and evaluate the tradeoffs involved in selecting a detector type, structure, and cooling method. Several considerations in the selection of a CCD for various applications are summarized in Table 6.3.8

6.2.5.2.4 Other Solid-State Detectors

Other popular types of solid-state detectors include charge-injection devices (CIDs) and active-pixel sensors (APSs). CIDs have pixels composed of two metal-oxide semiconductor gates that overlap and share the same row and column electrodes. The APS consists of a photodiode, a reset transistor, and a row-select transistor. These devices can be highly integrated and can be manufactured using complementary metal-oxide semiconductor (CMOS) technologies.

6.2.5.2.5 CMOS Array

PDs and phototransistors are single-channel solid-state detectors. With the silicon fabrication process, the integrated electro-optic system on integrated circuit (IC) microchips, photodetector elements with amplifier circuitry, has led to the development of a new generation of multichannel (one- and two-dimensional) detector arrays based on the CMOS technology.

CMOS is the semiconductor technology used in the transistors integrated into most computer microchips. Semiconductors are made of silicon and germanium, materials that "sort of" conduct electricity, but not enthusiastically. Areas of these materials are "doped" by adding impurities, which supply extra electrons with a negative charge (*N*-type transistors) or of positive charge carriers (*P*-type transistors). In CMOS technology, both kinds of transistors are used in a complementary way to form a current gate that creates an effective means of electrical control. CMOS transistors use almost no power when they are not needed.

The use of IC systems based on the CMOS technology has led to the development of extremely low-cost diagnostic sensor chips for medical applications. In CMOS, both *N*-type and *P*-type transistors are used to realize logic functions. Today, CMOS technology is the dominant semiconductor technology for microprocessors, memories, and application-specific ICs (ASICs). The main advantage of CMOS is the low power dissipation. Power is dissipated only if the circuit actually switches. This design allows integration of increased numbers of CMOS gates on an IC, resulting in much better performance.

Using the standard CMOS process allows production of PDs and phototransistors, as well as numerous other types of analog and digital circuitry, in a single IC chip. This feature is the main advantage of the CMOS technology compared with other detector technologies such as CCDs and CIDs. The PDs are produced using the *n*-well structure generally used to make resistors or as the body material for transistors. The capability of large-scale production using low-cost IC technology is an important advantage. The assembly process of various components is made simple by integration of several elements on a single chip. For medical applications, this cost advantage will allow the development of extremely low-cost, disposable biochips that can be used for in-home medical diagnosis of diseases without sending samples to a laboratory for analysis. ⁹⁻¹⁴ The use of CMOS sensor arrays for medical biochips is further discussed in Chapter 51 of this handbook.

6.2.5.2.6 Streak Cameras

Streak cameras are detectors that can provide very fast time gating with temporal resolution from several picoseconds to hundreds of femtoseconds. 15 Streak cameras operate by dispersing photoelectrons across an imaging screen at high speed using deflection plates within the detector. These cameras

can simultaneously provide measurements of time decay at different wavelengths. In general, they have a faster response time than that of microchannel plate PM tubes but exhibit relatively low S/N values and low dynamic ranges (three orders of magnitude).

6.2.6 Detection Methods

6.2.6.1 Direct Current Technique

The analog or DC method is the oldest and simplest detection technique. Because the anode is basically a current generator, a current meter may measure the anode current. It is common to measure the output by amplifying the voltage across a load resistor, typically between 10⁵ and 10⁸ ohms. The noise in the DC amplification signal is commonly reduced by a resistor-capacitor (RC) low-frequency band-pass filter. Too slow a response in the RC filter, however, necessitates very slow scanning speeds and long measurement times. A typical DC detection system involves the use of a picoammeter. The time constant for such an instrument at the highest intensity scale is a few seconds. A zero-suppression device is generally provided to compensate for dark current and zero drift.

6.2.6.2 Alternating Current Technique

The alternating current (AC) method consists of modulating the excitation signal using electronic or mechanical means. An AC amplifier is then tuned to the modulating frequency for detection. This technique rejects the noise outside the amplifier bandpass, eliminating the direct-current (DC) dark current. A further improvement is based on the technique of synchronous (or lock-in) detection. Stability is improved because any drift or instability of the modulating system is locked in by the amplifier. However, synchronous detection cannot eliminate some types of noise ("I/f noise," multiplicative noise) that are amplified along with the signal.

In certain situations, it is desirable to obtain spectral information in digital form to allow data processing for correction or smoothing of spectra. One simple method to obtain data from the DC anode current uses a voltage-to-frequency converter. This method is equivalent to using an analog-to-digital converter and counting the output pulses from the converter. A variety of voltage-to-frequency converters is at present commercially available.

6.2.6.3 Digital Photon Counting Technique

A truly digital technique that counts discrete photon pulses is the single-photon counting technique. Unlike the more conventional analog detection method, the single-photon counting signal output is digital in nature, producing discrete pulses of charge. The digital technique has proved to have several advantages over the analog method, especially for low-level signal detection. This method uses high-gain phototubes and high-speed electronics for detecting individual photon pulses.¹⁹

Unlike the previously described methods, in which the signal is analog, the PM signal output here is digital in nature. In the digital technique, discrete pulses of charge are produced at the anode, with the number proportional to the number of photons incident on the photocathode. This technique has proved to have several advantages over the conventional DC method, especially for low-level light detection. ^{17–19} First, the digital data can be processed directly in a manner suitable for further computer data treatment. The processing of information by digital circuitry is less susceptible to long-term drifts, which usually limit analog systems; this feature permits measurement of extremely low radiation flux. The method also makes optimization of the S/N ratio possible by discriminating against PM dark current.

With an ideal detection device, one would expect the pulses resulting from single photoelectrons to have exactly the same pulse height. Actually, the output pulses have a certain height distribution due to thermionic emission of higher dynodes and spurious pulses generated by the PM. Electrons that do not originate at the photocathode, but from farther down the dynode chain, are the main sources of PM noise or dark current. These undesired electron pulses have a height distribution that generally differs from that of the photoelectrons. For example, thermionic electrons have a pulse height distribution lower than that of photoelectrons, whereas other sources of noise — such as cosmic ray muons, after-pulsing,

and radioactive contamination of tube materials — generally produce pulses of higher amplitude. Most of these unwanted pulses can be eliminated by discriminatory units that select pulses within the range of height levels expected for true photosignals of interest.²⁰

Whereas digital photon counting techniques are very useful for low-level signal measurements, they may not be suitable for high-intensity conditions because of pulse pile-up phenomena. If two pulses arrive at the cathode at the same time or are closely spaced in time, they could be counted as a single pulse, resulting in an inaccurate count rate. The anode pulse width corresponding to a single photon for a typical PM is approximately 5 ns. This limits the maximum frequency response of the PM to 200 MHz for a periodic signal. For random events, the count rate needs to be about 100-fold less to avoid pulse pile-up. Therefore, the single-photon counting technique should be employed only for photon count rates of less than 2 MHz.

6.2.6.4 Time-Resolved and Phase-Resolved Detection Methods

Various detection techniques can be designed to measure optical signals from a wide variety of spectroscopic processes, including absorption, fluorescence, phosphorescence, elastic scattering, Raman scattering, etc. One important parameter of these signals is the lifetime of the radiation. The lifetimes of various processes are:

· Absorption: instantaneous with excitation

Fluorescence: 10⁻¹⁰ to 10⁻⁸ s
Phosphorescence: 10⁻⁶ to 10⁻³ s

· Scattering: almost instantaneous with excitation

Two methods of measuring signal that allow differentiation of lifetimes involve time-resolved and phase-resolved detection schemes.²¹ These methods also improve the S/N values by differentiating the actual signal of interest from the background noise (DC signal). The use of time-resolved and phase-resolved techniques in imaging is described in Chapter 9 of this handbook.

6.2.6.4.1 Time-Resolved Detection

In the time-resolved method, a pulse excitation source is used. The width of the excitation is generally much shorter than the emission process of interest, i.e., much shorter than the lifetime (decay time) of the samples. If one desires to measure the lifetime, then the time-dependent intensity is measured following the excitation pulse, and the decay time τ is calculated from the slope of a plot of $\log I$ (t) vs. t, or from the time at which the intensity decreases to 1/e of the initial intensity value I (t = 0). To measure the emission intensity free from the excitation pulse intensity, one can gate the detection after a delay time when the excitation pulse has decreased to zero (Figure 6.12A). Different compounds having different decay times can be differentiated by using different delay times (dT) and gate times (ΔT) (Figure 6.12B). An important source of noise in many measurement situations is the DC noise from the background. Improvement in the S/N ratio can be achieved by using multiple excitation pulses and applying the "boxcar" method by integrating the emission signal after each pulse (Figure 6.12B).

6.2.6.4.2 Phase-Resolved Detection

Another method that can differentiate the lifetimes involves the phase-resolved techniques (often referred to as the frequency domain techniques). In this case, the sample is excited with intensity-modulated light. The intensity of the incident light changes with a very high frequency ($\omega = 2\pi f$, where f is the frequency in hertz) compared with the reciprocal of the decay time τ . Following excitation with a modulated signal, the emission is also intensity-modulated at the same modulation frequency. However, because the emission from the sample follows a decay profile, there is a certain delay in the emission relative to the excitation (Figure 6.13). This delay is measured as a phase-shift (ϕ), which can be used to calculate the decay time. Note that at each modulation frequency $\overline{\omega}$, the delay is described as the phase shift ϕ_{ω} , which increases from 0 to 90° with increasing modulation frequency $\overline{\omega}$.

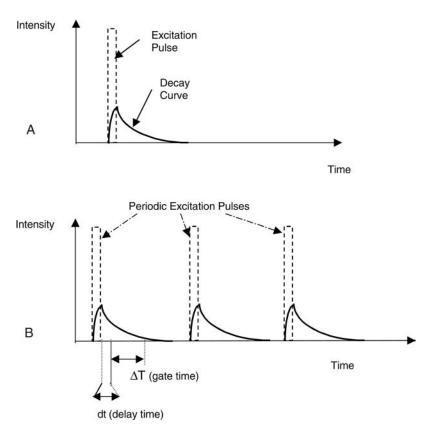

FIGURE 6.12 Time-resolved detection: (A) excitation and decay profiles; (B) gated detection technique.

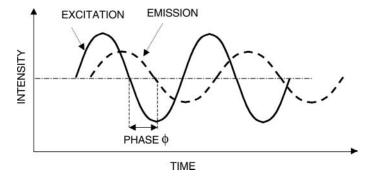

FIGURE 6.13 Phase-resolved detection.

The finite time response of the sample also results in demodulation of the emission by a factor m_{ϖ} . This factor decreases from 1.0 to 0 with increasing modulation frequency. At low frequency, the emission closely follows the excitation. Hence, the phase angle is near 0 and the modulation is near 1. As the modulation frequency is increased, the finite lifetime of the emission prevents the emission from closely following the excitation. This results in a phase delay of the emission and a decrease in the peak-to-peak amplitude of the modulated excitation (Figure 6.13).

The shape of the frequency response is determined by the number of decay times displayed by the sample. If the decay is a single exponential, the frequency is simple. One can use the phase angle or modulation at any frequency to calculate the lifetime. For single-exponential decay, the phase and modulation are related to the decay time (τ) by

$$\tan \phi_{\varpi} = \overline{\omega} \tau$$

and

$$m_{\omega} = (1 + \omega^2 \tau^2)^{-1/2}$$
.

Therefore, one can differentiate various emissions having different decay times by selecting the phase shift optimized to the decay time of interest. This method is referred to as phase-resolved detection.

6.2.6.5 Multispectral Imaging

Photonics diagnostic technologies can be broadly classified into two categories: (1) spectroscopic diagnostics and (2) optical imaging, often referred to as optical tomography. Spectroscopic diagnostic techniques are generally used to obtain an entire spectrum of a single tissue site within a wavelength region of interest. These techniques are often referred to as point-measurement methods. On the other hand, optical imaging methods are aimed at recording a two-dimensional image of an area of the sample of interest at one specific wavelength. A third category, which combines the two modalities, is often referred to as multispectral imaging or hyper-spectral imaging.

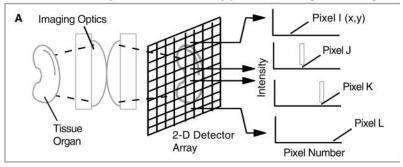

Spectral imaging represents a hybrid modality for optical diagnostics that obtains spectroscopic information and renders it in image form. In principle, almost any spectroscopic method can also be combined with imaging. Some of these techniques use computer-based image processing in combination with microscopy. These techniques have had a major impact on research and are being implemented in cytological diagnostics. There is also considerable future potential for direct clinical applications.

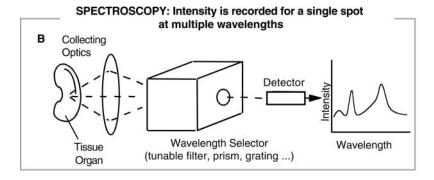

Instrumentation for multispectral imaging is described in detail in Chapter 8 of this handbook. Briefly, the concept of multispectral imaging is schematically illustrated in Figure 6.14. With conventional imaging, the optical emission from every pixel of an image can be recorded, but only at a specific wavelength or spectral bandpass. With conventional spectroscopy, the signal at every wavelength within a spectral range can be recorded, but for only a single analyte spot. The multispectral concept combines these two recording modalities and allows recording of the entire emission for every pixel on the entire image in the field of view with the use of a rapid-scanning solid-state devices, such as the acousto-optic tunable filter or a liquid crystal tunable filter. The multispectral imaging approach provides a "data cube" of spectral information of the entire image at each wavelength of interest (Figure 6.15).

6.3 Conclusion

Photonics instrumentation includes a wide variety of basic devices available to the investigator for many applications. A simple instrumental setup can be easily assembled using off-the-shelf components. More sophisticated devices can be designed for special research requirements. Selection of components or a complete system is based on the spectral range of interest, resolution, and expected optical signal level. No single system can satisfy all of the possible spectral and S/N requirements in spectroscopy. The user

should carefully analyze his or her needs and evaluate the tradeoffs involved in selecting a detector type, structure, and cooling method.

7.1 Introduction

Lasers are used in medical applications for a wide range of the electromagnetic spectrum: x-ray, ultraviolet (UV), the visible, the near-infrared, and ending, at this time, in the mid-infrared. This wide range of wavelengths must be transmitted from the source (laser) to the target tissue by a flexible device that enables easy manipulation of the laser beam in a medical setting.

At the beginning of laser use in medicine, energy was transmitted by an articulated arm, which was a set of tubes connected by joints and reflecting mirrors to three freedom ranks (Figure 7.1). With time, this setup was miniaturized and made more precise, and the drift of the laser beam was reduced, but the device is still cumbersome and limited to external use.

Surgical procedures are usually open procedures; however, with the introduction of the endoscope, the trend is toward noninvasive or minimally invasive procedures. This practice reduces hospitalization time, causes less postoperative pain and discomfort, and results in fewer complications. Surgical tools are inserted through existing openings of the body or through minor cuts to the skin. The development of the endoscope (especially the flexible one; see Figure 7.2 for schematic drawing) was enabled by optical fibers, which deliver the light into the body, and by the coherent optical bundle, which delivers the image from the body cavity outside to the eyepiece or monitor. The working channel is used to insert surgical microtools and an optical fiber that can deliver laser radiation into the body.

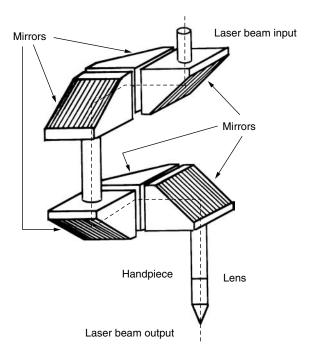

FIGURE 7.1 Laser-articulated arm.

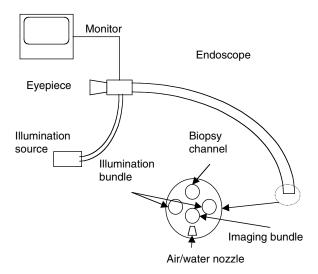

FIGURE 7.2 Schematic drawing of an endoscope.

Optical fibers, which can transmit specific laser wavelengths, will make minimally invasive procedures even more common. They can also transmit information from tissue back to a detector. When tissue is heated it radiates; the radiation wavelength is a function of the tissue temperature (Planck curves). This information can be transmitted by an IR transmitting fiber, and the temperature of the tissue can be measured. One such use is a feedback mechanism for tissue welding/soldering.¹ Developments in biomedical optics and photon migration in tissue have made it possible to measure specific tissue properties through transmission and reflection. Spectroscopy of tissue can be made through evanescent waves at fibers with no cladding.² Fluorescence signals from tissue (either endogenous fluorophores or exogenous materials present in tissue) can be transmitted to detectors³ or fluorescence cameras through coherent

FIGURE 7.3 General structure of a solid-core fiber.

optical bundles. These signals help diagnose changes in tissue, tissue transformations, and the presence of tumors. Measurements can be taken in a minimally invasive way using endoscopes. Diagnosis is immediate and less invasive, and response to treatment can be monitored.

7.2 Theory

Two types of optical fibers are used in medical applications: (1) the conventional solid-core fibers such as silica and (2) hollow waveguides. Each type of optical fiber guides radiation according to different physical phenomena. Solid-core fibers guide optical radiation by using total internal reflection, while most of the hollow waveguides guide optical radiation by pure reflection.

7.2.1 Solid-Core Optical Fibers

7.2.1.1 Fiber Basics

The general structure of a solid-core optical fiber (Figure 7.3) consists of a core, a clad, and a jacket. The optical radiation is guided through total internal reflection; hence, the core index of refraction is slightly higher than that of the clad. Solid-core fibers can be characterized by several criteria, the most common of which is index profile. According to this criterion there are two types of solid core fibers: (1) step index fiber, in which the refractive index profile of the core is a step function, and (2) graded index fiber, in which the refractive index of the core depends on the core radius. Fibers may also be single or multimode. Multimode fibers are the most commonly used type of fiber in medical applications.

7.2.1.2 Ray Theory

Ray theory is the simplest way to understand the guiding mechanism of a solid-core fiber. It is applicable as long as the wavelength is much smaller than the fiber core diameter ($\lambda >> a$). When a ray impinges on a surface between two materials, it changes its angle of propagation (Figure 7.4) according to Snell's law,

$$n_1 \sin \theta_1 = n_2 \sin \theta_2 \,, \tag{7.1}$$

where n is the material index of refraction and θ is the angle of propagation.

As can be seen from Snell's law, in an angle of incidence, θ_{Ic} , the angle of refraction equals 90°. Rays that impinge the surface at angles above θ_{Ic} will totally reflect from the surface. These rays will be guided through the fiber while other rays will be lost and decay in the clad region (Figure 7.5). Once the

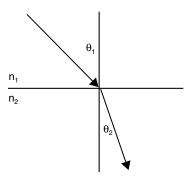

FIGURE 7.4 Snell's law.

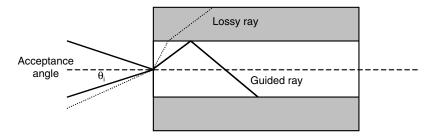

FIGURE 7.5 Guided ray and lossy ray.

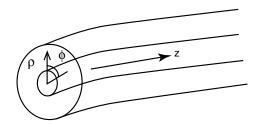

FIGURE 7.6 Cylindrical coordinates.

maximum angle of incidence is known, it is possible to determine the acceptance angle of the fiber or its numerical aperture (NA). The NA describes the ability of the fiber to collect light. The larger the NA, the greater the ability of the fiber to collect light. The NA is given by

$$NA = \sin \theta_i = \sqrt{n_1^2 - n_2^2} \ . \tag{7.2}$$

7.2.1.3 Mode Propagation in Solid-Core Optical Fibers⁴

An alternative means of ray analysis is to solve the Maxwell equation with the appropriate boundary condition. The wave equations are given by

$$\nabla^2 E - \frac{1}{c^2} \frac{\partial^2 E}{\partial t^2} = 0; \quad \nabla^2 H - \frac{1}{c^2} \frac{\partial^2 H}{\partial t^2} = 0; \quad \text{where } c^2 = \frac{1}{\mu \epsilon}.$$
 (7.3)

This is a representation of a single-frequency wave and phase velocity. The general wave motion can be represented by $\sin(wt - kz)$ or $\exp[i(\omega t - kz)]$, where ω is the *temporal frequency* and k is the *spatial frequency* (or *propagation vector*, *wave vector*, *wave number*). The temporal frequency denotes the number

of repetitions of a wave per unit time while the spatial frequency denotes the number of repetitions of a wave per unit distance; ω/k (or β) is known as the *phase velocity*, the velocity of any constant-phase point of a wave.

The wave equation in cylindrical coordinates (Figure 7.6) is given by

$$\frac{\partial^2}{\partial \rho^2} E_z + \frac{1}{\rho} \frac{\partial}{\partial \rho} E_z + \frac{1}{\rho^2} \frac{\partial^2}{\partial \phi^2} E_z + \frac{\partial^2}{\partial z^2} E_z - n^2 k_0^2 E_z = 0 \tag{7.4}$$

for a step index fiber

$$n = \begin{cases} n_1 & \rho \le a \\ n_2 & \rho > a \end{cases}.$$

It is possible to solve the wave equation by separating the variables according to the coordinates

$$E_z(\rho, \phi, z) = F(\rho)\Phi(\phi)Z(z), \qquad (7.5)$$

which yields

$$\frac{Z''}{Z} = \beta^2, \Rightarrow Z = e^{i\beta z}, \qquad (7.6)$$

$$\frac{1}{\rho^2} \frac{\Phi''}{\Phi} = \frac{m^2}{\rho^2}, \Phi = e^{im\phi}, \tag{7.7}$$

and

$$\rho^2 \frac{\partial^2 F}{\partial \rho^2} + \rho \frac{\partial F}{\partial \rho} + \left(k^2 \rho^2 - m^2\right) F = 0. \tag{7.8}$$

The famous Bessel functions are the solution to the latter equation. Because we want to confine the energy only to the core, all the energy that propagates in the radial direction through the clad must decay with the distance ρ . Thus, in the core the solution is

$$F(\rho) = AJ_m(k\rho) + A'Y_m(k\rho) \quad \rho < a$$
(7.9)

where

$$k^2 = n_1^2 k_0^2 - \beta^2 \tag{7.10}$$

and in the clad

$$F(\rho) = CK_m(\gamma \rho) + C'I_m(\gamma \rho) \quad \rho > a.$$
 (7.11)

In the clad, the energy decreases exponentially with the distance, with a factor γ given by

$$\gamma^2 = \beta^2 - n_2^2 k_0^2 \,. \tag{7.12}$$

It is possible to simplify the equations by setting

$$\rho \to \infty$$
 $F(\rho) \to 0$ $C' = 0$

$$\rho \to 0 \qquad F(\rho) \to \text{finite} \qquad A' = 0$$
(7.13)

and thus obtaining

$$E_{z} = \begin{cases} A J_{m}(k\rho) e^{im\phi} e^{i\beta z} & \rho \leq a \\ C K_{m}(\gamma) e^{im\phi} e^{i\beta z} & \rho > a \end{cases}$$
 (7.14)

and

$$H_{z} = \begin{cases} BJ_{m}(k\rho)e^{i\phi}e^{i\beta z} & \rho \ge a \\ DK_{m}(\rho)e^{i\phi}e^{i\beta z} & \rho > a \end{cases}$$
 (7.15)

7.2.1.4 Attenuation Mechanisms in Solid-Core Fibers

There are four attenuation mechanisms in solid-core fibers. The mechanisms and their causes are listed in Table 7.1.

7.2.1.5 Reflection

In solid-core fibers the difference in the index of refraction between the core and the entrance and exit surfaces causes backward reflection of some of the radiation. The amount of energy reflected depends on the difference between the index of refraction and the angle of incidence. If the ray impinges perpendicularly to the boundary the refection coefficient is given by

$$R = \left(\frac{n_1 - n_2}{n_1 + n_2}\right). \tag{7.16}$$

7.2.1.6 Scattering

Scattering in solid-core fibers can be divided into two categories: intrinsic scattering and extrinsic scattering. Mie, Rayleigh, Brillouin, and Raman are the four intrinsic scattering mechanisms. Mie and Rayleigh scattering are caused by inhomogeneity in the index of refraction, granulation of the fiber material, or geometric faults in the fiber. These mechanisms cause elastic scattering, i.e., the wavelength of the radiation does not change in the process. The attenuation is proportional to λ^{-4} and is the lower limit to the losses in the fiber.

Brillouin scattering is caused by interaction of the photon with acoustic phonons. Raman scattering is caused by interaction of the photon with acoustic photons, which changes the wavelength of the radiation.

Extrinsic scattering is caused by impurities in the fiber materials, faults during manufacturing, and the like. It is possible to decrease the effects of this type of scattering by closely controlling the manufacturing process of the fiber.

7.2.1.7 Absorption

When radiation propagates through a certain material, some of the energy is transferred to heat — a phenomenon known as *absorption*. All absorption mechanisms involve moving particles (molecules or electrons) from one energy level to another. The absorption process must satisfy the following condition:

$$\lambda = \frac{hc}{\Delta E} \,, \tag{7.17}$$

where ΔE is the difference between the energy levels.

TABLE 7.1 Loss Mechanisms in Fibers

Attenuation Mechanism	Cause
Reflection (Fresnel losses)	Difference in index of refraction at the entrance and exit surfaces of the fiber
Scattering	Intrinsic — Mie, Rayleigh, Brillouin, Raman
	Extrinsic — impurities and defects
Absorption	Intrinsic — material
	Extrinsic — impurities
Radiation	Mode coupling

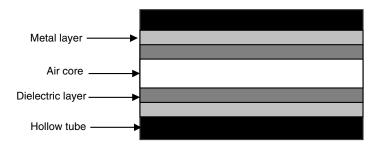

FIGURE 7.7 General structure of a hollow waveguide.

Intrinsic absorption depends on the material and determines the range of wavelengths that the material transmits. Electronic absorption occurs at the UV range, while multiphonon absorption occurs at longer wavelengths when the wavelength corresponds to an integer multiplication of the resonance frequency. Extrinsic absorption is caused by microscopic faults in the fibers, irregularities in the core materials, and impurities.

7.2.1.8 Radiation

Radiation losses are due to inappropriate coupling between the fiber and the laser beam, fiber bending, and intermodal interaction. Inappropriate coupling causes some of the rays to violate the total reflection condition and thus not to propagate through the fiber. Bending causes the rays to change their angle of incidence, and some may leave the fiber. Bending also causes coupling between low modes of propagation to higher ones. Since low modes are less attenuated, the attenuation of the fiber increases.

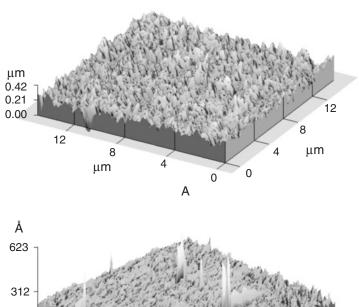

7.2.2 Hollow Waveguides^{5,6}

7.2.2.1 Hollow Waveguides Basics

The general structure of a hollow waveguide (Figure 7.7) consists of a hollow tube internally coated with a metal layer and a thin dielectric layer. (The dielectric layer is optional.) The optical radiation is guided through reflection from the inner layers. Hollow waveguides are characterized by guiding mechanism of the radiation. There are two types of hollow waveguides: (1) leaky waveguides, which have the same structure as that shown in Figure 7.7, and (2) attenuated total reflection (ATR) waveguides, which are made of hollow tubes. The tube index of refraction is lower than that at a region of wavelength; hence, its guiding mechanism is similar to that of solid-core fibers.

7.2.2.2 Attenuation Mechanisms in Hollow Waveguides

The main attenuation mechanisms in hollow waveguides are reflection from a thin layer and scattering due to surface roughness. The first mechanism determines the wavelength that will be transmitted through the waveguide and how much it will be attenuated. In this case, the reflection coefficients are given by Fresnel equations.

312 0 12 μm 4 0 0 4 μm B

FIGURE 7.8 AFM measurements for glass waveguide's Ag layer (A) and AgI layer (B).

The second mechanism, scattering, is caused by the roughness of the hollow tube and the deposited layers. Figure 7.8 shows the surface of Ag and AgI layers deposited on a glass tube. The measurement was made using an atomic force microscope (AFM). Measurements of the surface roughness and the height distribution enable us to compute the scattering coefficient⁷ and the influence of different parameters on the waveguide's attenuation. The main influence of scattering on the ray propagation is to change the ray's propagation angle and energy distribution. Some of the energy is reflected backward and is lost; the angle of incidence of the other part is changed (usually decreased).

7.2.2.3 Ray Theory

One advantage of hollow waveguides is their ability to be "tuned" to almost any wavelength. The tuning is done by coating the metal layer with a thin dielectric layer, whose thickness corresponds to the desired wavelength. This can be seen from the following equation for the reflection coefficient from a thin layer:

$$r_{\text{tot}} = \frac{r_2 + r_1 e^{-2i\delta}}{1 + r_1 r_2 e^{-2i\delta}},$$
(7.18)

where $r_{1/2}$ are Fresnel coefficients from a layer and δ is a phase shift that determines the wavelength and is given by

$$\delta = \frac{2\pi}{\lambda} n_1 d\cos(\phi_1) \tag{7.19}$$

To analyze the influence of the waveguide's geometrical parameters, let us calculate the distance that a ray passes between two hits on the waveguide wall; z_i can be calculated using Figure 7.9 and is given by

$$z_i = 2r \tan(\phi_i), \tag{7.20}$$

where r is the waveguide radius. The number of times the ray impinges on the waveguide wall of length l, p_i is given by

$$p_{i} = \inf\left(\frac{l}{z_{i}}\right) = \inf\left(\frac{l}{2r\tan(\phi_{i})}\right). \tag{7.21}$$

The total reflection coefficient of the ray, the multiplication of all the reflections it passed on the way, is given by

$$R_{\text{total}}(\phi_i) = R(\phi_i)^{p_i}. \tag{7.22}$$

The transmission, T, and the attenuation, A, are given by

$$T_{i} = \frac{I_{i,\text{out}}}{I_{i,\text{in}}}$$

$$A_{i} = -10\log(T)$$
(7.23)

More explicitly, the attenuation may be written as

$$A_{i} = -10 \left[\inf \left(\frac{1}{4r \tan(\phi_{i})} \right) \log(R(\phi_{i})) \right]. \tag{7.24}$$

From the last equation one can learn about the dependence of the waveguide's attenuation on its physical dimensions. It can be seen that, when the waveguide's length increases or its inner radius decreases, the attenuation increases.

As the preceding analysis shows, ray models explain the working principles of fibers and waveguides in a simple manner. A more complicated way is to solve Maxwell equations with the appropriate boundary

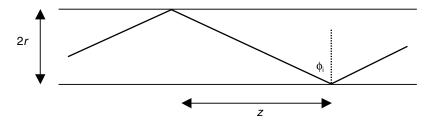

FIGURE 7.9 Representative ray in a waveguide.

conditions. This may provide additional knowledge about the different modes that may propagate through the waveguide.

7.3 Multilayer Waveguides

One way to overcome the attenuation mechanisms in solid-core fibers and hollow waveguides is to develop a new type of fiber, a multilayer one. The general structure of a multilayer fiber is shown in Figure 7.10. A multilayer waveguide is made of an alternating structure of two dielectric materials. Such a structure is also known as a photonic crystal. There are two ways to analyze such a structure. The first way⁸ is to use the symmetry properties of the system and quantum mechanics techniques to solve the Maxwell equation. This approach leads to an equation similar to the Bloch equation in solid-state physics. According to Bloch theory, forbidden band gaps exist through which photons (electrons in solid-state physics) with certain energies cannot propagate. In this case the photons are "perfectly" reflected; thus, such a device can have zero attenuation.

The second method is to solve the Maxwell equation with the appropriate boundary conditions. Consider the linearly polarized wave shown in Figure 7.11, impinging on a thin dielectric film between two semi-infinite transparent media. Each wave E_{rl} , E'_{rll} , E_{lll} , and so forth, represents the result of all possible waves traveling in that direction, at that point in the medium. The summation process is therefore built in. The boundary conditions require that the tangential components of the electric field, **E**, and the magnetic field, **H**, be continuous across the boundaries.

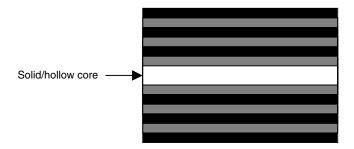

FIGURE 7.10 Schematic drawing of a multilayer waveguide.

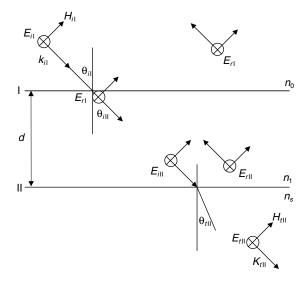

FIGURE 7.11 Fields at the boundaries.

By applying the boundary conditions and using the Maxwell equation, it is possible to relate the fields on each side of the boundary. The relations are given by

$$\begin{bmatrix} E_{\mathrm{I}} \\ H_{\mathrm{I}} \end{bmatrix} = \begin{bmatrix} \cos(k_{0}h) & (i\sin(k_{0}h)) \\ Y_{1}i\sin(k_{0}h) & \cos(k_{0}h) \end{bmatrix} \begin{bmatrix} E_{\mathrm{II}} \\ H_{\mathrm{II}} \end{bmatrix}$$
(7.25)

or

$$\begin{bmatrix} E_{\rm I} \\ H_{\rm I} \end{bmatrix} = M_{\rm I} \begin{bmatrix} E_{\rm II} \\ H_{\rm II} \end{bmatrix}, \tag{7.26}$$

where

$$Y_{1} \equiv \sqrt{\frac{\varepsilon_{0}}{\mu_{0}}} n_{1} \cos \theta_{iII} \tag{7.27}$$

or

$$Y_{1} \equiv \sqrt{\frac{\varepsilon_{0}}{\mu_{0}}} \frac{n_{1}}{\cos \theta_{\text{ill}}}$$
 (7.28)

for TE polarization and TM polarization, respectively. The same equations hold for the second and third boundaries. It follows, therefore, that if two overlaying films are deposited on the substrate, there will be three boundaries or interfaces, and now:

$$\begin{bmatrix} E_{II} \\ H_{II} \end{bmatrix} = M_{II} \begin{bmatrix} E_{III} \\ H_{III} \end{bmatrix}. \tag{7.29}$$

Multiplying both sides of this expression by M_b , we obtain

$$\begin{bmatrix} E_{\rm I} \\ H_{\rm I} \end{bmatrix} = M_{\rm I} M_{\rm II} \begin{bmatrix} E_{\rm III} \\ H_{\rm III} \end{bmatrix}. \tag{7.30}$$

In general, if p is the number of layers, each with a particular value of n and h, then the first and the last boundaries are related by

$$\begin{bmatrix} E_{\rm I} \\ H_{\rm I} \end{bmatrix} = M_{\rm I} M_{\rm II} \dots M_{p} \begin{bmatrix} E_{p+1} \\ H_{p+1} \end{bmatrix}. \tag{7.31}$$

The characteristic matrix of the entire system is the result of the product (in the proper sequence) of the individual 2×2 matrices, that is,

$$M = M_{\rm I} M_{\rm II} \dots M_{\rm p} = \begin{bmatrix} m_{11} & m_{12} \\ m_{21} & m_{22} \end{bmatrix}$$
 (7.32)

From the above equations we can derive the reflection and transmission coefficients. Defining Y_0 and Y_s for the medium and substrate, the reflection and transmission coefficients are given by

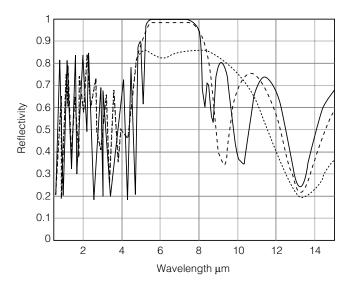

FIGURE 7.12 Transmission as a function of wavelength (6-µm optimized waveguide).

$$r = \frac{Y_0 m_{11} + Y_0 Y_s m_{12} - m_{21} - Y_s m_{22}}{Y_0 m_{11} + Y_0 Y_s m_{12} + m_{21} + Y_s m_{22}}$$
(7.33)

and

$$t = \frac{2Y_0}{Y_0 m_{11} + Y_0 Y_s m_{12} + m_{21} + Y_s m_{22}}$$
 (7.34)

To find r or t for any configuration of films, we need only compute the characteristic matrices for each film, multiply them, and then substitute the resulting matrix elements into the above equations.

As an example, let us design a multilayer mirror for a laser with a wavelength of 6 μ m. We use two dielectric materials that have indices of refraction far apart. Such materials could be germanium (n=4) and zinc selenide (n=2.4). Figure 7.12 shows the reflectivity of a multilayer film made of a different number of pairs of Ge and ZnSe as a function of wavelength for a 0° angle of incidence. As the figure shows, the more pairs, the sharper the region where the reflectivity is perfect. Attempts to create photonic crystal fibers have been made by several groups in the United States, Denmark, England, Australia, and Israel. $^{10-12}$

7.4 X-Ray Waveguides

X-ray radiation has been used for imaging in medicine for more than a century. X-ray laser sources have made new x-ray applications available. However, x-ray radiation is difficult to manipulate because it is very energetic. The conventional way to focus x-ray radiation is coherently by using Fresnel zone plates and Bragg Fresnel lenses or incoherently by using bent crystal optics and coated fibers. The main drawback to these methods is the large spot size, which is unsuitable for most applications (x-ray spectroscopy and microscopy), particularly noninvasive medical treatments, which require waveguides.

To overcome the drawbacks of focusing lenses and crystal, Feng and co-workers¹⁴ suggested a new device composed of a law density layer, such as carbon, surrounded by two high-density layers, such as nickel (Figure 7.13). They showed experimentally and theoretically that such a device may produce an

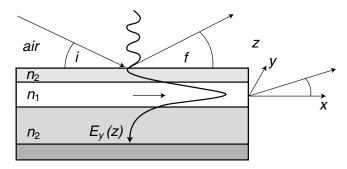

FIGURE 7.13 Single-layer x-ray waveguide. (Courtesy of Prof. Salditt's group, Saarbrücken, Germany.)

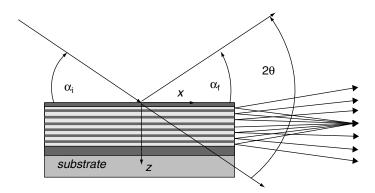

FIGURE 7.14 Multilayer x-ray waveguide. (Courtesy of Prof. Salditt's group, Saarbrücken, Germany.)

x-ray beam with defined beam shape, divergence, and coherence, which corresponds to the geometrical properties of the device.

Grazing angle incidence couples the x-ray beam to the device. Because only a discrete set of angles can propagate through the device, the output should be coherent and its spot size should correspond to the low-density layer thickness. Using such a device, Feng et al. produced an x-ray beam with spot size of less than 100 Å. However, a single layer structure also has drawbacks. Beam shape control is difficult because it corresponds to the geometrical structure that can produce only a single spot. Coupling efficiency is very limited, even poor, because a single layer has a very small angular acceptance.

Pfeiffer et al.^{15,16} suggested a multilayer structure to overcome the single layer structure drawbacks. The new structure (Figure 7.14) consists of one or more guiding layers and enables generation of more complicated beam shapes (Figure 7.15). This new concept enables new ways to perform x-ray spectroscopy and holography.

7.5 Coupling Devices

The laser beam can be coupled to the fiber in several ways. The first and most straightforward way is to use standard lenses. Other and more sophisticated ways involve different types of tapers. 17,18

Coupling the laser beam into the fiber using an ordinary lens is simple. All one has to do is to ensure that the focused laser spot size is less than the fiber's core diameter, that the NA of the lens is suitable to that of the fiber, and that the optical axis of the lens and the fiber are aligned.

The laser spot size at the entrance to the waveguide is given by

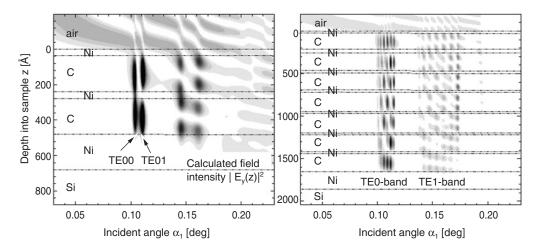

FIGURE 7.15 Field distribution of different multilayer x-ray waveguide. (Courtesy of Prof. Salditt's group, Saarbrücken, Germany.)

$$\omega_0 = \frac{1.9\lambda f}{D} \tag{7.35}$$

where f is the focal length of the coupling lens, D is its diameter, and λ is the laser wavelength. The maximum angle (i.e., the angle that determines the NA) at the entrance of the fiber is given by

$$\tan(\varphi) = \frac{D}{f} \tag{7.36}$$

If the laser spot size is larger than the core diameter of the fiber, then some of the energy will enter the fiber clad and be lost. Furthermore, if the laser beam is energetic enough it can cause damage to the fiber. If the NA of the focal end is greater than that of the fiber, then some of the rays will not be guided through the fiber, i.e., they would be lossy rays.

An alternative way to couple a laser beam into a fiber is to use a taper — a device that is attached to the fiber (see Figure 7.16). A taper increases the angle propagation through the waveguide and thus decreases the attenuation. Furthermore, because the taper changes the angle of propagation through the fiber it also functions as a higher mode filter or coupler, i.e., it couples higher modes of propagation to lower modes of propagation.

Let us look at a laser beam with a divergence angle, θ , and a fiber with an NA that corresponds to a certain angle, ϕ , as depicted in Figure 7.16. We want to find the angle β of the taper that would enable us to couple the laser beam into the fiber successfully, i.e., a ray that emerges from the laser with an angle equal to θ will propagate through the fiber.

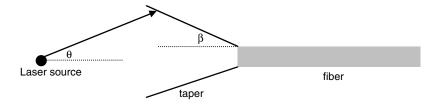

FIGURE 7.16 Tapering.

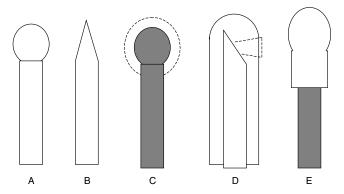

FIGURE 7.17 Types of fiber tips: (A) ball shape; (B) tapered; (C) diffusing probe; (D) side firing; (E) metal probe.

FIGURE 7.18 Waveguide with input taper and ball shape distal tip.

A simple geometric calculation shows that the angle β equals

$$\beta = \frac{\phi - \theta}{2} \,. \tag{7.37}$$

7.6 Distal Tips

Although coupling the laser beam into the fiber is very important, in many medical applications, controlling the beam shape at the fiber's exit is equally important. Laser beam manipulation at the end of the fiber is done using different types of tips (see Figure 7.17). The tips can be made by polishing the fiber materials (in the case of solid-core fiber) or from different materials adhered to the fiber.

The different tips play different roles in the various types of medical application. A few examples are described here (see Figure 7.17). Tip C is used in photodynamic therapy (PDT)¹⁹ application where radiation should diffuse to the surrounding area. Tip D is used in side firing of the laser beam to ablate tissue in the esophagus or colon. Tip E is used in thermotherapy.²⁰

We now examine the change in beam shape when an input taper and a ball-shape distal tip are added to a straight waveguide. We performed ray tracing on a straight waveguide and drew the beam shape of the emerging radiation at 20 cm after waveguide output. The result is shown in Figure 7.19. We have added an input taper and a ball shape distal tip and recalculated the beamshape in the new conditions. The results are shown in Figure 7.20.

The focusing of the beam is easily observed. Another advantage of the ball is that is seals the waveguide and enables work in liquid medium, such as in body cavities.

7.7 Materials for Fabrication of Optical Fibers and Waveguides

7.7.1 Silica Fibers^{21–24}

Silica fibers constitute the backbone of optical communication and are manufactured by many companies. The first silica fibers, manufactured by Corning in the mid-1970s, had an attenuation of about 20 dB/km. The manufacturing process had steadily improved, and attenuation has almost reached its theoretical

FIGURE 7.19 Energy distribution at the output of a straight waveguide.

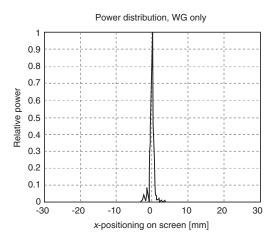

FIGURE 7.20 Beam shape at the a distance of 20 cm after the addition of the input taper and distal tip.

limit. (The typical attenuation of a silica fiber is about 0.2 dB/km.) The spectral range of the fibers begins at the UV region (200 nm) and ends at the NIR (2000 nm). These fibers are useful for telecommunication, medical applications, power delivery, and remote sensing.

Silica fibers are solid-core fibers. Their basic structure is core clad; the core is made of silica (SiO₂) and the clad is made of silica doped with other elements such as germanium (Ge), boron (B), fluoride (F), etc. Doping the clad is needed in order to change its index of refraction. The fiber is coated with a plastic material (polyimide) that protects it and improves its bending capabilities. Depending on the core diameter, the fiber can transmit either single-mode or multimode radiation. The fiber can be drawn at any length and its transmission characteristics are easily analyzed using conventional ray-tracing models.

It is possible to change the transmission characteristics by manufacturing multicomponent silica glasses, in which silica is less than 75%/w, or by high silica content fibers, in which silica comprises more than 90%. It was hoped that these types of fibers would have better transmission capabilities; however, impurities in these fibers increase scattering and high OH concentration increases absorption, thus increasing attenuation. Furthermore, multicomponent glasses have intrinsically lower strength and radiation hardness, while high-content silica fibers are very sensitive to moisture. These drawbacks limit their applications.

TABLE 7.2 Types of Hollow Waveguides

Tube	Metal Layer	Dielectric Layer	Group
Teflon, polyimide, fused silica, glass	Ag	AgI	Croitoru et al.
Nickel, plastic, glass, fused silica	Ag, Ni, Al	Si, ZnS, Ge, polymers	Miyagi et al.
Plastic, glass, fused silica	Ag	AgI	Harrington et al.
Silver	Ag	AgI	Morrow et al.
Stainless steel	Ag, Al, Au	ZnSe, PbF ₂	Laakman et al.

The OH concentration within the silica determines the transparency of the fiber. Although low OH concentration is needed for transmission in the IR region, a higher concentration contributes to a large transmission in the UV.

7.7.2 Hollow Waveguides^{25–39}

Hollow waveguides were initially developed for IR radiation delivery, but they may be adapted to almost any wavelength. The basic structure of a hollow waveguide is shown in Figure 7.6. A hollow waveguide consists of a hollow tube (glass, fused silica, plastic, etc.), internally coated with a metal layer (silver, nickel, gold, etc.) and a dielectric layer (AgI, Se, Ge, polymers).

Hollow waveguides are made from nontoxic materials. They have low attenuation (less than 1 dB at the IR region) and deliver high laser power (1 kW of CO₂ laser was demonstrated). They may be tuned to any desired wavelength by adapting the thickness of the dielectric layer and choosing the appropriate tube and inner layers. These characteristics explain why hollow waveguides are suitable for many medical applications.

Over the years most research on hollow waveguides concentrated on developing hollow waveguides for the mid-IR region because of the lack of materials and fibers with desirable characteristics needed for medical applications. Until now, different hollow waveguides have been developed for the IR region, especially for wavelengths of interest for medical applications.

Several research groups around the world have investigated hollow waveguides. Table 7.2 shows different hollow waveguides for different lasers. Their attenuation of a straight waveguide varies between 0.2 and 1 dB/m, depending on tube roughness and laser wavelength.

Another type of hollow waveguide is attenuated total reflection (ATR). These waveguides exploit the anomalous dispersion phenomena. Anomalous dispersion means that, at a certain wavelength, the material has an index of refraction of less than one. In this case, the guiding mechanism of the ATR waveguide is similar to that of a solid-core fiber.

7.8 Fibers for the IR Region

Silica fibers are suitable for a wide range of wavelengths from the UV to the NIR. Their manufacturing process is well controlled; hence, their low attenuation. This type of fiber is suitable up to 2000 nm, beyond which there is a need for new materials and fibers. For the past three decades intensive research has been conducted to develop optical fibers for the mid- and far-IR regions. One solution, hollow waveguides, was described in Section 7.7.2.

7.8.1 Glass Fibers

There are several glass-based fibers for the IR region. Silica-based fibers were discussed in Section 7.7.1. Other types are fluoride-based glass and chalcogenide fibers.

7.8.1.1 Fluoride-Based Glass⁴⁰⁻⁴²

Fluoride glass fibers are based on ZrF₄. They offer many advantages over silica-based glasses. Their theoretical attenuation is about 0.01 dB/km, which is an order of magnitude lower than that of silica.

TABLE 7.3 Attenuation of Chalcogenide Fibers

Chalcogenide Glass	Attenuation [dB/m]	Wavelength [µm]
Selenide	10	10.6
Sulfide	0.3	2.4
Telluride	1.5	10.6
	4	7

This is due to a shift to longer wavelength in phonon absorption. They also posses a negative thermooptic coefficient and are good hosts for rare earth elements. Such characteristics make fluoride glass fibers good candidates for optical fiber communications, laser amplifier, and chemical sensing applications.

Over the years different compounds of fluoride glass were investigated. The first compounds were composed of BeF₂. These compounds are very stable and resistant to damage. They are transparent in a wide region of wavelengths including the UV. However Be is a very toxic element and the hygroscopic nature of the compound make it difficult to handle, thus eliminating potential medical applications.

Other fluoride compounds are heavy metal fluoride glasses that include fluorozirconate (ZrF₄). Such compounds are ZB — ZrF₄–BaF₂, ZBT, and ZBL, which are ZB that include ThF₄ and LaF₃, respectively. Others are ZBLA–ZrF₄–BaF₂–LaF₃–AlF₃ and ZABLAN — ZrF₄–BaF₂–LaF₃–AlF₃–NaF. The main disadvantage of ZB is its instability. Adding other components to the compound increases its stability.

All fluoride glasses are transparent from the UV to the mid-IR and some of them even to the far-IR. However, it is difficult to achieve the ultralow loss that is predicted, especially due to bubble formation during fiber drawing, microcrystalization, and material contamination. Typical fluoride fiber loss is on the order of 10 dB/km.

7.8.1.2 Chalcogenide Fibers^{43–45}

Chalcogenide glass is formed when elements from groups 4B and 5B, such as As, Ge, Pb, Ga, Si, etc., are melted into silica glass. There are three groups of chalcogenide glass: sulfide, selenide, and telluride. The transparency of the glass depends on the glass composition. Sulfide glass is transparent in the visible region, while incorporating selenide or telluride into the glass shifts the transparency into the IR region.

Mechanical properties also depend on the glass composition. Although the mechanical strength and thermal stability are lower than those of silica glass they are sufficient for fiber drawing and typical fiber applications. The attenuation of chalcogenide glass also depends on the glass compound. Table 7.3 summarizes the attenuation of the different kinds of chalcogenide fibers.

The main drawback of these fibers is their poisonous nature. This characteristic makes them difficult to handle and limits their use in medical applications, unless protective coating is added.

7.8.2 Crystalline Fibers

About 100 crystalline materials are transparent in the infrared region. Most of these materials have similar optical characteristics but very different mechanical properties. Although transparency in a desired wavelength region is imperative, the mechanical strength and durability of the fibers cannot be overlooked.

7.8.2.1 Single-Crystal Fibers

Single-crystal materials have many advantages. It is possible to obtain a very pure material, thus over-coming scattering from impurities in the fiber material. Most of the materials have a high melting point, which makes them suitable for laser power delivery. They are also chemically inert, and thus can operate in harsh environments. An example of such a material is sapphire.

These materials also have drawbacks. Unlike silica fibers that can be drawn to considerable length, single-crystal fibers have to be grown from a melt; thus, long fibers are difficult to manufacture. Some of the crystals are poisonous and brittle.

- Sapphire fibers. $^{46-48}$ Sapphire is transparent up to 3.5 μ m. These fibers are grown at very low rates (about 1 mm/min). They are made as core-only fibers and have a core diameter between 0.18 and 0.55 mm. Their attenuation is 2 dB/m at 2.93 μ m and maximum power delivery is 600 mJ. Sapphire fibers have very good mechanical properties. They have a high melting point and mechanical strength. They are chemically inert, insoluble in water, and biocompatible. These properties make them good candidates for medical applications.
- AgBr.⁴⁹ These fibers are manufactured by a pulling method, in which the material is heated and then pulled through a nozzle, or by pressing the material through a nozzle. Fibers of up to 2 m have been manufactured using these methods. The attenuation of such fibers is 1 dB/m at 10.6 µm. AgBr fiber may transmit up to 4 W of CO₂ laser.

7.8.2.2 Polycrystalline Fibers

Polycrystalline fibers made of TlBr-TlI (KRS-5), KCl, AgCl, NaCl, and other compounds of heavy metals and halides are attractive because of their low theoretical attenuation. However, the attenuation of the first fibers manufactured was much higher and most of the early research concentrated on finding the origin of that loss.

Although transparency at the desired wavelength region is imperative, polycrystalline fibers must have additional attributes. The material must be deformed plastically in order to enable manufacturing of sufficiently long enough fibers. Furthermore, the crystal must be solid in nature and optically isotropic to avoid intrinsic scattering. Finally, the recrystallization of the material after fiber manufacturing must not impair the fiber optical characteristics. Potential materials for fiber manufacturing are thallium halides and silver halides, which are made using the extrusion method.

- Thallium halides. 50-52 Thallium halides have low theoretical attenuation (about 6.5 dB/km). However, the measured attenuation is much larger, between 120 and 350 dB/km. Scattering caused by material impurities, surface imperfection, grain boundaries, and dislocation lines is the main reason for the large attenuation. These fibers suffer from aging effects. They are soluble in water and sensitive to UV light.
- Silver halide.^{53–55} Silver halide fibers are made of AgCl_xBr_{1-x}. They have very low attenuation at 10.6 μm to 0.15 dB/m. The main reason for the attenuation is bulk scattering, and intrinsic and extrinsic absorption.

7.8.3 Liquid-Core Fibers^{56–57}

Liquid-core fibers are hollow tubes filled with liquid that is transparent in the IR region. The only advantage of these fibers over solid-core fibers is the possibility of obtaining a purer liquid than solid material. The liquids used are C_2Cl_4 , which has a very high attenuation of about 100 dB/m at 3.39 μ m, and CCl_4 , with an attenuation of about 4 dB/m at 2.94 μ m.

7.9 Conclusions

Fibers and waveguides play a major role in the application of lasers in medicine. A great variety of materials are used for laser transmission. Each fiber or waveguide can be used in some applications, but none can be used in all applications. Fibers need to be improved further for better laser transmission, wider range of spectrum, better beam shape at the output of the fibers, higher energy transmission, and ultrashort energetic pulses.

The ultimate optical fiber or waveguide for medical applications has yet to be developed.

8.1 Introduction

Improved detectors, new electro-optical devices, and vastly improved computational power for data analysis have fueled the recent interest in combining biology and spectroscopy. This chapter examines three aspects of biomedical imaging spectroscopy:

- 1. Data acquisition: What instruments are available for acquiring an image cube and what are the performance trade-offs involved in choosing one over the other?
- 2. Data analysis: What are some of the approaches for examining very large and multivariate data sets? We shall see that the remote sensing community, focused primarily on geology, has many tools that can be applied to biomedical data.
- 3. Applications: Which current research areas in biology and medicine can exploit the power of imaging spectroscopy?

It is reasonable to wonder what distinguishes spectral imaging from standard red, green, blue (RGB), full-color imaging. After all, our computer monitors tell us they can display 16.7 million colors — surely that should be enough. To answer this question, we need to understand the difference between "color" and spectral content. Light is composed of photons with different energies. Although we can think of higher-energy (shorter wavelength) photons as "blue" and less energetic (longer wavelength) photons as "red," these color attributes are an artifact of the human visual system. In fact, no simple relationship exists between wavelength content of light and the color we actually perceive. This is (in part) because our eyes (and conventional color film and color digital cameras) allocate visible light, no matter how

spectrally complex, into only about three different color bins: red, green, and blue. Light with completely different spectral content can have precisely the same RGB coordinates, a phenomenon known as metamerism. For example, red light and green light can combine to form yellow. If we see a yellow object, we cannot tell if the color is spectrally pure (as it would be if it were created by a prism or rainbow) or if it arose from a mixture of red and green.

Researchers have used human color vision to interpret images since the first microscope was developed. Although we perceive three spectral bands and cover a relatively narrow range, the human eye is quite sensitive to subtle color differences within that range. When exogenous dyes were used to color cellular structures or molecules differentially, the interpretation still relied on color vision, and more recently, on electronic color cameras. The addition of fluorescent dyes to the microscopist's tool kit began to push the limit of color vision, electronic or otherwise. The standard detection tool kit of fluorescence microscopy is an array of dichroic mirrors, filter cubes, and other filters designed to separate multiple colored probes in absorption or in fluorescence emission. Increasing the number of probes, as biologists want to do, creates so much spectral overlap that filtering cannot separate the probes; i.e., color images of fluorescent probes that differ only slightly spectrally appear the same. In that case, we need to use some sort of spectroscopy.

Spectroscopy usually uses single point detectors that cannot easily sample large areas or small areas at high resolution. On the other hand, imaging spectroscopy can spectrally image large areas, combining the function of a camera (recording spatial information) with that of a spectrometer. These devices can measure the spectral content of light at every point in the image: a 1000×1000 pixel sensor provides 1 million individual spectra. Once a spectral stack is acquired, mathematical approaches ranging from simple to very sophisticated can be used for analysis. Analysis of fluorescence microscopy uses spectral signatures to match each pixel with one of the known probes used in the experiment. Imaging spectroscopy tells us *what* is *where*.

Once properly calibrated, these images can be used to obtain corrected spectrum for each image pixel, which can then be used to identify components in the target. For the geologist, imaging spectroscopy yields compositional maps of geologic sites to show *which* minerals are *where*¹ or to determine the composition of the rain forest canopy.² It can detect agricultural pests,³ drought stress, or fertilizer application levels. Spectral imaging has uses in industrial process control, in detection of ordinarily invisible bruising in fruit, in assessing the viability of transplanted organs,^{4,5} in uncovering forgeries, etc. Finally, modifications in existing designs and novel approaches have made spectral imaging easy to accomplish with a microscope; this combination has promising applications in surgical pathology and molecular biology. Fluorescent dyes, which have recently become available, will increase the usefulness of spectral imaging in a variety of areas, including high-throughput screening, genomics, and clinical diagnostics.

8.2 Spectral Image Cubes

Simply put, an imaging spectrometer acquires the spectrum of each pixel in a two-dimensional spatial scene. As shown in Figure 8.1, the easiest way to think of such a scheme is as band sequential imaging, in which multiple images of the same scene at different wavelengths are acquired. A key point is that the spectra be sampled densely enough to reassemble a spectrum (commensurate with the needs for analysis). A remote sensing instrument may take hundreds more images over the visible to near-infrared (NIR) range. There are many technological means of obtaining these data, and this chapter presents a catalog of current technologies. The images are typically stacked in a computer, from the lowest wavelength to the highest, to create an image cube of the data set. The spectrum of a selected pixel is obtained by skewering it in its third dimension, wavelength, as the inset in Figure 8.1 shows. Although there are many ways of acquiring and storing the data, this representation is band-sequential (often termed BSQ), which the images are stacked like a deck of cards, and resembles a cube with sides x, y, and λ (wavelength). Even if the data are acquired in some other fashion, they can be reconfigured into this mode. Two other data modes are band-interleaved-pixel (BIP) and band-interleaved-line (BIL) modes. In BIP, the spectra of successive pixels are stored sequentially. This is advantageous for computation because the spectrum

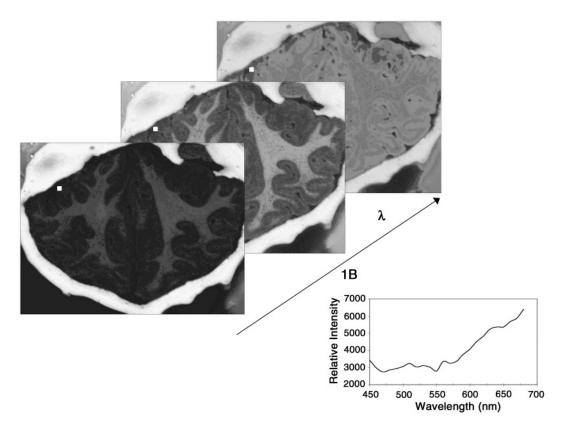

FIGURE 8.1 Basics of imaging spectroscopy. Multiple images of the same scene are acquired at many different wavelengths, as schematically shown. The spectrum of any pixel in the image can be obtained by plotting signal against wavelength over the spectral range available. The images here are from a human brain, imaged after being frozen. The white areas on the side are the frozen matrix that maintains the brain's shape and provide some hydration.

of each pixel can be read directly, as opposed to band-sequential data, where one must read in the entire cube to calculate a spectrum of any given pixel.

8.3 Instruments

Before describing specific instruments, it is worthwhile to compare spectral imaging with what can be accomplished using standard imaging systems based on conventional RGB sensors. Because most such systems rely on single-chip cameras, color images can be acquired in a single exposure, typically at near-video rate. In contrast, most spectral systems require a series of exposures, so improvements in the quality or utility of the data collected should be large enough to justify the potential penalties in cost, and throughput and data acquisition time.

For example, although earlier systems for automated or assisted immunohistochemistry quantitation — a relatively simple problem in color analysis — used grayscale cameras and two or more color filters somewhere in the light path, recent approaches exploit RGB cameras and analytical strategies of varying levels of sophistication and complexity. With automatic thresholding operations, Ruifrok⁶ was able to differentiate between a DAB (brown) stain alone, DAB plus hematoxylin (blue), and hematoxylin alone. More recently, this group has shown that conversion of RGB images into optical density units allowed for more accurate discrimination. However, RGB sensors have intrinsically broad and overlapping regions of spectral sensitivity for their three color channels; this adversely affects unmixing accuracy, especially when separation of similar chromogens is attempted. Thus, for example, a dense brown stain can generate

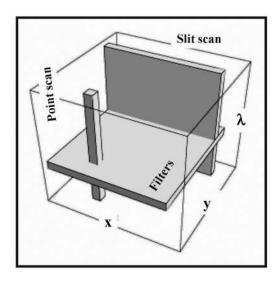

FIGURE 8.2 Schematic illustration of the various approaches requiring spectral image cubes. In each case, it is shown how a technique slices through an (x,y,λ) data set.

a signal in the postanalysis red channel.⁷ While it may be possible to unmix red, brown, and blue using only three input images, the optimal wavelengths and bandwidths will differ from the broad channels provided by standard RGB imaging systems.

Additional technical and practical problems are associated with conventional color imaging. First, many color cameras use a charge-coupled device (CCD) that produces a color-encoded analog signal that is digitized by a computer video board into R, G, and B pixel intensities The fidelity and consistency of such a system can be variable. Section-to-section variability, along with interactions with camera controls such as automatic gain control, can induce fluctuations in the image quality. Because the color of a stained object is a product of the stain's transmittance and the camera's spectral response, it is possible that the camera could sense dyes differing in spectral properties similarly and thus be indistinguishable. Finally, the spatial resolution of single-chip color CCD cameras is typically lower than that of monochrome cameras with the same pixel count because of the color mask and interpolation routines that merge information from three or more pixels when determining RGB and intensity values.

True imaging spectrometers, in some fashion, acquire a three-dimensional data set, spatial (two dimensional) and wavelength as the third dimension. The approaches for instruments traditionally involved scanning one of the dimensions, either acquiring a complete spectrum for each pixel (or line of pixels) at a single shot and then spatially scanning through the scene or, alternatively, taking in the complete scene in a single exposure, and then stepping through wavelengths to complete the data cube. Typically, the light emerging from the imaged object is filtered for spectral content, but it is also possible to control the spectral content of the illumination. Recently, other instruments have been developed that acquire spectral and spatial information in a single exposure, although with some trade-offs.

Figure 8.2 shows an image cube and how different cuts through the data illustrate the different approaches. Some of the terminology comes from the origins of imaging spectroscopy, which involved performing remote sensing from a moving platform. For example, the whiskbroom imaging spectrometer is one in which a single point is scanned perpendicularly (cross track) to the direction of motion. The spectrum of each pixel is acquired with a spectrometer and the data are taken a spectrum at a time, pixel by pixel, along a line. The name comes from the resemblance of the path of the scanned pixels to that of a whiskbroom in action. Similarly, a pushbroom spectrometer images a slit onto a focal plane array; the spatial dimension occupies one axis of the array and the spectrum for each pixel is spread out perpendicularly to it. A complete image is acquired one line at a time as the slit is scanned in the direction of motion. In biological imaging, point-scanning and slit-scanning confocal microscopes use similar

image collection geometries, respectively. In addition to these techniques, which collect spectral data directly, other modalities can require mathematical processing of the intermediate data.

We divide the discussion of instrument types into four general types:

- Spectral scanning: These use electro-optical devices such as liquid crystal or acousto-optic tunable filters, as well as filter wheels, and project complete images onto CCDs or other focal plane arrays. Controlling the spectral content of the illumination source rather than filtering the remitted light can also achieve spectral scanning.
- 2. Spatial scanning: These use either pushbroom or whiskbroom configurations with prisms, gratings, or beam-splitters to create spectral discrimination.
- 3. Interferometric: These typically (but not always) acquire a two-dimensional image and scan optical path differences in some manner to obtain a complete interferogram at each pixel; the data need to be mathematically converted into spectra in wavelength space.
- 4. Other approaches: These include instruments such as the computed tomographic imaging spectrometer and a polarization-dependent rotogram device.

8.3.1 Spectral Scanning Instruments

These instruments are easy to understand and have very simple optics. They consist of imaging optics, a tunable filter of some sort for spectral selection (or a tunable light source), and a camera. Because the components can be in-line or folded, such systems can be made rather compact, suitable for mounting on microscopes or other instruments. The tunable filter can be a mechanical filter wheel, a linear variable filter, or an electro-optical filter that can be tuned electronically.

8.3.1.1 Fixed Filters

The simplest implementation of an imaging spectrometer incorporates a filter wheel equipped with a set of fixed bandpass filters in a rotating mount. A variant often necessary for fluorescence imaging would substitute a set of filter cubes (combinations of dichroic mirrors, excitation, and emission barrier filters) for a simple filter wheel. For applications in which a relatively small number of pre-set and invariant wavelengths are needed, this can be a useful technique. For example, Speicher et al.⁸ have demonstrated fluorescence-based spectral imaging with a filter system generating a combinatorial library of 27 colors, enough to paint all the human chromosomes. Furthermore, compared with other approaches, a filter wheel can be relatively inexpensive and is also quite light efficient (although the latter consideration is not straightforward and can depend on the degree of spectral cross talk tolerated between channels). These instruments have limitations:

- 1. They lack spectral flexibility because only a relatively small number of wavelength choices are available in any one configuration. One could make the filter holder larger to accommodate more filters, but this would increase the size and expense commensurately.
- 2. The performance of the filters can change unpredictably over time due to aging.
- 3. Switching speeds can be low.
- 4. Moving parts create noise and vibration.
- 5. There can be image registration problems due to misalignment of filters.

8.3.1.2 Linear Variable Filters

A linear variable filter can also act as a spectral filtering element for an imaging spectrometer. For such filters, the transmission varies linearly along the filter; at any wavelength, λ_o (or position along the filter), the local transmission is a bandpass filter with a width that is a fixed fraction of λ_o . That width is 1 to 1.5%, depending on the filter, so a typical bandwidth is ~4 to 10 nm over the visible spectrum. One vendor, OCLI, has marketed a spectrometer without a grating, using a linear filter directly on top of a linear CCD detector array. Similar versions are known as circular variable filters (CVF); the transmission changes with rotational angle of the filter.

An optical system with a beam waist can use a linear or circular variable filter to create an imaging spectrometer by inserting the filter at the location of the minimum spot size. Because the filter's transmission is spatially dependent, a large spot size would give a large and spatially varying bandwidth, so the filter is located at a beam waist to reduce the resultant spectral smearing. In this mode, the filter acts like a filter wheel with a large number of filters. Images are acquired at each wavelength and filter translated or rotated to the next wavelength. Kairos Scientific (www.kairos-scientific.com) has developed a system using a circular variable filter that mounts onto a microscope. Surface Optics Corp. (San Diego, CA) has developed an innovative variant based on TDI (time-domain integration) that reads out an imaging array row by row, synchronized to the motion of a spinning CVF (to avoid the problem of spectral smearing). In conjunction with algorithms implemented in hardware, their instrument is capable of acquiring and processing 30 image cubes per second.

8.3.1.3 Tunable Filters

As the name implies, these devices can tune their spectral passband electronically, and without moving parts. Advantages include quiet and vibration-free operation, switching speed, spectral selectivity, spectral purity, and flexibility. Such filters need to meet several important criteria:

- 1. Because the entire image is being filtered, the filter wavelength needs to be constant over the entire image or meet some lower limit for edge effects.
- 2. Introduction of the filter into the optical path cannot introduce (significant) image distortion.
- 3. The tuning time must be commensurate with the dynamics of the experiment.
- 4. Out-of-band rejection must be sufficiently good that dim in-band signals are not contaminated by out-of-band intrusions.⁹

Liquid crystal tunable filters (LCTFs): LCTFs use electrically controlled liquid crystal elements that transmit a certain wavelength band while being relatively opaque to others. The rejection of the unselected wavelengths, without further manipulation, is about 10⁴:1.¹⁰ The bandpass can be as narrow as 1 nm or even less, and the spectral range with a single device can range from 400 to 720 nm in the visible. The LCTF is based on a Lyot filter — a device constructed of a number of static optical stages, each consisting of a birefringence retarder (quartz for LCTFs) sandwiched between two parallel polarizers. A stack of stages function together to pass a single narrow wavelength band. As the incident linearly polarized light traverses the retarder, it is divided into two rays, the ordinary and extraordinary, that have different optical paths given by

$$\Gamma(\lambda) = 2\pi^* \Delta d/\lambda$$
.

where Δ is the birefringence and d is the thickness. After transmission through the retarder, only those wavelengths of light in phase are transmitted by the polarizer and passed on to the next filter stage. The transmission of a stage is

$$T(\lambda) = \cos^2[\Gamma(\lambda)/2],$$

as illustrated in Figure 8.3. The overlap of these continuously varying transmission curves determines which wavelengths are passed by the filter stack as a whole. To introduce tunability, a liquid crystal layer is added to each stage, as shown in Figure 8.3A, that creates minor changes in retardance affecting the position along the spectrum where the curves constructively interact. Tunability is provided by the partial alignment of the liquid crystals along an applied electric field between the polarizers; the stronger the field, the more the alignment and the greater the increase in retardance. Tuning times for randomly accessing wavelengths depend on the liquid crystal material used and the number of stages in the filter. At the moment, commercial devices use nematic components that result in tuning times of approximately 50 to 75 ms.

Polarizers introduce some restrictions into the operating range of an LCTF filter. Plastic sheet polarizers function below ~730 nm and Polarcor glass polarizers are usable from ~630 to 1700 nm. In practical terms,

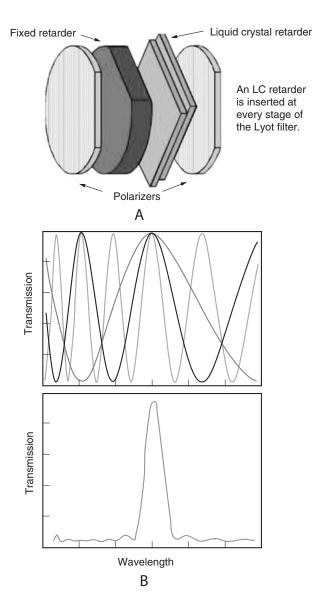

FIGURE 8.3 (A) Operation of a liquid crystal tunable filter. Each successive stage of the filter is used to help cancel unwanted transmission of the previous stages. (B) For a multistage filter, the final transmission is at a fixed peak. Tunability is introduced via the liquid crystal layer in (A), the voltage of which tunes the retardance of each stage. This tunability is used to move the band of constructive interference to the desired wavelength.

the visible to NIR range can be covered from 420 to 1800 nm using three devices available from Cambridge Research and Instrumentation (CRI, Inc.), which address the following spectral regions: 400 to 720 nm, 650 to 1100 nm, and 850 to 1800 nm; each device covers about 1 octave (twofold spectral range).

Although the position of the bandpass is actively tunable, its width is fixed and depends on the construction of the device. A typical bandpass in the visible is ~10 nm, which is wavelength dependent ($\propto \lambda^2$; 10 nm at 550 nm grows to 16 nm at 700 nm). Because the bandpass is related to the number of stages in the device, any bandpass can be designed and fabricated, from 16 cm⁻¹ to 50 nm. The 16 cm⁻¹ device has been used for Raman imaging spectroscopy. The devices are rather spectrally flat over a relatively large aperture (38 mm). Like the AOTF (acousto-optic tunable filter), the LCTF is polarization sensitive, which reduces the transmission by half, unless optical means are provided to harvest both polarization states.

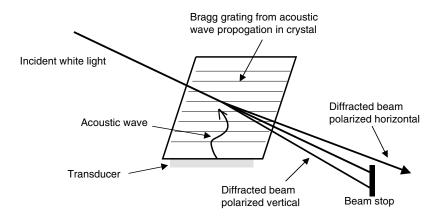

FIGURE 8.4 Operation of an acousto-optic tunable filter. An acoustic wave, launched into a crystal by a transducer, produces a Bragg grating that diffracts the incident light. There are three output beams, a undiffracted beam and two monochromatic ones, one polarized vertically and the other horizontally.

LCTFs work best in a collimated or telecentric optical space, because the maximum f-number that provides an off-axis shift of less than 2 nm at the filter edge is ~2.5. The device operation depends on interference effects, so photons that are significantly off-axis have a different optical path than on-axis photons, creating edge effects. However, because many optics are inherently slower than f/2.5, they can be used before optical elements. One of the authors (Bearman) has taken a number of image cubes of remote scenes with an LCTF mounted in front of a Nikon 135-mm lens operated at f/4, as have others. Similar arrangements are also available commercially from Opto-Knowledge Systems, Inc. (www.oksi.com).

The LCTF approach has been used to create image cubes for biological imaging (see below), confocal microscopy, ¹² and agriculture, and imaging archaeological documents such as the Dead Sea Scrolls. ¹³

Acoustic vave to diffract an incoming beam into a fixed wavelength, as shown in Figure 8.4. As an applied acoustic wave propagates through the crystal, it creates a grating by alternately compressing and relaxing the lattice. Those density changes create a local index of refraction changes that acts like a transmission diffraction grating, except that it diffracts one wavelength at a time, so it behaves as a tunable filter. In practice, the undiffracted zero-order beam is stopped with a beam stop and the monochromatic diffracted beam is available. Changing the frequency (and wavelength) of the acoustic wave changes the grating spacing, adjusting the wavelength of the diffracted beam. In addition, if multiple RF frequencies are launched into the crystal, then combinations of frequencies can be diffracted simultaneously; in this, this filter is more flexible than LCTFs, which generate only a single bandpass at a time.

For visible wavelengths in a tellurium oxide crystal, the applied acoustic wave is RF and can be switched very quickly (typically in less than 50 μ s) compared to other technologies. Unlike an LCTF in which the bandwidth is fixed by the design and construction, an AOTF can vary the bandwidth by using closely spaced RFs simultaneously. There are several standard problems with AOTFs, some of which have been successfully addressed: blurred images and poor out-of-band rejection ($<10^{-3}$). The acoustic wave spreads as it propagates through the crystal so diffracted rays leave at a variety of angles, resulting in blurred images. Use of a compensating prism¹⁴ has significantly improved resolution. Narrowing the acceptance angle and attending to details of crystal fabrication can also overcome image blur and shift, albeit at a cost in light throughput.¹⁵

Both the AOTF and LCTF imaging spectrometers share an important attribute: they make it easy to get very good signal-to-noise spectra, due to the band-sequential nature of their operation. When spanning a wavelength range, say 400 to 720 nm, the sample may have a considerable variation in reflectivity or transmission over that range. In addition, at the blue end of the spectrum CCD sensitivity declines, as does the illumination intensity of many laboratory light sources. As a result, typically less

signal is in the blue relative to the red or green part of the spectrum. However, that can be compensated for by longer integration times at the wavelengths with reduced signal, something not possible with many other devices. In fact, the ideal way to operate a BSQ imaging spectrometer is to set a pixel data target value and integrate at each wavelength as long as necessary to obtain that value, maintaining the signal-to-noise ratio (SNR) at each wavelength. In that case, the *model* raw data spectrum of the target pixel would be a straight line, with the real data contained in the varying integration times for each wavelength. This is a major advantage, especially when there are no restrictions on the data acquisition time.

Spectral leakage can contaminate the acquired spectra. One advantage of the LCTF is a high rejection ratio for out-of-band transmission (10^{-3} to 10^{-5}), critical for recovering spectra that can be compared with those from other laboratories or with standard spectral libraries. LCTFs can be fabricated with larger apertures than AOTFs, although that is not an issue for integration into microscopes, which do not need the large aperture. On the other hand, their major drawback is longer tuning time relative to an AOTF: \sim 30 to 50 ms vs. microseconds for the AOTF. A switching mode for LCTFs is somewhat faster, around 20 ms, but that is for a limited palette of perhaps three to four wavelengths. For situations in which the integration time is photon-limited and the exposure time is \geq 50 ms, the tuning time of either device becomes less of a bottleneck for data acquisition. In fact, it is usually the camera data transfer rate that dominates acquisition time when light is ample.

8.3.2 Spatial Scanning Systems

8.3.2.1 Pushbroom

Lightform, Inc.¹⁶ has developed a pushbroom imaging spectrometer designed to mount to a C-mount camera port. It collects a slit image from the object onto a two-dimensional camera in which the spatial information is displayed along one axis and wavelength information along the other. Wavelength dispersion is provided by a prism. This approach is well suited for scanning gels or searching an object for specific spectral features because the entire spectrum of each pixel in the slit image is available in real time. Because gels are too large to image easily, they can be mechanically scanned with this system. With this approach, the user does not have to collect an entire image cube, but can assemble an image that records hits only for the spectra of interest. If a spectral feature is a known, that feature can be identified in each spectral line scan in real time and used to assemble a classified image without acquiring the entire spectral cube for the whole image field.

8.3.2.2 Interferometers

Rather than scanning in wavelength space, one can also scan in optical-path-difference space and capture an interferogram for each pixel, which is then inverted via the fast Fourier transform (FFT) algorithm to obtain an image cube in wavelength space. Several devices have been developed and one is available commercially. Although seemingly different from instruments that acquire sequential wavelength images, many of the interferometric devices are similar in spirit and suffer from similar problems. Like the BSQ imagers, interferometric imaging spectrometers also require acquisition of many images — sometimes, an order of magnitude more images. For so many images, the data acquisition time may become limited by camera image transfer time.

Applied Spectral Imaging of Israel was perhaps the first company to make a commercially available imaging spectrometer. The device is a common-path Sagnac interferometer in which the interferogram is spread out over a two-dimensional sensor.¹⁷ An optical element changes the optical path difference (OPD) in stepwise fashion, while a CCD (or other technology) focal plane array captures the resulting interference pattern at each step. Because the interferogram moves with each OPD image, object motion is a challenge for this instrument. If the object moves and the images are corrected by re-registering the spatial content to compensate, any errors will show up as incorrect interferograms and propagate into the spectra after inversion. The ASI instrument has been used for cytogenetics¹⁸ and cell pathology,¹⁹ to name a few applications.

Itoh²⁰ has developed another interferometric device that uses a tilted and wedged lens array and mirrors to acquire all the necessary images at different OPD *simultaneously* on a two-dimensional imager. Itoh has demonstrated imaging of rapidly moving objects with this approach, a laser ablation plume, and rotating (1800 RPM) targets. Because all the multiple images must be acquired on a single detector, there is a trade-off between image size and spectral resolution.

One problem with interferometers is that of the center burst (OPD = 0), which is quite bright relative to the rest of the fringes. The detector is an imager, so the integration time or illumination intensity must be reduced sufficiently to avoid saturation (or blooming) for pixels at the center burst, thereby reducing the fringe contrast farther out in the interferogram. The reduced fringe contrast decreases the signal and results in increased noise in the image cube in wavelength space.

Considerable discussion has taken place in the literature about the relative photon efficiency of interferometers compared to scanning instruments. Although on the surface the interferometer appears to have a substantial advantage over other approaches due to the fact that it collects all the spectral information simultaneously,²¹ several papers^{22,23} have argued that, for real instruments with read-noise and other noise sources, this advantage disappears in most imaging regimes. Furthermore, in the spectrally sparse scenes typical of fluorescence imaging, in which signals occupy only a fraction of the total spectral range, the ability of tunable filters to capture images only at informative wavelengths improves their performance relative to interferometer-based approaches that need to collect all wavelengths, informative or not.

8.3.3 Other Approaches

8.3.3.1 Rotogram

Microcosm, Inc. (Columbia, MD) recently developed an imaging spectrometer using a new spectral imaging technique based on the phenomenon of the dispersion of optical rotation. Engure 8.5 schematically represents the optical layout of the HSI (hyperspectral imager) with polarizers at the input and output of an optically active rotating medium. The polarization plane of linearly polarized light is rotated during propagation through the optically active rotator element so that the rotation angle, $\varphi(\lambda)$, of the plane of polarization of the output light depends on the wavelength of the light and the path length through the optically active rotator element. The path length through the active medium can be varied,

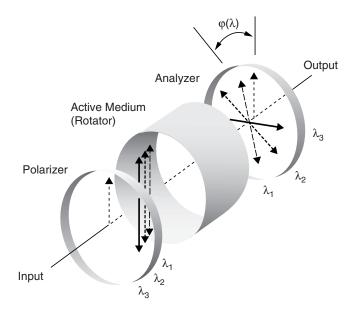

FIGURE 8.5 Operation of the microcosm imaging spectrometer.

thus incrementally increasing the rotation of each wavelength component present. After passing through the output polarization analyzer, an intensity function is measured for each incremental polarization path length. This arrangement permits the wavelength-dependent polarization rotation to be uniform over a large two-dimensional aperture so a CCD is a suitable detector. The intensity function resulting from a stack of images can be analyzed by mathematical methods at any pixel in the image to yield a highly accurate spectrum at each point in the image. As with several data acquisition methods, some computation is required for reconstructing the image cube.

Like the LCTF or the AOTF, the transmission is polarization dependent. The unit will transmit 40 to 45% of the incoming unpolarized light depending upon the rotator material. If the incoming light is polarized, then the throughput efficiency can reach 85 to 90%. The HSI can have a large clear aperture that provides excellent light coupling through the device for the use of wide-field spectral imaging. It does not induce any beam deflection or image movement and can be used in-line with almost any imaging system. In a different configuration, the HSI is suitable for use with a point-scanning device such as laser scanning microscopes or, alternatively, the classical pushbroom and whiskbroom configurations.

8.3.3.2 Computed Tomographic Imaging Spectrometer (CTIS)

A recent approach to imaging spectroscopy is tomographic imaging, as illustrated in Figure 8.6. With this technique, diffractive optics disperse the spectral and spatial information of each pixel onto an imaging sensor; an image cube in wavelength space is reconstructed from a *single* image. Because it turns out that the mathematics of the reconstruction is the same as tomographic imaging, such devices are known as computed tomographic imaging spectrometers (CTIS). Originally proposed by several researchers^{25,26} in the early 1990s, they have been further developed by Volin et al.²⁷

A diffractive optical element operating at multiple orders creates an array of images on the sensor. Development of techniques for fabricating the grating with e-beam lithography has been the main driver in development of this instrument. It is important to note that each image is not simply composed of single wavelengths; information is multiplexed over the entire array. Figure 8.6 shows how the diffractive disperser distributes the spectrum of a single pixel. Note the zero-order image, which can be used for focusing — a difficult task for many spectral imagers. A calibration matrix is necessary to perform the reconstruction; it is obtained by measuring the location on the image plane of pixels in the object plane at different wavelengths with a movable fiber optic coupled to a monochromator. A CTIS can operate over a large wavelength range, easily from 400 to 800 nm, and, with the proper detector, can operate in the IR or UV. The data from a single image can be reconstructed in a variety of ways to adjust image size and wavelength bands. For example, an image can be reconstructed with 128×128 pixels with 20 bands or 64×64 pixels and 32 bands, using the *same* data set. The only difference between the two reconstructions is the calibration matrix.

A major advantage of the CTIS is speed. Because it takes a single image that contains all the spectral/spatial data, it can be run at video rates,²⁷ assuming sufficient light and a high-speed camera (since a large pixel array is typically required by this method). This potential speed makes it suitable for studies such as endoscopy and rapid processes that other instruments cannot handle. Alternatively, it is useful for collecting ratiometric data because all wavelengths are acquired simultaneously. A major issue with spectral imagers has always been bandwidth — they tend to produce enormous amounts of data that present downlink or transmission problems. For example, a satellite hyperspectral imager can produce hundreds of gigabytes of data a day. In the same vein, a remotely sited or operated imaging spectrometer can easily present significant bandwidth demands for data transmission in a power-limited environment (power = bandwidth for telecommunications).

CTIS devices have been used for some real-world imaging studies; Descour et al. have demonstrated ratiometric pH-imaging with standard probes using a CTIS,²⁹ while Ford et al.³⁰ used one for toxicology studies. In both cases, the device allowed capture of the entire spectrum of fluorescent probes at once.

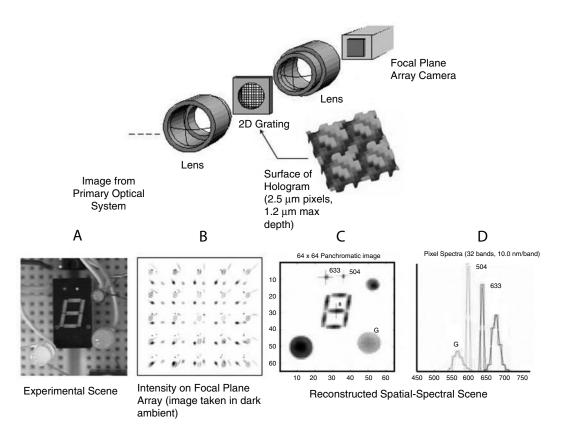

FIGURE 8.6 Computed tomographic imaging spectrometer. A diffractive grating, written by e-beam lithography, multiplexes the spatial and spectral information of a single pixel onto many sensor pixels. (A) The observed scene, consisting of three color LEDs, a HeNe laser spot, and an eight-segment indicator. (B) The resulting image from the focal plane. There is a zero-order image (C) that can be used for focusing as well as providing an initial starting point for the reconstruction of the image cube. (D) Recovered spectra.

8.3.3.3 Hadamard Transform Imaging Spectroscopy

Hadamard transforms have been used for spectroscopy for some time³¹ and have been adapted to fluorescence microscopy. The fabrication of large-format liquid crystal spatial modulators has made this application possible because they can create the Hadamard masks rapidly and with no moving parts. In a series of papers, Jovin and colleagues have developed this implementation of imaging spectroscopy and microscopy.³²

Like the CTIS or an interferometer, the Hadamard transform spectrometer requires computation to reconstruct the image cube in wavelength space. However, it also requires a large number of images; for example, Hanley reports acquiring 511 images in ~11 min with 5 min of computation to transform the data. Increasing optical efficiency can clearly reduce some of the data time but, like the interferometer, the basic nature of the device requires many images.

8.3.3.4 Fiber-Optic Image Compression

Several groups have developed fiber-optic-based systems that acquire spectral image cubes using a combination of a spectrograph, two-dimensional detector, and a custom fiber bundle. The fiber bundle has a two-dimensional input but the output is reordered into a line, which then serves as the input for a spectrograph. The spectrograph output is a two-dimensional image, containing the spatial pixel in one direction while the other dimension is the spectrum of that pixel. Myrick has constructed such a system³³ and used it to image laser ablation plumes.³⁴ This is, in fact, the same data format as that of

a pushbroom imaging spectrometer, except that the input now represents a scrambled two-dimensional image, rather than a line imaged across an object. Similarly, Amotz has used a fiber-optic compression system for Raman imaging with a 61-bundle (pixel) image.³⁵ One limitation of these systems is image size; the number of pixels in the image is limited to the number of rows in the detector. Myrick reports on a 17×32 image that uses a detector with 544 elements in the spatial dimension.

8.3.3.5 Spectral Source

For microscopy brightfield applications, it is possible to accomplish spectral imaging by tuning the illumination light as well as filtering or otherwise analyzing the remitted light. Monochromators (usually relying on diffraction gratings and white light sources) are available for such purposes. However, as the name implies, monochromators provide illumination consisting only of one spectral band of light at a time. Nevertheless, it is possible to create more flexible sources that can produce illumination of any desired pure wavelength (like a monochromator) or any selected mixture of pure wavelengths simultaneously, with white light output an easy option.³⁶ The resulting images can be collected by a high-resolution gray-scale CCD camera and interpreted using appropriate algorithms and displays. This can be used to create a complete spectral image cube for a sample by taking sequential images while illuminating with a series of pure wavelengths, with greater ease and economy than by means of devices on the imaging path, such as tunable filters or interferometers.

An advantage over tunable filters in some applications is that contamination of individual bands by out-of-band light is minimal. Furthermore, using software approaches such as projection pursuit vectors or principal components to define specific illuminants, the sample can be illuminated with a precisely controlled mixture of wavelengths so that the image presented to the detector is a linear superposition of the sample properties at many wavelengths. Thus, spectral discrimination that would previously have required the collection of complete spectral cubes might require acquisition of as few as one to three matched spectral images per field. Data acquisition is simplified and, because spectral processing is performed optically rather than computationally, acquisition and analysis times are greatly reduced.

8.3.3.6 Multispectral Confocal Microscopy

Much biology today uses confocal microscopy as a major tool to provide high-resolution three-dimensional imaging of cells and tissue. Considerable effort has gone into developing optics and software to provide diffraction-limited imaging in commercial instruments. Similar effort has been expended on fluorescent probes to illuminate cellular activity. Can we apply imaging spectroscopy to confocal microscopy? The answer is yes, but with some limitations.

Laser scanning confocal microscopes (LSCM) raster a laser spot across the object, obtaining a full image a point at a time, similar to the way that a whiskbroom imaging spectrometer operates. Because a pinhole present in the optical path to provide confocality attenuates the signal considerably, a PMT is typically used as a detector to provide sufficient gain and reasonably short pixel dwell time. To obtain an emission image cube of a fluorescently labeled sample, there are two options. Because the image is already being scanned, if one can somehow filter emission wavelength prior to detection, one can assemble an image cube. This was done recently by inserting an LCTF in front of the PMT in an LSCM and stepping through the emission wavelength range. One could also use an AOTF as the filtering element. While serviceable, this is not a practical method, because it requires multiple scans at different wavelengths to acquire a full image cube. Aside from the significantly increased time for assembling a z-stack or a time series, the repeated scans can cause excessive photobleaching.

For an LCSM, the best data collection scheme would be to acquire the entire spectrum from each spatial pixel as it is scanned, making it in effect a whiskbroom imaging spectrometer. In this approach, the instrument collects an entire image cube in the same time as a single spatial scan. Zeiss has recently introduced a spectral imager that obtains the spectrum for each pixel as the LCSM scans through the image. Due to scanning nature of the data collection and the need for gain, it would be largely unrewarding to adapt other spectroscopic techniques to an LCSM.

However, one could imagine adapting an interferometric or tunable filter device to a confocal microscope that uses a Nipkow disk because these present an entire image to a CCD. Thus, any spectroscopic device that can be interposed before a CCD camera should be compatible with this or similar confocal designs. However, any method that requires a lot of images may pose practical problems when conducting real experiments due to the possibility of photobleaching and the time involved in acquiring an (x,y,z,λ,t) image stack.

8.4 Data Analysis

8.4.1 Image Analysis

A number of freestanding spectral analysis tools are available commercially or as free-ware. These include ENVI™ and MultiSpec™ from Research System International.³⁷ Other programs can be assembled by the sophisticated user with resources such as the statistics, chemometrics, and image analysis toolboxes available in such packages as MatLab™, supplemented with researcher-generated MatLab-compatible algorithms downloadable from various Internet sites. Still others are available bundled with commercially available spectral imaging hardware (OKSI, Kairos Scientific, Spectral Dimensions, ChemIcon, etc.). These software tools will not be described further, except for some aspects that are touched on in the following discussion.

One of the appeals of developing spectral imaging systems or applications is the richness of the data sets comprising spatial and spectral information, which invites the use of intriguing analytical tools. Indeed, many of the algorithms, such as automatic clustering tools, developed for use with genomics data sets (such as the huge expression arrays) are applicable to spectral cubes, with the proviso that these methods do not encompass any of the spatial content to be found in the images. Methods attempting to link spatial and spectral data are under development.³⁸ Another thread in current investigations is determining how to select the minimum number of wavelengths needed to accomplish specific tasks.³⁹ It may seem intuitive that more spectral data and higher spectral resolution may provide increased analytical precision; however, this is often not the case. Many wavelengths may be "uninformative," and their inclusion in the data set merely adds noise. This consideration is partially related to the so-called "curse of dimensionality," which also deals with consequences of the huge internal volumes of the hyperspheres that can be used to represent high-dimensional data sets.⁴⁰ (This is more of a problem in remote sensing, in which data sets can contain images at hundreds of wavelengths.)

For the relatively simple problems posed by imaging in the visible range, and where the targets may be simply defined fluorescent dyes or chromogens, one may be able to lower the number of wavelengths acquired to approximate the number of distinct species sought in the image. Thus analytical techniques can be used not only to work with the data sets but also to shape how they are collected. At the limit, spectral flexibility can be used simply to provide a capability to select one or more specific wavelengths for the purposes of increasing contrast or enhancing the utility of straightforward image-analysis tools. In a recent publication, Ornberg et al.⁴¹ describe using a tunable filter to identify optimal wavelengths for separating signal from background in samples stained with a single chromogen plus background stain. Using a simple processing routine, the authors were able to collect and analyze two to three images per minute.

8.4.2 Analysis of Spectral Images

Assuming that more than a couple of wavelengths have been collected, the task of analysis usually involves classification, unmixing, or both. Classification involves assigning each pixel to one or more spectrally defined classes (or to an "unclassified" class). Classification is equivalent to spectral segmentation; it is an *exclusive* operation in which a pixel or object is assigned to a *single* class using one or more of a variety of metrics. On the other hand, when pixels can be or are composed of more than one spectral class, as is often

encountered when multiplexed protein or nucleic acid probes are used, then the pixels must be "unmixed," yielding estimates of the proportion of each class present. Overall, the steps involved typically consist of:

- 1. Detection or selection of appropriate spectra for subsequent analysis
- 2. Spectral classification or pixel unmixing

8.4.2.1 Pixel Classification

There are several approaches to classifying pixels in a spectral image. The minimum squared error method compares the spectra at each pixel in the image with a set of reference spectra, choosing the most "similar" and using a least-squares (Euclidean distance) criterion. This metric compares spectral means; other distance-metrics such as Mahalanobis distance⁴² can be used that are sensitive to higher-order statistics such as class variances. Related approaches convert spectra into *n*-dimensional vectors and the angles between such vectors can be used as measures of similarity.⁴³ Determining which spectra to use for the classification procedure is not always straightforward. In simple cases, the reference spectra can be selected from obvious structures in the image (foci of cancer vs. normal cells, for example) or from established spectral libraries. Alternatively, informative spectra can be extracted using statistical analysis methods, such as principal component analysis (PCA) or clustering methods.⁴⁴ Instead of using a classified pseudocolor display, spectral similarity can also be illustrated by mapping the degree of similarity using gray-scale intensity. This operation can reveal otherwise unapparent morphological details.⁴⁵

8.4.2.2 Pixel-Unmixing

Spectral classification methods are suitable for images in which no pure spectral components are likely to exist, such as in histologically stained samples. In other types of images, such as those generated by immunofluorescence or *in situ* hybridization procedures, multiple distinct spectral signals may co-exist in a single pixel to form the detected signal. Spectrally mixed pixels result when objects cannot be resolved either at an object boundary (spatial mixture), when more than one object is located along the optical path (depth mixture), or when multiple probes are co-localized within a pixel. In fluorescence, due to the additive nature of the light signal, the observed spectrum is a linear mixture of the component spectra, weighted by the amount of each probe. A linear combination algorithm can be used to unmix the summed signal arising from the pure spectral components in order to recover the weighting coefficients. Given an appropriate set of standards, the algorithm can quantitate the absolute amount of each label present.⁴⁶

In contrast to fluorescence images, imaging multiplexed samples (such as immunohistochemistry studies) in brightfield must take into account the behavior of absorbing chromophores that, rather than being additive, subtract signal from the transmitted light in a nonlinear fashion. Conversion of the brightfield image from transmittance to optical density (OD), a straightforward mathematical procedure, permits the use of the same linear unmixing algorithms that work with fluorescence.

Automated end-member detection: How does one select which spectra to use for unmixing? In many cases, this is easy. In standard immunofluorescence studies, the spectra of the fluorophores, imaged one at a time, can be stored in a spectral library and used to unmix images in which multiple fluorophores are present. But what if one does not have pure spectral species with which to work, for example, if a single, multiply labeled image is available, or if, to change applications, one is trying to analyze a remote scene about which little *a priori* knowledge is available? Some tools can identify the pure spectral species present in an image, without *a priori* knowledge by deconstructing the spectral content into its presumed components. ENVI™ provides a tool based on convex hull analysis that considers spectral end members (the pure species) to occupy the periphery of a data cloud, all of whose mixed species must fall within, rather than on, the surface. The cloud (in which each pixel's location is determined by its spectral content in *n*-dimensional space) is rotated randomly and projected onto a hyperplane. Pixels that repeatedly end up on the periphery after multiple projections are considered end members and can be used to unmix the image. This procedure can be quite time-consuming. Another specialized utility, N-FINDR, ⁴⁷ uses an analytical approach rather than multiple projections and accomplishes the same task quite efficiently.

Dimensionality reduction and automated cluster analysis: Spectral data, as noted above, can be expressed as points in hyperspace. Spectrally similar pixels will cluster together and algorithms, some of which are similar to those used for analyzing genetic expression arrays, can be used to identify such clusters that might represent meaningful bases for spectral classification. Frequently, such analysis is either impossible or inefficient when all wavelengths are included in the data set. Because a great deal of covariance exists in typical data sets (i.e., the intensity at one wavelength predicts to a high degree the intensity at neighboring wavelengths), the number of dimensions needed to express the actual information content in a data set is often far less than the number of dimensions in the data set.

PPCA is one of a family of statistical tools that can identify the most informative combinations of wavelengths (by rotating the basis vectors of the original data set) and segregate signal from noise (with some major limitations). Typically, the dimensionality of a 25-wavelength image cube of a standard histology sample can be reduced to three or four dimensions (composed of linear combinations of many of the original wavelengths) while preserving virtually all of the spectral information. Clustering algorithms can then readily work on such a reduced data set to identify meaningful spectral clusters, although some techniques, such as support vector machines, of are designed to use the original full feature space. A large variety of published and proprietary clustering methods, including iterative, analytical, neural net, fuzzy logic, and genetic algorithm-based approaches have been developed; however, their descriptions and virtues are beyond the scope of this review. A number of these tools are available as part of the software resources identified at the beginning of this section.

Combined spectral and spatial analysis: All the tools described here are designed to work only on the spectral content of the data cube. Remarkably, the pixels could be randomly scrambled and, if their associated spectra were preserved, analysis of the resulting scrambled images by the purely spectral-based algorithms would be unaffected. Obviously, a more powerful approach would somehow combine the rich spatial information present in the images with the spectral data. This is an evolving field with ongoing attempts to adapt remote-sensing expertise to problems in biomedical imaging.

8.5 Applications

Spectral imaging holds promise for a number of areas. This section concentrates on applications involving microscopy and visual light, while touching on applications in other areas. In microscopy, the goal can be variously the spectral measurements of natural chromophores or environmentally sensitive indicator molecules (imaging spectroscopy), the detection and discrimination of multiple analytes (multiplex imaging), and the analysis of complex scenes (spectral segmentation and morphometry); these functions can be combined. Microscopy can thus serve as a bridge between the morphological (the traditional strength of pathology) and the molecular.

8.5.1 Imaging Spectroscopy

Conceptually, the most straightforward application of spectral imaging involves the simple acquisition of spectra from naturally occurring or adventitious chromophores within a sample. Potential uses in biomedicine include the characterization of different melanin moieties in normal skin, dysplastic and malignant pigmented lesions, discrimination between oxy- and deoxyhemoglobin, or the study of any pigments of interest in biological or nonbiological samples. Comparison between the acquired spectra and preexisting spectral libraries can be used to aid in the identification of specific species. An example of oxygenation-based studies of ischemic regions in a pig heart perfusion model is shown in Figure 8.7, which demonstrates application of macroscopic optics and a spectral range encompassing the near-IR.

Another use of spectral imaging in which the acquired spectrum has intrinsic importance is the detection of spectral shifts in (typically fluorescent) indicator dyes. Ion-sensitive dyes that shift their emission maxima in response to changing ion concentrations are well known but are not as frequently used as dyes that change their excitation profile, in part because it has been easier to switch rapidly between excitation wavelengths than to do the same on the emission side. Emission-responsive dyes, such

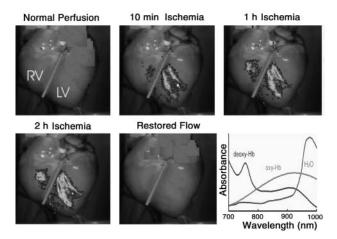

FIGURE 8.7 (Color figure follows p. 28-30.) Near-infrared spectroscopy can detect variations in tissue oxygen levels by means of hemoglobin absorption peaks (lower right). Wavelength control was achieved using a liquid crystal tunable filter in front of a CCD. Pseudocolor highlights left ventricle deoxygenation during occlusion of the artery that normally supplies it. (Images courtesy of Henry Mantsch, National Research Council, Winnipeg, Canada.)

as Indo-1, SNARF-1, Acridine Orange, and Nile Red, can be excited at a single wavelength and their emission behavior monitored using high resolution or spectroscopy or by detecting intensities at only two or (perhaps) more specific wavelength ranges. An example using propidium iodide, which is sensitive to the relative proportion of DNA and RNA in a specimen, is shown in Figure 8.8, which compares three samples of yeast under three different experimental conditions. Spectral shifts, highlighted using PCA, identify yeast in each class. Such small spectral shifts are easily separated by data from an image cube, but are not separable by filters without significant cross talk.

For ratio-based ion-sensitive imaging approaches, one would ideally wish to monitor emission at a number of wavelengths simultaneously, rather than sequentially, in order to obtain an instantaneous pixel-by-pixel measure of ion concentration. Although LCTFs can be configured to switch between wavelengths with a switching time of 1 to 5 ms, and AOTFs in around 30 µs, these still represent serial measurements. Simultaneous measures can be achieved by using the CTIS approach described earlier, or by using beam-splitters and interference filters to direct light with the desired wavelengths to one or more detectors in parallel. A commercial device that sends up to four images at different wavelengths simultaneously to a single detector is available from Optical Insights. To our knowledge, a comparison of the light efficiency and signal-to-noise capabilities of these different approaches has not yet been done.

8.5.2 Multiplex Imaging, Including Immunohistochemistry and *in Situ* Hybridizations

Spectral imaging on an analytic level facilitates multiprobe detection techniques for proteins, RNA, and DNA. Histochemical, immunohistochemical, immunofluorescent, and fluorescent molecular probes bind specifically to intra- or extracellular components and can be visualized with fluorescence or brightfield (transmission) optics. Ideally, one would like to apply more than one specific probe at a time.

8.5.3 Spectral Karyotyping

Pioneering work in spectral karyotyping (SKY) using combinatorial labeling of metaphase chromosomes⁵¹ allowed nonambiguous identification of 27 chromosomes or chromosome pairs. Applied Spectral Imaging has commercialized this approach, which has demonstrated considerable clinical utility when applied to difficult cytogenetic problems (Figure 8.9). Similar approaches using multiple fixed filter sets (M-FISH) have been described by David Ward and colleagues.⁸

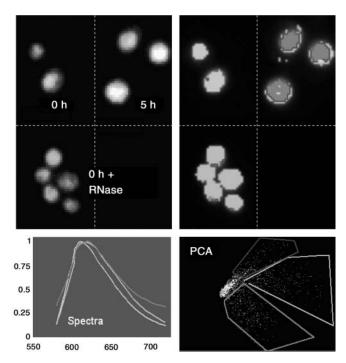

FIGURE 8.8 (Color figure follows p. 28-30.) Spectral imaging and image segmentation of yeast cells stained with propidium iodide (PI). Top left: Composite showing three panels of PI-stained yeast cells imaged under three conditions: immediately after transfer of yeast to new medium, after 5 h of culture, and after 5 h of culture plus the addition of RNAse. Bottom left: Spectra from yeast in each culture condition obtained by imaging using a liquid crystal tunable filter. Small differences in peak position and shoulder configuration are visible. Bottom right: Scatterplot of the spectral image after principal components analysis (PCA). Three clusters are circled and the pixels contained in each cluster pseudocolored. Top right: Result of mapping pseudocolored PCA clusters back to the original image, resulting in robust segmentation. (Analysis: R. Levenson, CRI, Inc.)

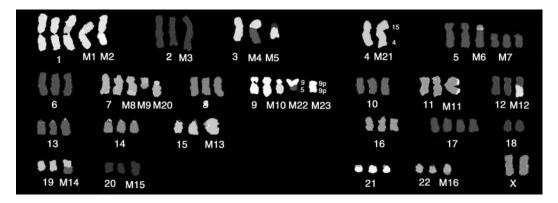

FIGURE 8.9 (Color figure follows p. 28-30.) Comprehensive cytogenetic analysis of a metaphase spread from a child (CK1) with dysmorphic features and developmental delay resembling an 18q-syndrome. Spectral karyotyping (SKY) was performed on a metaphase spread. The multicolor hybridization clearly reveals an aberrant chromosome (arrow) that contains chromosomes 18 (red) and X (dark green) material. The G-banding interpretation of a normal male. (From Schrock, E. et al., *Hum. Genet.*, 101, 255, 1997. With permission.)

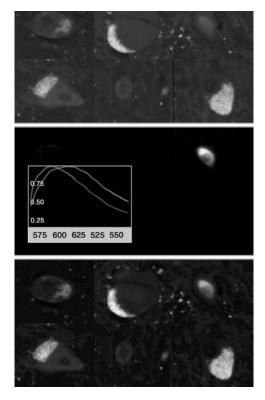

FIGURE 8.10 (Color figure follows p. 28-30.) Removal of autofluorescence using pixel unmixing. Top panel: Composite of six neurons in formalin-fixed, paraffin-embedded human brain stained with anti-GDNF labeled with Cy2. The bulk of the fluorescent signal is autofluorescence. Center panel: The single positively stained neuron is separated from the abundant autofluorescence using pixel unmixing (unmixing spectra shown in the insert). Bottom panel: Cy2 signal (in green) overlain on top of the autofluorescence signal (in gray). (Samples courtesy of Neelima Chauhan and George Siegel; analysis: R. Levenson, CRI, Inc.)

8.5.4 Immunofluorescence

Multiprobe immunophenotyping has become widely used in evaluation of hematological malignancies, with four or even as high as eight fluorescent signals discriminated with sophisticated flow cytometry instruments.⁵² The imaging approach to molecular characterization improves on flow cytometry in its ability to visualize the cells under study directly, to localize (and co-localize) cellular features, to count discrete objects on a per-cell basis, and to allow correlation with tissue microarchitecture in tissue sections. Using more than three or, at most, four labels simultaneously in the absence of spectral imaging tools is currently difficult because of the problem of spectral overlap: it is not easy to prevent signal from one dye "leaking" into the spectral channel of another. The problem becomes intractable for conventional interference filter sets as the number of dyes is increased.⁵³

Using spectral imaging, seven labels have been successfully discriminated.⁵⁴ Similar approaches can be used with multiple cell-compartment dyes. One problem with immunofluorescence is the interference of autofluorescence, which can be particularly troubling when formalin-fixed tissues are examined. Other troubling specimens include many plant samples, insects, and *Caenorhabditis elegans* nematodes. One solution to autofluorescence difficulties is to shift the excitation and emission wavelengths into the red and far-red, where autofluorescence is much less intense. If that is not possible, then spectral imaging can be used to separate the unwanted autofluorescence signal from that of specific fluorescent dyes (Figure 8.10). In this approach, autofluorescence is treated as another spectral feature, as if it were a fluorescent probe.

8.5.5 Immunohistochemistry

More popular in clinical applications than immunofluorescence, immunohistochemistry (IHC) is widely used clinically for the detection of diagnostically or prognostically significant molecules in or on cells. In the past two decades the technique has become central to the practice of oncologic pathology⁵⁵ because it can distinguish between look-alike lesions (mesothelioma vs. carcinoma, for example), or divine the cellular lineage of extremely undifferentiated neoplasms (lymphoma vs. other so-called "small blue cell" tumors). It can also be used to highlight the presence of otherwise easily overlooked microscopic foci of tumor, such as micrometastases lurking in lymph nodes, and can be used to measure quantitatively the levels of diagnostically or prognostically important markers such as estrogen- and progesterone-receptors, Her2-neu, p53, ki-67, and a host of others.⁵⁶

Under some clinical circumstances, and often in research situations, double- or triple-staining single slides with different chromophore-coupled antibodies may be desirable. Triple-staining procedures are not often performed because of technical difficulties; however, with the advent of programmable staining systems, complex staining protocols may become less of a hindrance. Despite the nonlinear effects of enzyme amplification, immunohistochemistry can be made quantitative, if precautions are taken.^{57,58} The major problem is the difficulty in visually determining where and to what extent the different stains may physically overlap when co-expression of two or more analytes may be in the same cellular compartment. Spectral imaging can overcome this difficulty, even in the presence of considerable spectral overlap with the chromogens. Figure 8.11 demonstrates spectral unmixing of a triple-stained breast cancer sample. This specimen was probed with an antiprogesterone receptor (PR) immunostain coupled to a brown chromogen (DAB) and an antiestrogen receptor (ER) immunostain coupled to a red chromogen (Fast Red); all nuclei were counterstained with a fairly dark hematoxylin wash. The RGB image reveals how difficult it is to determine by eye which cells are expressing PR, which are expressing ER, and which are expressing both. After converting the image to OD and using previously determined spectra for linear unmixing, separate images demonstrating localization of the PR, ER, and hematoxylin stains are shown.

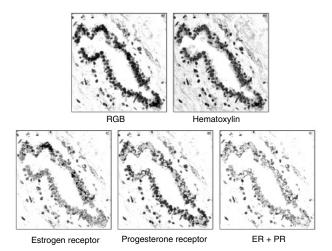

FIGURE 8.11 (Color figure follows p. 28-30.) Multicolor immunohistochemistry and spectral unmixing. Top left: RGB image of a cluster of breast cancer cells stained for the presence of estrogen receptor (ER, red), progesterone receptor (PR, brown); nuclei are counterstained with hematoxylin (blue). It is difficult to determine how much of each antigen is present in the cancer cell nuclei. After collecting a spectral stack, the signals corresponding to nucleus, ER, and PR are spectrally unmixed and shown in separate images. Bottom right shows where ER and PR are co-expressed (yellow signal). (Sample courtesy of DAKO, Inc.; analysis: R. Levenson, CRI, Inc.)

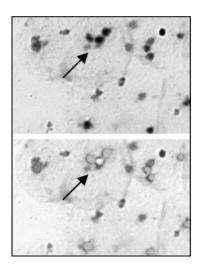

FIGURE 8.12 (Color figure follows p. 28-30.) Spectral unmixing of transmission *in situ* hybridization (TRISH). Nuclei of cytospun bladder carcinoma cells probed for three chromosome centromeres. Detection was performed using DAB, New Fuchsin, and TMB as chromogens. Lower panel: Spectral unmixing reveals overlap of brown and red signals (pseudocolored as green and red, respectively). The arrow points to a yellow spot representing the overlap. (Sample courtesy of Anton Hopman, University of Maastricht, Maastricht, the Netherlands; analysis: R. Levenson, CRI, Inc.)

8.5.6 FISH and TRISH

In situ hybridization (ISH) has proved to be an invaluable molecular tool in research and diagnosis and has enabled major strides in the fields of gene structure and expression at the level of individual cells and in complex tissues. To date, the vast majority of ISH applications have relied on fluorescence readout systems because of their sensitivity, spatial resolution, relative simplicity, and easy adaptation to multicolor and quantitative methods. As noted earlier, it can be difficult to use conventional filter sets to image multiple fluors simultaneously. With spectral imaging, it is possible to visualize six or more probes simultaneously, although similar feats can be accomplished using multiple filter cube sets and cross-talk correction (Larry Morrison, personal communication).

As noted earlier,^{22,23} speed and signal-to-noise issues with the various approaches have aroused some degree of controversy. In any event, FISH-based techniques have proved to be somewhat problematic in the clinical arena. Drawbacks include the disadvantage that most fluorescent signals fade upon exposure to light and during storage, interference by autofluorescence (which can be severe in formaldehyde-fixed tissues), and the cost of the microscopic and imaging equipment needed (not to mention the inconvenience of dimming the lights around the imaging station). In addition, it is difficult to combine FISH with routine histopathological stains that can reveal the morphological context of the images.

Some of these difficulties have recently been overcome with the development of nonfading, brightfield detection methods for ISH signals.⁵⁹⁻⁶¹ Signals can readily be detected in tissue sections, which can also be counterstained with hematoxylin or other general histology stains. Finally, brightfield, or transmission-ISH (TRISH), can be combined with immunohistochemistry to provide truly multiparameter molecular characterization. An example of spectrally unmixed three-color TRISH is shown in Figure 8.12, which includes an example of spectrally resolving physically overlapped centromeric chromosome probes.

8.5.7 Spectral Segmentation and Morphometry

Prostate cancer cells can be spectrally detected in images of prostate biopsy tissue stained with hematoxylin and eosin. This capability could be useful, for example, in automated screening of prostate "chips" removed

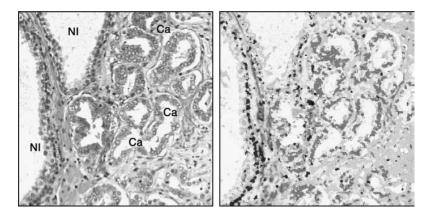

FIGURE 8.13 (Color figure follows p. 28-30.) Spectral segmentation of hematoxylin- and eosin-stained prostate cancer specimen. Left: RGB image of prostate cancer (Ca) and normal (Nl) glands. The normal glands are lined with a double cell layer consisting of epithelial and basal cells; the cancerous glands have a single cell layer. Right: Result of spectral segmentation using spectra chosen manually from representative pixels in the image and a minimum square error classification algorithm. The two cell layers (pseudocolored green and blue) are spectrally distinct from one another and from the cancer cells (pseudocolored red). (Analysis: R. Levenson, CRI, Inc.)

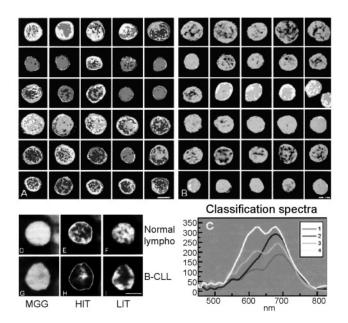

FIGURE 8.14 (Color figure follows p. 28-30.) Spectral classification and morphological analysis. Normal lymphocytes are compared to small B-cell lymphocytic leukemia cells, both stained with Giemsa. By eye these are virtually indistinguishable. Spectral classification, using the spectra shown in the lower right panel, reveals spectral differences in content and spatial distribution of the spectral features (top right and left panels). Lower left: Spectral similarity mapping algorithms indicate more clearly the differences in distribution of spectral features in normal vs. lymphocytic leukemia cells. (From Malik, Z. et al., *J. Histochem. Cytochem.*, 46, 1113, 1998. With permission.)

for benign prostatic hyperplasia. Large volumes of tissue must be examined in a search for potentially tiny foci of clinically unsuspected cancer. Figure 8.13 demonstrates that it is possible to separate malignant and normal epithelial cells spectrally and to detect basal cells as well. (These are a second cell layer found in normal prostate glands but absent in cancer.) The segmentation is not perfect. Some of the imperfections (such as isolated misclassified pixels) can be suppressed using image-processing techniques. However,

the limitations in the present case include use of the relatively unsophisticated minimum square error classification algorithm. More generally, it is likely that the stains hematoxylin and eosin — convenient, ubiquitous, and used for generations — may not be the optimal choice for spectral analysis of tissue.

Another demonstration of spectral classification (Figure 8.14) is provided by Malik and colleagues, who used spectral characteristics to distinguish between morphologically similar circulating B-cell lymphocytic leukemia cells and normal lymphocytes.⁶² These authors also showed how spectral tools can be used to highlight morphological features that can then be used to further characterize cells or tissues (Figure 8.14).

8.6 Conclusion

Fueled by rapid advances in instrumentation, software and algorithmic developments, novel dyes, and chromogens and improvements in sample processing, and stimulated by the genomics revolution and a need to increase throughput and multiplexing capabilities, spectral imaging is poised to make an ever-increasing contribution to biomedicine and related arts.

9.1 Introduction

Since the first report on the fluorescence phenomenon in 1845,¹ interest in fluorescence has rapidly increased. During the last two decades, fluorescence spectroscopy—in particular, time-resolved fluorescence—has become recognized as an important research tool in the biological sciences.^{2–5} Time-resolved fluorescence is of interest because the molecular information content is greater than for steady-state measurements. However, the information content of time-resolved fluorescence is usually not accessible with imaging techniques such as fluorescence microscopy. The situation has changed during the last decade as remarkable developments in time-resolved fluorescence facilitated the transfer of time-resolved fluorescence from solution spectroscopy to the field of lifetime-based sensing and imaging.^{6–8}

Fluorescence emission is a radiative process that occurs on the nanosecond timescale for most fluorophores. Normally, fluorescence is a first-order kinetic process and the intensity decay obeys the exponential law. The fluorescence lifetime τ characterizes the average amount of time that a molecule spends in the excited state following absorption of a photon. The importance of time-resolved fluorescence for imaging can be understood from the fact that unlike intensity, the fluorescence lifetime is largely independent of the probe concentration, photobleaching, and lightpath. All these parameters are extremely difficult to control during microscopic cellular experiments. The difficulties can be overcome by fluorescence ratiometric measurements; however, the number of fluorescent ratiometric probes is much smaller than the class of lifetime sensors.

Lifetime-based imaging is an experimental technique in which characteristics of the fluorescence decay are measured at each spatially resolvable location within a fluorescent image. This allows generation of image contrast based on the lifetime. The concept of the lifetime contrast and its advantages for imaging applications are demonstrated in Figure 9.1. This figure shows two adjacent capillary tubes containing

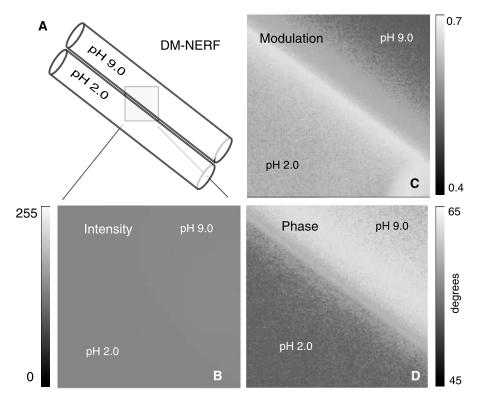

FIGURE 9.1 Demonstration of lifetime contrast. (A) Two capillaries filled with a buffer containing the pH-sensitive lifetime probe DM-NERF. The pH was adjusted to 9.0 and 2.0 in the upper and lower capillaries, respectively. Intensities in both capillaries were adjusted to the same level. (B) Fluorescence intensity image does not show any contrast. (C) Modulation image. (D) Phase image. Images (C) and (D) exhibit significant contrast because modulation and phase shift depend on fluorescence lifetime (see Equation 9.9).

the pH-sensitive fluorophore DM-NERF, but at two different pH values of 2 and 9. The steady-state intensities were identical (lower left). Differences between the two capillaries are seen in the phase angle and modulation images (right panels), reflecting these different lifetimes. Hence, lifetime imaging can reveal spatial differences in the sample even when the steady-state intensities are identical.

For simplicity we will not distinguish between fluorescence and phosphorescence lifetime imaging because the concepts are the same; only the timescales differ. Unless specifically noted, the same applies for fluorescence lifetime imaging (FLI) and fluorescence lifetime imaging microscopy (FLIM), where the main difference between the techniques is an optical system for imaging of macroscopic and microscopic samples, respectively.

FLIM has evolved as a part of a broader discipline called fluorescence lifetime microscopy, as shown in Figure 9.2. Fluorescence lifetime microscopy also includes nonimaging applications where fluorescence decays are acquired from one or several localized areas of the sample. Due to the potential of accessing intensity-independent lifetime information from subcellular volumes and due to a broad availability of lifetime probes, FLIM has gained popularity in cellular biology, biophysics, and biomedical sciences. Fluorescence lifetime microscopy and lifetime-based imaging have been discussed in several review articles. 6.7,19-22

9.2 Techniques for Lifetime-Based Imaging

Spatially resolved measurements of fluorescence lifetimes can be accomplished by several means. Generally we have two types of time-resolved fluorescence: time-domain (TD) and frequency-domain (FD)

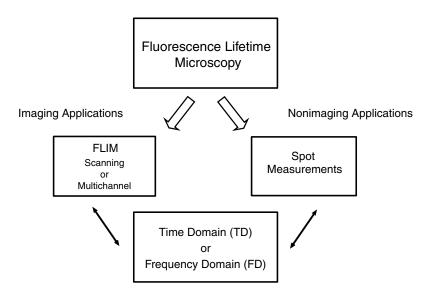

FIGURE 9.2 Fluorescence lifetime microscopy. Measurements may be done at a single point or as imaging. Both TD and FD techniques are used.

measurements. In principle, the two methods are equivalent. They yield the same kind of information about the examined object, and they are related to each other by the Fourier transform. In practice, however, the methods use different instrumentation. The experimental data have a different appearance and the data analysis is formally different. Depending on detailed experimental conditions, the TD lifetime measurements can gain comparative advantage over the FD method and vice versa. However, it is mostly a personal preference or availability of instrumentation that determines whether the TD or FD approach is used.

Another aspect of FLI is the imaging modality. Images can be acquired pixel by pixel with a single channel detector in a sequential scanning mode or line by line with an array detector in a line scanning or push-broom configuration. The scanning imaging techniques were developed for conventional and spectral imaging and can be applied for lifetime imaging as well. The FLIM images can also be acquired in a wide-field (WF) multichannel regime when lifetime information is simultaneously recorded from the whole field of view (from all pixels) by a two-dimensional detector. This detector is typically an intensified (CCD) camera even though other spatially sensitive detectors such as a multiple-anode photomultiplier (PMT) suitable for lifetime-based measurements have been reported.^{23–25} In the following paragraphs we discuss in more detail different approaches to fluorescence lifetime microscopy and lifetime-based imaging.

9.2.1 Time Domain

In time-domain measurement, the fluorophore is excited by a short pulse of light and a time course of the fluorescence response is recorded (Figure 9.3). The rate of photoemission is proportional to the number of excited fluorophores. The fluorescence intensity decay I(t) can be a monoexponential function. Typically, the intensity decay is a multiexponential function,

$$I(t) = \sum_{i} a_i \cdot e^{-t/\tau_i} \tag{9.1}$$

where τ_i are lifetimes and a_i are the corresponding amplitudes. For a mixture of fluorophores, each displaying a single exponential decay, the decay times will be those of the individual fluorophores and the amplitudes will be related to the intensity and concentration of each species.

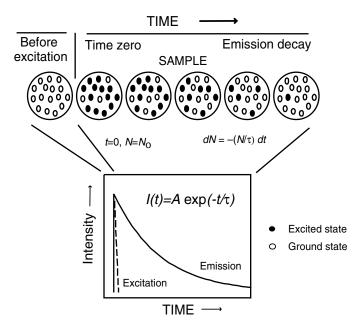

FIGURE 9.3 Concept of the emission lifetime. N = number of molecules in the excited state; $\tau =$ emission lifetime.

Several TD approaches have been used to measure fluorescence decays. They include single-shot experiments when the full fluorescence decay is acquired from a single-excitation pulse with fast digitizers or streak cameras, ²⁶ repetitive stroboscopic sampling, gated boxcar detection, and optical pump-probe methods, ²⁷ the widely used time-correlated single-photon counting (TCSPC), ²⁸ which is a dominant method in nonimaging TD fluorescence spectroscopy. A number of these methods were adopted for lifetime-based imaging in a wide variety of instrumental implementations.

9.2.1.1 Time-Correlated Single-Photon Counting

A great deal of literature is available on the subject of TCSPC. Extensive description and discussion of the method can be found in the monograph by O'Connor and Philips.²⁸ For purposes of comparison with other lifetime imaging methods, it is useful to reiterate some properties and limitations of TCSPC.

The principle of TCSPC is shown in Figure 9.4. The method is based on repetitive measurements of the time difference between the excitation flash and a subsequent detection of the first emission event. The time difference is measured electronically by a time-to-amplitude converter (TAC), which outputs electrical pulses with amplitudes proportional to the time difference between the start and stop pulses generated by detectors in the excitation and emission channels. The output of the TAC is digitized and sorted by the multichannel analyzer (MCA), where a probability histogram of the count number vs. time channels is built up by sampling a large number of excitation-emission events.

If the emission intensity is low enough so that no more than one photon is detected per start–stop cycle, the histogram exactly reflects time evolution of the fluorescence intensity decay I(t). In the opposite case the TAC does not register the second arriving photon and the measured intensity decay is biased to shorter times by the pile-up effect. To avoid pulse pile up, the detection rate has to be limited so that detection of the two photons per excitation pulse is unlikely. An acquisition rate lower than 1 to 2 photons per 100 excitation pulses is considered a practical limit for elimination of the pile-up effect. Even though the pile-up can be to some extent corrected mathematically $^{29-32}$ or suppressed by electronic discriminating the multipulse events, 33,34 the safest way to avoid pile-up problems is to use low counting rates.

The upper limit on the data acquisition rate places practical limitation on the two-dimensional lifetime mapping where thousands of fluorescence decays have to be accumulated in order to obtain a lifetime

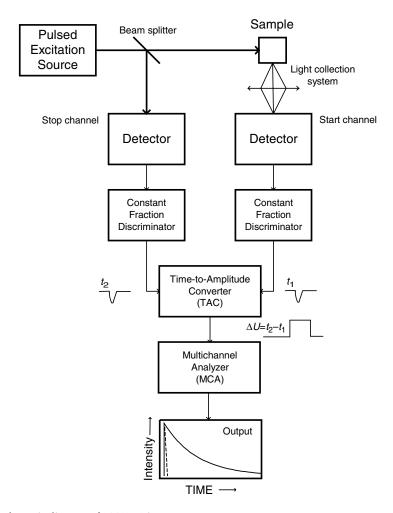

FIGURE 9.4 Schematic diagram of a TCSPC instrument.

image. As an example, let us assume a 512×512 -pixel image and an excitation repetition rate of 80 MHz. To eliminate pile-up artifacts, the data collection rate should not exceed 1% of the excitation frequency, i.e., 800 kHz. For cuvette experiments, it is not unusual to collect 10^6 counts/decay in order to have data with a good signal-to-noise ratio (SNR) for multicomponent decay analysis. In FLI we will be more likely to acquire only 10^3 counts/decay in a single pixel. This value is close to the limit where lifetime information starts to be hidden in the noise and further reduction of the counts per pixel might not be practical. Under these rather favorable conditions the acquisition of the 512×512 -pixel image would take more than 5 min.

In our example we used the laser repetition frequency of 80 MHz with light pulses separated by 12.5 ns. The time window between pulses allows measurements of only lifetimes up to 2 to 3 ns because fluorescence should substantially diminish before the next pulse arrives. For longer lifetimes, the excitation frequency has to be reduced and the acquisition time proportionally increases. It is evident that the TCSPC is impractical for FLI experiments with fluorophores exhibiting microsecond and longer lifetimes because image acquisition time would exceed several days.

Despite the acquisition rate limitation, TCSPC has single-photon sensitivity, excellent time resolution, and a wide dynamic range. This is why the technique was employed with single- and two-photon excitation for fluorescence lifetime microscopy or FLI by a number of researchers. ^{14,16,25,35–42} Applications

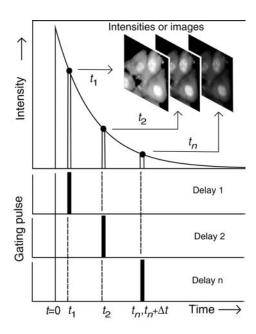

FIGURE 9.5 Gated detection. During each excitation cycle the detector is turned on for a period of time Δt and intensity is measured. Depending on the imaging mode, the image is acquired simultaneously or pixel by pixel for each time delay. The delay is changed until the whole emission decay is sampled.

range from time-resolved fluorescence measurements from single or multiple locations within a microscopic sample, 14,16 confocal scanning implementations, 36, 37,41,43 and three-dimensional imaging 40 to near-field scanning optical microscopy (NSOM) with fluorescence lifetime as a contrast mechanism. 44 Willemsen et al. 37 combined TCSPC-based lifetime imaging with atomic force microscopy in one scanning device. TCSPC has also been used for lifetime imaging in a scanning DNA sequencer. 39

Methods have been developed to increase the data collection rate above the TCSPC limit. One such method uses parallel data acquisition with multichannel position-sensitive detectors. The detector could be a multianode PMT^{23,25} placed in the image plane with outputs from the individual anodes routed to the multiplexed TCSPC detection system. In this system the count rate can be increased to a value close to 0.37,⁴⁵ which is a considerable improvement over single-channel TCSPC. Even though PMTs with up to 96 anodes have been reported,⁴⁶ the imaging capability and spatial resolution of FLIM instruments with the multianode PMTs is sufficient only for low spatial-resolution imaging.

9.2.1.2 Multichannel Photon Counting

In order to overcome limitations of TCSPC and increase the data collection rate required for twodimensional lifetime scanning, multichannel photon counting has been developed for lifetime microscopy.¹⁵ The method utilizes simultaneous digital sampling of all photons in the emission burst while preserving their arrival-time information. Because the method does not use TAC for time measurements, the detection rate can exceed the 1% limit of TCSPC, which substantially reduces measurement time compared to TCSPC. Modest time resolution in the nanosecond range, however, limits applicability of the technique for short-lived fluorophores.

9.2.1.3 Sampling Methods

Unlike the time-resolved cuvette experiments mostly performed by TCSPC, the field of TD lifetime imaging is dominated by sampling methods with gated detection. The principle of the most commonly used boxcar approach^{27,47} can be understood from Figure 9.5. The sample is excited by a periodic train of light pulses and the signal is recorded within a defined time interval Δt after each excitation pulse. More specifically, the detector is turned off during the fluorescence decay except for a brief period of

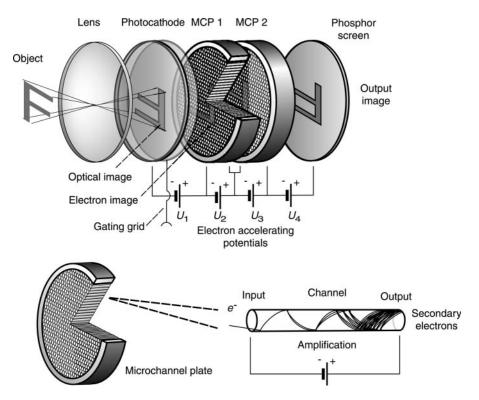

FIGURE 9.6 Schematic of a two-stage image intensifier. An image of the observed object is projected on the photocathode. Emitted primary photoelectrons are accelerated and enter a pair of the microchannel plates where the number of electrons is amplified. Accelerated secondary electrons impinge on the phosphor screen where the bright optical image of the object is generated. The gating grid allows the gain of the intensifier to be turned ON and OFF, or continuous modulation of the gain.

time Δt . The fluorescence intensity in the time window of t and $t + \Delta t$ is repetitively accumulated until a desired S/N ratio is reached. The process is repeated for a set of delays t_i , until the whole fluorescence decay is sampled. It is straightforward to implement the boxcar method for nonimaging time-resolved microscopy. 12,13 The boxcar method has been used also for scanning confocal FLIM with single-photon 48–52 or two-photon excitation 53–55 with a gated PMT as a detector. In such experiments full images are sequentially acquired for each delay t_i and fluorescence decays are constructed at each pixel as a function of the pixel intensity vs. t_i .

FLIM with gated image intensifier. The full advantage of gated detection in lifetime-based imaging was realized by the introduction of a gated image intensifier. The whole image can then be sampled at once without need of pixel-by-pixel scanning. For a given S/N ratio and image size, simultaneous sampling of all pixels brings tremendous improvement of the data acquisition time with respect to the serial scanning methods. This property allowed fast lifetime mapping to the WF imaging.⁵⁶⁻⁷⁶

An image intensifier is an optoelectronic imaging device that amplifies brightness of an input light pattern on the photocathode while preserving the pattern. The device comprises a photocathode, one or several microchannel plates, and a phosphorescent screen where the amplified optical image is formed. The screen is typically observed by a CCD camera for digital quantification of the image. The concept of the image intensifier is illustrated in Figure 9.6. Primary photoelectrons generated on the photocathode by an incident light are accelerated and enter microchannel plate (MCP) consisting of a large number of metal-lined capillaries. The opposite ends of the capillaries are held at the electron accelerating potentials and their inner walls are covered by an electron emissive material. The accelerated photoelectrons therefore generate an avalanche of secondary electrons, which subsequently form a bright fluorescence spot on the phosphor screen.

Modern intensifiers exhibit practically no crosstalk between adjacent channels and all components are proximity focused, so the image intensifier has a very low image distortion. Depending on the number of multichannel plates MCPs, the gain of the intensifier can typically range from 10^3 for a single-stage intensifier up to 10^7 for an intensifier with three MCPs in series. Gain gating can be achieved by biasing photocathode several volts positive with respect to the MCP (by reversing the voltage U_1 in Figure 9.6) in order to prevent photoelectrons from being collected on the MCP.⁷⁷ The gate pulse then drives the photocathode more negative than the MCP and the photoelectrons enter the MCP where they are amplified.

Alternatively, the gating can be accomplished with improved time response by biasing an auxiliary gating grid positioned on the back of the photocathode.⁵⁷ Shutter ratios as high as 10⁹ to 10¹² have been reported.⁷⁷ Recent gated intensifiers can operate at high repetition frequencies with gating pulses as narrow as several hundreds of picoseconds.^{78–80} Small-diameter gated intensifiers are becoming available with an exposure time as short as 50 ps. These intensifiers, however, can only operate with a very low duty cycle with repetition frequencies up to several kHz.^{79,80}

Although gating methods do not possess a dynamic range or the time resolution of the TCSPC with a microchannel PMT, they offer a number of important advantages for lifetime-based imaging. The boxcar acquisition method is highly configurable. The number and time-width of the individual gates can be arbitrarily changed in order to match the decay characteristics of fluorophores and balance data acquisition time vs. time resolution. The minimum number of time windows necessary to calculate the lifetime of monoexponentially decaying emission is two.⁵⁶ Such a double-gate approach to FLI experiments^{48,50,51} greatly reduces data acquisition and processing time while discarding a part of the information otherwise accessible by multigate methods. Nevertheless, double-gate FLI is very efficient in generating a lifetime contrast even for complex decays. The lifetime contrast can be calibrated against known samples, which consequently allows extraction of biologically relevant information.

Unlike the TCSPC, gating can be efficiently used with low repetition rate lasers. Also, multiple photons detected per laser flash are not a limitation of the technique, which can thus be used for measurements of lifetimes in the microsecond and millisecond time ranges. An important property of gating methods is the capability for background suppression. When gating is used with longer-lived fluorophores, scattered light, reflections, autofluorescence, and short-lived fluorescence, which usually decrease image contrast in conventional fluorescence microscopy, can be easily rejected.^{64,71} The normally off detector is turned on at the moment when the intensity of the short-lived components has diminished and only long-lived fluorescence is acquired. For very long-lived emission, such a gating scheme has also been accomplished without expensive electronics by attaching two phase-locked choppers to a microscope.⁸¹

Gatable CCD cameras. Lifetime imaging with long-lived millisecond or microsecond probes can be accomplished without expensive gatable image intensifiers. Khait et al.⁸² reported a fluorescence lifetime microscope with a millisecond temporal resolution equipped with a free-running externally synchronized CCD camera acquiring data with a speed of 33 images/second. A similar approach has been used for oxygen imaging with a millisecond phosphorescent sensor Green 2W.⁸³ Phosphorescence decays were sampled at preset times after the excitation flash by an externally triggered CCD camera working with an exposure time of 2.5 ms. Phosphorescence lifetime maps and a distribution of pO₂ in tissues were constructed by this method.

During the past decade, fast, directly gatable CCD cameras have become available. ^{84–86} The technology utilizes a semiconductor-based electronic shutter integrated into the structure of the CCD chip, which allows for short optical exposure times. Shutter rise and fall times shorter than 55 ns and opened/closed ratios as high as 10⁴ to 10⁵ have been reported. ⁸⁴ The directly gatable cameras have been used for microsecond lifetime imaging of luminescent ruthenium(II) complexes. ⁸⁵ Decay times shorter than 100 ns have been measured with the directly gatable cameras. ⁸⁶

9.2.1.4 Spatially Sensitive Multichannel Plate Detectors

The photoelectron emitted from the photocathode and amplified by the MCP creates a localized charge on the anode centered at positions corresponding to the positions of the incident photon. This property

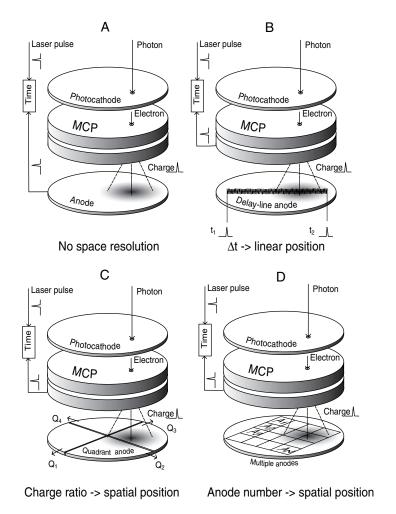

FIGURE 9.7 Principle of position-sensitive detectors for time-resolved spectroscopy. (A) Conventional MCP-PMT without space resolution. (B) Delay line anode MCP-PMT with linear position resolution. The position information is derived from the difference in pulse arrival times to the terminals of the delay-line anode. (C) Quadrant anode MCP PMT with two-dimensional spatial resolution. The position of the incident photon is calculated from the ratio of charges collected by the individual quadrants $Q_1 - Q_4$ of the anode. (D) Multiple-anode MCP-PMT. The spatial position correlates with the electrical signal on the individual, spatially separated anodes. (Modified from Kemnitz, K. et al., *J. Fluoresc.*, 7, 93, 1997.)

provides the means to record the spatial and temporal information about incident photons simultaneously and to use these fast detectors for lifetime-based imaging. The temporal information is typically measured by TCSPC electronics. Several strategies for retrieving the spatial information of the incident photons are illustrated in Figure 9.7.

The spatial information can be accessed by replacing a conventional disk anode (Figure 9.7A) with a resistive (R) or a delay-line (DL) anode (Figure 9.7B), quadrant anode (QA) (Figure 9.7C), or by a set of individual anodes (Figure 9.7D). While the DL-MCP-PMTs were used to encode a linear position across the photocathode, 35,87 the resistive 38 or quadrant anode 88 MCP-PMTs provide continuous two-dimensional position information. The detectors with continuously coded spatial location are not multichannel devices for simultaneous signal acquisition from multiple locations, because they can register only one detection event at a time. If multiple photons simultaneously strike the photocathode at different places, the photons are registered as one detection event and an incorrect location is assigned by

electronics. In order to alleviate such cases the detection rates have to be limited to an extent as described earlier for TCSPC.

From this point of view a lifetime mapping with such detectors is slow and can be compared with a sequential random scanning of the sample. Due to the recent advance in the image intensifier technology, which offers better spatial resolution, lower image distortion, and faster data acquisition, the importance of the position-sensitive detectors for lifetime-based imaging has decreased.

9.2.1.5 Multipulse Methods

Increasing the time resolution is not limited to creation of faster electronic and optoelectronic devices. The excited state population can be controlled by intense light pulses. The availability of femtosecond lasers offers time resolution on the time-scale of the pulse width. Nonlinear multipulse methods are especially suitable for confocal FLIM, because the laser light flux is concentrated in a diffraction-limited spot where a threshold for nonlinear phenomena is easier to reach.

One multipulse optical technique implemented on a scanning confocal microscope is a double-pulse fluorescence lifetime imaging (DPFLIM).^{89,90} The method is based on the excitation of fluorophores with ultra-short laser pulses, which populate the excited state to near the saturation value. The method does not require electronic gating of the detector, but rather relies on the optical pumping of the excited state of fluorophores. Because the time resolution depends mainly on the duration of the excitation pulses, the DPFLIM can have subpicosecond time resolution.

The principle of the method is schematically depicted in Figure 9.8. The sample is illuminated with intense single pulses saturating the first excited state and the time-integrated fluorescence intensity I_1 is measured by a conventional detector. Then the measurement is repeated with saturating pulse doublets and again the total intensity I_2 is measured. The two pulses from the excitation doublet are separated by the time delay Δt . Finally, the ratio R of the two intensities yields the fluorescence lifetime τ :⁸⁹

$$R = \frac{I_2}{I_1} = 2 - \exp(-\Delta t / \tau)$$
 (9.2)

From Figure 9.8 and Equation 9.2, it can be seen that, with increasing separation of the pulses, the ratio R increases until it reaches the limiting value of 2 for $\Delta t >> \tau$. By calculation of R at each pixel, the lifetime contrast is created and a fluorescence lifetime map can be constructed.

The DPFLIM was first used with a confocal microscope where saturation of the excited state can be reached without problem. With some modification, the DPFLIM is usable even with weaker nonsaturating illumination⁸⁹ and has a potential to be applied to conventional WF-FLIM.

Additional examples of multipulse nonlinear methods potentially useful for lifetime-based imaging have been outlined in Reference 47 and in the review of Lakowicz,²¹ where manipulation of the excited state population by light quenching has been proposed.

9.2.2 Frequency Domain

The history of FD fluorometry begins in 1926 when Gaviola performed his first fluorescence lifetime measurement. During the years the FD methodology rapidly evolved until in the last decades of the 20th century it was adopted for lifetime microscopy and lifetime-based imaging. The principle of phase and modulation measurement is schematically depicted in Figure 9.9 for a single point in the image. In FD lifetime imaging, the investigated object is exposed to the excitation light E(t), harmonically modulated at an angular frequency of $\omega = 2\pi f$ with a modulation degree of $m_E = a/A$:

$$E(t) = E_0 \cdot \left[1 + m_E \sin(\omega t) \right] \tag{9.3}$$

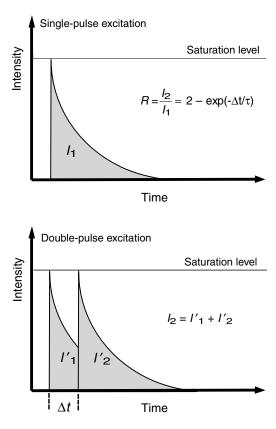

FIGURE 9.8 Principle of the optical double-pulse lifetime determination used for a confocal FLIM. (Figure was Redrawn from Muller, M. et al., *J. Microsc. (Oxford)*, 171, 177, 1995.)

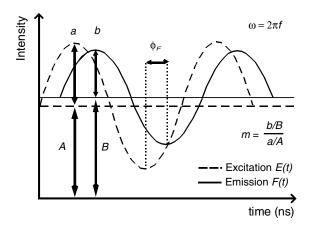

FIGURE 9.9 Concept of the frequency-domain measurements. The modulated excitation and emission light have DC components *A* and *B*, respectively, and modulation amplitudes *a* and *b*, respectively. The emission exhibits a phase lag ϕ_F with respect to the excitation light and a demodulation ratio *m*.

Such periodic excitation causes fluorophores to emit light F(t) with the same modulation frequency ω . Due to a finite fluorescence lifetime, the emission is delayed, exhibiting a spatially dependent phase lag $\phi_F(r)$ and decreased modulation $m_F(r) = b/B$, relative to the excitation radiation:

$$F(r,t) = F_0(r) \cdot \left\{ 1 + m_F(r) \sin[\omega t - \phi_F(r)] \right\}$$
 (9.4)

The spatial coordinate r maps the position within the object from where the emission is observed. For simplicity we set the excitation phase to zero because it can be freely manipulated, by insertion of a delay line to the excitation path, and all phases are measured relative to the phase angle. It has been shown that the fluorescence phase $\phi_F(r)$ and the demodulation ratio $m(r) = m_F(r)/m_E(r)$ depend on lifetime components of the emission: 94,95

$$\phi_F(\omega, r) = \arctan\left(\frac{N(\omega, r)}{D(\omega, r)}\right) \tag{9.5}$$

$$m(\omega,r) = \frac{m_F(\omega,r)}{m_F(\omega,r)} = \sqrt{N^2(\omega,r) + D^2(\omega,r)}$$
(9.6)

where

$$N(\omega, r) = \left[\sum_{i} \frac{a_{i}(r)\omega\tau_{i}^{2}(r)}{1 + \omega^{2}\tau_{i}^{2}(r)}\right] \cdot \frac{1}{\sum_{i} a_{i}(r)\tau_{i}(r)}$$
(9.7)

$$D(\boldsymbol{\omega}, r) = \left[\sum_{i} \frac{a_{i}(r)\boldsymbol{\tau}_{i}(r)}{1 + \boldsymbol{\omega}^{2}\boldsymbol{\tau}_{i}^{2}(r)}\right] \cdot \frac{1}{\sum_{i} a_{i}(r)\boldsymbol{\tau}_{i}(r)}$$
(9.8)

For the simplest case of a monoexponential decay, the lifetime $\tau(r)$ at any location of the sample can be directly calculated from Equations 9.5 through 9.8:

$$\tau_{\phi}(r) = \frac{1}{\omega} \arctan(\phi_F(r)), \qquad \tau_m(r) = \frac{1}{\omega} \cdot \sqrt{\frac{1}{m^2(r)}} - 1 \tag{9.9}$$

and $\tau = \tau_{\phi} = \tau_{m}$. Equation 9.9 can also be used to calculate the phase (τ_{ϕ}) and modulation (τ_{m}) lifetime for more complex decays. The resulting lifetimes, however, are apparent values representing complex mixing of different lifetime components.^{47,96,97} For a multiexponential decay, the phase lifetime is shorter than the modulation lifetime, $\tau_{\phi} < \tau < \tau_{m}$, and such inequality indicates heterogeneous fluorescence decay.

9.2.2.1 Homodyne and Heterodyne FLIM

Theory of the phase and modulation FLIM has been discussed in a number of papers. ^{98–103} Briefly, the fluorescent image F(r,t) (Equation 9.4) of an object excited by the modulated light is projected on the photocathode of the image intensifier that has the electronic gain G(t) modulated at the RF frequency $\omega + \Delta \omega$:

$$G(t) = G_0 \cdot \left\{ 1 + m_D \sin\left[(\omega + \Delta \omega) \cdot t - \phi_D(r) \right] \right\}$$
(9.10)

Inside the intensifier, frequency mixing occurs as the primary photocurrents modulated at the frequency ω interact with the electronic gain modulated at the frequency $\omega + \Delta \omega$. Due to the long time

constant of the phosphor screen caused by the millisecond phosphor lifetime, all high-frequency components become time averaged and we observe an amplified image with intensity slowly varying with the frequency $\Delta\omega$:

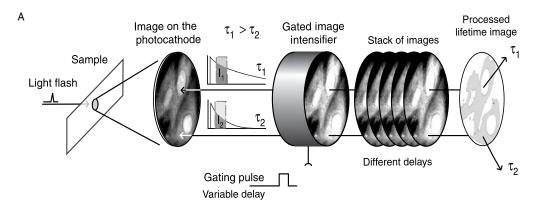

$$I(r,t) = I_0(r) \cdot \left\{ 1 + \frac{m_D \cdot m_F(r)}{2} \cos \left[\Delta \omega t - \Delta \phi(r) \right] \right\}$$
(9.11)

where

$$\Delta \phi(r) = \phi_F(r) - \phi_D \tag{9.12}$$

The phase and modulation information is retained after the frequency mixing and can be extracted from Equations 9.11 and 9.12. The method is called homodyne and heterodyne for $\Delta\omega = 0$ and $\Delta\omega \neq 0$, respectively. Both methods rapidly evolved when image intensifiers suitable for high-frequency gain modulation became available.^{98,104}

The homodyne method is the dominating method used in FD WF-FLIM.^{7,98–100,102,103,105–124} The principle of the method is schematically shown in Figure 9.10 with the time-domain counterpart. The generic

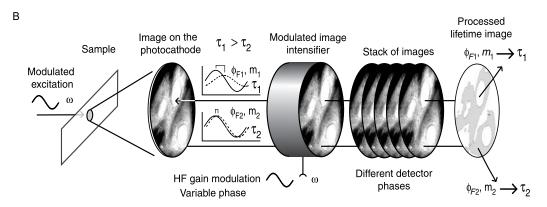

FIGURE 9.10 Schematic comparison of the time-domain (A) and the frequency-domain (homodyne) (B) methods for wide-field FLI. In the time domain, images are acquired for several delays of the gating pulse with respect to the excitation flash. Since the gain of the intensifier is on only during the presence of the gating pulse, fluorescence decays at different locations of the sample are simultaneously sampled and the lifetime image can be constructed on a pixel-by-pixel basis from the measured stack of the images. In the frequency domain homodyne, FLIM, the gain of the image intensifier is modulated at the same frequency as the excitation light. As a result, we observe a steady-state phase-sensitive image on the phosphor screen of the intensifier. After the stack of images is acquired at detector phases distributed between 0 and 2π , the modulation m and phase lag $φ_F$ are extracted and a lifetime image is generated.

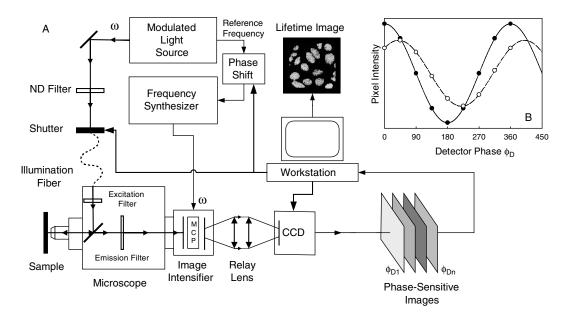

FIGURE 9.11 Homodyne FLIM. (A) Scheme of a generic instrument. (B) Intensity profile through the stack of phase-sensitive images at one arbitrarily chosen pixel as a function of a detector phase angle. Open circles represent intensities of a fluorescent signal with phase lag $\phi_F > 0$ (see Equation 9.13); closed circles show signal for a zero-lifetime reference (scatter) when $\phi_F = 0$.

scheme of an FD instrument is shown in Figure 9.11. In a homodyne FLIM the gain of the image intensifier is modulated at the same frequency as the excitation light, i.e., $\Delta \omega = 0$. We observe on the phosphor screen a steady-state phase-sensitive image:

$$I(r) = I_0(r) \cdot \left\{ 1 + \frac{m_D \cdot m_F(r)}{2} \cos[\phi_F(r) - \phi_D] \right\}$$
 (9.13)

The intensity I(r) at any location of the phosphor screen depends on the cosine of the difference between fluorescence and detector phase angles and on the lifetime through the phase angle $\phi_F(r)$, Equation 9.5, and the modulation factor $m_F(r)$, Equation 9.6. The value of ϕ_D is controlled by the apparatus and can be adjusted by a number of means. The phase-shift option can be within the frequency synthesizer. Alternatively the phase shift can be accomplished by an external digital phase-shifter or passively by a delay line consisting of a piece of coaxial cable inserted between the synthesizer and the image intensifier.

The dependence of I(r) on ϕ_D for a selected location in the image is shown in Figure 9.11B. The opened circles represent the measured fluorescent intensity and the closed circles show the signal for a zero-lifetime reference (scatter), when $\phi_F = 0$. During the experiment a stack of images is acquired for ϕ_D distributed between 0 and 2π . The images contain information about the $\phi_F(r)$ and $m_F(r)$ at each position, which can be extracted by Fourier analysis or by performing a linear least-squares fit for each pixel in the image. ^{99,100} Then the lifetime image can be constructed or one can simply use the phase angle or modulation images.

Heterodyne detection uses cross-correlation mixing for translation of the high-frequency fluorescence modulation to the frequency region of several hertz. When used with the image intensifier, an image with periodically oscillating intensity at the frequency $\Delta\omega$ is observed on the phosphor screen. The time-dependent image can be sampled by a CCD camera. This seems to be a disadvantage because camera exposure times much shorter than $1/\Delta\omega$ are required to sample the oscillations properly, which decreases the duty cycle for data acquisition. This is a disadvantage because measurements of dim samples may

require longer integration times, and because the longer illumination times may result in excessive photobleaching.

To overcome this drawback, a method combining high-frequency heterodyne mixing on the image intensifier with low-frequency optical-homodyne image acquisition has been developed. 101,104,125 The heterodyne signal on the phosphor screen was recorded during a fraction of the heterodyne cycle by a boxcar method. This resulted in a steady-state signal on the phosphor screen integrated by the camera. The heterodyne cycle was sampled by changing delay of the acquisition window.

The heterodyne detection method does not require as strict a high-frequency phase stability as the homodyne counterpart. Synchronization on the low cross-correlation frequency is much easier to achieve. However, with modern synthesizers phase stability is not a problem. Due to the boxcar integration when only a slice of the heterodyne cycle is used for data accumulation, the acquisition times are longer with heterodyne than with homodyne detection. This disadvantage, together with more complex instrumentation, has caused lower use of the heterodyne WF-FLIM compared to the homodyne counterpart. Nevertheless, the heterodyne method of the lifetime determination has been successfully implemented in a scanning microscope. 126

9.2.2.2 Optical Methods

Dong et al. have reported a unique optical cross-correlation method implemented on a scanning fluorescence lifetime microscope. 127 Cross-correlation frequency mixing was accomplished by periodic quenching of the fluorescence by stimulated emission. The method utilizes the harmonic content $^{128-130}$ of the two pulse trains from two lasers running at repetition frequencies offset by the $\Delta \omega$ and focused in the sample. One of the laser beams excites fluorescence and the wavelength of the other is tuned to quench the emission. At the place of the beam overlap a cross-correlation fluorescence signal at multiple harmonics of the frequency $\Delta \omega$ is created. The low-frequency fluorescence signal is detected by a standard PMT; the harmonics are electronically isolated and analyzed for demodulation and phase-shift.

Optical heterodyning has two main advantages. The low-frequency fluorescence signal implies that the FLIM can be carried out without using fast photodetectors. Lifetime measurements up to 6.7 GHz have been reported with a conventional PMT. Overlap of the pump-and-probe lasers also results in an axial sectioning since the out-of-focus signal is not cross correlated and is rejected by the electronic filters. Because of the wavelength used in the one-photon pump-and-probe process, the spatial resolution of the technique is comparable to confocal microscopy.

9.2.2.3 FLIM with Lock-In Amplifiers

Homodyne and heterodyne techniques are not the only detection methods for the FD FLI. Reports have been published where lifetime-based imaging was carried out with lock-in amplifiers (LIA) in place of the detection electronics. The LIAs are devices sensitive to frequency and phase of the input signal and work directly with the high-frequency signal from the detector. This makes lifetime microscopes simpler; however, due to a final bandwidth of the LIAs, their usage has been limited to a frequency range up to several hundred MHz. Since LIAs for massively parallel data processing are not available, the LIAs have been utilized with scanning lifetime microscopes only. Phase sensitivity of the LIAs has been used mainly for selective lifetime suppression in the intensity-modulated multiple wavelength scanning (IMS) technique. Recently, dual-phase LIAs have been demonstrated to be usable for lifetime mapping. The technique has been used for lifetime-based pH imaging with fluorescence probe SNAFL-2. The technique has been used for lifetime-based pH imaging with fluorescence probe SNAFL-2.

9.2.2.4 Multifrequency FLIM

Unlike solution spectroscopy in which multifrequency instruments have been used for a long time, ^{135,136} until recently, FD FLI has been limited to a single modulation frequency. The main reason was a relatively long time required for sequential acquisition of the multifrequency FLI data, which resulted in photobleaching and photodamage of the samples. Single frequency imaging allowed generation of lifetime contrast and calculation of apparent modulation and phase lifetime images (Equation 9.9). However, this is a limitation when taking into account that fluorescence kinetics are rarely pure exponentials in a biological environment. Moreover, the heterogeneity of the decay is often the information of interest

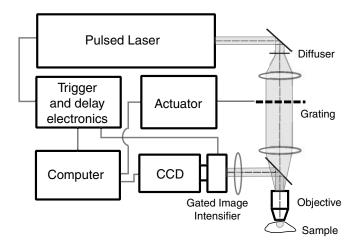

FIGURE 9.12 Scheme of a lifetime microscope with a structured illumination. A grid pattern produced by a grating in the illumination lightpath is projected on the sample. Three sets of time-gated images are taken at three positions of the grid and a deblurred stack of intensity images is calculated. To obtain a lifetime map, the resulting stack is processed by standard methods used with the time-gated FLIM. (Modified from Cole, M.J. et al., *Opt. Lett.*, 25, 1361, 2000.)

when looking for different fluorescence species within a cell. With the single-frequency FLIM, the information content of heterogeneous fluorescence decays remains inaccessible because resolution of N lifetimes needs at least N modulation frequencies.¹³⁷

Fortunately, a solution has been found for rapid multiharmonic data acquisition. The multiharmonic method utilizes the harmonic content of the excitation pulse train^{128–130} and the harmonic content of the pulse-modulated gain of a detector for simultaneous data acquisition at multiple modulation frequencies. The technique was initially applied for cuvette experiments^{138–141} and single-spot heterodyne frequency-domain microscopy.⁹ Recently, the multiharmonic approach has been implemented for the homodyne WF multifrequency FLIM (mfFLIM).¹⁴² Simultaneous multiharmonic detection is achieved by mixing frequencies from the harmonic content of the emission with corresponding harmonics from the pulse-modulated gain of the image intensifier. The resulting optical image on the phosphor screen is formed as a sum of phase- and modulation-dependent images corresponding to the different harmonic frequencies. The phase and modulation is extracted at each harmonic frequency by Fourier analysis.

Compared to the serial frequency acquisition, the main advantage of the multiharmonic approach is a shorter data acquisition time and a higher modulation depth. ¹⁴² The reduction of the data acquisition time is not as high as it would correspond to the number of simultaneously acquired frequencies. The reason is a lower duty cycle of the pulse-modulated detector. Performance of the mfFLIM has been demonstrated by the lifetime resolution of green fluorescent protein variants co-expressed in live cells.

9.2.3 Three-Dimensional Wide-Field FLIM

Wide-field microscopy suffers from the lack of sectioning capability, which is an inherent property of confocal and multiphoton imaging systems. The reason is a mixing of the signal from out-of-focus planes, which blurs the intensity image and decreases contrast and spatial definition of observed structures. WF-FLIM suffers from the same problem. At any spatial location, the measured lifetime is an intensity-weighted average of lifetime contributions arising from out-of-focus planes and the lifetime contrast is compromised. Improvement of the spatial and lifetime resolution of the WF-FLIM has been the subject of several studies.^{75,103,122,143,144}

One method for obtaining the optical sectioning with the WF lifetime microscope is depicted in Figure 9.12. The sectioning capability was achieved by implementation of a structured illumination, ^{145,146} when a grid pattern produced by a grating in the illumination lightpath is projected on the sample. Then three

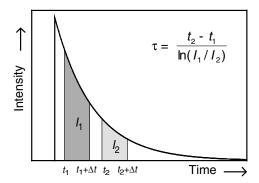

FIGURE 9.13 Principle of the two-gate method for the rapid calculation of the emission lifetime. The formula for calculation of the lifetime is valid for a monoexponentially decaying emission.

sets of the time-gated images are taken for three positions of the grid pattern. Calculations then yield a deblurred lifetime map.⁷⁵

Enhancement of the three-dimensional lifetime resolution of WF-FLIM can be achieved with multifocal multiphoton microscopy (MMM).¹⁴⁷ Multiphoton excitation and three-dimensional sectioning is accomplished by insertion of the spinning microlens disk to the illumination path of the conventional WF microscope. This causes a near-IR excitation light from the femtosecond laser to be transformed into an array of fast-scanning foci in the object plane where multiphoton excitation occurs. A WF-FLIM instrument based on the MMM technique and gated image intensifier has been recently reported.¹⁴³

If one knows the point spread function (PSF), the three-dimensional temporal and spatial resolution of the WF-FLIM can be increased by a numerical deconvolution. Squire et al. 103 performed deconvolution with the measured PSF in the Fourier space before construction of lifetime images. Alternatively, the FLIM data were first globally analyzed in order to separate fluorophore populations associated with different lifetimes. This allowed the separated image stacks to be individually corrected for photobleaching before the deconvolution. 122 In both cases significant enhancement of the spatial and temporal resolution was achieved.

9.3 Specifics of FLIM Data Analysis

Several methods have been proposed to analyze rapidly the substantial amount of data generated by lifetime imaging systems. Typically, this reduces a stack of images to a few images that contain spatial mapping of decay parameters, e.g., lifetimes and associated amplitudes. Going even a step farther, we usually want to obtain a single chemical image carrying biologically relevant information. Depending on the fluorescent lifetime sensor, it can be a spatial distribution of analyte concentration, two-dimensional map of a gas pressure, and, eventually, a spatial map of distances when FLIM is used for fluorescence resonance energy transfer (FRET) experiments.

9.3.1 Fast Two-Gate Analysis

Time-domain lifetime mapping does not require lengthy iterative fitting of a large number of points. Fluorescence lifetime maps can be calculated from two intensity images, $I_1(r)$ and $I_2(r)$, acquired in two distinct time windows. Assuming windows of the equal width of Δt delayed by t_1 and t_2 relative to the excitation pulse (Figure 9.13) we can write:

$$I_{1}(r) = \int_{t_{1}}^{t_{1}+\Delta t} a(r) \cdot \exp[-t/\tau(r)] dt, \qquad I_{2}(r) = \int_{t_{2}}^{t_{2}+\Delta t} a(r) \cdot \exp[-t/\tau(r)] dt$$
 (9.14)

$$\tau(r) = \frac{t_2 - t_1}{\ln[I_1(r)/I_2(r)]}$$
(9.15)

Equation 9.15 holds true for monoexponential decays and allows for very fast computation of the lifetime maps. To obtain good accuracy of the measured lifetime map, prior knowledge of the lifetime is essential for selecting optimal gating windows. Therefore, an effort has been made to evaluate errors associated with the gating technique^{149,150} and to develop optimal gating schemes.¹⁵¹ This rapid lifetime determination technique has been extended to evaluation of double-exponential decays.¹⁵²

9.3.2 Global Analysis of FLIM Data

Analysis of FLI data is a problem of the same scale as the analysis of 10⁵ to 10⁶ of time-resolved cuvette experiments. Besides the computational expenses, the number of data points on the time or frequency axis in the time or frequency domain, respectively, has to be limited in order to collect data before irreversible processes damage the sample. A smaller number of data points and lower S/N ratio, compared to values typically obtained for cuvette measurements, make reliable multicomponent lifetime analysis from a single pixel questionable. One can increase the S/N ratio by grouping several pixels together; however, the price is a deterioration of the spatial resolution. An important possibility in FLI data analysis is to use prior knowledge about the sample, which leads to a dramatic improvement of computational speed and fit quality. ^{117,142}

One of the approaches uses the global-analysis algorithm, ^{94,95,153–156} which analyzes all pixels simultaneously while constraining the component lifetimes in all pixels to be equal.¹¹⁷ This is an acceptable assumption for many FLI experiments where a spatially distributed mixture of fluorescence species is analyzed. Such an approach leads to a significant reduction of the number of fitted parameters and to improved fit reliability. It has been shown that the FD global analysis of multiple pixels can yield twice the number of lifetimes that could be recovered with ordinary single-point measurements.¹¹⁷ An important consequence is a possibility of recovering two lifetimes from a single-frequency FLI experiment. Examples and comparison of the single- and multifrequency global fit of FLIM data have been demonstrated on two co-expressed variants of the green fluorescence protein (GFP).¹¹⁷

A special case of the described method is called a lifetime invariant fit.^{117,142} When lifetimes are known *a priori*, their values can be fixed during the fit and only amplitudes or intensity fractions are calculated in each pixel. In this case the fitting process evaluates only linear parameters, which are usually less correlated and can be calculated significantly faster than the nonlinear lifetime parameters. The global approach with variable lifetimes is a more general approach, but the high speed of the data analysis could be of prime importance in real-time clinical applications.^{102,110}

The global fit and the lifetime invariant fit are not limited to the analysis of two-dimensional FLIM data. The concept of invariant lifetimes has been extended to the whole sample volume and used with the WF-FLIM for the three-dimensional deconvolution of fluorescent populations associated with phosphorylation states of the epidermal growth factor receptor ErbB1 tagged with GFP. 122

9.4 Selected FLIM Applications

Biological and biomedical applications of the FLIM technique have been treated in several recent reviews.^{5,8,22,157} The technique has been successfully applied in cell biology, clinical diagnostics, and analytical chemistry for determination of spatial ion and metabolite distributions, monitoring of interactions between cellular components by fluorescence resonance energy transfer (FRET), and for detection of abnormal tissues. In the following sections we briefly outline a few selected biological applications.

9.4.1 Intracellular Lifetime-Based pH Imaging and Ion Mapping

Cellular functions critically depend on the maintenance of a proper intracellular environment. Changes of pH and ion concentrations can trigger signalling pathways, activate expression of genes, or influence cellular morphology. A number of lifetime probes suitable for imaging of pH distribution in cytosol and cellular compartments have been characterized ^{158–160} and used for imaging of living systems. ^{48,53,134,161–163} Lifetime-based pH imaging has often been found to be more convenient than conventional ratiometric methods due to a simpler pH calibration ^{48,161} and possibly to distinguish between fractions of bound and free probe. ¹⁶² This allows for elimination of pH estimation errors caused by binding of the probe to cytosolic constituents, which is difficult to achieve with ratiometric imaging. The potential of the lifetime-based imaging with a multiphoton excitation has been demonstrated on microbial biofilms when pH gradients up to the biofilm depth of 140 µm were resolved with the carboxyfluorescein as the pH indicator. ⁵³

Lifetime-based detection has been applied for imaging of cellular ions as well. Spatial calcium distributions measured with nonratiometric lifetime probes have been reported from our laboratory; ^{100,164,165} concentrations of Na⁺ ions in HeLa cells have been monitored with sodium green and phase/modulation fluorometry. ¹¹ Optical sensors for a number of other biologically critical metal ions, e.g., Zn(II), Co(II), Cd(II), Cu(II), and Ni(II) have been systematically characterized ^{166–168} and can be used for lifetime-based imaging.

Similarly to lifetime-based pH indicators, the intracellular lifetime response of the ion-selective fluorophores is typically different from the response in a buffer. Differences are caused mainly by interactions of probes with cellular components or due to a mismatch of intracellular viscosity, pH, and temperature. Therefore, a careful *in vivo* calibration is usually necessary for reliable estimation of intracellular ion concentrations.

9.4.2 Lifetime-Resolved Imaging of Cellular Processes

Cellular FLIM utilizing environmental sensitivity of the emission lifetime provides more information than conventional intensity-based imaging methods. The two-photon FLIM has been used to monitor the macrophage-mediated phagocytosis with the fluorescein-BSA conjugate as an exogenous fluorescent antigen.¹⁷⁰ Due to intracellular proteolysis, the initial subnanosecond lifetime of the conjugate increased with time to a value close to 3.0 ns, providing a monitor of the cellular proteolytic activity.

Cells contain a variety of intrinsic fluorophores. One of them, NADH, can provide information about the oxidation-reduction status of cells and tissues. Lifetime images of the free and protein-bound NADH autofluorescence were first reported by Lakowicz et al. ¹⁰⁵ Later, the FLIM of the NAD(P)H/NAD(P) pairs revealed pathological effects induced by the exposure of cells to strong illumination pulses. ^{126,171}

Imaging of nuclear DNA is another example of the cellular FLIM. Cell cycle-dependent topology of DNA has been studied with the probe YOYO-1, which exhibits a base-pair dependent lifetime. Cells have also been studied by polarized time-resolved fluorescence. Intracellular anisotropy decays were used to map membrane fluidity and the spatial distribution of the cytoplasmic viscosity. The measured microviscosities served for assessment of the spatial organization of the cytoplasm and membranes.

9.4.3 Cellular Interactions Determined by the FRET-FLIM

Due to the inverse 6th power dependence of energy transfer efficiency on the distance between donor and acceptor molecules, ¹⁷² FRET is a powerful strategy to detect interactions, associations, and proximity of cellular components. ^{5,8} Pixel-by-pixel microscopic maps of FRET efficiency can be monitored by fluorescence lifetime imaging of the donor lifetime thus eliminating problems of intensity-based measurements.

Applications of the FRET-FLIM in cellular biology include monitoring phosphorylation, oligomerization and internalization of epidermal growth factor receptors, ^{114,173,174} studies related to signal transduction and imaging of the activated protein kinase C and its association with downstream effectors, ^{112,113,125} and, eventually, topological organization of nuclear DNA. ^{116,119} Time-resolved FRET microscopy has also

been employed to study vesicular transportation of the cholera toxin by following the energy transfer between toxin subunits.¹²⁵

A novel labeling strategy for FRET experiments involved tagging donor-acceptor pairs to the corresponding monoclonal antibody of the object proteins. Recently, genetically encoded fluorophores based on the GFP and its spectral variants represent an exciting possibility for *in vivo* protein labeling.¹⁷⁵ Today FRET experiments can take full advantage of the fusion proteins constructed as GFP-chimeras.¹⁵⁷

9.4.4 Tissue Imaging and Clinical Applications

In vivo applications of lifetime-resolved imaging at the tissue level are emerging. Compared to conventional fluorescence imaging that uses intensity and spectral information as an indication of a tissue abnormality, lifetime-based imaging provides additional physiochemical diagnostic information. Timegated imaging has been used for diagnosis of bones and teeth in order to develop diagnostic methods for bone fractures and early caries, respectively.^{73,74} The diagnostic potential of lifetime-based imaging has been demonstrated by distinguishing lifetime differences between intact tooth enamel and a white-spot lesion area.¹⁷⁶ Additionally, multiphoton excitation has been employed for generation of three-dimensional lifetime images of human skin autofluorescence.¹⁷⁷ Lifetime distributions from the near-surface skin area up to a depth of ~200 μm revealed variations in metabolic states of the cells and indicated a possibility of using lifetime-based imaging for dermatological diagnosis.

For an early clinical diagnosis of the tumor tissue in hollow organs, an endoscope equipped with a real-time, lifetime-based contrast microscopy has been developed.¹¹⁰ Preliminary results include endoscopic lifetime images of the excised bladder, where autofluorescence of the flavin molecules has been recorded. Finally, the frequency-domain photon migration technique has been applied to tissue-simulating phantoms in order to externally image fluorescence properties inside the tissue volume for possible disease detection.¹⁷⁸

9.4.5 Lifetime Imaging with Long-Lived Fluorophores

The best-known application of the long-lifetime fluorophores is for oxygen imaging. Emission of many Ru(II) complexes and Pt(II) porphyrines is dynamically quenched by oxygen and can be effectively used as a lifetime oxygen sensor. Two-dimensional oxygen fluxes and partial pressure maps of surface oxygen have been monitored using such long-lived fluorophores, as well as the TD and FD techniques. ^{109,179–181} The long lifetimes enable adaptation of inexpensive light-emitting diode (LED) light sources and allow for suppression of the short-lived background by proper gating of the detection. Planar chemical sensors based on the long-lived Ru(II) complexes with lifetimes responding to biologically relevant agents such as CO₂, K⁺, Cl⁻, NH₄⁺, and glucose have been integrated on microplate arrays for possible clinical applications. ^{86,182}

9.5 Outlook

Much progress has been made in technology and data analysis since lifetime-based imaging was first reported. Over the years, the potential of lifetime-based imaging has become well recognized and unquestionable. It seems evident that further progress of the technique is tightly linked not only to technological advances but also to advances of probe chemistry and to introduction of new concepts in fluorescence spectroscopy.

To answer the question of where the lifetime-based imaging is heading, one must identify current limitations of the technique and define application-driven goals. Real-world experience could be the starting point: (1) there have never been enough photons for imaging; (2) there is a need for high spatial resolution required by biological applications; (3) there is a demand for faster data acquisition and analysis to study dynamic processes. It seems evident that to satisfy all three requirements simultaneously is not an easy task and compromises must be made. Our vision of the future FLIM instrument is an affordable

real-time apparatus with a three-dimensional lifetime imaging capability and the possibility of multiphoton excitation. The instrument will probably combine lifetime, spectral, and conventional intensity imagers in one multifunctional device for simultaneous multidimensional imaging.

The quality and accuracy of lifetime imaging are determined by the S/N ratio of the data. This ratio can be improved mainly by acquisition of more photons per pixel. Due to the requirement for real-time operation, longer data integration time is unacceptable. Stronger excitation is also problematic due to photobleaching and sample destruction. The solution could be an introduction of brighter probes. Here the concept of fluorescence enhancement near the surface of metallic particles could play a significant role. 183,184 Because the enhancement of fluorescence intensity is caused by faster radiative rate, accompanied by decrease in fluorescence lifetime, future instruments utilizing the intensity-enhanced probes should operate with a picosecond lifetime resolution.

An effort has already been made to build a real-time FLIM apparatus suitable for clinical use and for monitoring dynamic biological events. 102,110,115 Overall data acquisition rate favors WF multichannel imaging systems with an image intensifier as compared to single-channel scanning imagers. A lack of sectioning capability of WF lifetime imagers, however, has been neutralizing this comparative advantage. At present, this drawback seems to be disappearing and technologies utilizing multifocal multiphoton microscopy or structured illumination 75,145,146 have enabled efficient three-dimensional fluorescence lifetime imaging with the WF imagers. In the future, we expect to see fast three-dimensional fluorescence lifetime imagers suitable for imaging turbid biological tissues 178 or for lifetime tomography.

Clinical and biological lifetime-based imaging of turbid samples will require not only a sectioning capability but also a high rejection of scattered light and suppression of autofluorescence. Two-photon excited long-lived long-wavelength fluorophores based on energy transfer^{185,186} or long-lived metalligand complexes^{187,188} will be useful with gated detection. Suppression of the prompt and short-lived emission components is no longer limited to TD gated methods; it also was recently introduced to FD fluorometry. ^{189,190}

It is reasonable to expect that price of future fluorescence lifetime imaging instruments will drop, since expensive pulsed laser systems could be replaced by pulsed or HF-modulated laser diodes or LEDs for routine applications.¹⁷

In this chapter, we were unable to discuss all possible modalities and applications of FLIM. It is obvious that each implementation of lifetime-based imaging has specific advantages and disadvantages and a chosen approach will always be dictated by the application. We conclude that lifetime-based imaging today is a mature technique that is emerging from research laboratories. Nevertheless, more powerful, less-expensive, and easier-to-operate apparatus for lifetime-based imaging is still a future goal.⁶

10.1 Introduction

It is probably fair to say that the development and wide commercial availability of the confocal microscope have been one of the most significant advances in light microscopy in the recent past. The main reason for the popularity of these instruments derives from their ability to permit the structure of thick specimens of biological tissue to be investigated in three dimensions by resorting to a scanning approach together with a novel (confocal) optical system.

The traditional wide-field conventional microscope is a parallel processing system that images the entire object field simultaneously. This is quite a severe requirement for the optical components, but we can relax this requirement if we no longer try to image the whole object at once. The limit of this relaxation is to require an image of only one object point at a time. In this case, all that we ask of the optics is to provide a good image of one point. The price that we pay is that we must scan in order to build up an image of the entire field. The answer to the question whether this price is worth paying will, to some extent, depend on the application in question.

A typical arrangement of a scanning confocal optical microscope is shown in Figure 10.1 in which the system is built around a host conventional microscope. The essential components are some form of mechanism for scanning the light beam (usually from a laser) relative to the specimen and appropriate photodetectors to collect the reflected or transmitted light. Most of the early systems were analog in nature; however, it is now universal, thanks to the serial nature of the image formation, to use a computer to drive the microscope and to collect, process, and display the image.

In the beam scanning confocal configuration of Figure 10.1 the scanning is typically achieved by using vibrating galvanometer-type mirrors or acousto-optic beam deflectors. The use of the latter gives the possibility of TV-rate scanning, whereas vibrating mirrors are often relatively slow when imaging an extended region of the specimen, although significantly higher scanning speeds are achievable over smaller scan regions. Note that other approaches to scanning may be implemented, such as specimen scanning and lens scanning. These methods, although not generally available commercially, do have advantage in certain specialized applications. This chapter is necessarily limited in length, but much additional material may be found in other sources! in which a detailed list of references may be found.

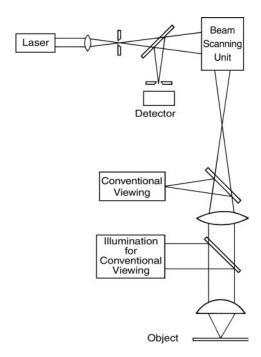

FIGURE 10.1 Schematic diagram of a confocal microscope.

10.2 Image Formation in Scanning Microscopes

We will not discuss the fine detail of the optical properties of confocal systems because this is already widely available in the literature. The essence is shown in Figure 10.1, where the confocal optical system consists simply of a point source of light that is then used to probe a single point on the specimen. The strength of the reflected or fluorescence radiation from the single object point is then measured via a point, pinhole detector. The confocal — point source and point detector — optical system therefore merely produces an "image" of a single object point and hence some form of scanning is necessary to produce an image of an extended region of the specimen. However, the use of single-point illumination and single-point detection results in novel imaging capabilities that offer significant advantages over those possessed by conventional wide-field optical microscopes. In essence, these are enhanced lateral resolution and, perhaps more importantly, a unique depth discrimination or optical sectioning property. It is this latter property that leads to the ability to obtain three-dimensional images of volume specimens.

The improvement in lateral resolution may at first seem implausible. However, it can be explained simply by a principle given by Lukosz,⁸ which states, in essence, that resolution can be increased at the expense of field of view. The field of view can then be increased by scanning. One way of taking advantage of Lukosz's principle is to place a very small aperture extremely close to the object. The resolution is now determined by the size of the aperture rather than the radiation. In the confocal microscope we do not use a physical aperture in the focal plane but, rather, use the back-projected image of a point detector in conjunction with the focused point source. Figure 10.2 indicates the improvement in lateral resolution that may be achieved.

The confocal principle, which was first described by Minsky,⁹ was introduced in an attempt to obtain an image of a slice within a thick specimen that was free from the distracting presence of out-of-focus information from surrounding planes. The confocal optical system fulfils this requirement; its inherent optical sectioning or depth discrimination property has become the major motivation for using confocal microscopes, and is the basis of many of the novel imaging modes of these instruments.

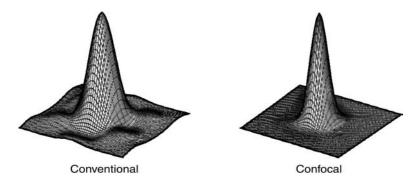

FIGURE 10.2 The point spread functions of conventional and confocal microscopes showing the improvement in lateral resolution that may be obtained in the confocal case.

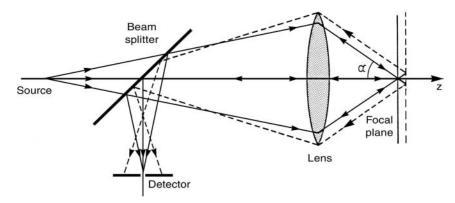

FIGURE 10.3 The origin of the optical sectioning or depth discrimination property of the confocal optical system.

The origin of the depth discrimination property may be understood very easily from Figure 10.3, where we show a reflection-mode confocal microscope and consider the imaging of a specimen with a rough surface. The full lines show the optical path when an object feature lies in the focal plane of the lens. At a later scan position, the object surface is supposed to be located in the plane of the vertical dashed line. In this case, simple ray tracing shows that the light reflected back to the detector pinhole arrives as a defocused blur, only the central portion of which is detected, and contributes to the image. In this way the system discriminates against features that do not lie within the focal region of the lens.

A very simple method of demonstrating the effect and giving a measure of its strength is to scan a perfect reflector axially through focus and measure the detected signal strength. Figure 10.4 shows a typical response. These responses are frequently termed the V(z) by analogy with a similar technique in scanning acoustic microscopy, although the correspondence is not perfect. A simple paraxial theory models this response as:

$$I(u) = \left\lceil \frac{\sin(u/2)}{u/2} \right\rceil^2 \tag{10.1}$$

where u is a normalized axial coordinate related to real axial distance, z, via:

$$u = \frac{8\pi}{\lambda} nz \sin^2\left(\alpha/2\right) \tag{10.2}$$

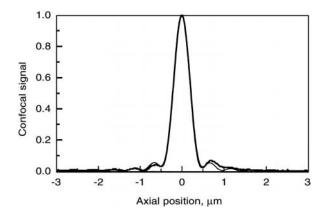

FIGURE 10.4 The variation in detected signal as a plane reflector is scanned axially through focus. The measurement was taken with a 1.3 numerical aperture objective and 633-nm radiation.

where λ is the wavelength and n sin α the numerical aperture. As a measure of the strength of the sectioning, we can choose the full width at half intensity of the I(u) curves. Figure 10.5 shows this value as a function of numerical aperture for the specific case of imaging with red light from a helium neon laser. These curves were obtained using a high aperture theory, which is more reliable than Equation 10.1 at the highest values of numerical aperture. We note, of course, that these numerical values refer to nonfluorescence imaging. The qualitative explanation of optical sectioning, of course, carries over to the fluorescence case, but the actual value of the optical sectioning strength is different in the fluorescence case.

10.3 Applications of Depth Discrimination

This property is one of the major reasons for the popularity of confocal microscopes, so it is worthwhile, at this point, to review briefly some of the novel imaging techniques that have become available with confocal microscopy.

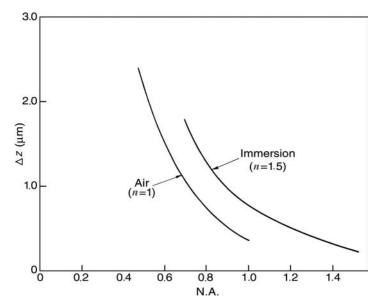

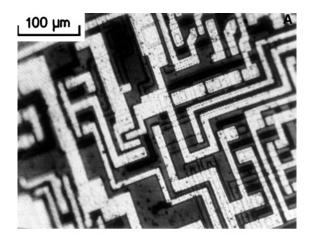

FIGURE 10.5 The optical sectioning width as a function of numerical aperture. The curves are for red light $(0.6328 \, \mu \text{m} \text{ wavelength})$. Δz is the full width at the half-intensity points of the curves of I(u) against u.

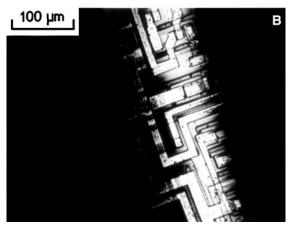

FIGURE 10.6 (A) Conventional scanning microscope image of a tilted microcircuit: the parts of the object outside the focal plane appear blurred. (B) Confocal image of the same microcircuit: only the part of the specimen within the focal region is imaged strongly.

Figure 10.6 illustrates the essential effect: Figure 10.6A shows a conventional image of a planar microcircuit that has deliberately been mounted with its normal at an angle to the optic axis. We see that only one portion of the circuit, running diagonally, is in focus. Figure 10.6B shows the corresponding confocal image: here the discrimination against detail outside the focal plane is clear. The areas that were out of focus in Figure 10.6A have been rejected. Furthermore, the confocal image appears to be in focus throughout the visible band, which illustrates that the sectioning property is stronger than the depth of focus.

This suggests that, if we try to image a thick translucent specimen, we can arrange, by the choice of our focal position, to image detail exclusively from one specific region. In essence, we can section the specimen optically without resorting to mechanical means. Figure 10.7 shows an idealized schematic of the process. The portion of the beehive-shaped object that we see is determined by the focus position. In this way, it is possible to take a through-focus series of images and obtain data about the three-dimensional structure of the specimen. If we represent the volume image by I(x,y,z), then, ideally, by focusing at a position $z = z_1$, we obtain the image $I(x,y,z_1)$. This, of course, is not strictly true in practice because the optical section is not infinitely thin.

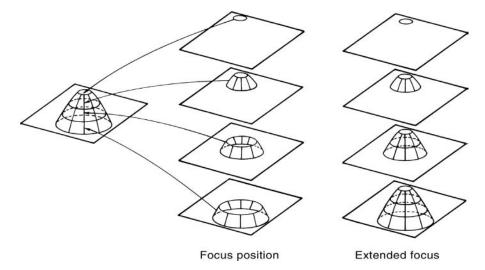

FIGURE 10.7 An idealization of the optical sectioning property showing the ability to obtain a through-focus series of images, which may then be used to reconstruct the original volume object at high resolution.

It is clear that the confocal microscope allows us to form high-resolution images with a depth of focus sufficiently small that all the detail that is imaged appears in focus. This suggests immediately that we can extend the depth of focus of the microscope by adding together (integrating) the images taken at different focal settings without sacrificing the lateral resolution. Mathematically, this extended-focus image is given by:

$$I_{FF} = I(x, y, z)dz \tag{10.3}$$

As an alternative to the extended-focus method, we can form an auto-focus image by scanning the object axially and, instead of integrating, selecting the focus at each picture point by recording the maximum in the detected signal. Mathematically, this might be written:

$$I_{AF}(x,y) = I(x,y,z_{max})$$

$$(10.4)$$

where z_{max} corresponds to the focus setting giving the maximum signal. The images obtained are somewhat similar to the extended focus and, again, substantial increases in depth of focus may be obtained. We can go one step further in this case and turn the microscope into a noncontacting surface profilometer. Here we simply display z_{max} .

It is clear by now that the confocal method gives us a convenient tool for studying three-dimensional structures in general. We essentially record the image as a series of slices and play it back in any desired fashion. Naturally, in practice it is not as simple as this, but we can, for example, display the data as an *x-z* image rather than an *x-y* image. This is somewhat similar to viewing the specimen from the side. As another example, we might choose to recombine the data as stereo pairs by introducing a slight lateral offset to each image slice as we add them up. If we do this twice, with an offset to the left in one case and the right in another, we obtain, very simply, stereo pairs. Mathematically, we form images of the form:

$$\int I(x \pm \gamma z, y, z) dz \tag{10.5}$$

where γ is a constant. In practice it may not be necessary to introduce offsets in both directions to obtain an adequate stereo view.

All that we have said so far on these techniques has been by way of simplified introduction. In particular we have not presented any fluorescence images, because these will be dealt with adequately later. The key point is that, in both bright-field and fluorescence modes, the confocal principle permits the imaging of specimens in three dimensions. Of course, the situation is more involved than we have implied. A thorough knowledge of the image formation process, together with the effects of lens aberrations and absorption, is necessary before accurate data manipulation can take place.

In conclusion to this section, it is important to emphasize that the confocal microscope does not produce three-dimensional images. The opposite is true: it essentially produces very high-quality two-dimensional images of a (thin) slice within a thick specimen. A three-dimensional rendering of the entire volume specimen may then be generated by suitably combining a number of these two-dimensional image slices from a through-focus series of images.

10.4 Fluorescence Microscopy

We now turn our attention to confocal fluorescence microscopy because this is the imaging mode usually employed in biological applications. Although we have introduced the confocal microscope in terms of bright-field imaging, the comments concerning the origin of the optical sectioning, etc. carry over directly to the fluorescence case. However, the numerical values describing the strength of the optical sectioning are, of course, different and we will return to this point later.

If we assume that the fluorescence in the object destroys the coherence of the illuminating radiation and produces an incoherent fluorescent field proportional to the intensity of the incident radiation, I(v,u), then we may write the effective intensity point spread function, which describes image formation in the incoherent confocal fluorescence microscope, as

$$I(v,u) I\left(\frac{v}{\beta}, \frac{u}{\beta}\right) \tag{10.6}$$

where the optical coordinates u and v are defined relative to the primary radiation and

$$\beta = \frac{\lambda_2}{\lambda_1}$$

is the ratio of the fluorescence to the primary wavelength. We note that

$$v = \frac{2\pi}{\lambda_1} r n \sin \alpha$$

where r denotes the actual radial distance.

This suggests that the imaging performance depends on the value of β . In order to illustrate this, Figure 10.8 shows the variation in detected signal strength as a perfect fluorescent sheet through focus. This serves to characterize the strength of the optical sectioning in fluorescence microscopy in the same way that the mirror was used in the bright-field case. We note that the half width of these curves is essentially proportional to β and so for optimum sectioning the wavelength ratio should be as close to unity as possible.

We have just discussed what we might call one-photon fluorescence microscopy in the sense that a fluorophore is excited by a single photon of a particular wavelength. It then returns to the ground state and emits a photon at the (slightly longer) fluorescence wavelength. It is this radiation that is detected via the confocal pinhole. Recently, however, much interest has centered on two-photon excitation fluorescence microscopy. ^{10,11} This process relies on the simultaneous absorption of two, longer wavelength

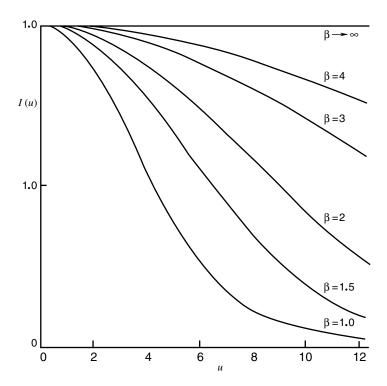

FIGURE 10.8 The detected signal as a perfect planar object is scanned axially through focus for a variety of fluorescent wavelengths. If we measure the sectioning by the halfwidth of these curves, the strength of the sectioning is essentially proportional to β .

photons, following which a single fluorescence photon is emitted. The excitation wavelength is typically twice that used in the one-photon case.

The beauty of the two-photon approach lies in the quadratic dependence of the fluorescence intensity on the intensity of the illumination. This leads to fluorescence emission, which is always confined to the region of focus. In other words, the system possesses an inherent optical sectioning property. Other benefits of two-photon fluorescence over the single-photon case include the use of red or infrared lasers to excite ultraviolet dyes, confinement of photo-bleaching to the focal region (the region of excitation), and the reduced effects of scattering and greater penetration. However, it should also be remembered that, compared with single photon excitation, the fluorescence yield of many fluorescent dyes under two-photon excitation is relatively low.¹²

In order to make a theoretical comparison between the one- and two-photon modalities, we shall assume that the *emission* wavelength λ_{em} is the same irrespective of the mode of excitation. Since the wavelength required for single-photon excitation is generally shorter than the emission wavelength, we may write it as $\gamma \lambda_{em}$ where $\gamma < 1$. Because two-photon excitation requires the simultaneous absorption of two photons of half the energy, we will assume that the excitation wavelength in this case may be written as $2\gamma \lambda_{em}$, which has been shown to be a reasonable approximation for many dyes.¹³

If we now introduce optical coordinates u and v normalized in terms of λ_{em} we may write the effective point spread functions in the one-photon confocal and two-photon case as

$$I_{1p-conf} = I\left(\frac{\nu}{\gamma}, \frac{u}{\gamma}\right) I(\nu, u) \tag{10.7}$$

and

$$I_{2p} = I^2 \left(\frac{v}{2\gamma}, \frac{u}{2\gamma} \right) \tag{10.8}$$

respectively. We note that, although a pinhole is not usually employed in two-photon microscopy, it is perfectly possible to include one if necessary. In this confocal two-photon geometry the effective point spread function becomes

$$I_{2p-conf} = I^{2} \left(\frac{v}{2\gamma}, \frac{u}{2\gamma} \right) I(v, u)$$
 (10.9)

If we now look at Equations 10.7 and 10.8 in the $\gamma = 1$ limit, we find

$$I_{1p-conf} = I^2(v,u)$$
 (10.10)

and

$$I_{2p} = I^2 \left(\frac{v}{2}, \frac{u}{2} \right) \tag{10.11}$$

We now see that, because of the longer excitation wavelength used in two-photon microscopy, the effective point spread function is twice as large as that of the one-photon confocal in both the lateral and axial directions. The situation is somewhat improved in the confocal two-photon case, but it is worth remembering that the advantages of two-photon excitation microscopy are accompanied by a reduction in optical performance compared to the single-photon case.

From the practical point of view, the two-photon approach has certain very important advantages over the one-photon excitation in terms of image contrast when imaging through scattering media apart from the greater depth of penetration afforded by the longer wavelength excitation. In a single-photon confocal case, it is quite possible that the desired fluorescence radiation from the focal plane may be scattered after generation in such a way that it is not detected through the confocal pinhole. Further, since the fluorescence is generated throughout the entire focal volume, it is also possible that undesired fluorescence radiation, which was not generated within the focal region, may be scattered so as to be detected through the confocal pinhole.

In either case this leads to a reduction in image contrast. The situation is, however, completely different in the two-photon case. Here the fluorescence is generated only in the focal region and not throughout the focal volume. Furthermore, because all the fluorescence is detected via a large area detector — no pinhole is involved — it is not so important if further scattering events take place. This leads to high-contrast images, which are less sensitive to scattering. This is particularly important for specimens that are much more scattering at the fluorescence ($\lambda/2$) wavelength than the excitation (λ) wavelength.

10.5 Optical Architectures

In addition to the generic architecture of Figure 10.1, a number of alternative implementations of confocal microscopes have been recently developed in order to reduce the alignment tolerances of the architecture of Figure 10.1 as well as to increase image acquisition speed. Because great care is required to ensure that the illumination and detector pinholes lie in equivalent positions in the optical system, a reciprocal geometry confocal system has been developed that uses a single pinhole to launch light into the microscope as well as to detect the returning confocal image signal. A development on this is to replace the physical pinholes with a single mode optical fiber. However, these systems are essentially developments of the traditional confocal architecture. We will now describe two recent attempts to develop new confocal architectures. The first system is based on the pinhole source/detector concept, whereas the second

approach describes a simple modification to a conventional microscope so as to permit optically sectioned images to be obtained.

10.5.1 The Aperture Mask System

The question of system alignment and image acquisition speed have already been answered to a certain extent by Petrán and his colleagues, who originally developed the tandem scanning (confocal) microscope;¹⁴ this was later reconfigured into a one-sided disk embodiment (see, for example, Corle and Kino⁴).

The main component of the system is a disk containing many pinholes. Each pinhole acts as the illumination and the detection pinhole, so the system acts rather like a large number of parallel, reciprocal-geometry, confocal microscopes, each imaging a specific point on the object. However, because it is important that no light from a particular confocal system enter an adjacent system, i.e., no cross talk between adjacent confocal systems, the pinholes in the disk must be placed far apart — typically ten pinhole diameters apart — which has two immediate consequences. First, only a small amount — typically 1% — of the available light is used for imaging and, second, the wide spacing of the pinholes means that the object is only sparsely probed. In order to probe, and hence image, the whole object, it is necessary to arrange the pinhole apertures in a series of Archimedean spirals and to rotate the disk. These systems have been developed and are capable of producing high-quality images without the need to use laser illumination in real time with TV rate as well as higher imaging speeds.

In order to make greater use of the available light in this approach we must, inevitably, place the pinholes closer together. This, of course, leads to cross talk between the neighboring confocal systems and thus a method must be devised to prevent this. In order to do this, we replace the Nipkow disk of the tandem scanning microscope with an aperture mask consisting of many pinholes placed as close together as possible. This aperture mask has the property that any of its pinholes can be opened and closed independently of the others in any desired time sequence. This might be achieved, for example, by using a liquid crystal spatial light modulator. Because we require no cross talk between the many parallel confocal systems, it is necessary to use a sequence of openings and closings of each pinhole completely uncorrelated with the openings and closings of all the other pinholes.

Many such ortho-normal sequences are in the literature. However, they all require the use of positive and negative numbers and, unfortunately, we cannot have negative intensity of light! The pinhole is either open, which corresponds to 1, or closed, which corresponds to 0. No position can correspond to -1. The way out of the dilemma is to not obtain the confocal signal directly. In order to use a particular orthonormal sequence, $b_i(t)$, of plus and minus ones for the ith pinhole, we must add a constant shift to the desired sequence in order to make a sequence of positive numbers that can be encoded in terms of pinhole opening and closing.

Thus we encode each of the pinhole openings and closings as $(1 + b_i(t))/2$, which will correspond to open (1) when $b_i(t) = 1$ and to close (0) when $b_i(t) = -1$. The effect of adding the constant offset to the desired sequence is to produce a composite image that will be partly confocal due to the $b_i(t)$ terms and partly conventional due to the constant term. The method of operation is now clear. We first take an image with the pinholes encoded as we have just discussed and so obtain a composite conventional plus confocal image. We then switch all the pinholes to the open state to obtain a conventional image. It is then a simple matter to subtract the two images in real time in a computer to produce the confocal image.

Although this approach may be implemented using a liquid crystal spatial light modulator, it is cheaper and simpler merely to impress the correlation codes photolithographically on a disk and rotate it so that the transmissivity at any picture point varies according to the desired ortho-normal sequence. A blank sector may be used to provide the conventional image. If this approach is adopted, then all that is required is to replace the single-sided Nipkow disk of the tandem scanning microscope with a suitably encoded aperture disk, as shown in Figure 10.9.¹⁵ Figure 10.10 shows a through-focus series of images of a fly's eye; Figure 10.11 shows three-dimensional representation of the fly's eye obtained with this white light real-time confocal system.

FIGURE 10.9 A typical aperture mask. When light passes through the encoded region of the disk, a composite conventional and confocal image is obtained. Light passing through the unobstructed sector provides a conventional image.

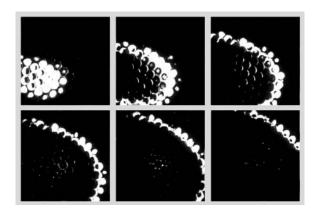

FIGURE 10.10 A through-focus series of images of a portion of a fly's eye. Each optical section was recorded in real time using standard nonlaser illumination.

10.5.2 The Use of Structured Illumination to Achieve Optical Sectioning

The motivation for the development we have just described was to produce a light-efficient, real-time, three-dimensional imaging system. The approach was to start with the traditional confocal microscope design — point source and point detector — and to engineer a massively parallel, light-efficient three-dimensional imaging system (see also Liang et al. ¹⁶ and Hanley et al. ¹⁷).

An alternative approach is to realize that the conventional light microscope already possesses many desirable properties: real-time image capture, standard illumination, ease of alignment, etc. However it does not produce optically sectioned images in the sense usually understood in confocal microscopy. In order to see how this deficiency may be corrected via a simple modification of the illumination system, let us look at the theory of image formation in a conventional fluorescence microscope and ask in what way the image changes as the microscope is defocused.

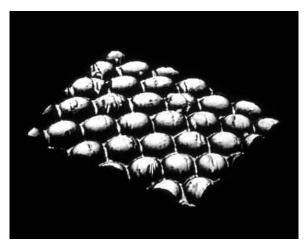

FIGURE 10.11 A computer generated three-dimensional representation of the fly's eye.

We know that in a confocal microscope the image signal from all object features attenuates with defocus and that this does not happen in a conventional microscope. However, when we look closely at the image formation process we find that it is only the zero spatial frequency (constant) component that does not change with defocus (Figure 10.12); all other spatial frequencies actually do attenuate with defocus to a greater or lesser extent. Figure 10.13 shows the image of a single spatial frequency one-dimensional bar pattern object for increasing degrees of defocus. When the specimen is imaged in focus, a good image of the bar pattern is obtained. However, with increasing defocus the image becomes progressively poorer and weaker until it eventually disappears, leaving a uniform gray level. This suggests a simple way to perform optical sectioning in a conventional microscope.

If we simply modify the illumination path of the microscope so as to project onto the object the image of a one-dimensional, single spatial frequency fringe pattern, then the image we see through the microscope will consist of a sharp image of those parts of the object where the fringe pattern is in focus, but an out-of-focus blurred image of the rest of the object. In order to obtain an optically sectioned image, it is necessary to remove the blurred out-of-focus portion as well as the fringe pattern from the in-focus optical section. There are many ways to do this — one of the simplest involves simple processing of three images taken at three different spatial positions of the fringe pattern. The out-of-focus regions remain fairly constant between these images and the relative spatial shift of the fringe pattern allows the three

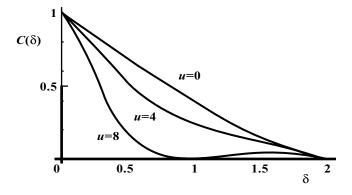

FIGURE 10.12 The transfer function for a conventional fluorescence microscope for a number of values of defocus (measured in optical units). The response for all non-zero spatial frequencies decays with defocus.

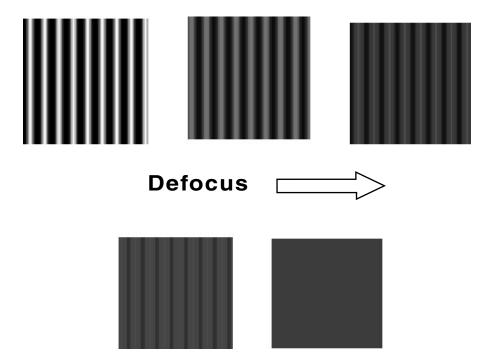

FIGURE 10.13 The image of a one-dimensional single spatial frequency bar pattern for varying degrees of defocus. For sufficiently large values of defocus, the bar pattern is not imaged at all.

images to be combined in such a way as to remove the fringes. This permits us to retrieve an optically sectioned image as well as a conventional image in real time.¹⁸

The approach involves processing three conventional microscope images, so the image formation is fundamentally different from that of the confocal microscope. However, the depth discrimination or optical sectioning strength is very similar and this approach, which requires very minimal modifications to the instrument, has been used to produce high-quality three-dimensional images of volume objects directly comparable to those obtained with confocal microscopes. A schematic of the optical arrangement is shown in Figure 10.14A together with experimentally obtained axial responses in Figure 10.14B. These responses are substantially similar to those obtained in the true confocal case.

As an example of the kinds of images that can be obtained with this type of microscope, Figure 10.15 shows two images of a spiracle of a head louse. The first is an auto-focus image of greatly extended depth of field constructed from a through-focus series of images. The second is a conventional image taken at mid-focus. The dramatic increase in depth of field is clear when compared with a mid-focus conventional image. These images were taken using a standard microscope illuminator as light source. Indeed, the system is so light efficient that good quality optical sections of transistor specimens have been obtained using simply a candle as light source.

Imaging using fluorescence light is also possible using this technique. However, an alternative approach that does not require a physical grid is possible if a laser is used as the light source. In this system, the laser illumination is split into two beams that are allowed to interfere at an angle in the fluorescent specimen. This has the effect of directly "writing" a one-dimensional fringe pattern in the specimen. Spatial shift of the fringe pattern is achieved by varying the phase of one of the interfering beams. As before, three images are taken from which the optically sectioned image and the conventional image may be obtained.¹⁹ The beauty of this approach is that no imaging optics are required at the illuminating wavelength and system alignment is trivial.

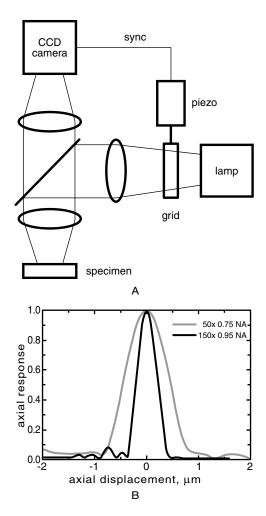

FIGURE 10.14 (A) Optical system of the structured illumination microscope together with experimentally obtained axial responses in (B), which confirm the optical sectioning ability of the instrument.

10.6 Abberation Correction

As we have seen, the most important feature of the confocal microscope is its optical sectioning property, which permits volume structures to be rendered in three dimensions via a suitable stack of through-focus images. However, in order to achieve the highest performance, it is necessary that the optical resolution be the same at all depths within the optical section. Unfortunately, there are fundamental reasons why this cannot be achieved in general. One is that high aperture microscope objectives are often designed to give optimum performance when imaging features located just below the cover glass. Another is more fundamental and is due to specimen-induced refractive index mismatches. These could be caused by a variety of reasons, such as the use of an oil immersion objective to image into a watery specimen, or may be due to refractive index inhomogeneities within the specimen. In many cases they cannot be removed by system design and a new approach must be taken. An adaptive method of correction in which the aberrations are measured using a wavefront sensor and removed with an adaptive wavefront corrector, such as a deformable mirror, is required.

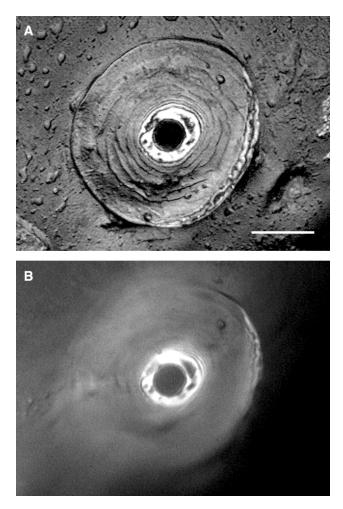

FIGURE 10.15 Two images of the region around the spiracle of a head louse. As in the previous figure, (A) is an autofocus image and (B) shows a mid-focus conventional image. Scale bar = $10 \mu m$.

A number of methods of wavefront sensing have already been developed for astronomical applications. Unfortunately these approaches are not necessarily appropriate for microscopy. Further, because the optical sectioning property of the confocal system limits the region of the specimen to be imaged to that lying close to the focal plane, it is clearly desirable that the wavefront sensor possess a similar optical sectioning property.

A very powerful method of describing a particular wavefront aberration is in terms of a superposition of aberration modes such as those described by the Zernike circle polynomials.²⁰ Mathematically speaking, the wavefront aberration is represented by a truncated series of Zernike polynomials (modes). These polynomials, which are two-dimensional functions, are orthogonal over the unit circle and hence are particularly useful in optics where apertures and lenses are typically circular in cross section. Their real power, however, lies in the fact that real-world aberrations can often be described by only a few low-order Zernike modes. We have shown, for example, that the aberrations introduced when focusing into a biological specimen are dominated by a few lower order modes.²¹ It is therefore attractive to consider basing an adaptive system on Zernike polynomials since it will be possible to simplify the overall system design because the Zernike modes of interest could be measured directly. Equally

importantly, because only a small number of modes need to be measured, the complexity of the wavefront sensor would be reduced.

The operation of the modal wavefront sensor is based upon the concept of "wavefront biasing." This process involves the combination of certain amounts of the Zernike aberration mode being measured (the "bias mode") with the input wavefront. Conceptually, this can be done by including appropriately shaped or etched glass plates in the optical beam path, although in practice other methods are used. First, the beam containing the input wavefront passes through a beamsplitter to create two identical beams. In the first beam, a positive amount of the bias mode is added to the wavefront, which is then focused by a lens onto a pinhole. In the second beam, an equal but opposite negative amount of the bias mode is added to the wavefront. This is again focused onto a pinhole. Behind each pinhole lies a photodetector that measures the optical power passing through the pinhole. The output signal of the sensor, which is taken to be the difference between the two photodetector signals, is found to be sensitive to the amount of the particular "bias" Zernike mode present in the input wavefront.²²

One method of implementation of this wavefront sensor permits the entire Zernike modal content of a wavefront to be measured simultaneously. This is achieved by using a computer-generated binary phase hologram, which produces a diffraction pattern consisting of a number of spots created with the appropriate bias aberrations. A pair of spots in the diffraction pattern corresponds to the two spots produced in the positively and negatively biased paths for a given bias mode. An array of pinholes and photodetectors is positioned behind the diffraction pattern and, as before, the output signal for each mode is taken as difference between the detector signals from oppositely biased spots.

Another implementation of the modal wavefront sensor involves the sequential application of bias modes using an adaptive element. Adaptive optics systems use some form of adaptive wavefront shaping element in order to remove unwanted aberrations from the wavefront. Suitable devices include membrane or bimorph deformable mirrors and liquid crystal spatial light modulators. Effectively, the device flattens the aberrated wavefront by adding an equal but opposite aberration to it. Naturally, a device with such capabilities can also be used to apply the bias aberrations in a wavefront sensor sequentially. The sensor in this case comprises simply the biasing element, one lens, and a single pinhole/photodetector. The positive and negative bias aberrations for each mode are applied in turn and the corresponding detector signals are measured. Because the adaptive element applying the bias modes can be the same device used for correction of the wavefront, the resulting adaptive optics system can operate without a separate wavefront sensor. Considering also that only a single photodetector is required, this facilitates the design of a simple, low-cost adaptive optics system.

The practicability of this new approach has been demonstrated in a confocal microscope and has been used to measure and correct aberrations in the imaging of biological specimens.²³ Figure 10.16 shows the uncorrected and corrected *x-y* and *x-z* images of a specimen of fluorescently labeled mouse intestine.

10.7 Summary

We have discussed the origin of the optical sectioning property in the confocal microscope in order to introduce the range of imaging modes to which this unique form of microscope leads. A range of optical architectures has also been described. By far the most universal is that shown in Figure 10.1 where a confocal module is integrated around a conventional optical microscope. Other, more recent real-time implementations have also been described. A number of practical aspects of confocal microscopy have not been discussed. This is because they are readily available elsewhere, such as advice on the correct choice of detector pinhole size, or because they are still the focus of active research, such as the development of new contrast mechanisms for achieving enhanced three-dimensional resolution such as the stimulated emission depletion method (STED)²⁴ or 4-Pi.²⁵ These are still under development but offer great promise.

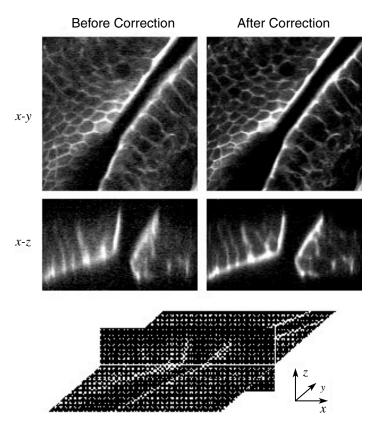

FIGURE 10.16 Confocal microscope scans before and after aberration correction. x-y (lateral) and x-z (axial) scans of a fluorescently labeled section of mouse intestine specimen are shown. The schematic beneath illustrates the relative three-dimensional orientation of the x-y and x-z scans. The image dimensions in the x and y directions are 80 μ m; the z dimension is 15 μ m.

11.1 Introduction

Maria Göppert-Mayer first predicted the possibility of multiphoton excitation process in her doctoral dissertation presented in Göttingen.¹ Experimental verification of multiphoton processes was not realized until 1963 when Kaiser and Garret first observed two-photon excitation of CaF₂:Eu²+ fluorescence.² Later, Kaiser and Garret further demonstrated two-photon excitation fluorescence from organic molecules. Three-photon excitation was subsequently reported by Singh and Bradley.³ Multiphoton excitation of biochemical molecules provides complementary spectroscopic information to standard one-photon studies.⁴-7

The utilization of nonlinear optical processes to provide image contrast for microscopic studies was realized by pioneers such as Freund, Hellwarth, and Chirstensen.⁸ Nonlinear optical imaging having inherent three-dimensioned (3D) resolution was first suggested by the Oxford group including Sheppard, Kompfner, Gannaway, and Wilson.^{9,10} They predicted that optical emissions that have quadratic or higher-order dependence on the excitation power will be confined to the focal plane of the microscope objective. The utilization of this principle for 3D imaging was realized in the seminal work of Denk, Strickler, and Webb.¹¹ Denk and co-workers further demonstrated the importance of this approach for limiting photodamage and for extending penetration depth in biological specimens. This work revolutionized

the application of 3D microscopy in biomedical imaging. The applications of other nonlinear optical mechanisms in biological imaging, such as second and third harmonic generation, sum frequencies generation, and coherent anti-Stokes Raman scattering, soon followed.^{12–14} This chapter focuses on multiphoton fluorescence microscopy, one of the most widely used nonlinear microscopy approaches, and its applications in biology and medicine.

The subject of multiphoton microscopy has been covered in a number of other excellent reviews providing different perspectives on this subject.^{15–18} This chapter presents a discussion of the basic principle of multiphoton excitation and image formation, a review of two-photon instrumentation, and fluorescent probe choices. Because multiphoton microscopy is finding its most important applications in tissue imaging, a discussion on the strengths and limitations of this technology for deep tissue imaging is provided. This chapter concludes with a review of successful tissue imaging applications using two-photon microscopy.

11.2 Basic Principles of Multiphoton Excitation and Image Formation

11.2.1 The Physics of Multiphoton Excitation

The theory of two-photon excitation was predicted by Göppert-Mayer in 1931. The basic physics of this phenomenon has also been described in a number of standard quantum mechanical texts. Fluorescence excitation is an interaction between the fluorophore and an excitation electromagnetic field and is described by a time-dependent Schroedinger equation where the Hamiltonian contains an electric dipole interaction term: $\vec{E}_{\gamma} \cdot \vec{r}$, where \vec{E}_{γ} is the electric field vector of the photons and \vec{r} is the position operator. This equation can be solved by perturbation theory. The first-order solution corresponds to the one-photon excitation with transition probability P.

$$P \sim \left| \left\langle f \middle| \vec{E}_{\gamma} \cdot \vec{r} \middle| i \right\rangle \right|^2,$$
 (11.1)

where $|i\rangle$ denotes the ground electronic state and $|f\rangle$ denotes the excited electronic state. The *n*-photon transitions are represented by the *n*th order solutions. In the case of two-photon excitation, the transition probability between the molecular ground state $|i\rangle$ and the excited state $|f\rangle$ is represented by

$$P \sim \left| \sum_{m} \frac{\left\langle f \middle| \vec{E}_{\gamma} \cdot \vec{r} \middle| m \right\rangle \left\langle m \middle| \vec{E}_{\gamma} \cdot \vec{r} \middle| i \right\rangle}{\varepsilon_{\gamma} - \varepsilon_{m}} \right|^{2}, \tag{11.2}$$

where ε_{γ} is the photonic energy associated with the electric field vector \vec{E}_{γ} , and the summation is over all intermediate states m with energy ε_{m} .

Therefore, two-photon excitation of molecules is a nonlinear process involving the absorption of two photons whose combined energy is sufficient to induce a molecular transition to an excited electronic state. Conventional one-photon technique uses ultraviolet or visible light to excite fluorescent molecules of interest. Excitation occurs when the absorbed photon energy matches the energy gap between the ground and excited state. The same transition can be excited by a two-photon process where two less energetic photons are simultaneously absorbed. Quantum mechanically, the first photon excites the molecule to a virtual intermediate state, and the molecule is eventually brought to the final excited state by the absorption of a second photon. A comparison of one- and two-photon absorption is shown in Figure 11.1. In the absence of major vibrational perturbations, inductive effects, or solvent relaxation, the probability of the transition depends on the magnitude of the overlap integrals between the ground,

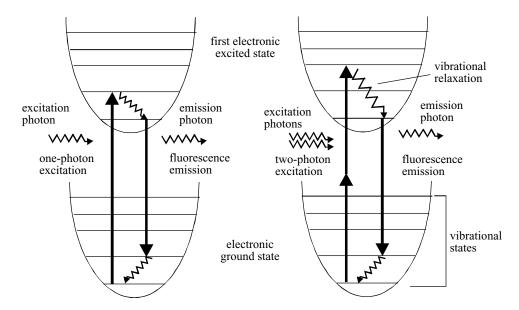

FIGURE 11.1 Jablonski diagrams for one-photon (left) and two-photon (right) excitation. Excitations occur between the ground state and the vibrational levels of the first electronic excited state. After either excitation process, the fluorophore relaxes to the lowest energy level of the first excited electronic states via vibrational processes. The subsequent fluorescence emission process for both relaxation modes is the same.

intermediate, and excited states of a particular fluorophore. Choosing fluorophores with higher multiphoton cross sections allows more efficient excitation with lower photon dose.

A molecular state can be described by an eigenfunction with a definite parity. For a molecular state with even parity, there is no change in the sign of the wavefunction when there are sign changes in the spatial coordinates. For a molecular state with odd parity, the sign of the wavefunction changes when the sign changes in the spatial coordinates. Because the dipole operator has odd parity (i.e., absorbing one photon changes the parity of the state), the one-photon transition couples initial and final states with opposite parity. On the other hand, the two-photon moment only allows transition between two states with the same parity. 19,20 In general, an n-photon process couples states with equal parity, if n is even, and opposite parity, if n is odd.

Finally, it should be noted that while the absorption cross sections for one-, two-, and multiphoton excitation of a given fluorophore are different, the molecule rapidly relaxes to the same vibrational level in the excited electronic state. The excited state residence time (fluorescence lifetime) and the fluorescence decay processes depend only on the molecular structure and its microenvironment. Therefore, the fluorescence quantum yield and emission spectra are independent of the initial excitation process.

11.2.2 Imaging Properties of Two-Photon Microscopy

One of the most important attributes of two-photon microscopy is its inherent 3D sectioning capability. The sectioning capability of this method originates from the quadratic and higher-order dependence of the fluorescence signal upon the excitation intensity distribution.

Consider the intensity distribution at the focal point of a high numerical aperture objective. The spatial profile of the diffraction-limited focus for an objective with numerical aperture, $NA = \sin(\alpha)$, is

$$I(u,v) = \left| 2 \int_0^1 J_0(v\rho) e^{-\frac{i}{2}u\rho^2} \rho \, d\rho \right|^2, \tag{11.3}$$

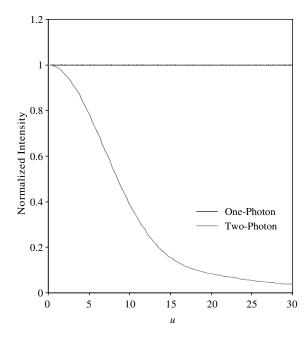

FIGURE 11.2 Total fluorescence generated at a given *z*-plane is calculated. This quantity is plotted as a function of its distance from the focal plane. For one-photon excitation, equal fluorescence intensity is observed in all planes and there is no depth discrimination. For two-photon excitation, the integrated intensity decreases rapidly away from the focal plane. In this figure, *u* is a dimensionless optical axial coordinate as conventionally defined in Wilson, T. and Sheppard, C.J.R., *Theory and Practice of Scanning Optical Microscopy*, Academic Press, New York, 1984.

where J_0 is the 0th-order Bessel function, λ is the wavelength of the excitation light, $u = 4k \sin^2(\alpha/2)z$ and $v = k \sin(\alpha)r$ are the respective dimensionless axial and radial coordinates normalized to wavenumber $k = 2\pi/\lambda$. The point-spread function (PSF) of the fluorescence signal is a quadratic function of the excitation profile, which is just $I^2(u/2,v/2)$. In contrast, one-photon fluorescence PSF has a functional form of I(u,v). For n-photon excitation, the fluorescence intensity profile is in general $I^n(u/n,v/n)$.

The difference of the fluorescence PSF resulting from one- and two-photon excitation is profound. The contribution of fluorescence signal from each axial plane can be computed for one- and two-photon excitation and is shown in Figure 11.2. Assuming negligible attenuation, the total fluorescence generated is equal at each axial plane for one-photon microscopy. In contrast, two-photon fluorescence falls off quickly from the focal plane resulting in the localization of the signal to the focal region. For higher-photon processes, the localization property is even more pronounced.

Qualitatively, the localization of multiphoton excitation can be understood by realizing that fluorescence generation is only appreciable at a region of high spatial photon density at the focal point of the microscope objective. The localization of the multiphoton excitation can be further appreciated by examining the dimensions of fluorescence PSF. Figure 11.3 illustrates the radial and axial PSF for two-photon microscopy at 960 nm. The two-photon photointeraction volume is on the order of 0.1 fl.

The axial depth discrimination of multiphoton microscopy greatly improves image contrast as compared with wide-field fluorescence microscopy, especially for thick specimens. This localization further reduces the photointeraction volume and greatly reduces photobleaching and photodamage in thick sample. Further, since photointeraction occurs in a femtoliter size volume, localized photochemical reactions can be initiated.²³

An important advantage of multiphoton excitation is the use of infrared light to excite fluorophores with one-photon excitation in the ultraviolet and blue–green spectral range. For one-photon excitation, the excitation spectral band overlaps the fluorescence emission band. Excitation light cannot be eliminated

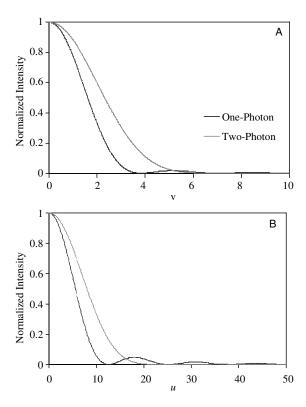

FIGURE 11.3 A comparison of the one- and two-photon PSF in the (A) radial and (B) axial directions. In these figures, v and u are dimensionless optical coordinates along radial and axial directions as conventionally defined in Wilson, T. and Sheppard, C.J.R., *Theory and Practice of Scanning Optical Microscopy*, Academic Press, New York, 1984.)

without losing a fraction of fluorescence photons; microscope sensitivity is reduced. For two-photon excitation, the excitation spectrum is completely separated from the emission spectrum and very efficient filters can be used to eliminate the excitation with a minimal loss of the fluorescence. For weak fluorescence specimen in one-photon excitation, noise originated from Raman scattering is Stokes-shifted into the emission band and can sometimes obscure the fluorescence signal. In multiphoton excitation, the Raman signal is red-shifted from the excitation light and is further removed from the emission band. Hyper-Raman and hyper-Rayleigh scattering can still occur in the emission band for multiphoton excitation but these processes are typically weak.²⁴

11.3 Experimental Considerations of Multiphoton Microscopy

11.3.1 Instrument Design of Multiphoton Microscopy

Multiphoton excitation efficiency increases with the spatial and temporal density of the excitation photons. Spatial localization of photons is relatively straightforward by using high-numerical-aperture optics. Temporal localization of photons is comparatively more difficult and was not efficiently achieved until the advent of femtosecond pulsed lasers. The typical cross section for two-photon absorption is on the order of 1 GM, which is equivalent to 10^{-50} cm⁴ s, a unit adopted in honor of Göppert-Mayer. The need for temporal localization of photons using pulsed laser can be observed by considering the absorption efficiency of a two-photon probe with cross section, δ . Two-photon absorption efficiency can be measured by n_a , the number of photons absorbed per fluorophore per pulse:

$$n_a \approx \frac{p_0^2 \delta}{\tau_p f_p^2} \left(\frac{(\text{NA})^2}{2\hbar c \lambda} \right)^2 , \qquad (11.4)$$

where τ_p is the pulse duration, λ is the excitation wavelength, P_0 is the average laser intensity, f_p is the laser's repetition rate, NA is the numerical aperture of the focusing objective, ν is Planck's constant, and c is the speed of light. Equation 11.4 shows that, for the same average laser power and repetition frequency, the excitation probability is increased by increasing the NA of the focusing lens, which increases spatial localization of the laser excitation. The absorption efficiency further improves linearly by reducing the pulse width of the laser indicating the importance of temporal localization.

For multiphoton excitation, femtosecond, picosecond, and continuous wave laser sources have been used. The most commonly used laser for multiphoton microscopy is femtosecond titanium-sapphire lasers. These lasers characteristically produce 100-fs pulse train at 100 MHz repetition rate. The tuning range of Ti:Sapphire systems extends from 680 to 1050 nm. Cr:LiSAF and pulse compressed Nd:YLF lasers are some of the other femtosecond lasers used in multiphoton microscopy.²⁵

Multiphoton excitation can also be generated using picosecond light sources, although at a lower excitation efficiency. Two-photon excitation has been achieved using mode-locked Nd:YAG (~100 ps), picosecond Ti:Sapphire lasers, and pulsed dye lasers (~1 ps). Two-photon excitation using continuous wave lasers has also been demonstrated using ArKr lasers and Nd:YAG lasers.²⁶

Comparing different laser sources, for fixed δ , P_0 , and NA, Equation 11.4 implies that the difference in excitation efficiency per unit time for pulsed and continuous wave lasers for a two-photon process is $\sqrt{f_p}\tau_p$. This factor is typically 300 for femtosecond Ti:Sapphire laser; two-photon excitation of a fluorophore that typically requires 1 mW of power using a femtosecond Ti:Sapphire laser will require 300 mW using a continuous wave laser.

The generalization of Equation 11.4 to the multiphoton case can be expressed as

$$n_a \propto \frac{1}{\tau_b^{n-1}}.\tag{11.5}$$

One can conclude that multiphoton excitation becomes increasingly difficult for nonfemtosecond light sources with increasing order of excitation process.

Because multiphoton excitation generates signal from a single point, the production of 3D images requires raster scanning of this excitation volume in 3D (Figure 11.4). In a typical multiphoton microscope, *x-y* raster scanning uses galvanometer-driven scanner. After beam power control and pulse width compensation optics, the *x-y* scanner deflects the excitation light into a fluorescence microscope.

A typical multiphoton microscope uses epi-luminescence geometry. The scan lens is positioned such that the *x-y* scanner is at its eye-point while the field aperture plane is at its focal point. For a telecentric microscope, this arrangement ensures that angular scanning of the excitation light is converted to linear translation of the objective focal point. A tube lens is positioned to re-collimate the excitation light directed toward the infinity-corrected objective via a dichroic mirror. The scan lens and the tube lens function together as a beam expander that overfills the back aperture of the objective lens to ensure that excitation light is diffraction limited. Typically, high numerical aperture objectives are used to maximize excitation efficiency. An objective positioner translates the focal point axially for 3D imaging.

In the emission path, the fluorescence emission is collected by the imaging objective and is transmitted through the dichroic mirror. Additional barrier filters are used to further attenuate the scattered excitation light and to select the emission band of interest. The fluorescence signal is subsequently directed toward the detector system. A number of photodetectors have been used in two-photon microscope including photomultiplier tubes (PMT), avalanche photodiodes, and charge coupled device (CCD) cameras. PMTs are the most common implementation because they are robust and low cost, and have a large active area and relatively good sensitivity. PMT and avalanche photodiode systems further allow the use of ultralow

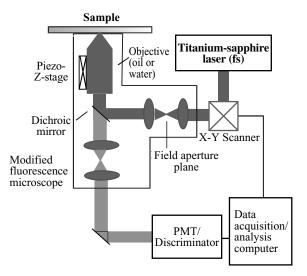

FIGURE 11.4 Schematic of a typical two-photon microscope.

noise and high-sensitivity, single-photon counting electronic circuitry. Electronic signal from the detector is converted to digital signal and is recorded by the data acquisition computer. The control computer further permits archival of the image data and 3D rendering of these images.

11.3.2 Two-Photon Fluorescent Probes and Their Biological Applications

The design of a multiphoton imaging experiment requires not only high-sensitivity optical instrumentation but also specific and efficient fluorophores. Most fluorophores can be excited in two-photon mode at approximately twice their one-photon absorption wavelength; similarly, n-photon excitation of fluorophores typically occurs at approximately n times their one-photon excitation wavelength. However, one- and multiphoton absorption processes actually have very different quantum mechanical selection rules. For example, a fluorophore's two-photon excitation spectrum scaled to half the wavelength is in general not equivalent to its one-photon excitation spectrum. Determining the multiphoton absorption spectra of fluorophores is required to optimize multiphoton imaging. Significant progress in this area has been made. $^{27-29}$

Multiphoton imaging can be based on both endogenous and exogenous fluorophores. On the one hand, endogenous fluorophores make multiphoton imaging easier by alleviating the difficulty of *in vivo* labeling of biological specimens, especially in thick tissues. On the other hand, multiphoton imaging based on endogenous fluorophores is difficult because endogenous probes typically have low extinction coefficients and low quantum efficiencies.

Considering imaging based on endogenous probes, most proteins are fluorescent due to the presence of tryptophan and tyrosine. Two-photon induced fluorescence from tryptophan and tyrosine in proteins has been studied extensively. $^{30-32}$ Although these fluorophores are occasionally used for multiphoton imaging, the application of these amino acid probes is not common due to the lack of efficient laser source for two-photon excitation of these probes. Endogenous β -nicotinamide-adenine dinucleotide phosphate (NAD(P)H) is the most common endogenous fluorophore used for *in vivo* cellular imaging. The production of NAD(P)H is associated with the cellular metabolism and the intracellular redox state. Flavoproteins are another endogenous marker in cellular cytoplasm and are present almost exclusively in the mitochondria. The multiphoton excitation spectrum of NAD(P)H and flavin mononucleotide (FMN) has been determined. Flavoproteins are determined.

Endogenous fluorophores are also present in the extracellular matrix; the primary fluorophores are collagen and elastin. Tropocollagen and collagen fibers typically have absorption spectra similar to amino acids; their fluorescent emission is typically weak in the excitation wavelength range of Ti:Sapphire lasers.^{34–36} Elastin fiber fluorescence, however, can be readily excited and visualized using two-photon excitation.^{37–39} While fluorescence imaging based on collagen is difficult, recent studies have shown that collagen can be imaged based on second harmonic generation due to its chiral crystalline structure.^{40–46}

Tissue imaging is one of the most important application areas of multiphoton microscopy. While cellular systems can be effectively labeled using standard organic dyes,^{27–29} effective uniform labeling of tissues with exogenous organic probes is extremely difficult due to limited diffusion and differential partitioning in 3D tissue components. The invention of fluorescence protein technology presents a powerful molecular biology solution to this dilemma.⁴⁷ By transfecting or inflecting cells and tissues with fluorescent protein vectors, one can monitor the activation of a particular gene, the trafficking of specific proteins, and the changes in local cellular biochemical environment. After the introduction of green fluorescent proteins, fluorescence proteins of a wide range of colors including blue, cyan, yellow, and red have been created.^{48,49} Two-photon absorption spectra for many fluorescent proteins have been determined.^{50,51}

While many existing one-photon fluorophores can be used for multiphoton imaging, they are not necessarily optimized. Optimizing two-photon absorption properties in fluorophores has two important consequences. The development of efficient fluorophores can reduce the excitation laser intensity required for imaging, and thus can reduce system cost and specimen photodamage. Alternatively, with high two-photon cross sections, significant excitation can be achieved with the more economical continuous wave lasers, thus reducing the cost of two-photon systems that typically use femtosecond Ti:Sapphire lasers. Recent searches for molecules with high two-photon absorption cross sections have led to the synthesis of molecules with two-photon cross sections over 1000 GM.⁵²

11.4 Optimization of Multiphoton Microscopy for Deep Tissue Imaging

Deep tissue imaging is an area in which multiphoton microscopy has found the most important and diverse applications. An understanding of how tissue optics affects light transmission and image formation properties is essential to optimize the use of multiphoton microscopy for deep tissue imaging. It is also important to consider photodamage mechanisms in tissues. Finally, some of the most promising deep tissue imaging applications of multiphoton microscopy are reviewed here.

11.4.1 Effect of Tissue Optical Properties on Multiphoton Microscopy Efficiency and Image Formation

On one level, light propagation through tissues can be characterized by multiple scattering of light in a homogeneous medium. In the multiple scattering regime, the modeling light propagation requires a knowledge of the scattering and absorption coefficients of the tissue. The scattering coefficient measures the propensity of the tissue to deflect photons from their path. The absorption coefficient measures the propensity of the tissue to absorb photons. To quantify scattering, in addition to the scattering coefficient, it is also important to quantify the directional change of the photon after scattering. The *g*-factor measures the cosine of the average angular change of the photon direction after scattering. Assuming small scattering and absorption coefficients, the light attenuation through a thickness of tissue can be modeled as an exponential function:

$$I(z) = I_0 e^{-[(1-g)\mu_s + \mu_a]z}, \qquad (11.6)$$

where I(z) is the intensity at depth z, I_0 is the intensity at tissue surface, μ_s is the scattering coefficient, μ_a is the absorption coefficient, and g is the g-factor. The scattering coefficient, absorption coefficient, and

the *g*-factor for typical tissues are 20 to 200 mm⁻¹, 0.1 to 1 mm⁻¹, and 0.7 to 0.9, respectively. Since the fluorescence signal depends quadratically on the excitation power, the fluorescence signal has a mean free path of 25 to $250 \,\mu m$.

In homogeneous media, these phenomenological parameters fairly well characterize the microscopic light—tissue interactions. However, real tissues are not homogeneous and mesoscopic variations in tissue optical properties can also have dramatic effects in light propagation. For example, the dermal system consists of multiple structural layers, each with very distinct scattering coefficients, absorption coefficients, and *g*-factors. Further, these layers also have very different indices of refraction. An understanding of light propagation in tissues will require knowing the geometries of these mesoscopic inhomogeneities.

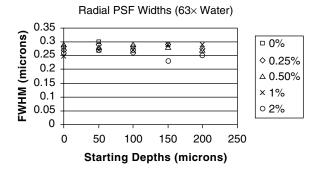

Effective multiphoton imaging of deep tissue requires efficient transmission of excitation light to the focal volume inside thick tissues and the efficient detection of the fluorescence signal generated. The imaging depth of two-photon microscopy can be limited by the efficacy of delivering femtosecond laser pulses into tissues. Assuming that the image point spread function is invariant with depth, excitation light penetration is limited by power delivery and pulse broadening. In terms of power delivery, average laser power as a function of depth is an exponential function of depth and is governed by Equation 11.6. Similar to the attenuation of the excitation light, the fluorescence signal generated is also reduced due to scattering and absorption effects. In fact, because scattering and absorption efficiencies are decreasing functions of wavelength, one expects attenuation of the fluorescence signal by the surrounding tissue to be more severe than the exciting light.

Compared with confocal microscopy, multiphoton microscopy is more efficient in signal detection inside multiple scattering medium. Because the mean free path of visible photons is less than 100 µm in typical tissues, the emitted photon will encounter one or more scattering events in thick tissues. However, many of these scattered photons can be collected because the *g*-factors of most tissue are close to unity (primarily forward scattering). In confocal microscopy, these scattered photons are lost at the confocal aperture. In two-photon microscopy, as long as the trajectories of these scattered photons remain within the collection solid angle of the objective lens, these photons are retained using a large area detector such as a PMT tube. Because these scattered photons have more divergent light paths, detection efficiency can be improved by increasing the solid angles of all optics in the emission light path and the physical size of the detector.⁵³

From Equation 11.5, one concludes that efficient multiphoton excitation requires ultrafast laser pulses. Laser pulses from Ti:Sapphire lasers, which are typically on the order of 150 fs, can be broadened in the sample, reducing the multiphoton excitation efficiency. This degradation is particularly important for higher-order multiphoton processes. Laser pulse dispersion in microscope objectives is significant and pulse width can easily broaden to beyond 500 fs. The effect of pulse broadening in the objective can be negated by the use of dispersion compensation optics to maintain a short pulse width. However, further pulse dispersion may occur in the tissues due to scattering and index of refraction heterogeneity. The severity of this broadening effect as femtosecond pulses travel through tissues has not been extensively studied.

In addition to the reduction in excitation and detection efficiency, light propagation through tissue may also result in contrast and resolution losses. While signal strength reduction can be compensated for by increasing laser power, as long as photodamage and photobleaching are not too severe, contrast and resolution loss can result in irreversible loss of image information content. The major factors that can be responsible for resolution degradation are the scattering of the excitation and emission light, and spherical aberration. Spherical aberration is caused by mismatch in the indices of refraction between the sample and the immersion medium of the objective.

Scattering of the excitation and emission photons from the femtoliter excitation volume may lead to a degradation of the image resolution. To quantify this factor, Dunn et al.⁵⁴ pioneered the study of the scattering effects on resolution degradation. Using Monte Carlo simulations, they showed that the loss of signal intensity was due more to the scattering of the excitation photons than to the emission

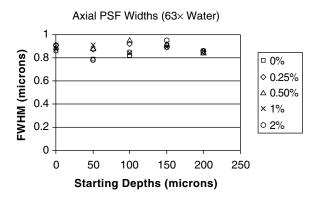

FIGURE 11.5 Averaged widths of the radial and axial PSFs measured in multiple scattering media with different scattering coefficients containing Liposyn III at concentrations of 0, 0.25, 0.5, 1, and 2%. Data were taken with a Zeiss 63X, water-immersion, C-Apochromat objective (NA 1.2).

photons. More importantly, this group further found that the signal strength is the limiting factor in two-photon microscope image quality. Their simulation showed that resolution did not change as the image depth was increased as measured by the full-width-at-half-maximum (FWHM) of the image PSF. Their simulation was further supported by experimental measurements and that is in agreement with Centonze et al.⁵⁵ Dong and co-workers (manuscript in preparation) further measure two-photon microscopy PSF directly by imaging 100-nm spheres in agarose gels with varying scattering coefficient. It is found that scattering coefficients up to physiological range have minimal or no effect on the lateral and the axial FWHM of the PSF for both oil and water immersion objectives (Figure 11.5).

Considering the effect of spherical aberration, Dong et al. showed that the water immersion objective suffers no significant PSF degradation in thick samples. On the other hand, the oil immersion objective suffered significant degradation due to the spherical aberration introduced by index of refraction mismatch. The lateral and axial FWHM were broadened. One may conclude that, for typical tissue thickness on the order of a few hundred microns, resolution loss due to scattering is insignificant, but index refraction mismatch can be a major factor. The use of water-immersion objectives is preferred in biological tissues in general, given better index matching.

However, Dong et al. also studied the performance of oil- vs. water-immersion objectives for imaging more optically heterogeneous biological tissues such as excised human skin. Human skin is an optically heterogeneous layered structure with significantly different index of refraction in each layer. It is found that there is significant spherical aberration in the imaging of dermal structures for both oil- and water-immersion objectives. These objectives perform equivalently because neither can match the varying index of refraction in the skin and both suffer from spherical aberration. For optically heterogeneous samples, it is best to choose an immersion media that best matches the average index of the

sample. For dermal structure, a glycerine-immersion objective may potentially outperform oil- or water-immersion lenses.

11.4.2 Photodamage Mechanisms in Tissues

Multiphoton microscopy is particularly suitable for *in vivo* tissue imaging due to its minimization of specimen photodamage. The region of photodamage is restricted to within the axial depth of the PSF. For specimens with thickness comparable to the thickness of the PSF, the use of multiphoton imaging does not significantly improve specimen viability. However, the decrease in photodamage is substantial for 3D imaging of thick tissues. Photodamage is approximately reduced by a factor equal to the ratio of the sample thickness to the axial dimension of the PSF. For 3D imaging of a 100-µm-thick specimen using multiphoton microscopy, the specimen is exposed to a light dosage about 100 times less than confocal microscopy.

A number of embryology studies demonstrate well the minimal invasive nature of multiphoton microscopy. Long-term monitoring of *Caenorhabditis elegans* and hamster embryos using confocal microscopy have not been successful due to photodamage-induced developmental arrest. However, these developing embryos can be repeatedly imaged using multiphoton microscopy for hours without appreciable damage.^{56–58} Further, hamster embryos that were reimplanted after imaging experiments were successfully developed into normal adults.

One should note that multiphoton microscopy can still cause considerable photodamage in the focal volume where photochemical interaction occurs. Multiphoton photodamage proceeds through three main mechanisms:

- 1. Oxidative photodamage can be caused by two- or higher-photon excitation of endogenous and exogenous fluorophores similar to ultraviolet exposure. Tissue fluorophores act as photosensitizers in the photo-oxidative process. ^{59,60} Photoactivation of these fluorophores results in the formation of reactive oxygen species that trigger the subsequent biochemical damage cascade in cells. Current studies found that the degree of photodamage follows a quadratic dependence on excitation power indicating that the two-photon process is the primary damage mechanism. ^{61–65} Experiments have also been performed to measure the effect of laser pulse width on cell viability. Results indicate that the degree of photodamage is proportional to two-photon excited fluorescence generation independent of pulse width; therefore, using shorter pulse width for more efficient two-photon excitation also produces greater photodamage. ^{62,64} Flavin-containing oxidases have been identified as one of the primary endogenous targets for photodamage. ⁶⁵
- 2. One- and multiphoton absorption of high-power infrared radiation can also produce thermal damage. The thermal effect resulting from two-photon absorption by water has been estimated to be on the order of 1 mK for typical excitation power. 16,66 Therefore, heating damage due to multiphoton water absorption is insignificant. However, there can be appreciable heating due to one-photon absorption in the presence of a strong infrared absorber such as melanin; 67,68 thermal damage has been observed in the basal layer of human skin. 69
- 3. Photodamage may also be caused by mechanisms resulting from the high peak power of the femtosecond laser pulses. There are indications that dielectric breakdown occasionally occurs.⁶¹

11.4.3 Tissue-Level Applications of Two-Photon Microscopy

Two-photon microscopy is well suited for imaging in highly scattering specimens. A recent comparison study has convincingly demonstrated that two-photon microscopy is a superior method for this application.⁵⁵

Multiphoton tissue imaging has been successfully applied to study physiology of many tissue types such as the cornea structure of rabbit eyes,^{69,70} the light-induced calcium signals in salamander retina,⁷¹ the toxin effect on human intestinal mucosa,⁷² and the metabolic processes of pancreatic islets.^{73,74} The combination of multiphoton imaging and magnetic resonance imaging was used to investigate the

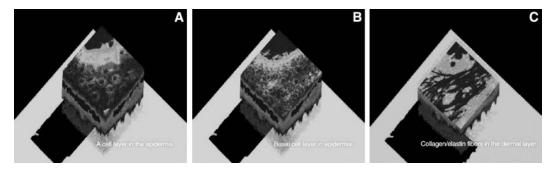

FIGURE 11.6 (Color figure follows p. 28-30.) Three-dimensional reconstructed two-photon images of dermal structures in a mouse ear tissue specimen. The three images show distinct structural layers: (A) epidermal keratinocytes; (B) basal cells; and (C) collagen/elastin fibers.

heterogeneous microscopic structure of mammalian tongue tissue to obtain spatial information on two different length scales.⁷⁵

Today, multiphoton microscopy is widely used in three areas: neurobiology,⁷⁶ embryology, and dermatology. In neurobiology studies, multiphoton microscopy has been applied to study the neuron structure and function in intact brain slices.⁷⁷ The role of calcium signaling in dendritic spine function,^{78–86} neuronal plasticity and the associating cellular morphological changes,⁸⁷ and hemodynamics in rat neocortex.⁸⁸ Hyman and co-workers further applied this technology to study the formation of β -amyloid plaques associated with Alzheimer's disease.^{89,90} In embryology studies, multiphoton imaging has been used to examine calcium passage during sperm–egg fusion,⁹¹ the origin of bilateral axis in sea urchin embryos,⁹² cell fusion events in *C. elegans* hypodermis,^{56,57} and hamster embryo development.⁵⁸

Multiphoton microscopy has been used extensively in dermatology studies. Masters et al.⁹³ employed multiphotons to image the autofluorescence of *in vivo* human skin down to a depth of 200 µm. Cellular strata in the epidermis, including the corneum, spinosum, and basal layer, can be clearly resolved based on NAD(P)H fluorescence in the cytoplasm. NAD(P)H fluorescence is seen to be more pronounced in the basal layer due to its relatively higher metabolic activity. Below the epidermis, the dermal structure is visible due to elastin fluorescence and second harmonic signal generated from the collagen matrix (Figure 11.6). Recently, two-photon microscopy has been further applied to study the transport properties of the skin, ^{94,95} facilitating the development of transdermal drug delivery technology.

11.5 Conclusion

Multiphoton fluorescence microscopy is becoming one of the most important recent inventions in biological imaging. This technology enables noninvasive study of biological specimens in three dimensions with submicron resolution. Two-photon excitation of fluorophores results from the simultaneous absorption of two photons. This excitation process has a number of advantages such as reduced specimen photodamage and enhanced penetration depth. It also produces higher-contrast images and is a novel method to trigger localized photochemical reactions. As the technology of multiphoton microscopy reaches maturity and becomes commercially available, the range of applications in biology and medicine is rapidly increasing. The suitability of multiphoton microscopy for studying the physiology of a variety of tissues has been clearly demonstrated. In the near future, other promising emerging applications of multiphoton microscopy include the use of multiphoton excitation for single molecular analysis for pharmaceutical drug discovery and the use of multiphoton processes for nanosurgery and nanoprocessing in cells and tissues. 96,97

12.1 Introduction

Optical microscopy is a standard technique in biology and medicine because it is convenient and easy to use and allows rapid assessment of problems at an early stage. Ability to view the sample is very important; all techniques other than optical microscopy must devise "tricks" to visualize sample information content. Samples ranging from tissue to single cells like bacteria can be investigated in a wide variety of environments, temperatures, and pressures. Sample preparation is straightforward and depends primarily on what information is desired. Because investigation is typically noninvasive, samples are not destroyed and can be reused in other applications.

From the beginning, a major challenge has been the need to improve spatial resolution. Since the late 19th century instrument resolution has come close to the so-called diffraction limit. This is a fundamental restriction that limits the resolution of any optical instrument based on diffraction. Essentially, the diffraction limit uses the greatest possible collection angle and the shortest possible wavelength. Simply put, blue light is better than red light and allows a spatial resolution of 300 nm and smaller. Using an electron microscope increases the resolution; the energy (wavelength) is very high (short) and a resolution down to 1 nm can be achieved. Elaborate sample preparation is a drawback; experiments require an extensive vacuum system. This method is not suitable for environments with great variations and high energy used often destroys the sample.

Another problem often encountered in biological samples is transparent specimens that show only weak contrasts. In the 20th century, contrast was improved by using the phase information of the image or special illumination schemes. One of the most important achievements was the introduction of fluorescent labeling of the specimen, which provided a means of distinguishing distinct cell compartments.

In 1928 the Irish scientist E. Synge proposed a totally different approach to imaging that scanned very small apertures across a surface.² It was almost 50 years before this approach was experimentally tested in the microwave region by Ash and Nichols.³ A decade later two research groups independently demonstrated use of the technique for optical frequencies.^{4,5}

Near-field optical microscopy uses different instrumentation based on scanning probe microscopies, such as scanning tunneling microscopy (STM) or atomic force microscopy (AFM).^{6,7} STM/AFM and NSOM are similar in two ways. First, image formation is based on step-by-step recording. Second, the electronic feedback mechanism that moves the subwavelength aperture across the sample is essentially the same. The acronyms used for the technique, NSOM for near-field scanning optical microscopy and SNOM for scanning near-field microscopy, refer to exactly the same technique. These feedback mechanisms have a very useful side effect unique to near-field microscopy. Because the tip–sample distance remains constant, the feedback signal directly yields a topographic image of the sample. Optical and topographical images are therefore measured simultaneously and can be directly correlated. In the last 10 years improvements have resulted in better stability and handling. As a result, near-field microscopy has become a powerful tool for a large variety of applications in physics, chemistry, and biology.⁸⁻¹²

Despite the differences in image formation mechanism, the basics of standard (far-field) microscopy and near-field optical microscopy are very similar. In both techniques a change in refractive index or in absorption can be identified. Consequently, many of the established techniques in microscopy can be adapted to the near-field optical technique. Fluorescence labeling has been especially successful in biological applications and can be used to increase spatial resolution to less than 50 nm.

This chapter provides a brief introduction to near-field optics (NFO); however, the main focus is on state-of-the-art applications for investigating biological samples. Many of the current investigations focus on model systems under precisely controlled conditions; however, the first investigations have already been made on living cells. Recently, new techniques related to the original idea of NSOM have been used successfully to investigate problems in life science. Some examples will be introduced here.

12.2 Near-Field Optical Microscopy

12.2.1 Basic Principles of Near-Field Optical Microscopy

A detailed review of the theory and physics of near-field imaging is not appropriate here. The reader is referred to several excellent publications and reviews.^{13–17} The focus here is on basic principles and the instrumentation required to conduct a near-field optical experiment.

Image formation in a classic (far-field) microscope is achieved by specimen illumination using a monochromatic plane wave. The object scatters the light in a characteristic way. The light is then collected by transmission or reflection and focused on a detector. The lens is several wavelengths away from the object, in the optical far-field. High spatial frequencies correspond to the fine details of the specimen and generate Fourier components of the field that decay exponentially along the normal object. Such frequencies cannot be collected by the lens. This effect is the well-known Abbé limit of diffraction, $\Delta x = 0.61 \cdot \lambda/NA$, where Δx corresponds to the smallest resolvable distance between two points, λ is the wavelength of the light, and NA is the numerical aperture of the microscope objective or the lens. If a confocal setup is used instead of wide-field illumination, the resolution increases slightly; multiphoton techniques can also improve the resolution.

In contrast to far-field microscopy in which the light source is confined by a lens, in near-field optical microscopy the light source is confined by a metal aperture. Within a short distance beyond the screen, the size of the illuminated spot is limited only by the dimensions of the aperture. This area

is the so-called optical near-field. If such a small light source is scanned above a surface and the distance between aperture and sample is in this near-field region, all scattering or absorption phenomena must originate from that small illumination spot. Consequently, aperture size and distance determine the resolution.

12.2.2 Instrumentation

12.2.2.1 General Considerations

The key development for practical application of near-field optics was the fabrication of a functional subwavelength aperture. Instead of a hole in a planar metal screen, an aperture was formed at the apex of a pointed glass tip by coating it with a metal.^{4,5,21–24} This design ensured an easy way to approach the sample and keep it in close proximity to the surface, while still satisfying the optical requirement for the aperture size. Figure 12.1 shows some of the most important setups using aperture tips. Figure 12.1A shows the most common setup. The sample is illuminated through the aperture and the light is collected by reflection or transmission by standard optical techniques (see, for example, References 4, 5, 11, 21–23, 12, and 25). Figure 12.1B shows an example in which the light is also collected back through the aperture in the illumination–collection mode.²⁴ Figure 12.1C shows a more specialized arrangement that uses a different illumination by evanescent waves.^{26–29} Figure 12.1D illustrates a relatively new development

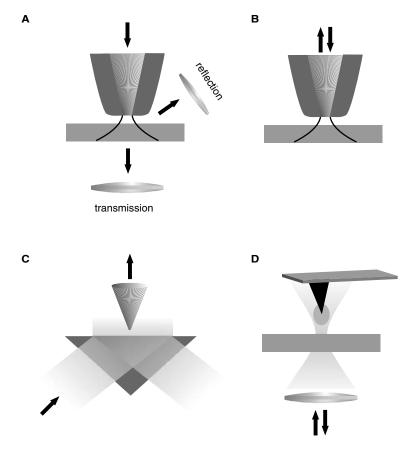

FIGURE 12.1 Different modes for near-field scanning optical microscopy: (A) illumination through the aperture, detection reflection or transmission via standard optics; (B) illumination—collection mode, both via the near-field aperture; (C) photon scanning tunneling microscope (PSTM); (D) apertureless or probe-enhanced techniques. The illuminated tip enhances the field and serves as a subwavelength light source.

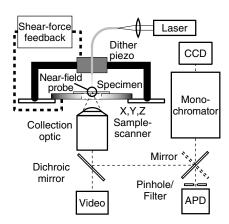

FIGURE 12.2 Standard experimental setup for transmission of NSOM. For specific analytic requirements different detection schemes can be applied.

without an aperture. Here, the light source is generated at the tip apex and can therefore be even smaller than any aperture.^{30–37} This technique will be discussed in more detail in Section 12.4.2.

The most commonly used setup is the design depicted in Figure 12.1A. The entire instrument is built around the core shown. It can be described as a microscope in which the standard illumination source has been replaced by a near-field probe. Figure 12.2 sketches the major parts of a modern NSOM. Laser light is coupled into the back end of the fiber probe, which is held above the sample at a distance of 5 to 15 nm by a shear-force feedback arrangement.

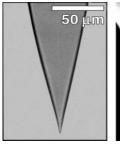

This is a noncontact AFM mode where the tip is vibrated at its resonance frequency.^{38,39} As soon as the tip "feels" the surface this vibration is damped. The damping serves as the feedback signal for the tip–sample distance control and accordingly allows topographical mapping synchronously to the optical signal acquisition. The light is collected in transmission by an appropriate objective and, depending on the experimental requirements, simply imaged onto a detector. If spectral information is also desired, the collected light is dispersed by a spectrograph and then imaged onto a multichannel detector. To maintain the alignment of near-field probe and collection optics the sample is scanned underneath the tip; hence, the image is built up, point by point.

12.2.2.2 Near-Field Optical Probes

The fabrication of near-field optical probes is a crucial prerequisite for the experiment. Aperture size, efficiency of light transmission, and the damage threshold are considerabions in probe fabrication. Because large taper angles result in a higher transmission,⁴⁰ the goal is to produce probes with a large angle that are still able to approach the sample surface and yield a useful topographical image. The straightforward approach would be a microfabrication similar to the process used to manufacture AFM cantilevers. However, because commercial microfabricated probes still are not readily available, many groups prepare these tips themselves. Recent progress made in the production of such tips may lead to commercial manufacture of these probes.^{41–47}

Fortunately, two rather simple methods are used to prepare the tips in virtually every lab. The most frequently used technique is the melt-drawn, or "heating and pulling," method. Glass fiber is heated locally using a laser or a filament and the fiber is then pulled apart. The resulting tip shapes depend largely on the temperature and the timing of the procedure.^{48,49}

The second method, based on chemical etching of glass fibers, is often called "Turner's method." ^{50,51} The tip formation occurs at the meniscus between hydrofluoric acid and an organic overlayer. Tips generated in this way generally show considerably larger angles and therefore the transmission is higher than for melt-drawn tips. ^{52,53} However, the parameters are difficult to control and the quality is less reproducible. Recently, a variation of the standard etching scheme was proposed in which the taper is

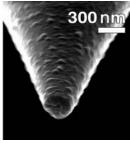

FIGURE 12.3 Optical (left) and scanning electron microscope image (right) of a "tube-etched" near-field probe.

formed inside the polymer cladding of the glass fibers.^{54,55} This so-called "tube-etching" preserves the advantages of the etching; however, it is much more reproducible compared to the original Turner etching.

The metal coating needed to form the aperture is relatively easy to achieve. The glass fiber tip is rotated along its main axis while the metal is evaporated. The arrangement is such that the metal vapor cannot reach the very end of the tip, but only the sides of the taper. Using this kind of shading, the aperture size can be selected by varying the angle between the rotating tip and the evaporation source. Figure 12.3 shows an example of a tube-etched near-field probe and a zoom into the aperture region.

Finally, the near-field tip must be mounted into the scanning probe head. Here the dithering necessary for the feedback loop will be applied by piezoactuators or quartz tuning forks.^{38,39,56,57}

12.3 Biological Applications of Near-Field Optical Microscopy

12.3.1 Practical Considerations

The main reason for using a near-field microscope in biological applications is the need for spatial resolution beyond the limits of a typical microscope. Another advantage is the synchronous sampling of the sample morphology and its optical characteristics. If one of these two considerations cannot be addressed using another, simpler method, then NSOM is the researcher's only choice. NSOM is only 20 years old and still not as developed as standard optical microscopy; hence, the technique is not yet used routinely. The scanning probe part of the instrument, the delicate probes, and the very long acquisition times are aspects still unfamiliar to scientists accustomed to confocal microscopes.

These problems are especially obvious when the method is applied to biological problems, where the samples and their environments differ considerably from those of surface science. Soft samples and scanning in liquids are still challenges peculiar to scanning probe microscopy. As the following discussion of biological and medical applications shows, model systems often must be considered before investigation can commence. Finally, we show that NSOM is now used to investigate living cells.

12.3.2 Investigation of Cell Material

12.3.2.1 Near-Field Fluorescence Microscopy

12.3.2.1.1 Stained Cell Tissue

Betzig and co-workers were among the first to investigate biological tissue using an NSOM.⁵⁸ Thin tissue sections from the hippocampus region of monkey brain were investigated in the standard transmission mode (see Figure 12.4.) From the toluidine blue stained section, different features can be clearly identified in Figure 12.4: pyramidal cell dendrites (D), nucleus (N), glial cell (Gc), and myelinated axon (M). As indicated by the scale bar, the spatial resolution is clearly better than that of a conventional microscope. An electron microscope would yield an even better resolution, but sample preparation for an NSOM is much simpler and the measurement can be done more quickly with an NSOM.

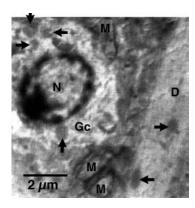

FIGURE 12.4 Illumination mode NSOM image taken from a thin-tissue section of the hippocampus region of the monkey brain. (From Betzig, E. and Trautman, J.K., *Science*, 257, 189, 1992. Copyright 2002, American Association for the Advancement of Science. Reprinted with permission.)

12.3.2.1.2 Actin Filaments

Similar experiments attempt to distinguish single actin fibers in the cyto skeleton. ^{59,60} Single filaments are too big for confocal microscopy and they cannot be readily accessed by force microscopy because they are below the cell membrane. Figure 12.5 illustrates one way to approach that problem. Here MDCK cells (Madin-Darby canine kidney) were grown on a silica slide using glutaraldehyde and lysed so that the interior of the cell walls became accessible. ⁶¹ The actin filaments were stained selectively with rhodamine labeled phalloidin. Figure 12.5A shows the NSOM fluorescence image and Figure 12.5B shows the topography image. In contrast to the fluorescence image, the topography image shows no clear structure inside the cell. This rules out topographic coupling, which often obscures near-field images and may give rise to incorrect or misleading results. ⁶² A line plot across the fluorescent image visualizes the spatial resolution of the measurement. In this case the so-called 10:90 step resolution is around 100 nm.

Recent experiments by Doyle et al. on fixed or living Glial cells involve a novel feedback scheme that relies on the detected fluorescence. By measuring the signal at different distances from the specimen, Doyle et al. distinguished between the pure near-field and the ubiquitous far-field contributions. Such experiments would then allow measurement of at least small distances through the plasma membrane. The achieved spatial resolution that has been extracted from the data is already on the order of 50 nm. Although no further conclusions have been drawn from the data, these experiments provide a useful methodology for soft samples such as cells.

12.3.2.1.3 NSOM inside Cells

Correlation of topographic and optical information is usually considered a unique advantage of NSOM. In the case of cell investigation, it can also be considered a great disadvantage because the interior of the cells cannot be accessed. Recently, Lei and co-workers⁶³ approached the mitochondrial membrane of a living breast carcinoma cell by penetrating the outer cell membrane. The cells were treated with JC-1, a dye that changes conformation — and hence its emission characteristics — when it is aggregated. This high concentration state occurs particularly in the mitochondrial membrane and thus distinguishes this membrane from other cell compartments.

To access the mitochondria, the surface topography of the cell was first determined, using the shear-force feedback in the aqueous environment of the setup. Next, the plasma membrane of the cell was penetrated by the NSOM probe and three fluorescence spectra were recorded at different distances from the mitochondrium. Figure 12.6 schematically shows this penetration of the cell membrane and the corresponding near-field fluorescence spectra, respectively. When the probe is close to the mitochondrial membrane a clear change in the two emission peaks can be detected. The relative peak height change between positions 1 and 2 is negligible and the overall intensity changes are due to concentration

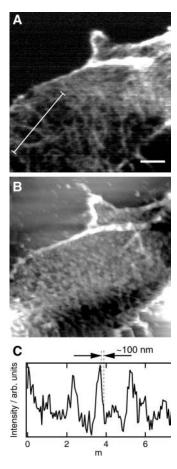

FIGURE 12.5 (A) Reflection NSOM image of labeled actin filaments in Madin-Darby canine kidney (MDCK) cells; (B) corresponding topography image; (C) line scan through the section marked in (A).

fluctuations. However, the ratio between the two emission peaks at position 3 changed significantly, which indicates that the probe is very close to the mitochondrial membrane.

The main emphasis here is on the height resolution, which is not generally considered in normal NSOM. Lateral scanning inside the cell is not possible with this technique because the tip would drag the entire cell. Therefore, high spatial resolution imaging in the x and y directions is not feasible.

12.3.2.1.4 In Vitro Chemical Imaging of Tobacco Mosaic Virus

An intriguing advantage of near-field optical microscopy is the ability to visualize virus particles that cannot be investigated at all by standard microscopy techniques. Keller and co-workers were the first to apply NSOM to virus samples. He was a special force feedback setup, in which the sample is placed on an AFM cantilever underneath the actual near-field aperture. Their specific arrangement allows a more sensitive feedback for the distance control between sample and near-field probe. This is important because of the previously discussed difficulties of measuring directly in liquids.

Figure 12.7 shows the results of this investigation. Figures 12.7A and 12.7B show the topography and near-field optical image, respectively. An interesting labeling technique was used to determine the direction of the virus. The tobacco mosaic virus (TMV) was labeled with a metatope monoclonal antibody (M) that binds only to the 5' end of the virus. A biotin labeled polyclonal antibody (P) was attached to the monoclonal antibody. Finally, an avidin labeled latex bead (~30 nm diameter) was bound to the remaining biotin sites. The composition can be seen from Figure 12.7D. The presence of bovine serum albumin (BSA) prevents aggregation of the virus and is needed to obtain single virus particles. This kind of label

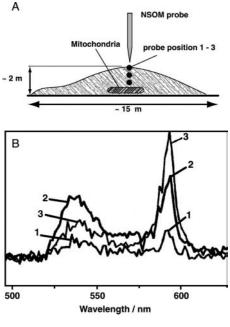

FIGURE 12.6 (A) Experimental setup for an inside cell near-field fluorescence experiment. (B) Fluorescence spectra taken at different distances from the mitochondrium. (Adapted from Lei, F.H. et al., *Appl. Phys. Lett.*, 29, 2489, 2001.)

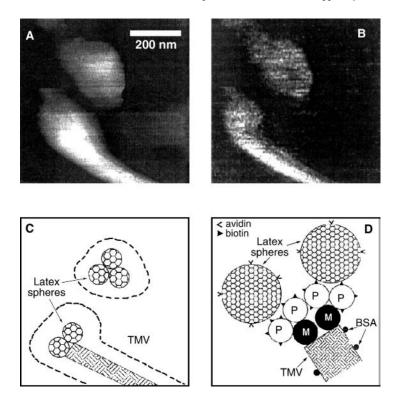

FIGURE 12.7 AFM and NSOM images of tobacco mosaic virus (TMV): (A) topography; (B) NSOM image; (C) interpretation of the optical image; (D) schematic diagram of the labeling procedure (P = polyclonal antibody, M = monoclonal antibody, BSA = bovine serum albumin). (From Keller, T.H. et al., *Biophys. J.*, 74, 2076, 1998. Copyright 2002, Biophysical Society. With permission.)

can be detected by either topographic or optical measurements, as shown in Figure 12.7. The sketch in Figure 12.7C shows the results from the raw images more clearly. Because a near-field optical image is always a convolution between the object size and the aperture dimensions, it is possible to extract the object features if the size and shape of the near-field source are known. This is also valid for the topographic image.

A remarkable fact that can be deduced from the images is that the optical resolution in this experiment was better than the topographic resolution. In principle, even without the extensive labeling, the features of the virus could be easily detected with a resolution of ~60 nm; however, only the label provides direct information about the virus.

A major drawback of this method is the elaborate sample preparation on an AFM cantilever. Nevertheless, this method offers a means to control environmental conditions in a way not possible with other methods.

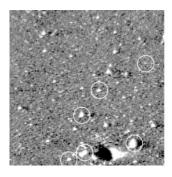

12.3.2.1.5 Single Green Fluorescing Proteins

The detection of intact single molecules is the ultimate goal of microscopy. In 1993, Betzig and Chichester⁶⁶ were the first to observe individual fluorescing molecules at room temperature, using a near-field optical microscope, thus establishing single-molecule detection as a new branch of science.^{67–72} Although, in principle, single-molecule sensitivity can be achieved readily by standard microscopy techniques and appropriate dilution, near-field optical techniques offer some distinct advantages:⁷³ the small detection volume, which allows localization to a few nm; the sensitivity toward the molecular orientation in all three dimensions; and, perhaps most important of all, the correlation to surface morphology resulting from the simultaneous detection of topography and optical signal.

As an example, the near-field fluorescence and the corresponding topography images of single green fluorescing proteins (GFP) are shown in Figure 12.8.⁷³ This molecule has attracted considerable attention because it can be produced by many proteins without changing the biological function. An extensive exogenous staining procedure is obsolete in many cases.^{74,75} The individual proteins were adsorbed on freshly cleaned hydrophilic glass.

The image shows a 2×2 - μ m scan of two distinct sample areas, each with corresponding fluorescence and topographic information. The most obvious feature is the irregular shape of the spots in the fluorescence image. This is a direct indication of single-molecule behavior, the so-called on/off switching observed very early by researchers. The origin of the photodynamic is not yet fully understood. The fluorescent events can be correlated with topographical features that, with a height of 2 to 5 nm and a width of ~10 nm, correspond well to the known size of 4 nm of the barrel-shaped GFP.

Interestingly, virtually all the fluorescent spots also can be found in the topography, whereas not all the morphological features fluoresce. Subsequent measurements revealed that most of the features are indeed proteins; however, they light up only from time to time. This indicates that only a few molecules are "active" at a given time and that most of the time the GFP is in a so-called dark state.⁷⁹ The structure

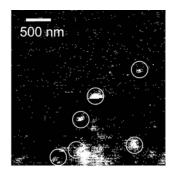

FIGURE 12.8 NSOM and topography images $(2 \times 2 \mu m)$ of individual S65T GFPs. Right: Fluorescence image showing abrupt changes in the emission of isolated spots (circles). FIGURE 12.9 Shear-force topography of a SERS substrate covered with brilliant cresyl blue labeled DNA fragments. The Raman spectra on the left correspond to the specified local positions on the substrate.

and biological nature of this dark state are still under investigation; nevertheless, these factor affect the sensitivity of the single-molecule detection because the off-time can last for several seconds and the probability of detecting a single GFP molecule is only 5%.

12.3.2.2 Near-Field Raman Spectroscopy of Labeled DNA

Raman spectroscopy has the potential to identify any material by its characteristic molecular vibration without the need for further labeling and, hence, in many cases without any further sample preparation. Raman microscopy is fast becoming a standard technique to characterize surfaces directly.⁸⁰ The major disadvantage of standard Raman spectroscopy is the poor scattering cross section. Its efficiency is about ten orders of magnitude lower than fluorescence spectroscopy. This makes routine investigations impossible for many analytical problems. In biology, nevertheless, many structural problems of proteins have been solved by using resonance Raman scattering.⁸¹ Here, the efficiency is much better because the molecules or certain fragments of the molecule are resonantly excited.⁸² This results in an enhancement of several orders of magnitude.

Even greater signal enhancements can be gained by the implementation of surface-enhanced Raman scattering (SERS).^{83–86} Using certain rough metal substrates, enhancement factors up to 10¹⁰ and even higher have been reported, resulting in single-molecule sensitivity comparable to fluorescence, as discussed previously.^{87,88} Kneipp and co-workers reported on the detection of single DNA base molecules using SERS.⁸⁸ At present, the still lower light emission of SERS compared with fluorescence restricts the use of near-field optical techniques. To utilize the enhancement it is helpful to label the substance of interest with an especially active SERS compound. This may seem like a more difficult way of performing fluorescence labeling, but the advantage here is the narrowness of the emission lines in Raman scattering compared to those in fluorescence. This narrowness allows the simultaneous detection of several labels with just one excitation line.

This kind of labeling is shown in Figure 12.9, which shows the rough topography of a SERS substrate covered with brilliant cresyl blue (BCB) stained DNA fragments. 89,90 Near-field Raman spectra were recorded simultaneously and some example spectra are shown. The change in the spectral pattern indicates a change in sample composition without an elaborate band assignment. The central part of the right substrate shown in Figure 12.9 differs clearly from the outer regions. The signal-to-noise ratio is not sufficient for further investigation. Because this was an atypical result, all but two prominent bands can be used for analysis. The only conclusion that can be drawn from the data is that the results are definitely not due to the dye label, and therefore a change in the sample composition occurred. The nature of this change remains, however, unclear.

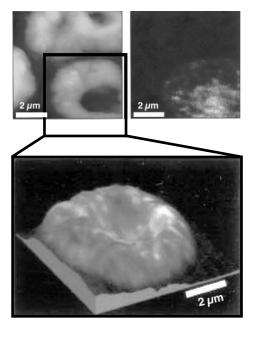

FIGURE 12.10 Fluorescence and topography images of malaria-infected cells.

The combination of SERS and near-field optical techniques is promising because of the ease of distinguishing many samples simultaneously. However, there are still drawbacks, the most important of which is the long acquisition time of about 1 min per position. Therefore, the specific investigation of selected regions of interest appears to be more promising than a complete imaging.

12.3.3 Model Cell Membranes

An important issue in biology is the probing of cell membranes. Typical questions concern the organization and orientation of the membrane or the location of specific molecules such as proteins. Because of their softness, many membranes tend to fluctuate, and this requires a very sensitive feedback scheme. Consequently, many researchers choose Langmuir-Blodgett mono- and bilayers that are easier to control and serve as a model system. 91–93 The capabilities of NSOM to gain information on phase changes or changes resulting from additives such as cholesterol or small peptides have been demonstrated by several research groups. 94–99 One very interesting approach is the detection of the three-dimensional dipole orientation of single fluorophores to determine the structure and phase composition of a membrane. 66,100 Depending on environmental conditions, these orientations change; in combination with simultaneous topographic measurements, the correlation between structure and morphology can be deduced.

Some groups have begun to look at cell membranes directly. ^{101–104} Figure 12.10, for example, shows the fluorescence and topography images of malaria-infected cells. ¹⁰⁵ Here the mapping of malarial protein in the erythrocyte membrane is shown. A blood sample was reacted with antibodies against a specific malaria protein (*Plasmodium falciparum* histidine-rich protein) and then stained with tetramethylrhodamine. The topography image clearly shows the red blood cells, but cannot distinguish between infected and healthy cells. The fluorescence image to the upper right clearly shows that only the cell in the lower right is infected. In the superposition of fluorescence and topography images, the distribution of the antibodies on the erythrocyte membrane can be visualized quite clearly. The investigators claim the resolution to be around 100 nm — well below the far-field control experiment. A further near-field dual-color experiment (not shown) proved that different malarial proteins interact differently with certain blood proteins. The high resolution of the near-field experiment is necessary to distinguish the local origins of the labeled proteins.

The progress in the feedback stability and resolution in such membrane investigations is very promising. In contrast to many other experiments, the resolving power of the instrument is a major issue here, because the concentration in these experiments cannot simply be diluted to make it convenient for standard microscopy. Furthermore, because the light field does not really extend into the cell, background fluorescence is a minor issue in the near-field. Finally, only NSOM offers the advantage of synchronous topography and light detection.

12.4 Special Near-Field Techniques for Biological Applications

This section provides an overview of some promising but not yet established techniques and approaches to obtain near-field optical resolution. Only time will tell whether these methods can compete with the methods currently used.

12.4.1 Fluorescence Resonance Energy Transfer

Fluorescence resonance energy transfer (FRET) is a method that uses the distance dependence of non-radiative energy transfer from an excited donor molecule to an acceptor molecule. The transfer efficiency is given by a sixth-power dependence on the intermolecular separation:

$$E = 1/(1 + (R/R_0)^6)$$
,

where R is the distance between donor and acceptor and R_0 is the distance at which 50% of the energy is transferred. Consequently, this interaction is sensitive even to angstrom scale distance changes. Experimentally, a pair of fluorescing molecules is needed, only one of which (the donor) can be excited directly with the excitation source. The acceptor dye only emits light if it is in close proximity to an excited donor. In an experimental setup one has to separate donor and acceptor fluorescence spectrally. A red shifted fluorescence then means that a donor resonantly transferred its energy to an acceptor. The relevant distance is on the order of a few nanometers, which is ideal for monitoring conformation changes in proteins or events in biomembranes. $^{106,108-112}$

Discussing the details of this technique is beyond the scope of this chapter; we outline only the results achieved in biology using a near-field aperture. In a simple scheme, a near-field microscope can be applied within a dual color mode scan (as already mentioned) to find resonant pairs simply with higher resolution.^{113,114} Sekatskii and Letokhov¹¹⁵ proposed an experimental setup that, in principle, could result in a resolution of a few nanometers. In their setup, the Förster pair is composed of an acceptor attached to the near-field aperture, whereas the donor is on the sample surface. The distance between donor and acceptor can then be controlled by the tip sample feedback regulation. Vickery and Dunn¹¹⁶ applied this technique to the near-field investigation of Langmuir-Blodgett films and observed an improvement in resolution; however, the results using this method are still at an early stage and no biosamples have been investigated.

12.4.2 "Apertureless" Near-Field Microscopy

The main restriction of near-field optical microscopy is the aperture. Although an aperture is necessary to achieve the resolution, it also imposes serious limitations. A different approach is the use of an active light source with subwavelength dimensions. Zenhausern and co-workers were the first to report that an externally illuminated sharp tip can serve as such a light source. These investigators used an elaborate setup to distinguish the minute differences of light intensity when the vibrating tip was either close to or away from the sample. Sanchez and co-workers utilized the strongly enhanced electric field at a metal tip to induce two-photon fluorescence. The spatial resolution on j-aggregates was about 20 nm, very

difficult to achieve with standard NSOM. The problem of background fluorescence signal was avoided by using two-photon excitation. In general, the signal was spectrally far from the fluorescence excited with one photon; furthermore, without the enhancing tip, no two-photon fluorescence signal at all was observed.

Another approach that involves field enhancement with metal was suggested by Wessel in 1985.¹¹⁸ He proposed that a sharp metal tip brought very close to the external sample surface would enhance the Raman signal in the same way as do the well-known rough metal surfaces used for SERS. Interestingly, a similar but much weaker enhancement effect exists for infrared spectroscopy; here, Knoll and Keilmann were the first to observe a vibrational signal that was enhanced by the presence of a metal tip.³⁵ The first reports on probe-enhanced Raman scattering followed shortly thereafter;^{37,119,120} the enhancement factors reported were on the order of several thousand compared to the background Raman signal.³⁷ This is still far from the maximum enhancement factors achieved with rough surfaces or even colloids;^{87,121} thus, there is room for improvement. Thus far, apertureless Raman or infrared spectroscopy have not been used on biological samples; however, there are no indications that the method would fail. All the advantages of Raman spectroscopy are maintained and the disadvantage of low scattering cross sections can be overcome. Thus, apertureless or probe-enhanced techniques may well be the future of high spatial resolution spectroscopy.

12.4.3 Multiphoton Near-Field Microscopy

In the previous section a type of multiphoton near-field microscopy was mentioned.³⁶ However, it is also possible to excite two- or three-photon processes with a standard near-field probe. Pulsed¹²² and continuous-wave (CW)¹²³ near-field experiments on cell material have been reported. The advantage of this approach, the high signal-to-background level, is identical to the two-photon probe enhanced technique mentioned in the previous section. The detected signal is blue shifted with respect to the excitation source, so that normal fluorescence is spectrally far away and can easily be filtered. In addition, a resolution enhancement occurs because the two-photon energy is the same as one single UV-photon of half the wavelength. Using a UV source directly can be disadvantageous because of absorption effects and possible destruction of the specimen. The advantage of using a longer wavelength laser source in combination with two-photon processes is therefore twofold. Very good results, with respect to the signal level, have been reported using two- and three-photon excitation on polytene chromosomes.^{122,123} The spatial resolution in these first experiments was below 200 nm but further improvement appears possible.

The application of this technique appears straightforward, at least for the CW technique. In cases where UV-dyes are the only choice, this method is a good alternative to direct excitation. For dye labels that absorb in the visible region the availability of an affordable laser source for two-photon excitation may be a problem.

12.4.4 Nonoptical Near-Field Microscopy

A unique scheme of observing biological specimens has been proposed by Kawata and coworkers. 124,125

The specimens are on top of a photosensitive copolymer. Instead of raster scanning the sample, the authors illuminate the whole area of interest with a short laser pulse. After the illumination the sample is washed and the polymer is then scanned with a standard AFM. Depending on the optical properties of the specimen and the polymer, a different corrugation is detected and the specimen is scanned indirectly. Using multiple illumination, even moving cells can be detected, as demonstrated by Kawata et al. 125

This method will probably not become a general tool for detecting subwavelength features because it cannot correlate topographical features with molecular contrast. Nevertheless, it is a surprisingly simple and straightforward technique that allows observation of dynamic phenomena on a rather large scale with high resolution.

12.5 Outlook and Conclusions

Since the first experiments about 20 years ago, near-field optics has been applied in many research fields. Particularly in biological and biomedical applications, the possibility of observing features below 100 nm is very tempting and it is not surprising that many NSOM applications are used in biology-related material. The most successful near-field application to date is fluorescence NSOM. A "down scaling" from standard microscopy rather than a new technique, it combines high lateral optical resolution with the synchronous detection of the sample topography. This combination is a unique advantage of near-field microscopy. Similar to microscopy, the sensitivity of the fluorescence NSOM is down to the single-molecule level, despite the notoriously low efficiency of the near-field probes.

Other spectroscopic techniques such as infrared or Raman are much more limited by restrictions imposed by the aperture. Collection of near-field Raman images, for example, still takes a matter of hours. The emergence of probe-enhanced or "apertureless" techniques might well change that situation. The implementation and testing of these new methods is still at an early stage. The enhancement factors found in macroscopic experiments and theoretically predicted have not yet been demonstrated in the near-field. Basic research in these fields is still required.

Compared to normal microscopy the market share of NSOM today is quite small. It will probably remain a specialized technique for some time to come. Interestingly, the development of new techniques in standard microscopy (for example, the 4Pi microscope¹²⁶ and the solid immersion lens microscope¹²⁷) that improve resolution, for the first time after almost a century, correspond to the rise of near-field techniques. Coincidence or not, developments in the two techniques will likely improve the applications of both in the future.

13.1 Introduction

Optical coherence tomography (OCT) is a fundamentally new type of optical imaging modality. OCT performs high-resolution, cross-sectional tomographic imaging of the internal microstructure in materials and biological systems by measuring backscattered or backreflected light.¹⁻³ Image resolutions of 1 to 15 µm can be achieved — one to two orders of magnitude higher than conventional ultrasound. Imaging can be performed *in situ* and nondestructively. High-speed, real-time imaging is possible with acquisition rates of several frames per second. OCT enables "optical biopsy," the imaging of tissue structure or pathology on resolution scales approaching that of histopathology, with imaging performed *in situ* and in real time, without the need to excise specimens and process them as in standard excisional biopsy and histopathology.

OCT has a number of technological features that make it attractive for a broad range of applications. OCT technology is fiber-optically based and uses components developed for the telecommunications industry. Thus, it takes advantage of a well-established technology base. OCT can be interfaced with a wide range of imaging delivery systems and imaging probes. Image information is generated in electronic form that is amenable to image processing and analysis as well as electronic transmission, storage, and retrieval. Finally, OCT systems can be engineered to be compact and low cost, suitable for applications in research, manufacturing, or the clinic.

OCT is a powerful imaging technology in medicine because it enables the real-time, *in situ* visualization of tissue microstructure without the need to remove and process a specimen excisionally. The concept of nonexcisional "optical biopsy" performed by OCT and the ability to visualize tissue morphology in real time under operator guidance can be used for diagnostic imaging and to guide intervention. OCT promises to be useful in three general types of clinical situations:

- 1. Where standard excisional biopsy is hazardous or impossible. Examples include imaging the eye, coronary arteries, or nervous tissues.
- 2. Where standard excisional biopsy suffers from sampling errors. Biopsy followed by histopathology is the standard for cancer diagnosis; however, if the biopsy misses the lesion, then a false negative result is obtained. OCT might be used to guide biopsy to reducing sampling error or may ultimately provide diagnostic information directly.
- 3. For guidance of interventional procedures. The ability to see beneath the surface of tissue enables the assessment and guidance of microsurgical procedures such as vessel and nerve anastomosis or the guidance of procedures such as stent placement or atherectomy in interventional cardiology. Coupled with catheter, endoscopic, or laparoscopic delivery, OCT promises to have a powerful impact on many medical applications, ranging from improving the screening and diagnosis of neoplasia to enabling new microsurgical and minimally invasive surgical procedures. This chapter provides an overview of OCT technology and applications.

13.2 Principles of Operation of Optical Coherence Tomography

OCT imaging is analogous to ultrasound B mode imaging except that it uses light instead of sound. OCT images are generated by performing axial measurements of the echo time delay and magnitude of reflected light at different transverse positions, as shown in Figure 13.1. OCT images are a two- or three-dimensional data set that represents differences in optical backscattering or backreflection in a cross-sectional plane or volume of a tissue or material. Because of the analogy between OCT and ultrasound, it is helpful to consider the factors that govern OCT imaging compared to ultrasound imaging.^{4–7} In ultrasound, a high-frequency sound wave is launched into the material or tissue being imaged using an ultrasonic probe transducer. The sound wave travels into the material or tissue and is reflected or backscattered from internal structures having different acoustic properties. The time behavior or echo structure of the

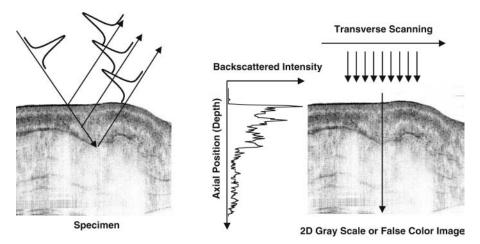

FIGURE 13.1 OCT performs imaging by measuring the echo time delay and magnitude of backreflected or back-scattering light. Cross-sectional images are constructed by performing axial measurements of the echo time delay and magnitude of backscattered or backreflected light at different transverse positions. This results in a two-dimensional data set that represents the backscattering in a cross-sectional plane of the material or tissue being imaged.

reflected sound waves is detected by the ultrasonic probe and the ranges and dimensions of internal structures determined from the echo delay. This principle is also similar to that used in radar.

In OCT, measurements of distance and microstructure are performed by directing a light beam onto the material or tissue and measuring the backreflecting and backscattering light from internal microstructural features as shown in Figure 13.1. For conceptual purposes, it is possible to visualize the operation of OCT by thinking of the light beam as composed of short optical pulses. However, although OCT may be performed using short pulse light, most OCT systems operate using continuous wave, short coherence length light.

The principal difference between ultrasound and optical imaging is the fact that the velocity of propagation of light is approximately a million times faster than the velocity of sound. Because distances within the material or tissue are determined by measuring the "echo" time delay of backreflected or backscattered light waves, distance measurement using light requires ultrafast time resolution. For example, the measurement of a structure with a resolution on the 10-µm scale, which is typical in OCT, corresponds to a time resolution of approximately 30 fs. Direct electronic detection is not possible on this timescale. Thus, OCT measurements of echo time delay are based on correlation techniques that compare the backscattered or backreflected light signal to reference light traveling a known pathlength. Although OCT imaging is analogous to ultrasound, the core technology of OCT is quite different.

Finally, since ultrasound imaging depends on sound waves, it requires direct contact with the material or tissue being imaged, or immersion in a liquid or other medium to facilitate the transmission of sound waves. In contrast, optical imaging techniques such as OCT rely on the use of light rather than sound and can be performed without physical contact to the structure being imaged and without the need for a special transducing medium. In applications such as ophthalmology, the ability to perform noncontact imaging is important for patient comfort during examination. In endoscopy or bronchoscopy, the ability to image without a sound transducing medium can be a powerful advantage because contact with or occlusion of the lumen is not required.

13.2.1 Measuring Ultrafast Optical Echoes

The concept of using high-speed optical gating to perform imaging in biological tissues was first proposed by M. Duguay almost 30 years ago.^{8,9} Duguay developed an ultrafast optical shutter to photograph light in flight based on the Kerr effect. The Kerr shutter can achieve picosecond or femtosecond resolutions and operates by using an intense light pulse to induce transient birefringence (the Kerr effect) in an optical medium placed between crossed polarizers. The principal disadvantage of the high-speed optical Kerr shutter is that it requires high-intensity laser pulses to induce the Kerr effect and operate the shutter. Duguay pointed out that optical scattering limits imaging biological tissues and that a high-speed shutter could be used to gate out unwanted scattered light, thereby detecting light echoes from internal structures at different depths in the tissue. Such a technology could be used to see through tissues and noninvasively image their internal structure.

An alternate approach to performing high-speed gating is to use nonlinear processes such as harmonic generation or parametric conversion. In this technique, short pulses are used to illuminate the object or specimen being imaged, and the backscattered or backreflected light is upconverted or parametrically converted with a reference pulse in a nonlinear optical crystal. The time resolution is determined by the pulse duration and the sensitivity is determined by the conversion efficiency of the nonlinear process. Optical time-of-flight ranging measurements were first demonstrated in biological tissues using short pulses and a nonlinear intensity autocorrelation technique to measure corneal thickness and the depth of the stratum corneum and epidermis. Dynamic ranges of 106 or higher can be achieved, but these are insufficient for imaging scattering tissues where the attenuation from scattering can be 10-10. Nonlinear cross correlation does not require intensity pulses as high as the Kerr shutter, but still requires the use of short pulses. It is also important to note that this technique detects the intensity (rather than the field) of the backscattered or backreflected light.

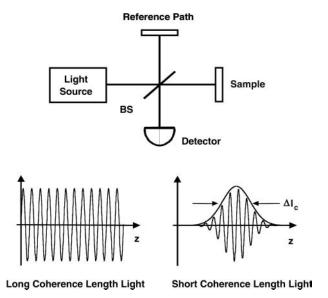

FIGURE 13.2 The echo time delay and magnitude of backreflected or backscattering light can be measured using interferometry. The most common detection method is based on a Michelson interferometer with a scanning reference delay arm. Backreflected or backscattered light from the object being imaged is correlated with light that travels a known reference path delay.

OCT uses interferometric detection and correlation methods to measure the echo time delay of backreflected or backscattered light with high dynamic range and high sensitivity. These techniques are analogous to coherent optical detection in optical communications. OCT is based on a classic optical measurement technique known as low coherence interferometry or white light interferometry, first described by Sir Isaac Newton. More recently, low coherence interferometry has been used to characterize optical echoes and backscattering in optical fibers and waveguide devices. ^{13–15} The first biological application of low coherence interferometry was in ophthalmologic biometry for measurement of eye length. ¹⁶ Since then, related versions of this technique have been developed for noninvasive high-precision and high-resolution biometry. ^{17,18} High-resolution measurements of corneal thickness *in vivo* have been demonstrated using low coherence interferometry. ¹⁹

Low coherence interferometry measures the field of the optical beam rather than its intensity. Figure 13.2 shows a schematic diagram of a simple Michelson type interferometer. The incident optical wave into the interferometer is directed onto a partially reflecting mirror or beamsplitter, which yields two beams, one of which acts as a reference beam and the other as a measurement or signal beam. The beams travel given distances in the two arms of the interferometer. The reference beam $E_r(t)$ is reflected from a reference mirror while the measurement or signal beam $E_s(t)$ is reflected from the biological specimen or tissue to be imaged. The beams then recombine and interfere at the beamsplitter. The output of the interferometer is a sum of the fields from the reference beam reflected from the reference mirror and the measurement or signal beam reflected from the specimen or tissue. The detector measures the intensity of the output optical beam that is proportional to the square of the electromagnetic field. If the distance that light travels in the reference path of the interferometer is l_R and the distance that light travels in the measurement path, reflected from the specimen, is l_s , then the intensity of the output from the interferometer will oscillate as a function of the difference in distance $\Delta l = l_r - l_s$ because of interference effects. The intensity as a function of E_s , E_r , and Δl is given as

$$I_o(t) \sim (1/4)|E_r|^2 + (1/4)|E_s|^2 + (1/2)E_rE_s\cos\{2(2\pi/\lambda)\Delta l\}$$
.

If the position of the reference mirror is varied, then the pathlength that the optical beam travels in the reference arm changes. Interference effects will be observed in the intensity detected by the detector if the relative pathlength is changed by scanning the reference mirror.

If the light is highly coherent (narrow linewidth or bandwidth) with a long coherence length, then interference oscillations will be observed for a wide range of relative pathlength delays of the reference and measurement arms. For applications in optical ranging or optical coherence tomography, it is necessary to measure absolute distance and dimensions of structures precisely within the material or tissue. In this case, light with a short coherence length (broad bandwidth) is used. Low coherence light can be characterized as having statistical discontinuities in phase over a distance known as the coherence length (l_c). The coherence length is inversely proportional to the frequency bandwidth.

When low coherence light is used, interference is only observed when the pathlengths of the reference and measurement arms are matched to within the coherence length of the light. If the pathlengths differ by more than the coherence length, then the electromagnetic fields from the two beams are not correlated, and there is no interference. The interferometer measures the field autocorrelation of the light. For the purposes of ranging and imaging, the coherence length of the light determines the resolution with which optical range or distance can be measured. The magnitude and echo time delays of reflected light can be measured by scanning the reference mirror delay and demodulating the interferometer interference signal.

13.2.2 Resolution and Sensitivity of Optical Coherence Tomography

In contrast to conventional microscopy, in OCT the mechanisms that govern the axial and transverse image resolution are decoupled. The axial resolution in OCT imaging is determined by the coherence length of the light source, and high axial resolution can be achieved independent of the beam focusing conditions. The coherence length is the spatial width of the field autocorrelation produced by the interferometer. The envelope of the field autocorrelation is equivalent to the Fourier transform of the power spectrum. Thus, the width of the autocorrelation function, or the axial resolution, is inversely proportional to the width of the power spectrum. For a source with a Gaussian spectral distribution, the axial resolution Δz is given as

$$\Delta z = (2 \ln 2/\pi)(\lambda^2/\Delta\lambda)$$
,

where Δz and $\Delta \lambda$ are the full-widths-at-half-maximum of the autocorrelation function and power spectrum, respectively, and λ is the source center wavelength. Broad bandwidth optical sources are required to achieve high axial resolution.

The transverse resolution in OCT imaging is the same as for conventional optical microscopy and is determined by the focusing properties of an optical beam. The minimum spot size to which an optical beam may be focused is inversely proportional to the numerical aperture or the angle of focus of the beam. The transverse resolution is given as

$$\Delta x = (4\lambda/\pi)(f/d)$$
,

where d is the spot size on the objective lens and f is its focal length. High transverse resolution can be obtained by using a large numerical aperture and focusing the beam to a small spot size. The transverse resolution is also related to the depth of focus or confocal parameter b, which is $2z_R$, two times the Rayleigh range:

$$b=2z_{R}=\pi\Delta x^{2}/2\lambda.$$

Thus, increasing the transverse resolution produces a decrease in the depth of focus, similar to that which occurs in conventional microscopy.

OCT can achieve high detection sensitivity because interferometry is equivalent to optical heterodyne detection and measures the field rather than the intensity of light. Because the beam from the reference mirror can have a large amplitude, the weak electric field of the signal beam from the specimen is multiplied by a large field, thereby increasing the magnitude of the interference output of the interferometer. The interferometer thus produces heterodyne gain for weak optical signals.

In most OCT embodiments the reference mirror is scanned at a constant velocity ν resulting in a Doppler shift of the reflected light. This produces a modulation of the interference signal at the Doppler beat frequency $f_D = 2\nu/\lambda$, where ν is the reference mirror velocity. By electronically bandpass filtering and demodulating the photodetector signal, echoes from different reflecting surfaces in the biological specimen may be detected. The signal-to-noise ratio (SNR) performance can be calculated using well-established mathematical models and is given as

$$SNR = 10 \log (\eta P / 2hv NEB),$$

where η is the detector quantum efficiency, hv is the photon energy, P is the signal power, and NEB is the noise equivalent bandwidth of the electronic filter used to demodulate or detect the signal. This expression implies that the SNR scales as the detected power divided by the noise equivalent bandwidth of the detection. High image acquisition speeds or higher image resolutions require higher optical powers for a given SNR.

The performance of optical coherence tomography systems varies widely according to their design and data acquisition speed requirements. However, for typical measurement parameters, sensitivities to reflected signals in the range of -90 to -100 dB can be achieved, corresponding to the detection of backreflected or backscattered signals that are 10^{-9} or 10^{-10} of the incident optical power.

13.2.3 Image Generation in Optical Coherence Tomography

Optical coherence tomography cross-sectional imaging is achieved by performing successive axial measurements of backreflected or backscattered light at different transverse positions. Figure 13.1 schematically illustrates one example of how optical coherence tomography is performed. A two-dimensional cross-sectional imaging is acquired by performing successive rapid axial measurements of optical backscattering or backreflection profiles at different transverse positions by scanning the incident optical beam. The result is a two-dimensional data set where each trace represents the magnitude of reflection or backscattering of the optical beam as a function of depth in the tissue.

OCT image data are acquired by computer and displayed as a two-dimensional gray scale or false color image. Figure 13.3 shows an example of a tomographic image of the retina. The image displayed consists of 200 pixels (horizontal) by 500 pixels (vertical). The vertical direction corresponds to the direction of the incident optical beam and the axial data sets. The backscattered signal ranges from approximately –50 dB, the maximum signal, to –100 dB, the sensitivity limit. Because the signal varies over five orders of magnitude, it is convenient to use the log of the signal to display the image. This expands the dynamic range of the display but results in compression of relative variations in signal.

The previous images of the retina are examples of imaging media that have weak reflections. Figure 13.4 shows an OCT image of the human bronchus *in vitro* as an example of an image in highly scattering tissue. In a highly scattering material or tissue, light is rapidly attenuated with propagation depth resulting in a gradation of signal in the image. Also, significant levels of speckle noise or other noise can arise from the microstructural features of the material or specimen. For these reasons it is more common to display OCT images in highly scattering materials or tissues using a gray scale.

The detection sensitivity determines the imaging performance of optical coherence tomography for different applications. When OCT imaging is performed in very weakly scattering media, the imaging depth is not strongly limited, because there is very little attenuation of the incident beam. Instead, the sensitivity of the OCT detection establishes a limit on the smallest signals that can be detected. For example, in ophthalmic imaging, high sensitivity is essential in order to image structures, such as the

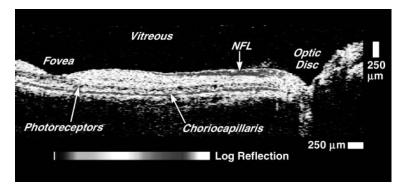

FIGURE 13.3 False color OCT image in low scattering tissue. Example of an OCT image of the normal retina *in vivo* in a human subject. The image was performed at 800 nm and has a 10-μm axial resolution. The image consists of 200 axial scans and shows the differentiation of retinal layers possible using false color display. The log of the backscattering or backreflected signal is mapped to a false color scale. The retinal pigment epithelium, choroid, and retinal nerve fiber layers are visible as highly backscattering red layers. (From Hee, M.A. et al., *Arch. Ophthalmol.*, 113, 325, 1995. With permission.)

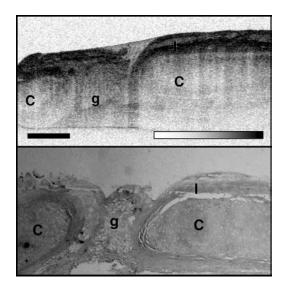

FIGURE 13.4 Gray scale OCT image in scattering tissue. Example of an OCT image of the human secondary bronchus *in vitro* and corresponding histology. Cartilage, lamina propria, and glands can be visualized. OCT was able to image through the entire thickness of the bronchus. This image was performed at 1300-nm wavelengths and illustrates features common in many scattering tissues. These images show strong attenuation of the signal with depth as well as speckle noise; hence, they are more prone to display artifacts than OCT images in weakly scattering tissues and are often displayed using a log gray scale. The bar represents 500 μm. (From Pitris, C. et al., *Am. J. Respir. Crit. Care Med.*, 157, 1640, 1998. With permission.)

retina, that are nominally transparent and have very low backscattering. In ophthalmic applications, image contrast arises because of differences in the backscattering properties of different tissues. Structures such as the retinal pigment epithelium (RPE) or retina nerve fiber layer can be differentiated from other structures because of their different scattering amplitudes. Typical retinal images have signal levels between –50 to –100 dB of the incident signal. For retinal imaging, the ANSI standards govern the maximum permissible light exposure and set limits for the sensitivity of OCT imaging and OCT imaging speeds. ^{20,21}

In contrast, OCT imaging in highly scattering media also requires high sensitivity and dynamic range. In this case, the detection sensitivity determines the maximum depth to which imaging can be performed.

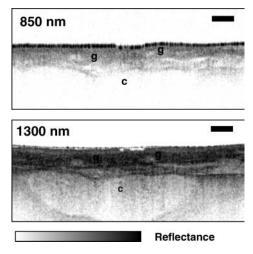

FIGURE 13.5 Wavelength dependence of OCT imaging depth. OCT images of human epiglottis *in vitro* performed with light sources at 850 and 1300 nm. Attenuation from scattering is reduced using longer wavelengths. Superficial glands (g) can be visualized at both wavelengths but underlying structures such as cartilage (c) can be imaged only with 1300-nm light. With a 100-dB detection sensitivity, image penetration depths of 2 to 3 mm are achieved in most scattering tissues. The bar represents 500 μ m. (From Brezinski, M.E. et al., *Circulation*, 93, 1206, 1996. With permission.)

Most biological tissues are highly scattering and OCT imaging in tissues other than the eye became possible with recognition that using longer optical wavelengths, 1300 nm compared to 800 nm, can reduce scattering and increase image penetration depths. ^{18,22–24} Figure 13.5 shows an example of OCT imaging in a human epiglottis *in vitro* comparing 800- to 1300-nm imaging wavelengths. The dominant absorbers in most tissues are melanin and hemoglobin, which have absorption in the visible and near-infrared wavelength range. Water absorption becomes appreciable for wavelengths approaching 1.9 to 2 μ m. In most tissues, scattering at near-infrared wavelengths is one to two orders of magnitude higher than absorption. Scattering decreases for longer wavelengths, so that OCT image penetration increases. ²² For example, if a tissue has a scattering coefficient in the range of ~40 cm⁻¹ at 1300 nm, then the round-trip attenuation from scattering alone from a depth of 3 mm is $e^{-24} \sim 4 \times 10^{-11}$. Thus, if the detection sensitivity is –100 dB, backscattered or backreflected signals are attenuated to the sensitivity limit when the image depth is 2 to 3 mm. Because the attenuation is exponential with depth, increasing the detection sensitivity would not appreciably increase the imaging depth. Image penetration depths of 2 to 3 mm are possible in most scattering tissues.

13.3 Optical Coherence Tomography Technology and Systems

Optical coherence tomography has the advantage that it can be implemented using compact fiber-optic components and integrated with a wide range of medical instruments. Figure 13.6 shows a schematic of an OCT system using a fiber-optic Michelson-type interferometer. A low coherence light source is coupled into the interferometer, and the interference at the output is detected with a photodiode. One arm of the interferometer emits a beam that is directed and scanned on the sample being imaged, while the other arm of the interferometer is a reference arm with a scanning delay.

OCT systems can be considered from a modular viewpoint in terms of integrated hardware and software modules with various functionalities. Figure 13.7 shows a schematic of the different modules in an OCT imaging system. The OCT system can be divided into the imaging engine, low coherence light source, beam delivery and probes, computer control, and image processing.

In general, the imaging engine can be any optical detection device that performs high-resolution and high-sensitivity detection of backreflected or backscattered optical echoes. Most OCT systems have

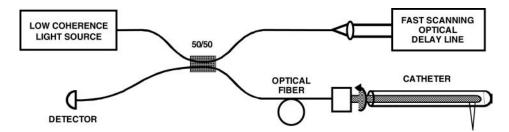

FIGURE 13.6 Schematic showing of an OCT instrument using a fiber-optic Michelson interferometer with low coherence light source. One arm of the interferometer is integrated with an imaging probe, and the other arm has a scanning delay line. The system shown is configured for catheter/endoscope imaging. The fiber-optic implementation allows OCT to be integrated with a wide range of instruments.

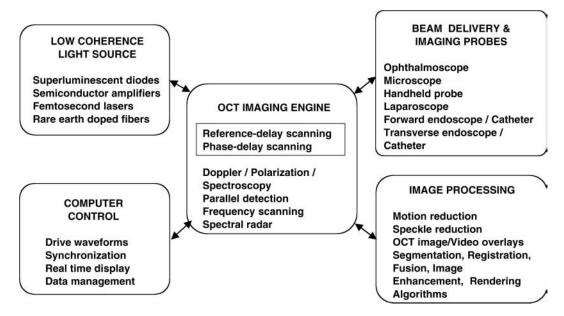

FIGURE 13.7 OCT from a systems viewpoint. OCT is a modular technology consisting of hardware and software. The major modules in the OCT system include the imaging engine, light source, delivery system and optical probes, computer control, and image processing.

employed a reference delay scanning interferometer using a low coherence light source. There are many different embodiments of the interferometer and imaging engine for specific applications such as polarization diversity (insensitive) imaging, polarization sensitive imaging, and Doppler flow imaging. Doppler flow imaging has been performed using imaging engines that directly detect the interferometric output rather than demodulating the interference fringes.^{25–27} Polarization sensitive detection techniques have been demonstrated using a dual channel interferometer.^{28–30} These techniques permit imaging of the birefringence properties of structures. Conversely, polarization diversity or polarization insensitive interferometers can also be built using well-established detection methods from coherent heterodyne optical detection. Finally, other imaging engine approaches have been demonstrated that are based on spectral analysis of broadband light sources as well as tunable narrow linewidth sources.³¹ These imaging engines have the advantage that they do not require scanning an optical delay, and thus no moving parts are required.

The short coherence length light source determines the resolution of the OCT system. For clinical applications, compact superluminescent diodes or semiconductor-based light sources have been used. Although these sources have not yet reached the performance levels of research systems, they are compact and robust enough to be used in the clinical environment. Ophthalmic OCT systems have employed

commercially available compact GaAs superluminescent diodes, which operate near 800 nm with bandwidths of 20 to 30 nm and achieve axial resolutions of ~10 μ m with output powers of a few milliwatts. Commercially available sources based on semiconductor devices or amplifiers operating at 1.3 μ m can achieve axial resolutions of ~15 μ m with output powers of 15 to 20 mW, sufficient for real-time OCT imaging.

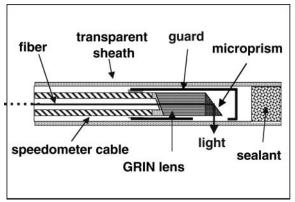

For research applications, short pulse lasers are powerful light sources for OCT imaging because they have extremely short coherence lengths and high output powers, enabling high-resolution, high-speed imaging. Studies have been performed using a femtosecond Cr^{4+} :Forsterite laser. This laser produces output powers of greater than 100 mW with ultrashort pulses of less than 100 fs at wavelengths near 1300 nm. By using nonlinear self-phase modulation in optical fibers, the spectral output can be broadened to produce bandwidths sufficient to achieve axial resolutions of 5 to 10 μ m. Image acquisition speeds of several frames per second are achieved with SNRs of 100 dB using incident powers in the 5 to 10 mW range.

Short pulse Ti:Al₂O₃ lasers operating near 800 nm have also been used to achieve high resolutions. Early studies demonstrated axial resolutions of 4 μ m.³³ Recently, using Ti:Al₂O₃ laser technology that generates pulse durations of ~5 fs and bandwidths of over 300 nm, axial resolutions of 1 μ m have been achieved.³⁴ Broadband light can also be generated using standard commercial femtosecond lasers by using continuum generation in nonlinear fibers. Using a high nonlinearity photonic crystal fiber, a broadband continuum extending from 1400 to 400 nm can be generated using 100-fs pulses from a standard Ti:Al₂O₃. Recently, OCT image resolutions of ~3 μ m were achieved at 1300-nm wavelengths using a nonlinear photonic crystal fiber in conjunction with a commercially available Ti:Al₂O₃ laser.³⁵ With further development, other types of low coherence light sources based on rare earth doped fibers, Raman conversion, and other nonlinear conversion processes may also become feasible for clinical OCT systems.

In OCT systems that use reference delay scanning, the optical delay scanner determines the image acquisition rate of the system. High-speed OCT imaging requires technology for high-speed optical delay scanning of the reference pathlength. The earliest scanning devices were constructed using galvos and retroreflectors. These systems are simple and easy to use and can scan up to a centimeter or more. However, scan repetition rates are limited to approximately 100 Hz. A novel technique using PZT scanning of optical fibers has been developed that can achieve scan ranges of a few millimeters with repetition rates of 500 Hz or more. This device is based on pulse shaping techniques from femtosecond optics. The grating phase control scanner is attractive because it achieves extremely high scan speeds and also permits independent control of the phase and group velocity of the scanning. Imaging can be performed at several frames per second.

OCT beam delivery and optical probes can be designed for many applications. Because OCT technology is fiber-optic based, it can be easily integrated with many standard optical diagnostic instruments including instruments for internal body imaging. OCT has been integrated with slit lamps and fundus cameras for ophthalmic imaging of the retina. The ophthalmic imaging a pair of galvonometric beam steering mirrors and relay imaged onto the retina. The ophthalmic OCT imaging instrument is a relatively complex design because it must allow the retina (fundus) to be viewed *en face* while showing the position of the tomographic scanning beam as well as the resulting OCT tomographic image. The ability to register OCT images with *en face* features and pathology is an important consideration for many applications. Similar principles apply for the design of OCT using low numerical aperture microscopes, which have been used for imaging developmental biology specimens *in vivo* as well as for surgical imaging applications. ^{43–45}

Other beam delivery systems include forward imaging devices that perform one- or two-dimensional beam scanning. Rigid laparoscopes are based on relay imaging using Hopkins-type relay lenses or graded index rod lenses. OCT can be readily integrated with laparoscopes to permit internal body OCT imaging with a simultaneous *en face* view of the scan registration.^{37,46} Handheld imaging probes, devices that resemble light pens and use piezoelectric or galvonometric beam scanning, have also been demonstrated.^{46,47} Handheld

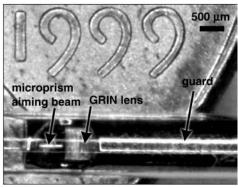

FIGURE 13.8 Miniature fiber-optic OCT catheter probe. This catheter is designed for transverse scanning OCT imaging. A single-mode fiber is contained in a rotating flexible speedometer cable. The distal end has beam delivery optics that direct and focus the beam at 90° from the axis of the catheter. The rotating cable and optics are enclosed in a protective plastic sheath. The diameter of the catheter is 2.9 F or 1 mm. The catheter is shown on a penny for scale.

probes can be used in open field surgical situations to permit the clinician to view the subsurface structure of tissue by aiming the probe at the desired structure. These devices can also be integrated with conventional scalpels or laser surgical devices to permit simultaneous, real-time viewing as tissue is being resected.

Another class of imaging probes includes flexible miniature devices for internal body imaging. Because OCT beam delivery is performed by fiber-optics, small-diameter scanning endoscopes and catheters can be developed.⁴⁸ The first clinical studies of internal body imaging were performed using a novel forward scanning flexible probe that could be used in conjunction with a standard endoscope, bronchoscope, or trocar.^{37,49} This device used a miniature magnetic scanner to produce a one-dimensional forward beam scanning in a 1.5- to 2-mm-diameter probe.

Transverse scanning OCT catheters/endoscopes have also been developed and demonstrated. 41,48,50 Figure 13.8 shows an example of a transverse scanning OCT catheter/endoscope. This device has a single-mode optical fiber encased in a hollow rotating torque cable coupled to a distal lens and a microprism that directs the OCT beam radially outward from the catheter. The cable and distal optics are encased in a transparent housing. The OCT beam is scanned by rotating the cable to perform imaging in a radar-like pattern, cross sectionally through vessels or hollow organs. Imaging may also be performed in a longitudinal plane by push–pull movement of the fiber-optic cable assembly. The catheter/endoscope shown in Figure 13.8 has a diameter of 2.9 French or 1 mm, comparable to the size of a standard intravascular ultrasound catheter. The development of even smaller diameter OCT catheters/endoscopes is possible. These types of OCT imaging probes are small enough to fit in the accessory port of a standard endoscope or bronchoscope and permit an *en face* view of the area being scanned simultaneously with OCT imaging. Alternately, catheters/endoscopes can be used independently, for example, in intravascular imaging.

Even smaller needle imaging devices can be developed.⁵¹ Recently, a 27-gauge OCT imaging needle has been developed for performing OCT imaging in solid tissues or tumors, as shown in Figure 13.9. Following the concept of acupuncture needles, these devices can be inserted into solid tissues with minimal trauma. Since imaging can be performed to depths of 2 to 3 mm in most tissues, image needles enable imaging a cylindrical volume of tissue with a radius of 2 to 3 mm or a diameter of 4 to 6 mm and with arbitrary length. Figure 13.9 shows a protoype of an OCT imaging needle constructed using an optical fiber, graded index lens, and microprism as well as an example of *in vivo* OCT imaging the hamster leg muscle, an example of solid tissue. Ultimately, OCT imaging devices could be integrated with excisional biopsy devices such as needle or core biopsy devices to enable imaging of the tissue to be excised, thereby reducing sampling errors.

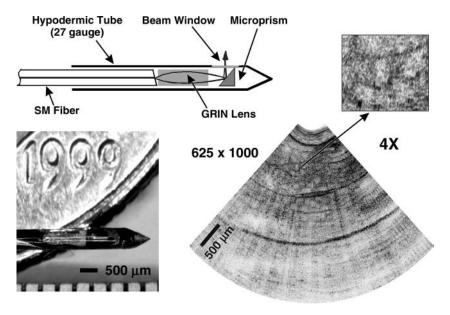

FIGURE 13.9 OCT imaging needle. This needle consists of a single mode optical fiber with a GRIN lens and a micoprism used to focus and deflect the beam. A thin-wall, 27-gauge, stainless steel hypodermic tube houses the optical fiber and distal optics. A photo of a prototype OCT needle on a U.S. dime shows the size of the needle. Also shown is an OCT image of a hamster leg muscle *in vivo* acquired with the needle. Muscle fascicles are clearly discerned. The needle enables imaging of a 4- to 5-mm-diameter cylindrical region in solid tissues. The scale bar is 500 μm. (From Li, X.D. et al., *Opt. Lett.*, 25, 1520, 2001. With permission.)

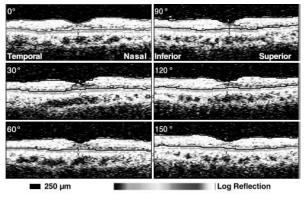

13.4 Applications of Optical Coherence Tomography

Optical coherence tomography — performing two-dimensional measurements of optical backscattering of backreflection to image internal cross-sectional microstructure — was demonstrated in 1991.¹ OCT imaging was first demonstrated *in vitro* in the human retina and in atherosclerotic plaque as examples of imaging in transparent, weakly scattering media and highly scattering media. Since that time, numerous applications of OCT for both materials and medical applications have emerged. The performance and capabilities of OCT imaging technology have also improved dramatically. The next sections describe different examples of general areas of application for OCT.

13.4.1 Optical Coherence Tomography Imaging in Ophthalmology

Optical coherence tomography was first applied for imaging in the eye and, to date, OCT has had the largest clinical impact in ophthalmology. The first *in vivo* tomograms of the human optic disc and macula were demonstrated in 1993.^{20,52} Numerous clinical studies have been performed in the last few years. OCT enables the noncontact, noninvasive imaging of the anterior eye, including the cornea, iris, and lens, as well as imaging of morphologic features of the human retina including the fovea and optic disc.^{21,42,53}

Figure 13.3 showed an example of an OCT image of the normal retina of a human subject, which provides a cross-sectional view of the retina with unprecedented high resolution. Although the retina is almost transparent and has extremely low optical backscattering, the high sensitivity of OCT allows extremely small backscattering from features such as inter-retinal layers and the vitreal–retinal interface to be imaged. The retinal pigment epithelium, which contains melanin, and the choroid, which is highly vascular, are visible as highly scattering structures in the OCT image. Because typical OCT retinal images have a resolution of $10~\mu m$, there can be residual motion of the patient's eye during the measurement. However, image processing algorithms can be used to measure the axial motion of the eye and correct for motion artifacts.²⁰

OCT NORMAL MACULAR THICKNESS (µm)

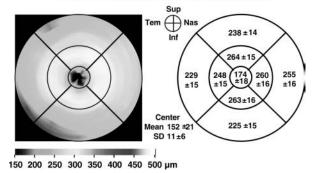

FIGURE 13.10 Topographical mapping of retinal thickness as an example of image processing and display. The topographical representation is constructed by performing six OCT tomograms at different angles through the fovea. The tomograms are image-processed to segment the retinal thickness and the thickness values linearly interpolated over the macular region. The retinal thickness is displayed using a false color scale. Quantitative data of retinal thickness in nine different zones are also shown. These values are from a normative database and are displayed as mean and standard deviation. Quantitative data are more useful for screening or detection purposes. (From Hee, M.R. et al., *Ophthalmology*, 105, 360, 1998. With permission.)

OCT has been demonstrated for the detection and monitoring of a variety of macular diseases,⁵³ including macular edema,⁵⁴ macular holes,⁵⁵ central serous chorioretinopathy,⁵⁶ and age-related macular degeneration and choroidal neovascularization.⁵⁷ The retinal nerve fiber layer thickness, a predictor for early glaucoma, can be quantified in normal and glaucomatous eyes and correlated with conventional measurements of the optic nerve structure and function.^{58–60} In addition, OCT has been applied for the evaluation of choroidal tumors,⁶¹ congenital optic disc pits,⁶² and argon laser lesions.⁶³ Retinal OCT images have been compared to histology,⁶⁴ and OCT has been used to investigate retinal degeneration in transgenic animal models.⁶⁵

OCT is especially promising for the diagnosis and monitoring of diseases such as glaucoma or macular edema associated with diabetic retinopathy because it can provide quantitative information on retinal pathology that is a measure of disease progression. Images can be analyzed quantitatively and processed using intelligent algorithms to extract features such as retinal or retinal nerve fiber layer thickness. Mapping and display techniques have been developed to represent the tomographic data in alternate forms, such as thickness maps, in order to aid interpretation.

As an example, consider the measurement of retinal thickness, shown in Figure 13.10. Measurement of retinal thickness in the macula is important in patients with diabetes who are prone to macular edema and diabetic retinopathy. The utility of OCT in clinical practice depends on the ability of the physician to accurately and quickly interpret the OCT results in the context of conventional clinical examination. Standard ophthalmic examination techniques give an *en face* view of the retina. Therefore, OCT topographic methods of

displaying retinal and nerve fiber layer thickness, which could be directly compared with standard view of the retina during ophthalmic examination, were developed.⁶⁶

Figure 13.10 shows an example of an OCT topographic map of retinal thickness. The thickness map is constructed by performing six standard OCT scans at varying angular orientations through the fovea. The images are then segmented to detect the retinal thickness along the OCT tomograms. The retinal thickness is then linearly interpolated over the macular region and represented in false color. The diameter of the topographic map is approximately 6 mm. Retinal thickness values between 0 and 500 μ m are displayed by colors ranging from blue to red. This yields a color-coded topographic map of retinal thickness that displays the retinal thickness in an *en face* view.

For quantitative interpretation, the macula was divided into nine regions including a central disc of 500 μ m diameter (denoted as the foveal region), and an inner and outer ring, each divided into four quadrants, with outer diameters of one and two disc diameters, respectively. Figure 13.10 also shows the average retinal thickness measured from OCT imaging on 96 normal individuals with statistics including mean values and standard deviations. The mean \pm standard deviation (SD) of central foveal thickness was also recorded for the six A-scans at the intersection of all the tomograms in the central macula. The SD provides a simple estimate of the measurement reproducibility. The ability to reduce image information to numerical information is important because it allows a normative database to be developed and statistics to be calculated.

In order to be used for screening or diagnosis, a normative database must be developed and extensive cross-sectional studies performed. A diagnostic model must be developed that allows the OCT image or numerical information to be analyzed to determine the presence or the stage of a given disease. These diagnostic criteria must perform with sufficient sensitivity and specificity. In many cases, screening or diagnosis is complicated by natural variations in the normal population. For example, normal subjects lose retinal nerve fibers with age, so retinal nerve fiber layer thickness measurements must be age adjusted.⁶⁷ Ongoing clinical studies are addressing the viability of using OCT for screening and diagnosis of diabetic macular edema and glaucoma, two of the leading causes of blindness.

OCT has the potential to detect and diagnose early stages of disease before physical symptoms and irreversible loss of vision occur. Furthermore, repeated imaging can easily be performed to track disease progression or monitor therapy. Many thousands of patients have been examined to date, and numerous clinical studies are currently under way in many research and clinical groups internationally. The technology was transferred to industry and introduced commercially for ophthalmic diagnostics in 1996 (Zeiss Humphrey Systems, Dublin, CA); a third-generation ophthalmic instrument was introduced in 2001. With continued development and investigation, we expect OCT ultimately to become a standard ophthalmic diagnostic.

13.4.2 Optical Coherence Tomography and Optical Biopsy

With recent research advances, OCT imaging of optically scattering, nontransparent tissues has become possible, thus enabling a wide variety of applications in internal medicine and internal body imaging. One of the techniques that enabled OCT imaging in nontransparent tissues was imaging at longer wavelengths where optical scattering is reduced. ^{18,23,24} Using 1.3-µm wavelengths, image penetration depths of 2 to 3 mm can be achieved in most tissues. This imaging depth is shallow compared to ultrasound, but is comparable to the depth over which many biopsies are performed. In addition, many diagnostically important changes of tissue morphology occur at the epithelial surfaces of organ lumens. The capability to perform "optical biopsy" — the *in situ*, real-time imaging of tissue morphology — could be important in a variety of clinical scenarios, including:

- 1. Assessing tissue pathology in situations where conventional excisional biopsy is hazardous or impossible
- 2. Guiding conventional biopsy to reduce false negative rates from sampling errors
- 3. Guiding surgical or microsurgical intervention

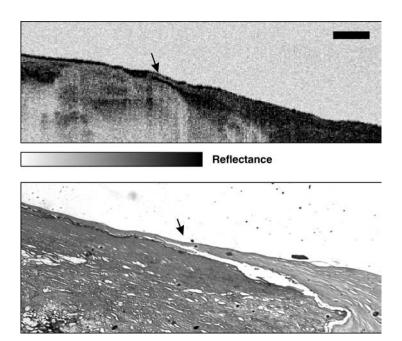

FIGURE 13.11 OCT image showing atherosclerotic plaque *in vitro* and corresponding histology. This shows an example of OCT imaging in tissues where standard excisional biopsy is not possible. The plaque is highly calcified with a low lipid content and a thin intimal cap layer is observed. The high resolution of OCT can resolve small structures, such as the thin intimal layer, that are associated with unstable plaques. The bar is $500 \, \mu m$. (From Brezinski, M.E., *Circulation*, 93, 1206, 1996. With permission.)

13.4.3 Imaging Where Excisional Biopsy Is Hazardous or Impossible

One class of applications where OCT could be especially powerful is where conventional excisional biopsy is hazardous or impossible. In ophthalmology, biopsy of the retina is not possible and OCT can provide high-resolution images of retinal structure that cannot be obtained using any other *in situ* imaging technique. Another situation where biopsy is not possible is in assessing atherosclerotic plaque morphology in the coronary arteries.^{24,68} Recent research has demonstrated that most myocardial infarctions result from the rupture of small to moderately sized cholesterol-laden coronary artery plaques followed by thrombosis and vessel occlusion.^{69–72} The plaques at highest risk for rupture are those that have a structurally weak fibrous cap.⁷³ These plaque morphologies are difficult to detect by conventional radiologic techniques and their microstructural features cannot be determined. Identifying high-risk unstable plaques and patients at risk for myocardial infarction is important because of the high percentage of infarctions that result in sudden death.⁷⁴ OCT could be a powerful diagnostic tool for intravascular imaging in risk stratification as well as guidance of interventional procedures such as atherectomy or stenting.

Imaging studies of arterial lesions *in vitro* have been performed to investigate the correlation of OCT and histology. 24,68,75 Figure 13.11 shows an example of an unstable plaque morphology from a human abdominal aorta specimen with corresponding histology. OCT imaging was performed at 1300-nm wavelength with an axial resolution of $\sim 16~\mu m$. The optical scattering properties of lipid, adipose tissue and calcified plaque are different and provide contrast between different structures and plaque morphologies. The OCT image and histology show a small intimal layer covering a large atherosclerotic plaque that is heavily calcified and has a relatively low lipid content. The thin intimal wall increases the likelihood of plaque rupture. Currently, these lesions can only be accurately diagnosed by postmortem histology; therefore, interventional techniques cannot be used effectively to treat them. The ability to identify structural details such as the presence and thickness of intimal caps using catheter-based OCT imaging techniques could lead to significant improvements in patient outcome.

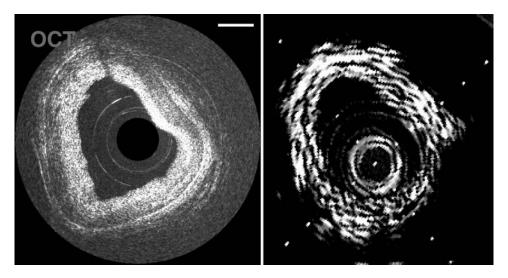

FIGURE 13.12 OCT catheter-based image (left) vs. IVUS (right) in a human artery *in vitro*. OCT imaging was performed with a prototype OCT catheter. The OCT image enables the differentiation of the intima, media, and adventitia of the artery. Intimal hyperplasia is evident in the OCT image. (From Tearney, G.J. et al., *Circulation*, 94, 3013, 1996. With permission.)

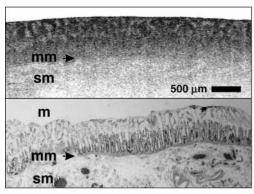

Studies have been performed that compare IVUS and OCT imaging *in vitro* and demonstrate the ability of OCT to identify clinically relevant pathology.^{68,76} Figure 13.12 shows a comparison of an OCT catheter image vs. an intravascular ultrasound (IVUS) in a human artery *in vitro*. *In vivo* OCT arterial imaging has also been performed in New Zealand white rabbits and porcine coronary arteries using a catheter-based imaging system.^{50,77} For *in vivo* imaging, optical scattering from blood limits OCT imaging penetration depths so that saline flushing at low rates is required for imaging. These effects depend on vessel diameter as well as other factors, and additional investigation is required. Clinical studies of intravascular OCT imaging human subjects are just beginning.

13.4.4 Detecting Early Neoplastic Changes

Another major class of OCT imaging applications is in situations where conventional excisional biopsy has unacceptably high false negative rates due to sampling errors, important for cancer diagnosis. OCT can resolve changes in architectural morphology that are associated with many early neoplasias. Studies have been performed *in vitro* to correlate OCT images with histology for pathologies of the gastrointestinal, biliary, female reproductive, pulmonary, and urinary tracts. ^{78–87} One of the key issues for the use of OCT imaging in the detection of early neoplastic changes is the ability to differentiate clinically relevant pathologies with a given image resolution. Many early neoplastic changes are manifested by disruption of the normal glandular organization or architectural morphology of tissues. These changes can be imaged using standard 10 to 15 μ m resolution OCT systems.

Figure 13.13 shows an example of an *in vitro* OCT image of normal colon and carcinoma. The OCT image of the colon epithelium shows normal glandular organization associated with columnar epithelial structure. The mucosa and muscularis mucosa can be differentiated due to the different backscattering characteristics within each layer. Architectural morphology such as crypts or glands within the mucosa can be seen. The OCT image of carcinoma shows disruption of architectural morphology or glandular organization with dilation and distortion of crypt structures.

Standard OCT has image resolutions of $10 \text{ to } 15 \,\mu\text{m}$, which are sufficient to visualize tissue architectural morphology. OCT can also be used to assess other features such as the integrity of the basement membrane. However, the resolution of standard OCT is not sufficient for cellular level imaging and visualization of nuclear features. Thus, cancer diagnosis would be difficult using OCT images alone, and

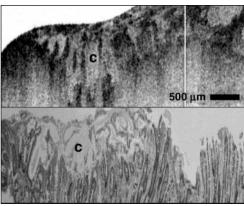

FIGURE 13.13 OCT images of gastrointestinal tissues *in vitro* showing normal colon and carcinoma. OCT can image differences in architectural morphology or glandular organization that are associated with neoplasia. The normal colon shows columnar epithelial morphology with crypt structures visible. The image of carcinoma shows a loss of normal epithelial structure with disruption and disorganization of the crypts. Architectural morphology such as this can be imaged with standard OCT resolutions of 10 to 15 μm. (From Tearney, G.J. et al., *Am. J. Gastroenterol.*, 92, 1800, 1997. With permission.)

it is more feasible to apply OCT to guide conventional excisional biopsy. Ultrahigh-resolution OCT with resolutions of 1 to 5 µm enables cellular level imaging and could expand the range of neoplastic changes that can be imaged.^{35,88,89} The imaging depth of OCT is 2 to 3 mm, less than that of ultrasound. However, for diseases that originate from or involve the mucosa, submucosa, and muscular layers, imaging the microscopic structure of small lesions is well within the range of OCT.

Conventional excisional biopsy often suffers from high false negative rates because the biopsy process relies on sampling tissue and the diseased tissues can easily be missed. OCT could be used to identify suspect lesions and to guide excisional biopsy and reduce the false negative rates. This would reduce the number of costly biopsies; at the same time, clinical diagnoses could be made using excisional biopsy and histopathology, which is the established clinical standard. In the future, after detailed clinical studies and more extensive statistical data are available, it may be possible to use OCT directly for the diagnosis of certain types of neoplasias or for determining the grade of dysplasias. For example, OCT might be used to determine whether there is submucosal vs. mucosal involvement in early gastric cancer, a criterion used to determine the therapy. OCT imaging has the advantage of providing a real-time diagnostic that could enable the integration of diagnosis and treatment.

The development of miniature, flexible OCT imaging probes and high-speed OCT imaging systems enables OCT imaging of internal organ systems. Imaging the pulmonary, gastrointestinal, and urinary tracts and arterial imaging have been demonstrated in New Zealand white rabbits. 41,50 A short-pulse Cr^{4+} :Forsterite laser was used as the light source to achieve high resolution with real-time image acquisition rates. 32 The laser output was near 1.3 μ m with a spectral bandwidth of 75 nm (FWHM), to yield an axial resolution of 10 μ m. A sensitivity of 110 dB was achieved with 5- to 10-mW power incident on the tissue. In order to achieve high-speed imaging at several frames per second, a novel high-speed phase scanning optical delay line was used. 39

Figure 13.14 shows an example of a catheter/endoscope OCT image of the gastrointestinal tract in the rabbit. The image shown was obtained with a 512-pixel lateral resolution at 4 frames per second in order to optimize lateral sampling. The two-dimensional image data were displayed using a polar coordinate transformation and inverse gray scale. As shown in Figure 13.14, the mucosa of the esophagus was readily identifiable because of its low optical backscattering compared with the submucosa. The ability to differentiate mucusal vs. submucosal invasion of early cancers can be an important criterion for determining therapy in early cancers.

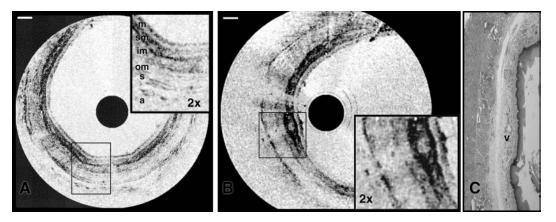

FIGURE 13.14 Endoscopic OCT imaging of the rabbit esophagus *in vivo*. (A) OCT enables visualization of the esophageal layers of the rabbit including the mucosa (m), the submucosa (sm), the inner muscular layer (im), the outer muscular layer (om), the serosa (s), and the adipose and vascular supportive tissues (a). (B) A blood vessel (v) can be seen within the submucosa of the esophagus. (C) Corresponding histology for (B). The scale bars are 500 μm. (From Tearney, G.J. et al., *Science*, 276, 2037, 1997. With permission.)

Endoscopic OCT imaging in humans can be performed by introducing OCT imaging probes into the accessory port of standard endoscopes. Figure 13.15 shows an example of endoscopic OCT imaging of the human esophagus. Imaging was performed with 13- μ m resolution at 1.3- μ m wavelengths. These images show representative linear scan OCT images, endoscopic images, and biopsy histology of normal squamous epithelium compared to Barrett's esophagus, a metaplastic condition associated with increased cancer risk. The OCT image (4 × 2.5 mm, 512 × 256 pixels) of normal epithelium illustrates the epithelium, lamina propria, muscularis mucosa, submucosa, and muscularis propria. The OCT image

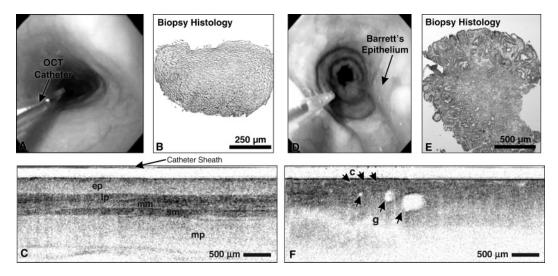

FIGURE 13.15 Clinical endoscopic OCT imaging of the human esophagus. Images were performed using a linear (push–pull) scanning OCT probe introduced through the working port of a standard endoscope. (A) Endoscopic image of normal region. (B) Biopsy histology of normal squamous epithelium. (C) OCT image of normal squamous epithelium with relatively uniform and distinct layered structures. (D) Endoscopic image of region showing pathology (finger-like projection of Barrett's epithelium). (E) Biopsy histology of Barrett's esophagus showing characteristic specialized columnar epithelium. (F) OCT image of Barrett's epithelium with disruptions of layered morphology due to multiple crypt- and gland-like structures (arrows). (From Li, X.D. et al., *Endoscopy*, 32, 921, 2000. With permission.)

of Barrett's metaplasia shows loss of normal structure and replacement of squamous epithelium with columnar epithelium and glandular structures, which are characteristic of Barrett's metaplasia.

OCT imaging studies in patients have been performed in many different organ systems, including the gastrointestinal, urinary, pulmonary, and female reproductive tracts. ^{37,49,90–94} These studies demonstrate the feasibility of performing clinical OCT imaging and suggest a broad range of future clinical applications. Additional systematic studies that compare OCT imaging with histological or other diagnostic endpoints are still needed.

13.4.5 Guiding Surgical Intervention

Another important class of applications for OCT is guiding surgical intervention. The ability to see beneath the surface of tissue in real time can guide surgery near sensitive structures such as vessels or nerves as well as assist in microsurgical procedures. ^{44,45,95} Optical instruments such as surgical microscopes are routinely used to magnify tissue to prevent iatrogenic injury and to guide delicate surgical techniques. OCT can be easily integrated with surgical microscopes. Handheld OCT surgical probes and laparoscopes have also been demonstrated. ⁴⁶

One example of a surgical application for OCT is the repair or anastomosis of small vessels and nerves following traumatic injury. A technique capable of real-time, subsurface, three-dimensional, micronscale imaging would permit the intraoperative monitoring of microsurgical procedures, giving immediate feedback to the surgeon that could improve outcome and enable difficult procedures. Studies have been performed *in vitro* that demonstrate the use of OCT imaging for diagnostically assessing microsurgical procedures using an OCT microscope.⁴⁵

Figure 13.16 shows OCT images of an arterial anastomosis of a rabbit inguinal artery, demonstrating the ability of OCT to assess internal structure and luminal patency. An artery segment was bisected cross sectionally with a scalpel and then reanastomosed using a No. 10-0 nylon suture with a 50- μ m diameter needle in a continuous suture. Cross-sectional OCT images (2.2 × 2.2 mm, 250 × 600 pixel) of a 1-mm-diameter rabbit inguinal artery are shown. Figures 13.16A through 13.16D were acquired transversely at different positions through the anastomosis. The images of the ends of the artery clearly show arterial morphology corresponding to the intimal, medial, and adventitial layers of the elastic artery. The image

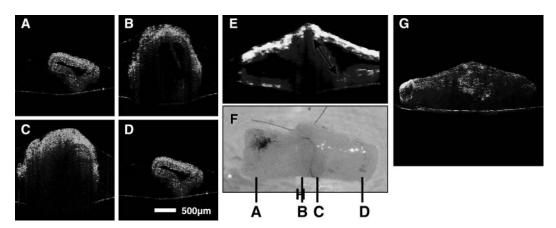

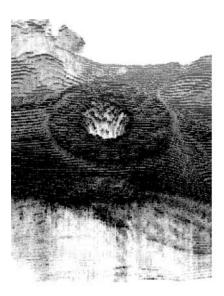

FIGURE 13.16 OCT images of an anastomosis in a rabbit artery as an example of microsurgical imaging. The 1-mm-diameter rabbit artery was anastomosed with a continuous suture as seen in the digital image (F). The labels indicate the planes from which corresponding cross-sectional OCT images were acquired (A, D). Opposite ends of the anastomosis show the multilayered structure of the artery with a patent lumen. (B) Partially obstructed lumen and the presence of a thrombogenic flap. (C) Fully obstructed portion of the anastomosis site. (E) Longitudinal section virtual view constructed from three-dimensional image data sets shows the obstruction (o). (G) Three-dimensional data set. (From Boppart, S.A. et al., *Radiology*, 208, 81, 1998. With permission.)

from the site of the anastomosis shows that the lumen was obstructed by a tissue flap. By assembling a series of cross-sectional two-dimensional images, a three-dimensional data set was produced as shown in Figure 13.16G. Arbitrary virtual image planes (Figure 13.16E) can be constructed from the three-dimensional data set and corresponding virtual cross sections displayed.

Because OCT imaging can be performed in real time at high speeds, it can be integrated directly with surgery. The feasibility of using high-speed OCT imaging to image the dynamics of surgical laser ablation has been investigated. Here studies show examples of image rendering and reconstruction techniques as well as real-time imaging. The use of OCT to monitor ablative therapy in real time could enable more precise control of laser delivery and reduction in iatrogenic injury.

Argon laser ablation was performed in five different $ex\ vivo$ rat organs to assess OCT imaging performance and variations between tissue types. These studies were performed using a commercially available low-coherence light source with a wavelength at 1.3 μm and an axial resolution of 18 μm . The signal-to-noise ratio was 115 dB using 5 mW of incident power on the specimen. For high-speed image acquisition, the size of the region imaged was 3×3 mm and 256×256 pixels with an acquisition rate of 8 frames per second or 125 ms for each image. Images were displayed on a computer monitor and simultaneously recorded to video. The argon beam was aligned and centered within the OCT imaging plane. Specimens were obtained from Sprague–Dawley rats after euthanasia, including brain, liver, kidney, lung, and rectus abdominis muscle. A three-dimensional, micron-precision, computer-controlled stage was used to position the specimens under the OCT imaging beam and was used to acquire three-dimensional data sets.

Figure 13.17 shows an example of a three-dimensional projection of a laser ablation crater in a rat rectus abdominis muscle. The laser exposure was 3 W of argon laser power focused to a 0.8-mm-diameter spot for 10 s. The OCT images show the ablation zone viewed from an external and an internal virtual viewpoint. Because image data are acquired over a three-dimensional volume, arbitrary cross-sectional tomographic planes can be synthesized. Figure 13.18 shows a series of virtual *en face* images at various depths through the ablation crater. OCT imaging of laser ablation can also be performed in real time. Figure 13.19 shows an example of real-time OCT imaging during laser ablation of a bovine muscle

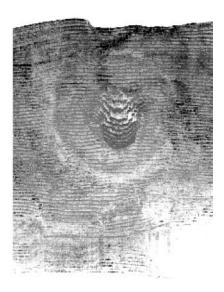

FIGURE 13.17 Three-dimensional OCT projection image of a laser ablation crater demonstrating the ability to reconstruct OCT images with different perspective views. The lesion was produced in rat rectus abdominis muscle by a 3-W, 10-s argon laser exposure. The projection view illustrates a central ablation crater and concentric zones of thermal injury. (From Boppart, S.A. et al., *J. Surg. Res.*, 82, 275, 1999. With permission.)

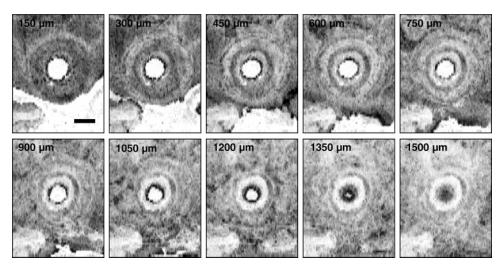

FIGURE 13.18 *En face* images through an ablation crater. These images demonstrate the ability to render different planes of view using a three-dimensional OCT data set. *En face* sections at varying depths illustrate concentric zones of damage. The numbers show the depth below surface. The bar represents 1 mm. (From Boppart, S.A. et al., *J. Surg. Res.*, 82, 275, 1999. With permission.)

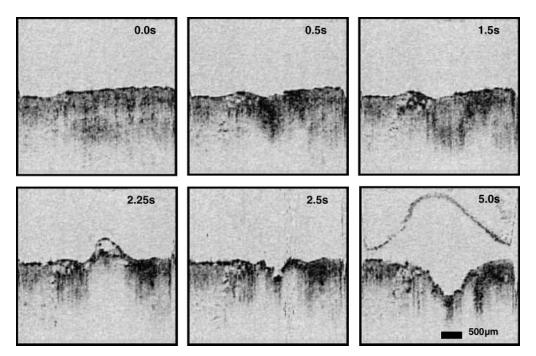

FIGURE 13.19 Real-time OCT imaging of laser ablation showing a series of OCT images taken at 8 frames per second during argon laser exposure of beef muscle. The exposure was 1 W with a 0.8-mm spot diameter on tissue. The times indicated are in seconds after exposure is initiated. At 2.25 s, the formation of a blister at the surface is observed. At 2.5 s, the blister explodes and a crater develops (5 s). These images show the ability of OCT to perform high-speed, real-time imaging during interventional procedures. (From Boppart, S.A. et al., *J. Surg. Res.*, 82, 275, 1999. With permission.)

specimen. The laser exposure was 2 W from the argon laser. At 0.5 s, changes in optical properties of the tissue are observed due to heating, and explosive ablation begins at 2.25 s.

These examples demonstrate the ability of OCT to perform real-time imaging, as well as the use of image processing and rendering techniques to provide a more comprehensive view of tissue microstructure. Optical coherence tomography should improve intraoperative diagnostics by providing high-resolution, real-time, subsurface, cross-sectional imaging. Three-dimensional imaging and image reconstruction permit assessment of the spatial orientation of morphology.

13.4.6 Ultrahigh-Resolution Optical Coherence Tomography

The development of ultrahigh-resolution OCT is also an area of active research. As discussed previously, the axial resolution of OCT is determined by the coherence length of the light source used for imaging. Light sources for ultrahigh-resolution OCT imaging must have a short coherence length or broad bandwidth, but also must be single spatial mode to enable interferometry. In addition, since the SNR depends on the incident power, light sources with average powers of several milliwatts are typically necessary to achieve real-time imaging. One approach for achieving high resolution is to use short-pulse, femtosecond solid-state laser light sources.^{34,43,97}

State-of-the-art femtosecond $Ti:Al_2O_3$ lasers can now directly generate pulse durations of ~5 fs. ^{89,98} These pulse durations correspond to only two optical cycles and have bandwidths of up to 400 nm centered around 800 nm. These high-performance lasers have been made possible through the development of double-chirped mirror technology, which yields extremely wide bandwidths and also compensates for higher-order dispersion in the laser. Unlike ultrafast femtosecond time-resolved measurements, where special care must be exercised to maintain the short pulse duration, OCT measurements depend on field correlations rather than intensity correlations. Thus, dispersion in the reference and signal paths of the interferometer must be precisely matched, but need not be equal to zero.

Figure 13.20 shows an example of an ultrahigh-resolution OCT image of the normal retina of a human subject compared to standard resolution OCT. ⁸⁹ The axial resolution is 3 μ m and is by limited chromatic aberration in the eye. Comparison to standard resolution OCT imaging with 10 μ m resolution shows that ultrahigh-resolution OCT significantly improves image quality and the ability to resolve internal retinal architectural morphology. It also enables visualization of the foveal and optic disc contour, as well as

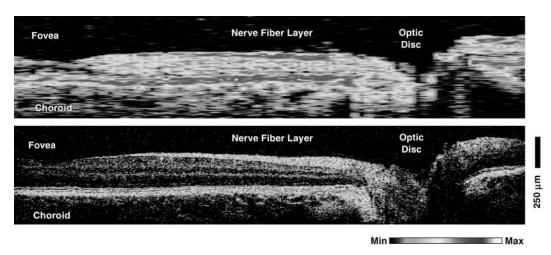

FIGURE 13.20 Ultrahigh- vs. standard-resolution OCT images of the normal human retina. The ultrahigh-resolution image has a 3-μm axial resolution compared to the standard image with a 10-μm axial resolution. The images have been expanded by a factor of two in the axial direction to permit better visualization. Ultrahigh-resolution OCT enables the architectural morphology of the retina to be imaged noninvasively and in real time. (From Drexler, W. et al., *Nat. Med.*, 7, 502, 2001. With permission.)

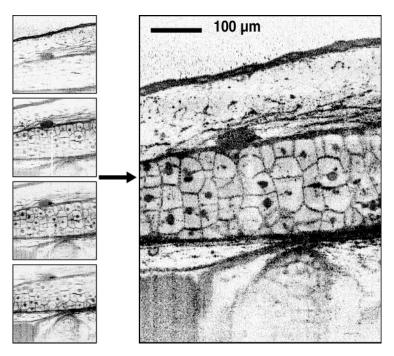

FIGURE 13.21 Ultrahigh-resolution cellular imaging. *In vivo* subcellular level resolution 1×3 µm (axial × transverse) 1700×1000 pixel image of an African frog (*Xenopus laevis*) tadpole. Images were recorded with different depths of focus and fused to construct the image shown. Multiple mesenchymal cells of various sizes and nuclear-to-cytoplasmic ratios and intracellular morphology, as well as the mitosis of cell pairs, are clearly shown. The bar is $100 \, \mu m$. (From Drexler, W. et al., *Opt. Lett.*, 24, 1221, 1999. With permission.)

internal architectural morphology of the retina and choroid that is not resolvable with conventional resolution OCT. The retinal nerve fiber layer (NFL) is clearly differentiated and the variation of its thickness toward the optic disc can be observed. In ophthalmology, improving the resolution should allow more precise morphmetric measurements of retinal features such as retinal thickness and retinal nerve fiber layer thickness, which are relevant for the detection of diseases such as macular edema and glaucoma.

Cellular level OCT imaging can also be performed.^{34,88} Figure 13.21 shows an example of ultrahigh-resolution OCT imaging of a *Xenopus laevis* tadpole (African frog) *in vivo*. Imaging was performed with ~1 µm axial and 3 µm transverse resolution; subcellular features are visible at these resolutions. Depth of field limitations may be overcome by using a novel technique from ultrasound known as C mode imaging. Multiple images are acquired with the focus set to different depths within the specimen. Each image is in focus over a depth range comparable to the confocal parameter. The in-focus regions from each of the images are selected and fused together to form a single image, which has a greatly extended depth of field.

The fused image covers an area of 0.75×0.5 mm and consists of 1700×1000 pixels. Because of the small focal spot size, the confocal parameter was only 40 μ m; however, using image fusion of eight images enabled imaging over a depth of 750 μ m. Because the axial and transverse resolutions are extremely fine, images have large pixel densities. These images can be beyond the resolution of a standard computer monitor and need to be viewed with panning and zooming.

In developmental biology, the ability to image subcellular structure can be an important tool for studying mitotic activity and cell migration, which occur during development. Ultrahigh-resolution imaging would also extend the diagnostic capabilities of OCT for early neoplasias. Standard OCT image resolutions enable the imaging of architectural morphology on the 10- to 15-µm scale and can identify many early neoplastic changes. The extension of imaging to the cellular and subcellular level would not

only enhance the spectrum of early neoplasias and dysplasias that could be imaged, but should also improve sensitivity and specificity.

13.5 Summary

OCT is a fundamentally new imaging modality with rapidly emerging applications spanning a range of fields. OCT can perform micron-scale imaging of internal microstructure in materials and biological tissues *in situ* and in real time. For medical imaging applications, OCT can function as a type of optical biopsy; image information is available immediately without the need for excision and histological processing of a specimen. The development of high-speed OCT technology permits real-time imaging with high pixel densities.

A wide range of OCT imaging platforms and probes has been developed, including ophthalmoscopes, microscopes, laparoscopes, handheld probes, and miniature, flexible catheters/endoscopes. These imaging probes can be used separately or in conjunction with other medical imaging instruments such as endoscopes and bronchoscopes; they can permit internal body imaging in a wide range of organ systems. There are numerous research applications of this technology in a broad range of fields. In addition, advances in the technology are continuing. More research remains to be done, and numerous clinical studies must be performed in order to determine where OCT can play a role in clinical medicine. However, the unique capabilities of OCT imaging suggest that it will have a significant impact on fundamental research as well as on medicine.

Acknowledgments

Our research and development in optical coherence tomography would not have been possible without the long-term collaboration and support of a talented multidisciplinary research team. The invaluable contributions of Dr. Joel Schuman and Dr. Carmen Puliafito, from the New England Eye Center and Tufts University School of Medicine, Eric Swanson from Sycamore Networks, Dr. Jacques Van Dam from Stanford University School of Medicine, Dr. Annekathryn Goodman from Massachusetts General Hosptial, Dr. Hiroshi Mashimo from the Veterans Administration Medical Centers, and Dr. Scott Martin from the Brigham and Women's Hospital are greatly appreciated. Postdoctoral associates, M.D./Ph.D. students, and Ph.D. students, including Dr. Stephen Boppart, Dr. Brett Bouma, Dr. Stephane Bourquin, Dr. Christian Chudoba, Dr. Wolfgang Drexler, Dr. Ravi Ghanta, Dr. Ingmar Hartl, Dr. Michael Hee, Dr. Juergen Herrmann, Pei-Lin Hsiung, Dr. David Huang, Christine Jesser, Tony Ko, Dr. Xingde Li, Nirlep Patel, Dr. Constantinos Pitris, Kathleen Saunders, and Dr. Gary Tearney, have made invaluable contributions.

This research was supported in part by the National Institutes of Health, contracts NIH-1-RO1-CA75289-04 and NIH-1-RO1-EY11289-15, the Medical Free Electron Laser Program, F49620-01-1-0186, the Air Force Office of Scientific Research, contract F49620-98-01-0084, and National Science Foundation contract ECS-0119452.

14.1 Introduction

Scattering of coherent light by spatially inhomogeneous disordered media and rough surfaces leads to the formation of stochastic spatial distributions of the scattered light intensity, or *speckle* patterns. These patterns have a specific granular structure that results from the random interference of a great number of partial waves scattered by bulk or surface inhomogeneities (see Figure 14.1). The stochastic nature of scattering systems causes random phase shifts between these waves and results in statistical properties of the amplitude, phase, and intensity of speckle-modulated scattered fields.

Historically, attempts to understand how properties of observed speckles are related to the structural characteristics of a scattering system and observation conditions began with pioneer studies of laser light–matter interaction. The classic works dedicated to analysis of the statistical properties of laser speckles were made by Goodman, Dainty, Pedersen, Jakeman, Pusey, Asakura, Ioshimura, and many other researchers in the 1960s, 1970s, and early 1980s (see, for example, References 1 through 14). In these works, the concepts of speckle-pattern formation were based in general on the scalar approach for description of the random interference of partial waves scattered by the small-scale inhomogeneities of a scattering medium. Such an assumption leads to certain limitations in description of speckle formation by various scattering systems (especially in the case of bulk multiple scattering, where a significant change in the polarization state of propagating light occurs) but, despite these restrictions, the theory of speckle-pattern formation based on the scalar wave approach has allowed a rigid interpretation or prediction of a large number of experimentally observed phenomena. Moreover, the scalar theory can be applied for interpretation of the statistical properties of multiply scattered speckle patterns for certain observation conditions (in particular, with use of the polarization discrimination of scattered field partial components).

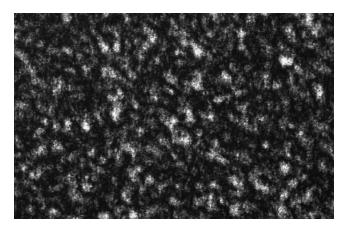

FIGURE 14.1 Speckle pattern induced in the case of laser beam scattering by a layer of human epidermis (*in vitro* sample).

Beginning in the mid-1980s, further development of speckle science was related to the establishment of certain analogies between classical waves propagating in disordered media and quantum-mechanical behavior of electrons forced by potential with random spatial fluctuations. The pioneering studies of interference effects were conducted by Golubentsev, Stephen, John, MacKintosh and other researchers^{15–18} in the area of light propagation in random multiply scattering media. The classic examples of these effects are the manifestation of the weak localization of light in the form of coherent backscattering^{19–21} or the existence of long-range correlations of scattered stochastic optical fields.^{22,23} The fundamental phenomena accompanying coherent light propagation in disordered and weakly ordered systems and related to the statistical properties of multiply scattered speckles are now the object of significant research interest from many research groups. These studies resulted in modern diffusing light technologies,^{24–28} widely applied in material science, biology, and medicine for probing and imaging optically dense scattering media.

Speckle patterns form when coherent light is scattered by living tissue or *in vitro* tissue samples and is sometimes termed biospeckles, or biospeckle phenomena. However, there is no noticeable difference between the general properties of biospeckles and the properties of speckles induced when light is scattered by a weakly ordered nonbiological system characterized by the same optical properties as the scattering tissue. The possibility of obtaining information about structure and dynamic properties of tissues by using statistical or correlation analysis of biospeckles for certain illumination and detection conditions has initiated an abundance of theoretical and experimental works dedicated to various applications of speckle technologies in biomedicine. Various applications of speckle methods in medical diagnostics (especially in the case of bioflow monitoring) are now possible, due to tremendous work by Stern, Fercher, Briers, Asakura, Aizu, Ruth, Nilsson, and many other researchers in the developing theoretical and experimental bases for biospeckle technologies.²⁹⁻⁴²

This chapter presents a brief review of the basic principles of speckle technologies in the context of potential applications for medical diagnostics. Typical examples of such applications are also discussed.

14.2 Statistical Properties of Speckles: Basic Principles and Results

14.2.1 First-Order Speckle Statistics

Speckle patterns result from the random interference of a great number of statistically independent waves scattered by inhomogeneities inside the scattering volume. Therefore, they may be characterized by amplitude, phase, and intensity, the values of which vary randomly from one detection point to another in the scattered optical field. The probability of determining these parameters for an arbitrarily chosen detection point within the given ranges of their possible values is characterized by the corresponding

probability density functions. Knowledge of the probability density distributions of scattered-field characteristics for a given detector position allows one to evaluate the statistical moments, such as mean values and variances, for these characteristics and thus obtain the description of the first-order statistics of the observed speckle pattern. Only the intensity fluctuations can be analyzed in a conventional speckle experiment carried out without any specific interference technique. Thus, the study of the first-order statistics of speckle intensity for known illumination and observation conditions can be considered the basis for certain types of speckle technologies.

The simplest and best-known case of the first-order statistics of speckles corresponds to so-called "fully developed speckles" and can be obtained in terms of the scalar wave approach. Let us consider a stochastic field induced by single scattering of a plane monochromatic wave by an ensemble of N statistically independent scatters. For example, if an incident collimated laser beam undergoes random spatial modulation of phase (e.g., by transmittance through a thin, inhomogeneous nonabsorbing layer in which the thickness or refractive index varies from point to point in a stochastic manner and in which the characteristic length of these variations is much larger than the wavelength used*), the number of independent scatters inside the illuminated area can be estimated as $N \approx (D/d)^2$, where D is the illuminating beam aperture and d is the correlation length of the phase fluctuations of boundary field associated with the spatial distribution of the complex amplitude of the transmitted light immediately behind the scattering object. In this case, the scattered field in an arbitrarily chosen point within the diffraction zone can be considered as the sum of partial waves scattered by statistically independent scattering sites:

$$E(\bar{r},t) = \sum_{i=1}^{N} E_i \exp[j(\omega t - \phi_i(\bar{r}))], \qquad (14.1)$$

where ω is the frequency of incident light and statistical properties of the ensemble $\phi_i(\bar{r})$ of phase shifts for each partial wave are determined by structural characteristics of the scattering object and observation conditions. In the case of a large N and

$$\sigma_{\phi}^{2}=\left\langle \left(\phi_{i}-\left\langle \phi
ight
angle
ight) ^{2}\right
angle >>1$$
 ,

the mean value of the scattered field amplitude is very close to zero and the induced speckle pattern is classified as the fully developed one. For such speckles, the probability density distributions of the real and imaginary parts of the scattered-field complex amplitude have a Gaussian form derived from the central limit theorem.⁴⁴ The probability density of the field phase is characterized by a distribution that is very close to the uniform one. Correspondingly, the intensity probability density for such fully developed speckles has the well-known negative exponential form:

$$\rho(I) = \frac{1}{\langle I \rangle} \exp\left(-\frac{I}{\langle I \rangle}\right). \tag{14.2}$$

A manifestation of such exponential statistics is the high visibility of fully developed speckle patterns. This property is manifested as the unit value of the speckle contrast, which is estimated as the ratio of the standard deviation of speckle intensity fluctuations to the mean value of speckle intensity:

$$C = \sigma_I / \langle I \rangle = 1$$
.

^{*}This scatter model is usually determined as the random phase screen (RPS) and, with certain limitations, allows the description of scattered field formation in terms of scalar diffraction theory (see Reference 43).

Another intrinsic property of intensity fluctuations for fully developed speckle patterns is the relation between high-order and first-order statistical moments of speckle intensity,

$$\frac{\left\langle I^{n}\right\rangle}{\left\langle I\right\rangle^{n}}=n!\,,\tag{14.3}$$

which can easily be obtained by calculating the statistical moments

$$\langle I^n \rangle = \int_0^\infty I^n \rho(I) di$$

using the probability density given by Equation 14.2. In the case of fully developed speckle patterns, the first-order statistics of speckle-intensity fluctuations are independent of the structural properties of the scattering object and thus cannot be used for its characterization.

This situation dramatically changes with transition from the fully developed speckle patterns to the partially developed speckles. This transition can be caused by a change in scattering or illumination and observation conditions. In particular, a decrease in the effective number of scattering sites N causes the divergence of the speckle-amplitude statistics from the Gaussian statistics; this divergence leads to formation of partially developed speckles in the diffraction zone. If deep phase modulation of an incident beam by a scattering system takes place ($\sigma_{\phi}^2 \gg 1$), the contrast of partially developed speckles may significantly exceed 1; in many cases the dependence of C on the effective number of scattering sites may be approximated by the following relation:

$$C \approx \sqrt{1 + K/N} , \qquad (14.4)$$

where the dimensionless parameter K is determined by properties of a scattering system. Analytical forms of K for various scattering systems with small numbers of N were reviewed by Jakeman. In particular, for a scattering system with the Poisson-distributed number of identical scatters into a scattering volume, the parameter K is equal to 1. An ensemble of identical spherical particles that move into and out of a scattering volume can be considered as an example of such a scattering system.

Another type of scattering system that causes non-Gaussian speckles is a scattering surface consisting of equal-sized facets with statistically independent slopes. The speckle patterns producted by this scattering system are characterized by the following dependence of normalized second-order moment-of-intensity fluctuations on system parameters:

$$\langle I^2 \rangle / \langle I \rangle^2 = 2(1 - N^{-1}) + [k^2 \xi^2 / 4\pi P(\theta)] N^{-1},$$
 (14.5)

where k is the wave number of light, N is the number of facets inside the illuminated area, ξ is the facet radius, and $P(\theta)$ is the probability of finding a facet facing the detector. It is easy to see that this expression may be reduced to a form similar to Equation 14.4 with K depending on k, ξ , and $P(\theta)$.

If a weak phase modulation of the illuminating beam occurs ($\sigma_{\phi}^2 \leq 1$), then the dependence of the speckle contrast on N has a nonmonotonic character with the expressed maximum. The value of C falls to 0 with N diminishing to 0. In the case of a large, increasing N, the contrast value asymptotically approaches magnitudes that depend on the standard deviation σ_{ϕ} of phase fluctuations and is less than 1. In particular, theoretical analysis of similar behavior of first-order speckle statistics was given by Escamilla⁴⁵ for the case of a random phase screen with a finite correlation length of phase fluctuations and that is illuminated by the bounded monochromatic collimated beam.

Similar effects can be obtained in the case of illumination of a random phase-modulating object by a plane wave if the scattered field is observed in the near-field zone.⁴³ Figure 14.2 illustrates the typical behavior of the speckle contrast in the Fresnel diffraction zone for these conditions. If the illuminating

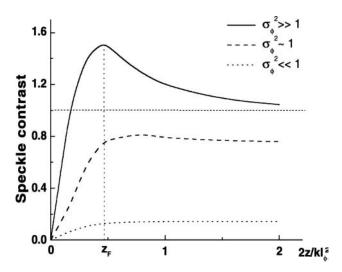

FIGURE 14.2 Typical behavior of the speckle contrast in the near-field diffraction zone in the dependence on the depth of incident wave phase modulation; l_{ϕ} is the correlation length of the boundary field phase fluctuations; z is the distance between scatter and observation plane.

wave undergoes strong phase modulation (phase fluctuations of the boundary field are characterized by $\sigma_{\phi} > 1$), the dependencies of C on the detection point position z behind a scattering object exhibit the nonmonotonic behavior with expressed maxima located at certain values of z_F and asymptotic decay to 1 with increasing z. Scatter parameters such as σ_{ϕ} and correlation length of boundary field phase fluctuations can be estimated by measuring the values of z_F and C_F .

Sharp increase of the speckle contrast in the vicinity of z_F can be explained by a manifestation of the "focusing" effect. Scattering of a plane wave by an inhomogeneous medium causes the formation of a boundary field with wavefront inhomogeneities; the development of these phase inhomogeneities in the course of scattered field propagation at relatively short distances from the object leads to the appearance of a random network of caustics formed within the focusing zone behind the scattering object by structural inhomogeneities as the set of stochastically distributed small-sized lenses. For $z > z_P$ the contributing fields propagating from different inhomogeneities will overlap; this leads to interference effects. Finally, for $z > z_P$ the fully developed speckle pattern appears.

Non-Gaussian statistics of the scattered field amplitude fluctuations in the case of a small number of scatters are manifested in the peculiarities of the probability density distributions of speckle-intensity fluctuations such as, for example, the appearance of probability density bimodality for certain illumination and detection conditions.⁴⁶

One specific case is speckle formation in the diffraction or near-field zone caused by random scatterers that exhibit the self-similarity property⁴⁷ at different length scales (fractal-like scatterers). In particular, if speckles appear when an illuminating beam is scattered by a rough surface with fractal properties, two different regimes can be considered:⁴⁸

1. Scattering by the surfaces with fractal distribution of the relative heights measured from the baseline $D_h(\bar{r}) = \langle \{h(0) - h(\bar{r})\}^2 \rangle \sim |\bar{r}|^{\rm v}$, where the exponent v of the surface height structure function $D_h(\bar{r})$ is related to a specific parameter of the fractal surface, such as its fractal dimension; this relation can be written as v = 2(2 - D). Theoretical estimations of the second-order statistical moment of scattered light intensity fluctuations for a scattering model made for the far diffraction zone (i.e., at distances from the scattering object that significantly exceed the ratio W^2/λ , where W is the characteristic size of illuminated area and λ is the wavelength used) as well as for the near diffraction zone (i.e., at distances that are comparable or less, W^2/λ) gives the value of

- $\langle I^2 \rangle / \langle I \rangle^2$ close to 2, as for conventional cases of Gaussian speckles (see, for example, References 1 through 4).
- 2. Scattering by subfractal surfaces, which are characterized by fractal distributions of the local surface slope. In this case, formation of a scattered field can be described in terms of ray optics, and simple consideration leads to the power-law dependence of the normalized second-order statistical moment of scattered intensity on the illuminated area:

$$\left\langle I^{2}\right\rangle /\left\langle I\right\rangle ^{2}\sim W^{2-\mathsf{v}}$$
 , (14.6)

where v is the exponent of the structure function $D_s(\bar{r}) = \langle \{s(0) - s(\bar{r})\}^2 \rangle^v$, which characterizes the properties of distribution of the surface local slope $s(\bar{r})$.

Statistical analysis of partially developed speckle patterns in the near or far diffraction zone can be applied in comparative study of the morphological differences between diseased tissues and healthy tissues. Figure 14.3 illustrates the typical shapes of histograms that characterize intensity probability distributions for partially developed speckle patterns induced by probe-light scattering in thin layers of healthy and diseased (psoriasis) human epidermis.⁴⁹

Experiments with *in vitro* epidermis samples prepared as skin strips were carried out with the focused beam of an He-Ne laser; speckle patterns were caused by random interference of the forward-scattered partial components and were analyzed in the diffraction zone behind the sample. Intensity fluctuations at the detection point were induced by the lateral scanning of the probed sample with respect to the illuminating beam. The characteristic changes in epidermal structure caused by the progress of psoriasis (e.g., the appearance of parakeratosis focuses, desquamation, and some other phenomena) are manifested as the noticeable distortion of intensity histograms and, as a result, a decrease of the contrast value for observed speckle patterns.

14.2.2 Second-Order Speckle Statistics

The statistical properties of a scattered field can also be characterized by simultaneous analysis of the correlation of the complex amplitude values for two spatially separated observation points and for

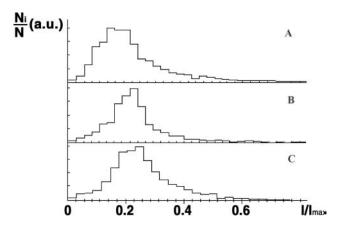

FIGURE 14.3 Histograms of intensity distributions for partially developed speckle patterns induced by focused laser beam scattering in healthy (A) and diseased (B, C, psoriasis) human epidermis layers. The thickness of the layers is about 30 to 40 μm. The diameter of the light spot on the sample surface is approximately 100 μm.

different moments of time. In this way, the spatial-temporal correlation function of scattered-field fluctuations is introduced as follows:

$$G_{1}(\bar{r}_{1},t_{1},\bar{r}_{2},t_{2}) = \langle E_{1}E_{2}^{*} \rangle = \langle E(\bar{r}_{1},t_{1})E^{*}(\bar{r}_{2},t_{2}) \rangle, \qquad (14.7)$$

where the symbol * denotes complex conjugation. For many cases, the spatial–temporal fluctuations of scattered-field amplitude can be considered the stationary random fields; this leads to the following form of $G_1(\bar{r}_1, t_1, \bar{r}_2, t_2)$:

$$G_{1}(\bar{r}_{1},t_{1},\bar{r}_{2},t_{2}) = G_{1}(\bar{r}_{1},\bar{r}_{2},t_{1}-t_{2}) = G_{1}(\bar{r}_{1},\bar{r}_{2},\tau). \tag{14.8}$$

In a similar manner, the spatial-temporal correlation function of scattered light intensity fluctuations can be introduced:

$$G_{2}(\bar{r}_{1},\bar{r}_{2},\tau) = \langle I_{1}I_{2} \rangle = \langle I(\bar{r}_{1},t)I(\bar{r}_{2},t+\Delta\tau) \rangle. \tag{14.9}$$

Moreover, for statistically homogeneous speckle patterns, the field and intensity correlation functions depend only on $\Delta \bar{r} = \bar{r}_2 - \bar{r}_1$:

$$G_1(\bar{r}_1, \bar{r}_2, \tau) = G_1(\Delta \bar{r}, \tau); G_2(\bar{r}_1, \bar{r}_2, \tau) = G_2(\Delta \bar{r}, \tau).$$
 (14.10)

If a scattered optical field is characterized by the Gaussian statistics of a complex amplitude that has zero mean value, then the normalized correlation functions of amplitude and intensity fluctuations

 $g_2(\Delta \bar{r}, \tau) = \langle I_1 I_2 \rangle / \langle I_1 \rangle \langle I_2 \rangle$ and, correspondingly, $g_1(\Delta \bar{r}, \tau) = \langle E_1 E_2^* \rangle / ((|E_1|^2)(|E_2|^2))^{1/2}$ are related to each other as follows:^{9,43}

$$g_2(\Delta \bar{r}, \tau) = 1 + \left| g_1(\Delta \bar{r}, \tau) \right|^2. \tag{14.11}$$

This is the well-known Siegert relation.

Three types of correlation measurements are typically considered:

- Correlations between spatially separated detectors measured with zero time delay; this type of measurement gives information about the typical size of a feature of a speckle intensity pattern that can be considered the average speckle size in the detection plane.
- Temporal intensity correlations measured at a single detection point; this type of measurement is the most typical for many practical applications and is therefore an object of further consideration.
- Simultaneous measurement of spatial-temporal correlations provided by changes in the positions
 of two detectors and by changes in the time delay τ.

Usually, the correlation analysis of speckle intensity fluctuations is used to study a dynamic behavior of scattering media as well as their structural characteristics; in the latter case, the dependence of speckle intensity on time may be caused by controllable motion (e.g., lateral displacement) of the probed medium with respect to the illuminating laser beam. The relationship between the dynamic properties of the scattering medium and time-dependent behavior of speckle-intensity fluctuations sufficiently depends on observation conditions. In particular, three specific zones of observation in scattered optical fields induced by probe light scattering by inhomogeneous objects with properties of the random phase screen can be mentioned:

- The near-field region in vicinity of the scattering object ($z << z_F$); in this case, each point of the observed speckle pattern is associated with a certain region of the phase front of the boundary field emerging from the scattering object. For the case of strong phase modulation of a probe beam by the scattering object, the average size of this region is significantly less than the phase correlation length that characterizes the scattering object as the random phase screen. Thus we should expect the temporal evolution of the observed speckle pattern to reflect the time-dependent dynamics of local fluctuations of the boundary field phase. In its turn, this dynamic is determined by local motions of scattering sites.
- The "focusing" region with z ~ z_F; for this detection condition, the intensity in each point of the speckle pattern is the result of superposition of partial waves coming from local areas inside the region of the boundary field phase front with a characteristic dimension of the order of ξ. Local changes in time-dependent spatial distributions of speckle intensity depend on the relative motions of spatially separated regions of the scattering object. Therefore, the relationship between the time-dependent correlation decay of intensity fluctuations and the dynamic properties of a scattering system has a more complicated form than in the case of near-field detection.
- The far field region with $z \gg z_F$; in this case, each point of the detection plane receives all contributions coming from the whole scattering region of the probed object.

The influence of detection conditions on the correlation decay of speckle intensity fluctuations is evident for speckle patterns that result from laser light scattering by moving a spatially heterogeneous "frozen" object that exhibits no mutual motions of local scattering sites and that displaces with respect to the illuminating beam as a whole. In this case, the specific property of the time-dependent spatial distributions of speckle intensity is the existence of two different types of speckle pattern evolution during the observation time; these are associated with two types of speckle motions: "boiling" motion and "translational" motion.

In the common case, the dynamic speckles translate while changing their structure and a decorrelation of intensity fluctuations occurs because of the mutual effect of the displacement and deformation of speckles. The difference between these types of speckle pattern evolution, which is intuitively understandable, can be explained in terms of an approach suggested by Yoshimura¹³ and Yoshimura et al. ¹⁴ In particular, for a scattering object with properties of the random phase screen characterized by the Gaussian statistics of boundary field phase fluctuations and by the Gaussian-like form of their spatial correlation function, the normalized spatial–temporal correlation function of speckle intensity fluctuations can be expressed as

$$g_2(\Delta \bar{r}, \tau) = 1 + \exp\left(-\frac{\left|\Delta \bar{r}\right|^2}{r_s^2} + \frac{\tau_d^2}{\tau_s^2}\right) \exp\left(-\frac{\left(\tau - \tau_d\right)^2}{\tau_s^2}\right),\tag{14.12}$$

where the parameters r_s , τ_s , and τ_d are determined by the illumination and detection conditions as well as by the scattering object velocity. If intensity fluctuations are detected with two spatially separated detectors with zero time delay, then the parameter r_s can be associated with the average size of the speckles. In order to characterize speckle motion, two additional parameters, such as the correlation distance, r_c , and translation distance, r_D can be introduced. With used notations and following Yoshimura's considerations, these parameters may be introduced as:

$$r_{c} = \left(1/r_{s}^{2} - \tau_{c}^{2} V_{s}^{2} / r_{s}^{4}\right)^{-1/2}; r_{T} = V_{s} \left(1/\tau_{c}^{2} - V_{s}^{2} / r_{s}^{2}\right)^{-1/2}, \tag{14.13}$$

where V_s is the speckle velocity. If the absolute value of ratio r_T/r_s is less than 1, then the boiling motion is dominant.

In the opposite case of $|r_T/r_T| > 1$, we can observe the more expressed translation motion of speckles. In the particular case of Gaussian beam illumination of in-plane moving scatter and free-space formation of a speckle field, this consideration leads to the relation

$$r_T/r_s = \{(l+z)l/a + a\}/z$$
, (14.14)

where z is the distance between the scattering object and the observation plane, l is the distance between the object and the waist plane, and a is the Rayleigh range parameter of illuminating beam evaluated as $\pi w_0^2 / \lambda$, where w_0 is the waist radius.

It is easy to see that if l = 0 (the moving object is positioned in the waist plane), then speckles observed near the scattering object (z < a) exhibit the dominating translation motion; in contrast, far-zone speckles are characterized by the boiling-like motion with a vanishing translation component.

The most typical speckle-correlation measurement applied to study the dynamic behavior of various scattering systems (e.g., living tissues) is single-point correlation analysis, or measurement of the time-dependent correlation decay of speckle intensity fluctuations. The basic principles of such measurements are discussed in the next section.

14.3 Temporal Correlation Analysis of Speckle Intensity Fluctuations as the Tool for Scattering Media Diagnostics

14.3.1 Single-Scattering Systems

For a single-scattering system consisting of moving scattering particles, the scattered field in the detection point can be expressed using a simple modification of Equation 14.1:

$$E(t) = \exp(j\omega t) \sum_{i=1}^{N} |E_i(t)| \exp\{-j\phi_i(t)\}, \qquad (14.15)$$

where the dependence of phase for each partial contribution on time is caused by scatter motions and therefore causes fluctuations of the scattered field amplitude in the detection point. Thus, the temporal correlation function of scattered field fluctuations in the detection point can be written as follows:

$$G_1(\tau) = \left\langle E(t)E^*(t+\tau) \right\rangle = \left\langle \exp(-j\omega\tau) \sum_{i=1}^N \sum_{i'=1}^N \left| E_i(t) \right| \left| E_{i'}(t+\tau) \right| \exp\left[-j\left\{ \phi_i(t) - \phi_{i'}(t+\tau) \right\} \right] \right\rangle.$$

By using simplifying assumptions about the statistical independence of partial contributions scattered by different scattering sites and slow varying amplitudes of scattered waves, $|E_i(t)| \approx E_i(t+\tau)$, the temporal correlation function can be expressed as (see Reference 9):

$$G_1(\tau) \approx \exp(-j\omega\tau)N\langle |E_i(t)|^2 \exp\{j\Delta\phi_i(\tau)\}\rangle.$$
 (14.16)

Here we consider motions of scattering sites as the stationary and ergodic random process causing the increments of phase of interfering partial waves that depend only on the time delay value τ . For the zero time delay, the value of $G_I(0)$ is equal to the mean intensity of scattered light in the detection point:

 $G_1(0) = \langle I \rangle \approx N \langle \left| E_i \right|^2 \rangle$. For simplicity, without loss of generality, we can assume the equality of contributions from each partial scattered wave and express the temporal correlation function as:

$$G_{I}(\tau) \approx \langle I \rangle \exp(-j\omega\tau) \langle \exp\{j\Delta\phi(\tau)\}\rangle.$$
 (14.17)

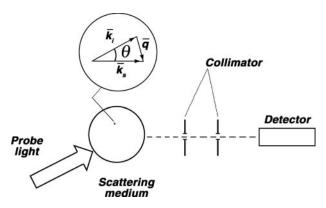

FIGURE 14.4 Typical scheme of the dynamic light scattering experiment: \vec{k}_i = the wave vector of the incident wave; \vec{k}_i = the wave vector of the detected scattered wave; θ = the scattering angle.

Phase increment $\Delta \phi_i(\tau)$ for each partial wave can be expressed as $\Delta \phi_i(\tau) = \overline{q}_i \Delta \overline{r}_i(\tau)$, where \overline{q}_i is the momentum transfer for each scattering event and $\Delta \overline{r}_i(\tau)$ describes the displacement of *i*-th scattering site for the observation time τ . For the observation geometry presented in Figure 14.4, the momentum transfer module $|\overline{q}_i|$ for each scattering event can be presented as $|\overline{q}_i| \approx |\overline{q}| = (4\pi/\lambda)\sin(\theta/2)$, where θ is the scattering angle.

Finally, taking into account the property of a complex exponent with an argument as a combination of three independent random variables with the same statistical properties, the temporal correlation function of field fluctuations for single scattered dynamic speckles can be written as follows:

$$G_1(\tau) \approx \langle I \rangle \exp(-j\omega\tau) \exp\left\{-\left(4\pi \sin(\theta/2)/\lambda\right)^2 \Delta \bar{r}^2(\tau)/6\right\},$$
 (14.18)

where the displacement variance for scattering sites measured with the given time delay is determined by the dynamic properties of the scattering system. In particular, for ensembles of Brownian particles (this model is usual for description of the dynamical behavior of various biological systems), the value of $\Delta \bar{r}^2(\tau)$ is equal to $6D\tau$ (D is the self-diffusion coefficient of scattering particles).

In conventional schemes of scattering experiments with no use of a reference beam for detection of scattered light, the measurable parameter of a scattered optical field is the instantaneous value of speckle intensity in the detection point. The detected intensity fluctuations are usually characterized by the intensity correlation function $G_2(\tau)$. For Gaussian scattered fields with zero mean amplitude, the normalized correlation function of intensity fluctuations $G_2(\tau) = G_2(\tau)/G_2(0)$ is related to the normalized correlation function $G_1(\tau)$ by the previously presented Siegert relation (see Equation 14.11):

$$g_2(\tau) = 1 + \beta |g_1(\tau)|^2$$
, (14.19)

where the parameter β depends on detection conditions. For ideal conditions (i.e., when the detector aperture is significantly smaller than the speckle size), $\beta = 1$.

Thus, for Brownian scattering systems the normalized correlation function of intensity fluctuations has the exponential form:

$$g_2(\tau) \approx 1 + \exp\left\{-2\left(4\pi\sin\left(\frac{\theta}{2}\right)/\lambda\right)^2 D\tau\right\},$$
 (14.20)

and the corresponding power spectrum has the Lorentzian form. The value of $\tau_0 = (4\pi^2 D/\lambda^2)^{-1} = (k^2 D)^{-1}$ is usually considered the correlation time of the field fluctuations. One of the traditional approaches to

measure the properties of scattering particles (in particular, their diffusion coefficient) is the estimation of the correlation time of speckle intensity fluctuations for given scattering angle and wavelength of the probe light.

A specific case involves coherent light scattering by moving phase scatters with a fractal-like structure. In this case, the temporal intensity fluctuations detected in the fixed point of the far diffraction zone have the properties of the one-dimensional random fractal process and the corresponding fractal dimension of such a process is directly related to the fractal dimension of the scattering object (e.g., a fractal-like surface). The form of corresponding relationship depends on illumination conditions. In particular, use of a sharply focused illuminating beam causes increase of the fractal dimension of detected speckle intensity fluctuations in comparison with the fractal dimension of scattering object (the effect of "stochastization" of speckle intensity fluctuations).⁵⁰

14.3.2 Multiple-Scattering Systems

The formation of multiply scattered dynamic speckles is a significantly more interesting case and is important for practical applications. The discrete scattering model (Equation 14.15) can be modified in order to describe dynamic speckle formation due to multiple light scattering in disordered systems; such an approach was discussed in the classic work by Maret and Wolf. 51 In this case, each partial contribution is considered as the result of sequence of n scattering events:

$$E_k(t) = \exp(j\omega t) \prod_{i=1}^{N_k} E_i \exp(-j\overline{q}_i\overline{r}_i(t)),$$

and the total scattered field in the detection point is expressed as follows:

$$E(t) = \sum_{k} E_{k}(t).$$

In further analysis, the single-path correlation function of field fluctuations is introduced as

$$G_{2}^{k}(\tau) = \left\langle E_{k}(t)E_{k}^{*}(t+\tau) \right\rangle \approx \exp(-j\omega\tau) \left\langle \prod_{i=1}^{N_{k}} \left| a_{i} \right|^{2} \exp\left\{ j\overline{q}_{i}\Delta \overline{r}_{i}(\tau) \right\} \right\rangle$$

$$\approx \exp(-j\omega\tau) \left\langle \left| a_{i} \right|^{2} \right\rangle \exp\left\{ -\left\langle \overline{q}^{2} \right\rangle \left\langle \Delta \overline{r}^{2}(\tau) \right\rangle N_{k} / 6 \right\}.$$
(14.21)

For the discussed case, the mean value of \overline{q}^2 estimated for a sequence of scattering events can be expressed as $\langle \overline{q}^2 \rangle = 2k^2l/l^*$, where l is the scattering mean free path and l is the transport mean free path for the scattering medium. The number of scattering events for each partial contribution can be expressed as $N_k \approx s_k/l$, where s_k is the corresponding propagation path for k-th partial component inside a scattering medium. Thus, the single-path correlation function has the following form:

$$G_1^k(\tau) \approx \exp(-j\omega\tau) \langle |a|^2 \rangle \exp\{-k^2 \langle \Delta \bar{r}^2(\tau) \rangle s_k / 3l^* \}.$$
 (14.22)

The temporal correlation function of field fluctuations in the detection point $G_1(\tau) = \langle E(t)E^*(t+\tau) \rangle$ can be obtained by the statistical summation of the single-path correlation functions over the ensemble of partial contributions:

$$G_1(\tau) \approx \sum_k P(k)G_1^k(\tau),$$

where P(k) are the statistical weights characterizing contributions of partial components to formation of a scattered field in a detection point. This expression may be modified for multiple scattering systems characterized by the continuous distribution of optical paths s by integration over the range of all possible values of s:

$$G_1(\tau) \approx \int_0^\infty \exp\left(-\frac{k^2 \langle \Delta \bar{r}^2(\tau) \rangle s}{3l^*}\right) \tilde{\rho}(s) ds$$
, (14.23)

where $\tilde{\rho}(s)$ is the probability density of optical paths that obeys the following normalization condition: $\int_0^\infty \tilde{\rho}(s)ds = \langle I \rangle$. The normalized temporal correlation function can be introduced as $g_1(\tau) = \int_0^\infty \exp(-k^2 \langle \Delta \bar{r}^2(\tau) \rangle s/3l^*) \rho(s) dx$ by using the following normalization condition: $\rho(s) = \tilde{\rho}(s)/\int_0^\infty \tilde{\rho}(s) ds$. In particular, for Brownian scattering systems, the argument of exponential kernel on the right-hand side of Equation 14.23 has the well-known form $2\tau s/\tau_0 l^*$, where τ_0 is the previously introduced correlation time of function of scattered field fluctuations for a single-scattering regime.

If a localized light source is used for illumination of a dynamic scattering system, then the correlation characteristics of scattered field fluctuations (e.g., the correlation time) strongly depend on observation conditions because of sensitivity of these characteristics to changes in path statistics characterized by variations of the pathlength density $\rho(s)$. This gives the opportunity for probing various spatially inhomogeneous dynamic media by the spatially separated light source and detector (for instance, by the probe system consisting of light-delivering and light-collecting optical fibers). Various examples of such probing technology are illustrated in Figure 14.5.

In this case, the probed scattering system consists of two layers — the superficial "static" layer consisting of motionless scatters, and underlying "dynamic" or "modulating" layer with moving scattering sites. Burned tissue with shallow necrotic layer with no blood microcirculation is a good example of a real scattering system with similar geometry. Below this layer, the living tissue is characterized by a sufficient level of blood microcirculation. For small source-detector separations, the depth of light penetration into the probed volume is small compared with the thickness of "static" layer; this scattering geometry causes the formation of dynamic speckles with large values of the correlation time. Increase of the penetration depth due to enlargement of the distance between source and detector fibers leads to faster decay of the field temporal correlation.

Potential applications of this technique were demonstrated by Boas and Yodh for burn depth diagnostics. 52 In their experiment, an Ar-ion laser was used as an illumination source. Laser light was delivered to the probed tissue by a multimode optical fiber. Probe light scattered in the backward direction was collected by an eight-channel fiber-optic probe. The input tips of each single-mode light-collecting fiber were fixed along the detection line with 1.5 mm of separation between them. Output tips were connected with a photodetector unit through the 8×1 fiber-optic switcher. A photomultiplier tube (PMT) in the photon-counting mode was used as photodetector. Each sequence of photocounts was processed by digital correlator. This construction allowed the investigators to provide correlation analysis of speckle-intensity fluctuations for various distances between source and detector without mechanical scanning.

In vivo pig skin with thermally induced burn diseases of different levels was used to study the influence of the burned tissue thickness on parameters of normalized temporal correlation function $g_2(\tau)$ of intensity fluctuations at a given detection point. Burn diseases were induced by applying a heated metal block to the skin surface. Diseases of various levels with significantly differing thicknesses of necrotic layers can be obtained by varying the provocation time. For experimental conditions used in the study, the necrotic layer thickness was varied from $\approx 100 \, \mu \text{m}$ (shallow burn) to $\approx 1000 \, \mu \text{m}$ (deep burn, average level of disease).

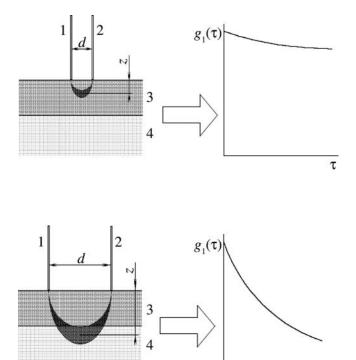

FIGURE 14.5 Location of the underlying dynamic layer (4) using measurements of the correlation decay of speckle amplitude fluctuations. 1 = light-delivering fiber; 2 = light-collecting fiber; 3 = superficial static layer. $g_1(\tau)$ is the normalized temporal correlation function of the scattered-field fluctuations.

τ

The parameter most sensitive to changes of the burned tissue structure was found to be the slope of $\ln\{g_2(\sqrt{\tau})\}$ dependencies obtained for different source-detector separations. For instance, this parameter slowly increases with an increase in source-detector separation up to the value of the order of the necrotic layer thickness. After the "critical" penetration depth comparable with the layer thickness is reached, the dramatic change in slope value occurs.

Correlation analysis of speckle intensity fluctuations associated with object scanning by the probe (for instance, as shown in Figure 14.5) can be applied for location and imaging of dynamic macro-inhomogeneities in multiple-scattering media. This possibility was demonstrated by Boas et al. 26 in experiments with a phantom scattering object such as a resin cylinder (a static scatterer) with dynamic inclusions (a spherical cavity filled with a colloidal suspension). Titanium dioxide particles were added to resin in order to improve its scattering properties. Both scattering substances (the mixture of resin and ${\rm TiO_2}$ particles and the colloidal suspension) were carefully prepared in order to provide equal values for the transport mean free path length. A set of data collected for different positions of a light source and a detector around the surface of the resin cylinder was used for reconstruction of the object image. The image reconstruction algorithm was based on the concept of field correlation transfer in turbid media. 53 Under these experimental conditions, this concept leads to a correlation diffusion equation similar to the light diffusion equation; the reconstructed image of the phantom object adequately characterizes the position, form, and dynamic properties of the spherical inclusion.

The possibility of recognizing various types of dynamic inhomogeneities hidden in a multiply scattering dynamic medium with use of correlation analysis of speckle intensity fluctuations was shown by Heckmeier et al.⁵⁴ They studied the dynamic light-scattering response of a multiply scattering system consisting of a Brownian medium with an embedded glass capillary in which the regular flow of a scattering substance (a suspension of polystyrene beads in water) was provided. The dependence of the

decay of the temporal correlation of speckle intensity fluctuations on capillary position inside the Brownian scattering medium and flow rate was studied theoretically and experimentally. Regular flow was found to be reliably located at the depths on the order of the transport mean free path length.

Some applications of speckle correlometry techniques to *in vitro* tissue diagnostics are discussed in References 55 through 59.

14.4 Angular Correlations of Multiply Scattered Light

The existence of long-range angular correlations, a fundamental property of optical fields multiply scattered by random media, was considered in terms of "angular memory" effect by Feng et al.²² Berkovits and Feng discussed⁶⁰ the possibility of using this effect as the physical basis for tomographic imaging of optically dense disordered media. The relations between angular correlations of multiply scattered coherent light and optical properties of scattering media for the transmittance mode of light propagation were studied theoretically and experimentally by Hoover and co-workers.⁶¹ In this study, the potential of using the angular correlation analysis for disordered scattering media characterization was investigated.

Also, Tuchin et al. 62 considered an original approach to this problem, based on the influence of angular correlation decay on an interference of optical fields induced by two illuminating coherent beams incoming in the scattering medium at different angles of incidence. In this case, the probed medium is illuminated by a spatially modulated laser beam formed by overlapping the two collimated beams. The spatial modulation of the resulting illuminating beam has the form of a regular interference pattern with the fringe spacing determined by the angle between the overlapping beams. In the absence of scattering, the angular spectra of incident beams have the δ -like forms; the appearance of scattering causes broadening of these angular spectra and decay in the interference pattern contrast of the outgoing spatially modulated beam. Analysis of the interference pattern contrast for the outgoing beam and its dependence on the distance between the scatter and the observation plane and interference fringe period allows one to characterize the scattering properties of the probed medium.

14.5 Use of Time-Varying Speckle Contrast Analysis for Tissue Functional Diagnostics and Visualization

Analysis of speckle intensity fluctuations can be provided by acquisition of time sequences in the fixed detection point with further data processing. Another approach can be based on the statistical analysis of spatial fluctuations of time-averaged dynamic speckle patterns. Evaluation of the parameters of time-dependent intensity fluctuations (e.g., the correlation time) by use of this technique is possible in the case of ergodic dynamic speckle patterns. In this case, ensemble statistical averaging leads to the same results as temporal statistical averaging. Usually, statistical analysis of spatial fluctuations of speckle images captured with given exposure time can be carried out in the image or diffraction plane.

Two typical examples of biomedical applications of this technique can be considered; one is laser speckle contrast analysis, or the LASCA technique, developed by Fercher and Briers³³as the tool for microcirculation analysis in upper layers of *in vivo* human tissues. The typical scheme of the LASCA device is very simple, as shown in Figure 14.6. The surface of probed tissue is illuminated by the broad collimated laser beam. A speckle-modulated image of the tissue surface is captured by a charge-coupled device (CCD) camera with given exposure time. In the case of expressed blood microcirculation in the upper layer of the probed tissue, the speckle pattern, which modulates the surface image, has a dynamic character due to random Doppler shifts of partial contributions scattered by moving erythrocytes. Temporal fluctuations of modulating speckles in the image plane cause the blurred captured image with a decayed value of contrast.

The contrast value for the time-averaged image depends on exposure time and falls when exposure increases. The following expression can be obtained for time-dependent contrast:

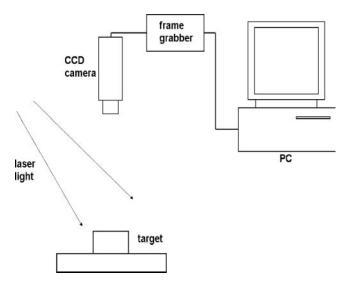

FIGURE 14.6 Basic setup for LASCA.

$$C(T) = \left(\frac{1}{T} \int_{0}^{T} \tilde{g}_{2}(\tau) d\tau\right)^{1/2}, \qquad (14.24)$$

where $\tilde{g}_2(\tau) = \left(G_2(\tau) - \left\langle I\right\rangle^2\right) / \left\langle I\right\rangle^2$ and T is the exposure time. In particular, if the intensity correlation function exhibits the exponential decay: $\tilde{G}_2(\tau) = \left\langle I\right\rangle^2 \exp(-2\tau/\tau_c)$, where the correlation time $\tau_c = 1/akv$ depends on the mean velocity v of erythrocytes, wavenumber k of probe light and scattering properties of tissue described by the factor a, then the time-dependent speckle contrast and the correlation time are related through

$$C(T) = \left\lceil \frac{\tau_c}{2T} \left\{ 1 - \exp(-2T/\tau_c) \right\} \right\rceil^{1/2}. \tag{14.25}$$

If the analyzed tissue has the layered structure with significantly differing blood perfusion levels from layer to layer (e.g., human skin), then the average velocity, or mobility, of erythrocytes, which is evaluated by use of the LASCA technique, typically characterizes some average level of mobility for tissue volume with the thickness of the order of the depth of probe light penetration. This is the main disadvantage of speckle contrast analysis with broad collimated beam illumination, when a modulating speckle pattern is induced by random interference of partial components of a backscattered optical field coming from different depths of probed tissue.

In the case in which significant differences exist in the local perfusion level for various zones of the probed tissue area, the spatially inhomogeneous dynamic speckle pattern modulates the image of the tissue surface. For such an image, local estimations of exposure-dependent contrast can be used for characterization of the differences of average perfusion level from one zone of imaged surface to another. Estimated local values of the average mobility of erythrocytes can be used for reconstruction of "microcirculation maps." In the course of reconstruction of these maps, each pixel of the probed tissue surface is imaged by use of the color or gray-level scale related to the range of estimated erythrocyte mobility levels.

Briers et al.⁶³ demonstrated the potential of this technique for functional tissue imaging; more recent results in this field were reported by Dunn et al.⁶⁴ In this study, the LASCA technique was applied for dynamic imaging of cerebral blood flow (CBF). By illuminating the cortex with laser light and imaging the resulting speckle pattern, relative CBF images with tens of microns of spatial resolution and milliseconds

of temporal resolution were obtained. This technique is easy to implement and can be used to monitor the spatial and temporal evolution of cerebral blood flow changes with high resolution in studies of cerebral pathophysiology.

The possibilities of using time-integrated speckle contrast analysis as well as speckle correlometry for studying the mechanical properties of tissue samples were demonstrated in recent works by Jacques and Kirkpatrick⁶⁵ and Duncan and Kirkpatrick.⁶⁶ This approach can be classified as the "speckle elastography of tissues."

Axial resolution in the case of time-dependent speckle contrast analysis in the image plane can be significantly improved by the use of a localized light source such as focused laser beam. Used for study of macroscopically homogeneous scattering media with thick slab geometry, this illumination scheme causes formation of statistically heterogeneous dynamic speckle patterns across the surface of the probed medium. This is because the average path of probe light propagation from the source points to the detection point strongly depends on the spatial separation between these points. The increasing distance from source and detection points causes spectral broadening of speckle intensity fluctuations from the center of the backscattered light spot on the surface of the probed medium to its edge, due to an increase in the average number of scattering events for partial contributions with large propagation paths.

The study of spatial distributions of correlation time for such statistically inhomogeneous speckle patterns allows one to obtain information not only about dynamic properties of the scattering medium, but also about conditions of probe light propagation inside the scattering volume. In particular, if the probe light travels in a layered scattering medium characterized by significant differences in dynamic properties from layer to layer, the analysis of time-averaged speckle-modulated images of the illuminated surface in the part of spatial distributions of local estimates of the time-dependent speckle contrast makes it possible to characterize the geometry of scattering system. A good example is the study of speckle contrast analysis potential for burn-depth diagnostics carried out by Sadhwani et al.⁶⁷ In this experiment, they used a burned tissue phantom composed of two layers — the static layer as the phantom of a superficial necrotic tissue layer and a modulating layer as the phantom of living tissue with an expressed microcirculation of blood (Figure 14.7).

Such scattering geometry in the case of a localized probe source leads to formation of two specific zones inside the backscattered light spot. Surrounding the source light spot, the first is characterized by the presence of a modulating static speckle pattern induced by scattering of probe light inside the static layer. The influence of partial contributions that reach the modulating layer and come back is negligibly small. The second zone, or area of dynamic speckle modulation, is located around the first. If the surface of the phantom scattering system is imaged with exposures significantly exceeding the typical value of correlation time of speckle intensity fluctuations, image for the second zone blurs with contrast value approaching 0. Thus, it is possible to estimate the thickness of the static ("necrotic") layer by measuring the inner radius of the blurred zone.

The following phantom object was used for approbation of this technique. Teflon films of various thicknesses (from 0.13 to 1.3 mm) were applied as static layers. A lipid solution (Intralipid-10%) was used as the modulating medium. An He-Ne laser operating at 633 nm, used as a source of probe light, was focused to an 80- μ m diameter spot on the Teflon film surface. The image of the illuminated surface was captured by CCD camera with a Nikkor 50 mm f/1.8AF lens. The lens aperture diameter was set to minimum value (f/22) to maximize the average speckle size in the image plane. A polarizer was used between the CCD lens and the target in order to minimize the influence on image formation of specular reflection from the target surface.

Experiments with the burned tissue model have shown the strong correlation between the diameter of the nonblurred speckle pattern and the thickness of static layer. Because of the relative simplicity of the design, the inexpensive arrangement, and unsophisticated image-processing algorithm, this technique seems to be an adequate prospective tool for clinical applications.

The important question for various methods to monitor blood microcirculation on the basis of statistical, correlation, or spectral analysis of dynamic speckles is the influence of the detected light component induced by scattering of probe light by motionless scatterers existing in the scattering volume

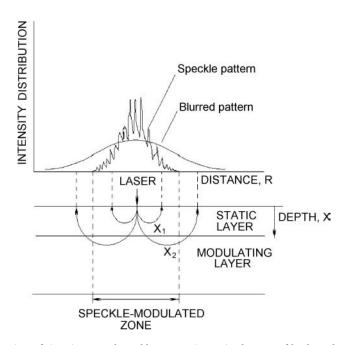

FIGURE 14.7 Formation of time-integrated speckle pattern image in the case of backward multiple scattering of the probe laser light by a two-layered medium. Photons that travel to depth x_1 in the static layer produce a speckle pattern upon returning to the surface, whereas photons that travel to depth x_2 in the modulated layer produce a time-averaged blurred pattern at the surface. The size of the speckle-modulated zone is determined by the thickness of the static layer.

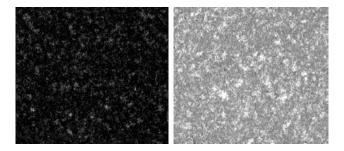

FIGURE 14.8 Time-integrated speckle patterns recorded with differing exposure times (object under study is the nail bed of a 44-year-old male). Left: 8-ms exposure time; right: 25-ms exposure time.

of probed tissue. For instance, this influence will be significant in the case of laser diagnostics of blood microcirculation in the dermal layer. In the case of blood flow monitoring by means of speckle contrast analysis (e.g., the LASCA technique), the presence of a static component in the image-modulating speckle pattern will cause a noticeable value of the residual speckle contrast even for large values of exposure time — values that significantly exceed the correlation time of intensity fluctuations for the dynamic component. This effect is illustrated by Figure 14.8, which presents two time-averaged dynamic speckle patterns induced by laser light scattering in human forearm skin.

The residual contrast depends on the ratio of mean intensity values of the fluctuating component and the static component of an observed speckle pattern, and on the fraction of Doppler-shifted partial contributions f in the scattered optical field. The simple analytical model that describes this ratio in the dependence on f for the case of single-point detection of fluctuating speckle intensity was considered by

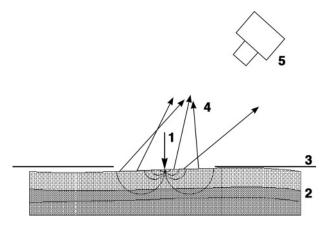

FIGURE 14.9 Use of spatial filtering of a backscattered optical field in the object plane makes it possible to improve the spatial resolution of the speckle contrast technique. 1 = localized light source (focused laser beam); 2 = tissue under study; 3 = filtering diaphragm; 4 = scattered light; 5 = CCD camera without imaging lens. (Detection of scattered light in the diffraction regime allows one to exclude the saturation of captured speckle pattern.)

Serov et al.⁶⁸ They found that the modulation depth of fluctuating intensity in the detection point can be expressed as

$$\frac{\delta_I^2}{\langle I \rangle^2} = \frac{1}{N} f(2 - f), \qquad (14.26)$$

where N is the number of speckles inside the detector aperture.

Having been verified for the case of a layered scattering model, this expression has shown excellent agreement with experimental results. Measurements of the residual contrast for *in vivo* tissues in combination with spatial filtration of a backscattered optical field by use of ring-like diaphragms offer the opportunity to analyze depth distributions of erythrocyte concentrations in probed tissue. The basic idea of this technique is illustrated by Figure 14.9. By using the circular and ring-like diaphragms of different radii, one can select the partial contributions of light penetrating into different depths of the tissue layer.

14.6 Imaging of Scattering Media with Use of Partially Coherent Speckles

If a scattering medium is illuminated by partially coherent light, only partial waves with pathlength differences less than the coherence length of the illuminating light will contribute to the formation of a random interference pattern. Such discrimination of partial contributions will lead to decay of the contrast of observed speckle patterns with an increase in the spectral width of the illumination source. This effect is clearly observed in the case of multiply scattering disordered media illuminated by a broadband light source (e.g., a superluminescent diode). Qualitative analysis of the physical picture of scattered field formation due to stochastic interference of partial waves, each of them characterized by the random value of the propagation path s_i , leads us to the following condition for the visibility of an observed speckle pattern: if the mean value of the pathlength difference $\Delta s = s_i - s_j$ for two arbitrarily chosen partial contributions i and j is significantly less than the coherence length l_c of used light source: $\langle \Delta s \rangle = \int_0^\infty \Delta s \rho(\Delta s) d(\Delta s) << l_c \ [\rho(\Delta s)]$ is the probability density function of the pathlength difference), then the partial coherence of the illuminating beam does not strongly influence the visibility of the speckle pattern. In the opposite case of $\langle \Delta s \rangle >> l_c$, the speckle modulation of scattered field is suppressed and speckle contrast falls to zero.

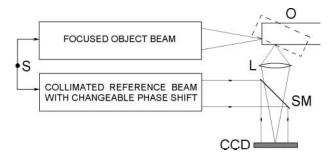

FIGURE 14.10 Schematic of low-coherence optical system for a scattering media probing with use of the *photon horizon* detection technique. S is the low-coherent light source, O is the object under study, L is the imaging lens, and SM is the semitransparent mirror.

The strong influence on speckle visibility of pathlength statistics, determined by the propagation conditions for partially coherent light in a multiple-scattering medium, allows one to consider the measurements of the contrast of partially coherent speckles as a technique for inhomogeneous media probing and imaging. The presence of scattering or absorbing inhomogeneities in a probed medium between the light source and detector area will distort the pathlength distribution inside the scattering volume; consequently, they will appear as changes in the contrast of speckles observed in the detection area in comparison with the homogeneous medium with the same background optical properties.

In particular, Thompson et al.^{69,70} considered one version of this technique. They measured the contrast of speckles that result from propagation of laser light in the multiple-scattering slab with a strongly scattering or absorbing inclusion, because the position of the inclusion varied with respect to illuminating beam and detector (a CCD camera). A speckle-modulated image of the backward surface of the illuminated slab was formed by a lens; therefore, the observed speckles were subjective ones with the average size depending on the aperture size of the imaging lens. A polarization filter was used to improve the visibility of the observed speckles by selection of the linearly polarized component of the scattered field. The experimental results have shown that it is possible to use partially coherent speckle contrast analysis for probing and imaging macroscopically heterogeneous scattering media with the appropriately chosen spectral bandwidth for the illumination source.

The original version of an imaging technique based on observation of spatial distributions of partially coherent speckle contrast was reported by Hausler et al.⁷¹ The schematic of the experimental setup is presented in Figure 14.10. In this case, adjustment of the reference arm of the interferometer (e.g., a Mach-Zehnder interferometer) allows one to find a region on the tissue surface where partial components of a scattered field with a certain propagation path will emerge after propagation through a scattering volume. In order to measure the speckle contrast, subtraction of two sequential images of a scattering object is used. In this case, the second image is obtained with the reference phase shifted by π .

By using this technique, the region of interest, which can be interpreted as the position of the photon horizon for the given time delay, is imaged as a border of speckle-modulated area on the image of the object surface (Figure 14.11). Varying the time delay by changing the pathlength difference between the reference and object arms of interferometer, one can study light propagation in the probed medium based on its optical properties.

14.7 Summary

Various speckle technologies based on analysis of decay of statistical moments of spatial, temporal, or angular fluctuations of scattered optical fields are adequately powerful tools for diagnostics and visualization of structure and dynamic properties of multiply-scattering, weakly ordered media such as human and animal tissues.

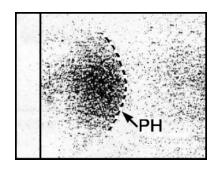

FIGURE 14.11 Visualization of the *photon horizon* (PH) with use of the speckle contrast imaging technique. The vertical line in the left part of the figure shows the front surface of the object, which is illuminated by a low-coherent beam. The speckle-modulated image is formed by light emerging from the side surface of sample.

15.1 Introduction

Microcirculation — including capillaries, small arteries (arterioles), small veins (venules), and shunting vessels (arteriovenous anastomosis) — comprises the blood vessels of the most peripheral part of the vascular tree. In the skin, the microvascular network is composed of different compartments, each with a different anatomy and function. The top layer of the skin, the epidermis, is avascular, while the dermal papillae host the capillaries responsible for the exchange of oxygen and metabolites with the surrounding tissue. Therefore, the blood perfusion through the capillaries is frequently referred to as the nutritive blood flow. Although this nutritive blood flow is low during resting conditions, it is of vital importance for maintaining the minute but important metabolic requirements of the skin. In the deeper dermal structures, the arterioles, venules, and shunting vessels reside. The main role of these vessels is to feed and drain the capillary network and to promote the maintenance of an adequate body temperature by dissipating heat to the environment through the modulation of shunting vessel blood flow.

Microvascular blood perfusion possesses temporal fluctuations and spatial variability. Temporal fluctuations may be either rhythmic, as in the case of vasomotion,² or more stochastic³ and are of either local or central origin; spatial variability originates in the anatomical heterogeneity of the microvascular network.⁴ Perfusion of blood in the skin is influenced by external factors such as heat and topically applied vasoactive substances and by the intake of beverages and drugs, as well as by smoking and mental stimuli. In addition, microvascular blood perfusion is regulated via the autonomous nervous system and through vasoctive agents released by the endocrine glands into the bloodstream.

A number of common diseases — including various inflammatory conditions, allergic reactions, and tumors — influence perfusion of blood in the skin. In addition, impaired circulation in association with diabetes and peripheral vascular disease may lead to the formation of ulcers and ultimately to tissue necrosis. Consequently, the perfusion of blood in the skin as well as in other tissues needs to be investigated by the use of noninvasive methods with a minimal influence on the parameters under study. In addition,

such methods should preferably record the perfusion in real time and be applicable in experimental and in clinical settings. In order to evaluate the dynamics of blood perfusion and its spatial variability over a given tissue surface, methods that enable the recording of both of these microvascular aspects need to be employed.

Many methods for the assessment of microvascular blood perfusion have been presented in the literature, including photoelectric plethysmography,^{5,6} thermal⁷ and radioisotope^{8,9} clearance, orthogonal polarization spectral imaging,^{10,11} and video-photometric capillaroscopy.^{12,13} None of those methods, however, has fulfilled the requirements of noninvasiveness and applicability to a large number of tissues as well as offering the possibility of recording the tissue perfusion continuously or visualizing the results in terms of two-dimensional perfusion maps. Laser Doppler flowmetry (LDF) has emerged in the absence of any other method to fulfill those requirements.

The first measurements of microvascular blood flow employing the Doppler shift of monochromatic light (named after the Austrian scientist Johan Christian Doppler¹⁴) were reported by Riva et al.¹⁵ in 1972; they studied blood cell velocity in the rabbit eye. Some years later the blood velocity of exposed microvessels was investigated by use of a laser Doppler microscope.^{16,17} *In vivo* evaluation of skin microcirculation by the use of coherent light scattering was first demonstrated by M.D. Stern in 1975.¹⁸ In his setup, in which an He-Ne laser beam illuminates the skin, a portion of the laser light is scattered by moving blood cells as well as static tissue structures, while the remaining light is scattered by static tissue structures alone. If the backscattered Doppler-broadened light is brought to the surface of a photodetector, the speckle pattern appearing on the detector surface fluctuates because of the optical mixing of waves of different frequencies. These fluctuations are manifested as audiofrequency components in the photocurrent superimposed on a steady baseline. Analysis of the photocurrent reveals a clear shift of the spectral content toward lower frequencies following the occlusion of the brachial artery by use of a pressure cuff placed around the upper arm and with the laser beam aimed at the fingertip. This fundamental discovery was soon implemented in a portable fiber-optic-based laser Doppler flowmeter, which provided results comparable with those obtained by the ¹³³Xe-clearance technique for assessment of tissue blood perfusion.

As this early prototype was used more extensively, laser mode interference noise proved to be a major limitation of the system. To overcome this problem, a differential detector system was introduced²⁰ that rejected the common mode modal interference signal while amplifying the sum of the uncorrelated blood perfusion—related signals from each detector. A signal processor using the first un-normalized moment of the photocurrent as a continuous output signal was introduced,²¹ and a theory describing quasi-elastic light scattering in perfused tissues was proposed by Bonner and Nossal.²² This signal-processing algorithm still remains the most favorable way of producing a laser Doppler flowmeter output signal that scales linearly with the average speed and concentration of moving blood cells within the scattering volume. In the context of LDF, this quantity is generally referred to as the perfusion.²³ Although LDF does not selectively record the movement of red blood cells (RBCs), it is frequently assumed that the RBCs represent the majority of the blood-borne objects in the undisturbed microcirculation.

As LDF was commercialized in the early 1980s, laser Doppler perfusion monitoring (LDPM) became available to a wide range of researchers and clinicians. The ease of use of this new technology quickly created an extensive interest in recording microvascular perfusion in a wide variety of disciplines, and to date several thousands of publications in the scientific literature cite its use.^{24–26}

One of the most remarkable features of microvascular blood perfusion is its substantial temporal and spatial variability. Consequently, the comparatively small sampling volume (about 1 mm³) of fiber-optic-based LDPM instruments constitutes one of the main limitations of this technology: with the spatial variability in tissue blood perfusion, gross differences in perfusion readings may appear at recordings from adjacent sites. This disadvantage of LDPM triggered the development of multichannel instruments²⁷ and the laser Doppler perfusion imaging (LDPI) technology at the end of the 1980s.^{28–30} In LDPI, an airborne laser beam successively probes a large number of tissue volumes, and a data set of perfusion values is generated from which a color-coded perfusion map is compiled. The commercialization phase of the LDPI-technology started in the early 1990s, and several hundred publications have already verified its usefulness, particularly in dermatology,³¹ wound healing,³² and burn treatment.³³

LDPM and LDPI constitute a versatile pair of related noninvasive medical technologies that facilitate the study of temporal and spatial variability of tissue blood perfusion. Both technologies are easy to use, but the design of a study and interpretation of the results require establishment of a well-prepared protocol and an understanding of microcirculation as well as the factors that influence it. Consequently, guidelines have been developed to assist the safe and reliable use of LDPM³⁴ and LDPI.³⁵

15.2 Theory

Coherent light directed toward a tissue will be scattered by moving objects and by static tissue structures as the photons migrate through the tissue in a random pattern. Scattering in moving objects (predominantly RBCs) changes the frequency of the light according to the Doppler principle, while light scattered in static structures alone remains unshifted in frequency. If the remitted light is detected by a photodetector, optical mixing of light shifted and unshifted in frequency will result in a stochastic photocurrent, the power spectral density of which depends on the number of RBCs and their shape and velocity distribution within the scattering volume. In the following section we present a theory³⁶ that relates the photocurrent power spectrum $P(\omega)$ to the properties of the blood cells in the illuminated volume. More precisely, we will show that the quantity $\int \omega P(\omega) d\omega$ scales with the product of the RBC concentration and average velocity, while $\int P(\omega) d\omega$ scales with the concentration of moving RBCs alone, provided that the RBC concentration in tissue is low.

15.2.1 The Single Scattering Event

The starting point of this derivation is the interaction of a single photon and a scattering object, generally referred to as a *single scattering event* (Figure 15.1). If the incident wave \mathbf{E}_i propagating in the direction \mathbf{k}_i is denoted $\mathbf{E}_i = E_{io}e^{i(\omega t + \mathbf{k}_i \mathbf{r})}$, where E_{io} is the amplitude and ω the angular frequency, t is time and \mathbf{r} represents the spatial coordinates, the scattered wave \mathbf{E}_s in the direction of \mathbf{k}_s can be written in the form

$$E_{s} = E_{so}e^{i((\omega - k_{s}v)t - k_{s}r_{o} - k_{s}(r_{1} - vt))} = E_{so}e^{i\omega t}e^{-i(k_{s} - k_{s})vt}e^{-i(k_{s}r_{o} + k_{s}r_{1})},$$
(15.1)

where E_{so} is the amplitude of the scattered wave, \mathbf{v} is the particle velocity and $e^{-i(\mathbf{k_i} \mathbf{r_0} + \mathbf{k_s} \mathbf{r_1})}$ is a time-invariant phase factor. Defining the scattering vector as $\mathbf{q} = \mathbf{k_i} - \mathbf{k_i}$, and neglecting the time-invariant phase factor, the scattered wave can be written as being composed of the product of the carrier frequency factor and the time variant phase factor according to

$$\mathbf{E}_{s} = E_{so}e^{i\omega t}e^{-i\mathbf{q}vt} . \tag{15.2}$$

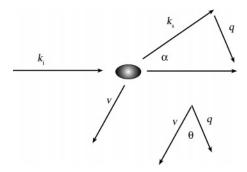

FIGURE 15.1 The single scattering event.

If the scattering object is stationary ($\mathbf{v} = 0$), if the wave is not scattered by the object ($\mathbf{q} = 0$) or if the \mathbf{v} and \mathbf{q} vectors are perpendicular, the wave remains unshifted in frequency. Because $k_i \approx k_s$, the magnitude

of the scattering vector equals $q = 2ksin\left(\frac{\alpha}{2}\right) = \frac{4\pi}{\lambda_t}sin\left(\frac{\alpha}{2}\right)$, where α is the scattering angle and λ_t the

wavelength in tissue. The frequency-determining argument of the time-variant phase factor $\mathbf{q}\mathbf{v} = \text{qvcos}(\theta)$ constitutes the angular Doppler frequency ω_D which amounts to

$$\omega_D = \frac{4\pi}{\lambda_t} \sin\left(\frac{\alpha}{2}\right) v \cos(\theta) , \qquad (15.3)$$

where θ is the angle between \mathbf{v} and \mathbf{q} .

15.2.2 Detection

When a laser beam impinges on the tissue surface, the individual photons migrate through the tissue matrix in a random pattern to a depth determined by the optical properties of the tissue. This migration process implies a multitude of single scattering events with or without associated frequency shifts (Figure 15.2). A portion of all photons injected return to the tissue surface, where they become available for detection. This backscattered light is Doppler-broadened by an amount dependent on the average individual RBC velocity and scattering vectors. Therefore, the expectation value of the time-variant phase factor $\langle e^{-iqv\tau} \rangle$, according to Equation 15.2, needs to be determined in order to calculate the tissue perfusion.

When the backscattered light impinges on the surface of a photodetector, a fluctuating speckle pattern is formed. The frequency and magnitude of intensity fluctuations in the individual coherence areas of this speckle pattern are related to the average speed and number of moving objects within the scattering volume. The extension of a single coherence area A_c in the speckle pattern is determined by the wavelength

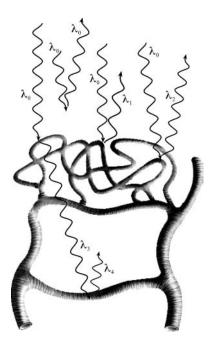

FIGURE 15.2 Migration of photons through the tissue matrix including numerous single scattering events where scattering in moving objects involves a frequency shift according to the Doppler principle. λ_0 constitutes the laser wavelength while λ_1 , λ_2 , λ_3 , and λ_4 represent the wavelengths after single or multiple scattering in moving objects.

in vacuum (λ) and the solid angle (Ω) under which the laser spot on the object is seen from the detector surface according to References 37 through 39:

$$A_c = \frac{\lambda^2}{\Omega} \,. \tag{15.4}$$

In the photodetector, the instantaneous light intensity is converted to a photocurrent. If the average and the fluctuating portions of the photocurrent produced by coherence area j are denoted as $\langle i_c \rangle$ and $\Delta i_{cj}(t)$, respectively, the total photocurrent i(t) proportional to the instantaneous light intensity can be expressed as⁴⁰

$$i(t) = \sum_{i=1}^{K} \left(\left\langle i_c \right\rangle + \Delta i_{ci}(t) \right), \tag{15.5}$$

where K is the total number of coherence areas on the detector surface and all noise factors are neglected. Since i(t) is a stochastic process, its characteristics may be described by the autocorrelation function

$$\langle i(0)i^{*}(\tau)\rangle = \sum_{j=1}^{K} \left(\langle i_{c}\rangle + \Delta i_{cj}(0)\right) \sum_{l=1}^{K} \left(\langle i_{c}^{*}\rangle + \Delta i_{cl}^{*}(\tau)\right)$$

$$= \sum_{j=1}^{K} \sum_{l=1}^{K} \langle i_{c}\rangle\langle i_{c}^{*}\rangle + \sum_{j=1}^{K} \sum_{l=1}^{K} \Delta i_{cj}(0)\Delta i_{cl}^{*}(\tau)$$

$$= K^{2}\langle i_{c}\rangle^{2} + K\langle\Delta i_{c}(0)\Delta i_{c}^{*}(\tau)\rangle,$$
(15.6)

where $\Delta i_c(\tau)$ represents the average fluctuating portion of the photocurrent produced by a single coherence area. Equation 15.6 is valid under the assumption that the fluctuating portions of the photocurrents produced by the individual coherence areas are independent, i.e., all elements $\Delta i_{cj} \Delta t_{cl}^*(\tau)$ are nonzero only for j=l, and each fluctuating component has an average value equal to zero. From Equation 15.6 it can be concluded that the Doppler-related portion of the photocurrent autocorrelation function scales linearly with the number of coherence areas, while the stationary part scales with the square of the number of coherence areas. Furthermore, the performance of the entire system is uniquely described by the statistics of the photocurrent produced by a single coherence area.

Because the photodetector is a square-law detector, the photocurrent produced by a single coherence area is related to the electromagnetic field $\mathbf{E}(t)$ as $i_c(t) \propto \mathbf{E}(t) \mathbf{E}^*(t)$. Hence, the autocorrelation of the photocurrent produced by a single coherence area can be expressed as

$$\langle i_c(0)i_c^*(\tau)\rangle \propto \langle \mathbf{E}(0)\mathbf{E}^*(0)\mathbf{E}(\tau)\mathbf{E}^*(\tau)\rangle,$$
 (15.7)

where the E-vector represents the sum of the electromagnetic field vectors impinging on the actual coherence area. This sum can be split into two parts, of which one is the sum of all field vectors representing photons that have undergone a Doppler shift, and the other is the sum of the field vectors representing photons with no frequency shift.

Evaluating Equation 15.7 thus results in 16 terms, 10 of which have an average value that equals zero because their fluctuating parts are independent and uncorrelated. Three terms include components that are time-invariant and thus represent the average photocurrent produced by the coherence area in question. Two terms represent *heterodyne* mixing of beams shifted in frequency with beams not shifted in frequency, while one term represents *homodyne* mixing of beams that have all undergone at least one

frequency shift. The overall autocorrelation function of the photocurrent produced by a single coherence area can therefore be written in the form

$$\left\langle i_{c}(0)i^{*}_{c}(\tau)\right\rangle = \underbrace{2i_{Re}i_{Sc} + i_{Re}^{2} + i_{Sc}^{2}}_{\text{Stationary}} + \underbrace{i_{Re}i_{Sc}\left(\left\langle e^{iqv\tau}\right\rangle + \left\langle e^{-iqv\tau}\right\rangle\right)}_{\text{heterodyne -mixing}} + \underbrace{i_{Sc}^{2}\left\langle \frac{1}{S^{2}}\sum_{k=1,k\neq l}^{S}\sum_{l=1}^{S}\sum_{l=1}^{S}e^{i(\mathbf{q}_{k}\mathbf{v}_{k}-\mathbf{q}_{1}\mathbf{v}_{1})\tau}\right\rangle}_{\text{homodyne -mixing}}, \quad (15.8)$$

where i_{Re} and i_{Sc} represent the average currents produced, respectively, by photons not shifted in frequency and those shifted in frequency within a single coherence area, S denotes the total number of photons

with Doppler shifts, and
$$\left\langle e^{i\mathbf{q}\mathbf{v}\tau}\right\rangle = \left\langle \frac{1}{S}\sum_{k=1}^{S}e^{i(\mathbf{q}_{k}\mathbf{v}_{k}\tau)}\right\rangle$$
. For a low and moderate RBC concentration (C_{RBC}),

 i_{Sc} is proportional to the total photocurrent produced by a single coherence area and $i_{Sc} \approx C_{RBC}i_{Re}$ for $i_{Re} >> i_{Sc}$.

In most applications, including low and moderate tissue blood volumes, the heterodyne terms dominate over the homodyne term. Under those circumstances, the homodyne term may be disregarded.

15.2.3 Signal Processing

Correctly processing the detected fluctuations in the photocurrent and development of an algorithm producing an output signal that scales with the product of RBC speed and concentration requires derivation of the relationship between velocity distribution, the scattering vector distribution at an RBC single scattering event and the recorded autocorrelation function of the photocurrent. This derivation starts with calculation of $\langle e^{iqv\tau} \rangle_{\bf v}$ for the actual three-dimensional velocity distribution $N_0({\bf v})$. Then the average value of this quantity $\langle e^{iqv\tau} \rangle_{\bf v} \rangle_{\bf q}$ with respect to the scattering vector distribution $S_0({\bf q}(\alpha))$ is calculated. According to the Wiener–Khintchine theorem,⁴¹ the Fourier transform of $\langle e^{iqv\tau} \rangle_{\bf q} \rangle_{\bf q}$ gives the photocurrent power spectral density. These successive calculations allow the recorded power spectral density to be linked to the RBC velocity distribution for the actual laser wavelength.

Certain assumptions need to be made regarding the velocity distribution of the RBCs. These assumptions include (1) a velocity distribution $N_0(\mathbf{v})$ that is independent of the spatial coordinates, (2) independent movements of the individual RBCs, and (3) an RBC concentration low enough to justify negligence of the homodyne term in the photocurrent autocorrelation function. These assumptions may not be entirely fulfilled in real tissues. Nevertheless, they are important for the derivation of a suitable and robust algorithm for laser Doppler flowmeters and imaging systems.

15.2.3.1 Derivation of $\langle e^{iqv\tau} \rangle_v$

The expectation value of $\langle e^{i\mathbf{q}\mathbf{v}\tau}\rangle_{\mathbf{v}}$ with reference to \mathbf{v} for a fixed value of \mathbf{q} can be calculated according to

$$\left\langle e^{iqv\tau}\right\rangle_{\mathbf{v}} = \int_{\mathbf{v}} N_0(\mathbf{v})e^{iqv\tau}d\mathbf{v} .$$
 (15.9)

Assuming that the RBCs move randomly without any preferential direction, and making the transformation to spherical coordinates, Equation 15.9 can be written in the form

$$\left\langle e^{iqv\tau}\right\rangle_{\mathbf{v}} = \int_{\mathbf{v}=0}^{\infty} N(v) \frac{\sin(qv\tau)}{qv\tau} d\mathbf{v}$$
, (15.10)

where the one-dimensional velocity distribution $N(\mathbf{v}) = 4\pi \mathbf{v}^2 N_0(\mathbf{v})$.

15.2.3.2 Derivation of $\langle \langle e^{iqv\tau} \rangle_{v} \rangle_{q}$

The expectation value of $\langle e^{iqv\tau} \rangle_v$ with reference to **q** can be calculated according to

$$\left\langle \left\langle e^{i\mathbf{q}\mathbf{v}\tau}\right\rangle _{\mathbf{v}}\right\rangle _{\mathbf{q}}=\int\limits_{\alpha=0}^{\pi}\left\langle e^{i\mathbf{q}\mathbf{v}\tau}\right\rangle _{\mathbf{v}}S_{0}(\mathbf{q}(\alpha))d\alpha\ . \tag{15.11}$$

Assuming that $S_0(\mathbf{q}(\alpha))$ possesses circular symmetry with respect to \mathbf{k}_i , the one-dimensional scattering vector distribution $S(\mathbf{q}(\alpha))$ may be written in the form

$$S(q(\alpha)) = \frac{2S_0(q(\alpha))}{\sin(\alpha)}.$$
 (15.12)

Inserting Equations 15.10 and 15.12 into Equation 15.11 yields

$$\left\langle \left\langle e^{i\mathbf{q}\mathbf{v}\tau}\right\rangle_{\mathbf{v}}\right\rangle_{\mathbf{q}} = \int_{\alpha=0}^{\pi} \int_{\mathbf{v}=0}^{\infty} N(\mathbf{v}) \frac{\sin(\mathbf{q}\mathbf{v}\tau)}{2\mathbf{q}\mathbf{v}\tau} S(\mathbf{q}(\alpha)) \sin(\alpha) d\mathbf{v} d\alpha. \tag{15.13}$$

Equation 15.13 relates the RBC one-dimensional velocity $(N(\nu))$ and scattering vector $(S(q(\alpha)))$ distributions to the measurable photocurrent autocorrelation function produced by the heterodyne mixing term in Equation 15.8.

15.2.3.3 Power Spectral Density

The power spectral density $P_c(\omega)$ of the photocurrent produced by the heterodyne mixing term in a single coherence area can thus be calculated by applying the Wiener-Khintchine theorem to Equation 15.8, neglecting the stationary and the homodyne mixing terms

$$P_c(\omega) \propto C_{RBC} i_{Re}^{2} \int_{v=0}^{\infty} N(v) \int_{\alpha=0}^{\pi} \sin(\alpha) S(q(\alpha)) \int_{\tau=-\infty}^{\infty} \frac{\sin(qv\tau)}{qv\tau} e^{i\omega\tau} d\tau d\alpha dv.$$
 (15.14)

Using the fact that $q = \frac{4\pi}{\lambda_t} \sin\left(\frac{\alpha}{2}\right)$, Equation 15.14 can, by way of pure mathematical manipulations, be reduced to

$$P_{c}(\omega) \propto C_{RBC} i_{Re}^{2} \int_{v = \frac{\lambda_{t}\omega}{4\pi}}^{v_{max}} \frac{N(v)}{v} \int_{q = \frac{\omega}{v}}^{\frac{4\pi}{\lambda_{t}}} S(q) dq dv.$$
 (15.15)

After normalization with the total light intensity in order to render the output signal independent of the power of the laser, and taking into account that stationary components scale with K^2 while the Doppler-related portion of the signal scales with K alone, according to Equation 15.6, the total photocurrent power spectral density $P(\omega)$ corresponding to the heterodyne mixing term can be written in the form:

$$P(\omega) \propto \frac{C_{RBC}}{K} \int_{v = \frac{\lambda_t \omega}{4\pi}}^{v_{max}} \frac{N(v)}{v} \int_{q = \frac{\omega}{v}}^{\frac{4\pi}{\lambda_t}} S(q) dq dv .$$
 (15.16)

The integration limits of Equation 15.16 indicate that, in order for an RBC single scattering event to contribute to the photocurrent power spectral density at the angular frequency ω , the associated scattering vector q needs to have a magnitude of at least $q = \frac{\omega}{v}$. In addition, the magnitude of the RBC velocity needs to be higher than $v = \frac{\lambda_r \omega}{4\pi}$.

As a final step we can now calculate $\int \omega^n P(\omega) d\omega$ and demonstrate that this quantity scales linearly with the RBC concentration for n=0 and the product of the RBC speed and concentration for n=1. An arbitrary velocity distribution can be written as the sum of its individual parts $N(v) = \sum_{v_0} N_{v_0} \delta(v - v_0)$.

The contribution to $\int \omega^n P(\omega) d\omega$ from $N(v) = N_{v_0} \delta(v - v_0)$ can then be written in the form

$$\int \omega^{n} P(\omega) d\omega \propto \frac{C_{RBC}}{K} \int_{\omega=0}^{\infty} \omega^{n} \int_{v=\frac{\lambda_{r}\omega}{4\pi}}^{v_{max}} \frac{N(v)}{v} \int_{q=\frac{\omega}{v}}^{\frac{4\pi}{\lambda_{r}}} S(q) dq dv d\omega$$

$$= \frac{C_{RBC} N_{v_{0}}}{K} \int_{\omega=0}^{\infty} \omega^{n} \int_{v=\frac{\lambda_{r}\omega}{4\pi}}^{\infty} \frac{\delta(v-v_{0})}{v} \int_{q=\frac{\omega}{v}}^{\frac{4\pi}{\lambda_{r}}} S(q) dq dv d\omega$$

$$= \frac{C_{RBC} N_{v_{0}}}{K} \int_{x=0}^{\infty} (xv_{0})^{n} \int_{v=\frac{\lambda_{r}xv_{0}}{4\pi}}^{\infty} \frac{\delta(v-v_{0})v_{0}}{v} \int_{q=\frac{xv_{0}}{v}}^{\frac{4\pi}{\lambda_{r}}} S(q) dq dv dx$$

$$= \frac{C_{RBC} N_{v_{0}} v_{0}^{n}}{K} \int_{x=0}^{\infty} x^{n} \int_{q=x}^{\infty} S(q) dq dx$$

$$= \frac{C_{RBC} N_{v_{0}} v_{0}^{n}}{K} \int_{x=0}^{\infty} x^{n} \int_{q=x}^{\infty} S(q) dq dx$$

$$= \frac{C_{RBC} N_{v_{0}} v_{0}^{n}}{K} \int_{x=0}^{\infty} x^{n} \int_{q=x}^{\infty} S(q) dq dx$$

and the contribution from the complete velocity spectrum yields

$$\int \omega^{n} P(\omega) d\omega \propto \frac{C_{RBC}}{K} \int_{v=0}^{\infty} v^{n} N(v) dv \propto C_{RBC} \langle v^{n} \rangle.$$
(15.18)

This processor algorithm scales with the RBC concentration (n = 0) and with the product of RBC concentration and speed (n = 1) for an arbitrary velocity distribution.

15.2.4 Sampling Volume

If the spatial distribution of photons available for detection within the sampling volume is described by a weighing function $H(\mathbf{r})$ that is dependent on the tissue optical properties at location \mathbf{r} , the output signal from the laser Doppler flowmeter is proposed to be²³

$$\int_{r^3} H(r)v(r)C_{RBC}(r)dr^3$$
 (15.19)

 $H(\mathbf{r})$ can be estimated for a specific combination of probe design and tissue optical properties by use of the Monte Carlo simulation, allowing a derivation of the median sampling depth.⁴² In contrast to analytical models, Monte Carlo models have the added advantage of accounting for spatial coordinate-dependent distributions of velocity $\mathbf{v}(\mathbf{r})$ and concentration $C_{RBC}(\mathbf{r})$. The contribution to the output signal of blood flow in single vessels located at a specific depth⁴³ and the presence of multiple Doppler shifts for a given microvascular architecture can be readily predicted.^{44,45}

15.3 Instrumentation

This section describes the instrumentation principles of LDPM and LDPI. In most LDPM devices the light is brought to and from the tissue by optical fibers. LDPM is well suited for continuous real-time monitoring of tissue blood perfusion at a single site. In LDPI, an airborne laser beam scans the tissue and successively records the tissue perfusion from a number of sites; from these data a two-dimensional map of the microvascular perfusion is generated. LDPI is primarily intended for studies of the spatial variability of tissue blood perfusion.

15.3.1 Laser Doppler Perfusion Monitoring

15.3.1.1 First Experimental Setup

Following the demonstration of backscattered Doppler-broadened light from a perfused tissue, ¹⁸ the first prototype of a laser Doppler flowmeter was constructed. ⁴⁶ This early experimental setup utilized as light source a 15-mW He-Ne laser, emitting coherent light at 632.8 nm. The large laser and a photomultiplier tube were positioned about 1 m above the tissue. In order to limit stray light, the returning light passed through a 2-mm aperture positioned at the surface of the tissue. A 0.5-mm pinhole was placed in front of the detector in such a way that only a single coherence area was selected. A flow parameter was obtained by use of an algorithm calculating the root mean square (rms) bandwidth of the un-normalized second moment of the Doppler signal power spectral density. With measurements on skin subjected to ultraviolet-induced erythema, a linear relationship with a first-order correlation coefficient of 88% between this flow parameter and values obtained by the ¹³³Xe-clearance technique could be demonstrated.

15.3.1.2 LDPM Devices

Although the early experimental prototypes worked well in the laboratory, they proved to be too bulky for use in the clinical environment. LDPM devices, in which optical fibers guided the light to and from the tissue and a semiconductor diode replaced the photomultiplier tube, were therefore developed.¹⁹ In LDPM, step-index or graded-index optical fibers are used as light guides. In modern equipment these fibers have a core diameter ranging from 50 to $120 \,\mu m$. The light is coupled via a microlens from the laser to the transmitting fiber that guides the light to the probe attached to the tissue by double adhesive tape. One or more fibers pick up a portion of the backscattered and Doppler-broadened light and bring it back to the photodetector unit in the instrument. In the probe tip, the fibers are typically positioned with a core center spacing of 250 to 500 μm . In the tissue the photons migrate in random pathways from the transmitting to the receiving fiber.

Widening the distance between the fiber tips in the probe tends to increase the average path length of the detected photons as well as the measurement depth.⁴² Both of those quantities are dependent on the optical properties of the tissue. Consequently, perfusion recorded in different organs cannot be directly compared, and no universal absolute flow unit has so far been presented for LDF applications. Depending on the intended use of the instrument, the probes may be designed for attachment to the tissue surface or as small-diameter needle probes for recording deep muscle perfusion.^{47,48} Because skin perfusion is especially sensitive to the ambient temperature, probe-holders incorporating a thermostatic element that allows the skin temperature to be kept at a preset value have been developed.⁴⁹

Incorporating optical fibers as light guides between the tissue and the device, however, generally implies that the number of coherence areas on the photodetector surface increases and renders the system less coherent. According to Equation 15.6, this reduces the ratio of the photocurrent produced by the Doppler signal to the total light intensity by an amount proportional to the number of coherence areas. When fiber-optic-based devices were first tested, the superimposition of large spikes on the output signal at regular intervals significantly distorted the measurement. Closer analysis⁵⁰ identified optical mixing of longitudinal laser modes on the detector surface, giving rise to audio-range frequencies sweeping through the bandwidth of the device, as the origin of the problem. Since these signals are of common-mode origin, their adverse effect on the signal-to-noise ratio increases with the number of coherence areas. This problem was overcome by the introduction of a differential detector system²¹ that effectively suppressed the common-mode signals, while not affecting the difference of the uncorrelated Doppler signals from the two detectors. Reducing the diameter of the fiber renders the detected signal more coherent and suppresses the influence of laser-mode artifacts⁵¹ as well as the adverse effects of fiber motion artifacts.^{49,52–54}

As LDPM technology matured, a diode laser replaced the He-Ne laser as the light source, ^{55,56} making a range of wavelengths available. The most commonly used wavelength today (780 nm), offers a deeper penetration as well as reduced dependence on skin color and is also close to the isobestic points, thus eliminating dependence on oxygen saturation.²³ In order to avoid beat notes in the Doppler signal caused by mode interference, the diode lasers need to be thermally stabilized.

In the signal processing unit, a high-pass filter with a cutoff frequency set to 20 Hz extracts the Doppler signal from the average photocurrent and pulse-synchronous light intensity fluctuations. This signal is amplified and normalized by the average photocurrent in order to make it independent of the light intensity. By using the algorithm derived in Equation 15.18 (with n = 1) an output signal that scales with perfusion can be implemented by calculating the instantaneous power after feeding the normalized Doppler signal through an ω -weighing filter. The upper bandwidth limit is generally set to a value between 3 and 23 kHz,²³ depending on the expected highest RBC velocity. This output signal can be fed to a recorder or a display for continuous tracking of the perfusion, or to a computer for further postprocessing analysis.^{57–59} In order to obtain an output signal that scales linearly with perfusion in tissues with an RBC concentration so high that the multiple generation of Doppler shifts cannot be neglected, a linearizer circuit may be utilized.⁶⁰ In this linearizer circuit, the output signal, implemented according to Equation 15.18 (n = 1) is multiplied by a compensation factor derived directly from the RBC concentration signal (Equation 15.18 with n = 0).

Double wavelength LDPM devices have been designed with the aim of penetrating different tissue depths and discriminating between superficial and global blood perfusion.⁶¹ Green laser light (543 nm) with a short penetration depth has been tested especially with regard to its ability to record nutritive blood flow selectively, but with negative results.⁶² Modulation of the average measurement depth can also be attained by widening the distance between the transmitting and receiving fiber,⁶³ but no clear indication has been obtained regarding whether this approach can discriminate between capillary and global tissue perfusion.⁶⁴ In order to suppress the adverse effect of the high spatial resolution of LDPM standard probes, integrating probes that record the average blood perfusion have been designed and tested with positive results.⁶⁵ The use of laser diodes integrated in the probe with photodetectors further eliminates the need for fiber optics and makes the device less sensitive to movement artifacts.⁶⁶

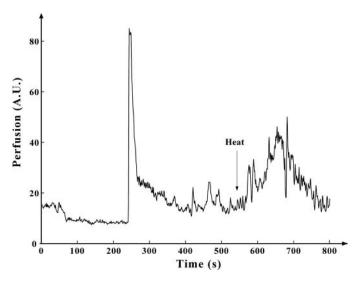

FIGURE 15.3 Forearm skin blood perfusion recorded with LDPM following occlusion (at t = 70 s), release of occlusion (at t = 240 s), and hyperemia caused by heating (starting at t = 550 s).

15.3.1.3 Recording Tissue Perfusion

In their present design, LDPM devices are generally better suited for measurements where the probe is attached to a fixed tissue position than for measurements at multiple sites with intermittent movement of the probe.⁴⁹ The reason for this constraint is that moving the probe from one skin site to another may disturb the microcirculation under study. A typical registration demonstrating (1) the influence of a temporary occlusion of forearm skin perfusion, (2) the resulting hyperemic response following release of the occlusion, and (3) the slow increase in perfusion instituted by heating the skin may serve as an example (Figure 15.3).

The recording in Figure 15.3 was performed in accordance with the following recommended protocol.³⁴ Prior to recording, the test subject refrains from smoking and from the intake of food and beverages for 2 h and rests in a relaxed position for at least 20 min. The preparations start with positioning the probe in a probe holder attached to the skin and by placing a pressure cuff around the upper arm. Initially, the resting perfusion is recorded for about a minute. When the pressure cuff is inflated to above systolic pressure, the perfusion value is reduced to a stable level representing "biological zero" — which does not generally coincide with the zero output level of the instrument.⁶⁷ The predominant contribution to biological zero has been demonstrated to be Brownian motion arising from interstitial tissue.⁶⁸ When the pressure in the cuff is again released, the perfusion rapidly and intermittently increases to a peak value above the resting perfusion level. This phenomenon, generally referred to as "reactive hyperemia," represents a rapid flow of blood into the fully dilated microvascular bed. The perfusion value then returns to preocclusion levels. A successive increase in skin perfusion is then recorded as the skin temperature increases.

In the interpretation of the results of this recording, the biological zero has generally been taken as the zero perfusion level^{69,70} from which the actual perfusion is calculated. Because the LDPM output signal is expressed in arbitrary units, it is generally better to present recorded alterations in blood perfusion as percentages of the resting value. In many situations, the latency time from the onset of stimuli to the appearance of the peak perfusion value may provide useful information.^{71,72}

15.3.2 Laser Doppler Perfusion Imaging

15.3.2.1 From Monitoring to Imaging

When repetitive recordings in adjacent sites on a tissue with seemingly homogenous perfusion are made, identical perfusion values are generally not recorded. By comparing biopsies with results obtained using

LDPM, Braverman and co-workers⁴ demonstrated that the heterogeneous skin perfusion pattern recorded by LDPM at adjacent sites coincides with the underlying microvascular architecture. High, pulsatile perfusion values were found directly over ascending arterioles, whereas low values correlated with areas containing only capillaries and postcapillary venules. Topographic maps generated by successively moving the LDPM probe in 1-mm steps further demonstrated that high-perfusion spots correlated well with the presence of arterioles and low-perfusion areas with avascular zones.⁷³ To visualize this spatial variability, tissue perfusion needs to be investigated by use of a multipoint LDPM system²⁷ or presented as a two-dimensional flow map,⁷⁴ rather than by a curve trace displaying temporal variations at a single site alone.

15.3.2.2 LDPI Devices

In LDPI two-dimensional mapping of tissue blood perfusion is performed by moving the laser beam in a raster scan over a predetermined area with no need for physical contact with the tissue (Figure 15.4). The light is guided from a low-power laser operating in the visible range to the tissue via a moving mirror system. A portion of the backscattered, Doppler-broadened light is brought back via the same mirror system to detectors placed in the proximity of the laser. This arrangement facilitates automatic focusing on and tracking of the laser spot as the beam moves over the tissue surface, thereby effectively suppressing the adverse effects of ambient stray light. Further rejection of ambient light is attained by utilizing a differential detector technology similar to that used in LDPM. In LDPI the laser and detector units are placed in a camera-like scanner head positioned 0.1 to 1 m above the tissue surface.

Two fundamentally different LDPI systems — one that utilizes a stepwise scanning beam, 28,30 and one that is based on a continuously moving beam 29 — have been presented in the literature. In stepwise scanning LDPI, the beam is stopped at each measurement site while the backscattered, Doppler-broadened light is sampled. This arrangement avoids the interference caused by a laser beam moving in relation to the tissue, which may generate Doppler components not related to tissue perfusion. The exact duration of the beam stop is determined by the trade-off between image integrity and maximum permissible time for capturing the image. If the beam is arrested for 50 ms at each measurement site, a full-format image, including 64×64 measurement sites, is generally captured in about 4 min (Figure 15.5).

In the LDPI system based on a continuously moving beam, the backscattered Doppler-broadened light is captured "on the fly." This method allows more points to be sampled per unit time, and a full-format image may typically include 256×256 true measurement sites. The relative motion between the laser beam and the tissue when the backscattered light is sampled may, however, result in the generation of nonperfusion-related Doppler components and other intensity fluctuations in the backscattered light.²⁹ Those Doppler components are generally of low frequency, and their adverse influence on the perfusion

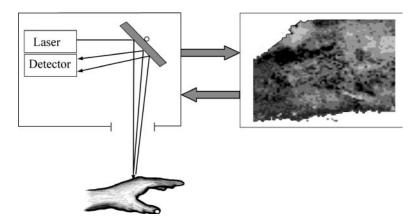

FIGURE 15.4 Operating principle of LDPI. The laser beam moves stepwise or continuously in a raster scan over the tissue by moving the mirror. A portion of the backscattered light is brought back via the same mirror to impinge on the surface of a photodetector.

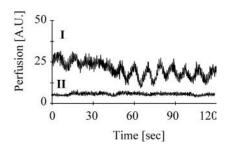

FIGURE 15.5 Perfusion image of fingertip with continuous recordings made at two single skin areas. The continuous recordings each comprise the average perfusion value recorded in four adjacent sites. (From Wårdell, K., *Proc. 10th Nordic-Baltic Conf. Biomed. Eng.*, 271, June 9–13, 1996. With permission).

signal can be reduced by increasing the lower cutoff frequency of the instrument bandwidth or by reducing the scanning speed. Increasing the lower cutoff frequency, however, also tends to reject the low-frequency Doppler components of the blood perfusion–related signal;⁷⁵ increased scanning speed distorts the image⁷⁶ and reduced scanning speed prolongs the image capturing process.

In contrast to the situation in LDPM, with the use of LDPI devices the number of coherence areas and thus the inherent amplification factor change as the distance between the detector and object is altered. This difficulty has been overcome by introducing as a light source a slightly divergent laser beam maintaining a fixed solid angle under which the laser spot on the tissue is seen from the detector, thereby keeping the number of coherence areas constant, according to Equation 15.4.³⁰ It has been demonstrated empirically that the distance-dependent amplification factor of LDPI systems utilizing a collimated beam can also be reduced by using an algorithm that normalizes the perfusion signal with the light intensity raised to the power of β , where β is close to unity (rather than 2, as suggested by Equation 15.15).

LDPI systems utilize a signal processor similar to that in LDPM and can generate full-format images of objects from the size of a fingertip to a complete torso. The intensity of the backscattered light can be used for discriminating the object from its background. Therefore, whenever possible the object should be placed on a light-absorbing background to facilitate this discrimination process.

In LDPI, all parameters controlling image size, resolution, scanning speed, background threshold, etc. are set in the system software. The image can generally be displayed in an individual color scale, in which the lowest and highest perfusion values constitute the endpoints of the scale. This option is probably the best choice for color representation if only the relative variation in perfusion within a single image is to be investigated. If several images are to be compared, they must be set to the same color scale before a comparison is made. Basic image-processing routines are available in the LDPI system software packages and the images can readily be exported to more sophisticated packages for further analysis as needed.

15.3.2.3 Monitoring Mode

One important feature of LDPI is the capability of operating the system in a monitoring mode. In this mode a small image comprising (for example) 4×4 measurement sites is continuously updated, and the result can be displayed as a series of mini-images or as a time trace continuously displaying the average perfusion. This feature makes the system less dependent on the exact measurement site than single-point LDPM.⁷⁷

15.3.2.4 High-Resolution LDPI

Lateral resolution of standard LDPI is limited by the effective diameter of the laser beam (approximately 0.6 to 0.8 mm) and by the step-length in the stepwise scanning LDPI. By keeping the distance between the scanner head and the tissue constant, focusing the laser beam onto one spot on the tissue surface, and reducing the step-length, the resolution can be significantly increased and full-format images of tissue sites less than 1 cm² generated.⁷⁸ This arrangement also reduces the solid angle under which the

laser spot is seen on the tissue surface, thereby increasing the average size of a coherence area on the detector surface and the inherent system amplification factor.

15.3.2.5 Recording an Image

In addition to the procedure recommended when using LDPM, the following precautions should be noted when recording a perfusion image by LDPI. The subject needs to be placed in a comfortable and relaxing position during image recording in order to avoid unintentional influence on microcirculation. If the subject moves during image recording, the image will have isolated horizontal stripes, indicating a movement artifact. Likewise, temporal fluctuations on a timescale shorter than the image recording time will result in the appearance of horizontal perfusion stripes in the image with no correspondence in the microvascular architecture. A liquid film on the skin surface may cause direct reflections of the laser light to the detector at a single spot, mimicking a (falsely) reduced tissue perfusion.

15.3.3 Performance Check and Calibration

The algorithm for LDF devices based on ω -weighting filtering of the power spectral density of the unnormalized Doppler signal was derived under assumptions that are not necessarily fulfilled in *in vitro* and *in vivo* situations. Therefore, both flow simulators, with separate controls for the speed and concentration of RBCs or other scatterers, and *in vivo* models have been used in the evaluation of the processor algorithm.

Most flow simulator experiments demonstrate that a linear relationship between RBC speed and LDF output signal can be obtained, provided compatibility with the instrument bandwidth^{21,54} is maintained. In the evaluation of the bandwidth requirements, however, it must be borne in mind that the size of the moving scatterer substantially influences the scattering angle distribution and thus the Doppler shift generated for a given speed according to Equations 15.3 and 15.16. For low and moderate RBC concentration, the probability for multiple Doppler shift generation and homodyne mixing is low. This implies that the LDF output signal also scales linearly with RBC concentration.²¹ Recently, a novel flow simulator based on rotating disks with embedded scatterers has been constructed⁷⁹ and used to assess the influence of optical properties and separation of the transmitting and receiving fiber on measurement depth.⁸⁰

In vivo calibration involves comparison of results obtained by LDF devices and other methods for assessment of the microvascular perfusion. Since no "gold standard" for recording tissue blood perfusion exists, the correlation of LDF data and reference method data is highly dependent on whether the two methods sample the same microvascular compartment and the degree of noninvasiveness of the reference method. Moving the LDPM probe from one position to an adjacent site while the global flow through an organ is used as the independent reference generally reveals a linear relationship with global flow at each site, albeit with a difference in scale factors caused by the heterogeneity of the tissue perfusion. One of the most promising animal models for evaluation of LDPM performance is the feline intestine because of its uniform and easily controlled blood perfusion. In this model, a specific segment of the intestine is drained through a single vein, the blood flow of which can be accurately determined by a drop-counting technique. A linear relationship between LDPM output signal and intestinal blood perfusion has been demonstrated within the range from zero to 300 ml g⁻¹.

Because the processing algorithm of LDPI is identical to that of LDPM, it is expected and has been demonstrated²¹ that results similar to those for LDPM are obtained when using LDPI. In addition to those performance tests, the uniformity in sensitivity over the entire image plane and the dependence on the distance between the scanner head and tissue also need to be controlled.

The day-to-day sensitivity of LDPM instruments, including the probe, is checked by placing the probe tip in a suspension of latex spheres in random motion.⁴⁹ The well-defined mobility pattern of such particles should result in a stable and reproducible output signal. By use of those "motility standards" two LDPM devices with identical specifications can be calibrated to the same sensitivity. A new calibration standard that includes latex spheres undergoing Brownian motion while diffusing through a porous polyethylene material has proven to give Doppler spectra closely resembling those obtained from human skin.⁸⁴ In LDPI the day-to-day calibration procedure can, in accordance with the procedure used in

LDPM, be made by way of a two-point calibration method based on a calibration box incorporating a transparent container with "motility standard" and a white surface "zero-reference," giving the high and zero calibration points, respectively.³⁵

15.4 Applications

15.4.1 LDPM Applications

Because of the ease of use of LDPM, experimental investigations and clinical trials aiming at evaluating the method's practical usefulness have been undertaken on many organs and in a variety of disciplines. The most commonly investigated organs include the kidney,^{85,86} the liver,^{87,88} the intestines,^{89,90} the brain,^{91–93} and the skin.^{19,94–99} By use of needle probes, the perfusion can furthermore be continuously monitored with minimal tissue trauma, for example, in skeletal muscle and tendons^{47,48,100} and bone tissue.^{101–107} Among the clinical applications, evaluation of the tissue perfusion in association with Raynaud's phenomenon,^{108–110} diabetes microangiopathy,^{111–115} plastic surgery and flap monitoring,^{116–120} peripheral vascular disease,^{71,72,121–124} thermal injury,^{125–127} bowel ischemia and gastric blood perfusion,^{128–132} pharmacological trials,^{133,134} and numerous skin diseases^{135–137} are most frequently represented in the literature. A thorough overview of many of those applications can be found in a review paper,²⁵ in two books on laser Doppler flowmetry, ^{24,26} and in the reference lists of the LDPM manufacturers.^{138,139}

15.4.2 LDPI Applications

Following the introduction of LDPI in the early 1990s, this emerging technology was soon evaluated in numerous applications in which the spatial heterogeneity of tissue perfusion is significant.

In irritant^{140,141} and allergy^{142–144} patch testing, perfusion images visualize and quantify the erythema produced by a compound applied topically to the skin. The LDPI technology produces data that are well in accordance with visual scoring, in the assessment of skin irritation¹⁴⁵ and allergy.¹⁴² It is therefore possible to grade irritation and type irritant reactions for individual compounds. In allergy patch testing, the optimal dose, influence of the vehicle, and the application and reaction time for different allergens can be readily detected and quantified.

Malignant skin tumors are highly vascularized compared to benign lesions; LDPI has been used to characterize the perfusion pattern of lesions such as basal cell carcinoma, ¹⁴⁶ malignant melanomas, and nevi. ¹⁴⁷ Furthermore, LDPI has been used in the assessment of basal cell carcinoma perfusion in conjunction with cryotherapy and photodynamic therapy. ¹⁴⁸ This report suggests that LDPI can be used, not only to follow up on the healing process, but also to find recurrent or residual tumor growth.

LDPI has further been used to assess the depth and the healing process of burns^{149,150} and a recommendation has been issued to include LDPI as a clinical tool in the evaluation of severely burned patients.³³ Characterization of perfusion in leg ulcers in combination with capillary microscopy has been performed by Gschwandtner and co-workers,^{32,151,152} while perfusion in and around pressure sores was investigated by Mayrovitz.^{153–156}

Other studies and applications of LDPI include assessment of diabetes neuropathy following contralateral cooling, ¹⁵⁷ endothelial cell malfunction investigated by iontophoresis infusion of acethylcholine and nitroprusside in diabetes ¹⁵⁸ and Alzheimer's disease, ¹⁵⁹ angiogenesis and growth factor research, ^{160,161} psoriasis, ^{162,163} scleroderma, ¹⁶⁴ and Raynaud's disease, ¹⁶⁵ as well as flap surveillance, ¹⁶⁶ microdialysis, ¹⁶⁷ and phototesting. ¹⁶⁸

15.5 Conclusions

This chapter has covered the history and development of LDF, the theoretical background of this technology, its realization in versatile devices such as the laser Doppler perfusion monitor and imager and

associated applications. Although it is a relatively recent medical technology, many reports on its use, especially in research applications, are already available in the scientific literature. The much slower introduction of the technology in clinical routines is probably because tissue perfusion is poorly predictable at any given tissue site and time. Furthermore, the natural variability of tissue perfusion in terms of temporal fluctuations and spatial heterogeneity makes it difficult to define any rules of thumb for normal conditions. Instead, stimuli–response experiments need to be applied in order to challenge the tissue and reveal possible malfunctioning of the minute vessels of the vascular tree. The main advantages and disadvantages of LDF are listed below.

Advantages:

- LDF makes possible noninvasive recording and imaging of tissue perfusion with minimal impact on microcirculation.
- · LDF devices are easy to use.
- Continuous recordings over unlimited periods of time can be made with LDPM.
- Two-dimensional perfusion maps can be visualized by LDPI.
- · The theoretical basis of LDF is well established.

Disadvantages:

- No absolute calibration is possible, and results obtained from different organs cannot be directly
 compared because of variations in photon path lengths due to the different optical properties of
 the tissue.
- Results obtained by recording at a single site using LDPM may not be representative for the entire tissue.
- LDF does not distinguish between nutritive (capillary) perfusion and global tissue perfusion.
- LDPI assumes steady-state conditions in perfusion during the image-capturing period, which may amount to 4 min or longer.

One of the main features of LDF in monitoring and imaging is that time traces and images can easily be recorded, while the interpretation of the results implies a thorough understanding of microcirculation and its regulation.

Overview

Thin *ex vivo* biological specimens, such as single cells and tissue slices, are widely used in biology and medicine. Optical microscopic imaging and spectroscopic techniques are ideal tools for probing the composition of these specimens nondestructively and with minimal sample preparation and handling. This chapter focuses on elastic scattering as one of these optically based analytical techniques. Unlike most turbid tissues analyzed *in vivo*, light scattering in these relatively thin *ex vivo* specimens is dominated by single scattering. Here, we describe the methods currently used to collect and interpret elastic scattering data from thin biological specimens, and biomedical applications in this field.

16.1 Introduction

The optical analysis of single cells or thin biological specimens, such as cells and tissue slices, plays an important role in many clinical and biological diagnostic studies, including the evaluation of diagnostic biopsies and the examination of live tissue metabolism in real time. Several optical techniques are available to study *ex vivo* biological specimens and serve as probes of human disease and biological function. These

include microscopic imaging techniques and spectroscopy. Diagnostic tests based on fluorescent labels of cellular metabolism as well as intrinsic fluorescence, elastic scattering, and Raman scattering from natural biomolecules have all been described. Typically, fluorescence and Raman scattering techniques are used to identify or localize specific biochemical entities. However, an important aspect of tissue diagnosis is based on assessing cellular and subcellular morphology. The morphological analysis of cells and subcellular organelles is the primary objective of biomedical optical techniques based on elastic light scattering.

Alterations in tissue morphology and composition will result in detectable changes in the way light is transmitted, refracted, diffracted, or reflected from a given tissue specimen. Experimental measurements, such as light scatter intensity and its angular dependence, can be used to infer changes in size and shape or refractive index of the specimen under study. Biological analysis methods based on elastic light scattering include microscopic imaging techniques, such as dark field, phase contrast, or differential interference contrast, as well as quantitative spectroscopic methods, in which the sample is not visualized. In phase contrast and differential interference contrast microscopy, variations in the refractive index of the tissue are utilized to optically manipulate the scattered wavefronts and produce a high-resolution image of the biological specimen under study. These types of microscopic images are widely used, for example, to visualize the morphology of the cells in culture or track cell movement. In these cases, morphological analysis of the tissue stems from direct observation by the user.

On the other hand, spectroscopy-based techniques find their way into applications that require automated quantification of cellular and subcellular morphology, without visualization of the specimen by a qualified technician. Such techniques are very useful in cell and tissue screening procedures in clinical and biological studies. Emerging techniques that combine imaging and spectroscopy are also increasingly utilized to localize the scatter information within a tissue slice or a monolayer of cells.

The constituent parts of cells and biological tissue, such as organelles or connective tissue fibers, are often at the limit of the resolution of optical microscopes. Alterations in organelle or subtissue morphology can be important indicators of underlying biochemical activity in living cells. While these changes could be quantified by electron microscopy in fixed tissue, greater insight about a biological process can be gained from minimally invasive techniques that require minimal sample preparation and are suited for live tissue monitoring. Quantitative light scattering techniques are an ideal tool to address this problem and complement the existing microscopic techniques. They are noninvasive and sensitive to changes in the dimension and optical properties of particles with size on the order of the wavelength.

Light scatter measurements have had a significant impact in medicine and biology. Applications in flow cytometry include cell identification and differential blood cell count^{1–5} and human and bacterial cell response to various agents.^{6–9} In static suspensions, light scattering has been used to monitor platelet aggregation,^{10–12} the mitochondrial permeability transition,^{13–16} and the optical properties of normal and tumor cells for future tissue diagnosis.^{17,18} Optical analysis of thin biological specimens may involve monolayers of cells in culture and tissue slices. These *ex vivo* experimental models are used extensively to study important biological processes, and are crucial to advancing our understanding of biological processes at the cellular and molecular level in a controlled laboratory environment. As we will see, numerous applications of quantitative light scattering exist for the analysis of cells, organelles, and tissue slices. These biological specimens are usually thin enough to be dominated by single scattering, as opposed to studies of turbid whole tissue samples, where multiple scattering prevails.

The use of light scattering techniques to analyze thin biological specimens is the subject of this chapter. In particular, this chapter focuses on applications of quantitative light scattering, where a specific light scattering parameter is measured, such as intensity of the scattered light, or angular dependence of the scattered light. Methods for data acquisition and interpretation are discussed, as well as ongoing work in this field.

16.2 Brief Theoretical Overview

A very brief overview of the light scattering problem is given here. The general treatment of light scattering by a single particle can be found in Van de Hulst¹⁹ and Bohren and Huffman.²⁰

16.2.1 General Formulation of Scattering by a Single Particle

The biological samples considered in this chapter will contain many scattering particles; however, the samples studied will be sufficiently thin to safely assume single scattering. This condition may be satisfied if $e^{-\mu_s z} \ll 1$, where μ_s is the tissue scattering coefficient and z is the sample thickness. μ_s is a function of wavelength, and $1/\mu_s$ represents the mean free path of the light before a scattering event occurs. Values of μ_s have been tabulated in the literature.²¹ For example, μ_s is on the order of 100 cm⁻¹ at 780 nm for biological tissue.²² When single particle scattering is considered, the following conditions ensue.

- · Multiple scattering will be neglected.
- · Each scatterer within the tissue will be exposed only to the radiation of the original incident beam.
- · Light scattered from one particle will not be subjected to further scatter by another particle.

Thus, when only a single scattering event is considered for each particle making up the tissue, the total amount of scatter intensity by N particles will be equal to the sum of the individual scatter intensities by each of the N particles. If the particles in the sample are of varying size, the number density distribution of the particles may be taken into account. A case commonly considered is a distribution of spherical particles with different radii, a, in which

$$N = \int_{0}^{\infty} N(a) da.$$

The geometry of the scattering problem for an arbitrary scatterer is shown in Figure 16.1A. Given a particle of a given size and refractive index, m, relative to the surrounding medium, and given a plane wave of intensity I_o and wavelength λ , incident on this particle, then the far-field scattered wave will be

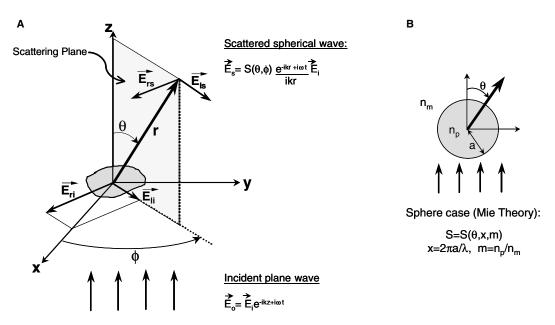

FIGURE 16.1 Relationship between incident and scattered fields. (A) The scattered field by an arbitrary scatterer is related to the incident field by a complex amplitude function, S, which depends on scattering angles, θ and ϕ , the geometry of the scatterer, and the refractive index of the scatterer compared to the surrounding medium. (B) For a sphere with symmetry around ϕ , S is a function of θ , x, and m, where x is a normalized size parameter equal to the ratio of the sphere circumference to the wavelength of the light, $x = 2\pi a/\lambda$, and m is the ratio of the sphere's refractive index to the medium's refractive index, $m = n_p/n_m$.

a spherical wave originating at the particle. The intensity of the scattered wave, I_s , at any distance, r, in the far field can be written as $I_s = I_o F(\theta, \phi)/k^2 r^2$, where the scattering direction is defined by the angles θ and ϕ , and k is the wave number with $k = 2\pi/\lambda$. The angle θ is the angle between the incident direction and the scattered direction and ϕ is the azimuthal angle of scatter. The scattering cross section of the particle is defined as

$$C_{sca} = \frac{1}{k^2} \int F(\theta, \phi) d\omega$$

where $d\omega$ is a solid angle differential element with $d\omega = sin\theta d\theta d\phi$. The function $F/(C_{sca}k^2)$ is the nondimensional phase function, whose integral over solid angle is equal to 1.

Solving the scattering problem typically consists of solving for $F(\theta,\phi)$, which can therefore be used to calculate the scattered light intensity in all directions. Solving for $F(\theta,\phi)$ involves solving for the electromagnetic field everywhere in space. Maxwell's equations are solved to calculate the electromagnetic fields inside the particle and in the medium outside the particle. The field outside the particle will be a superposition of the incident field and the field scattered by the particle. The boundary conditions at the particle/medium interface require that the tangential components of the electric and magnetic field be continuous to satisfy conservation of energy at the interface. The problem is then reformulated in terms of electric fields, where the scattered field, E_s , is related to the incident field E_i by a complex amplitude function, $S(\theta,\phi)$. The function S may be represented as a matrix, such that

$$\begin{pmatrix}
E_{ls} \\
E_{rs}
\end{pmatrix} = \begin{pmatrix}
S_2 & S_3 \\
S_4 & S_1
\end{pmatrix} \cdot \frac{e^{-ikr + ikz}}{ikr} \begin{pmatrix}
E_{li} \\
E_{ri}
\end{pmatrix}$$
(16.1)

where

$$S = \begin{pmatrix} S_2(\theta, \phi) & S_3(\theta, \phi) \\ S_4(\theta, \phi) & S_1(\theta, \phi) \end{pmatrix}.$$

The elements of the matrix S in Equation 16.1 are complex numbers having amplitude and phase and are functions of θ and ϕ . The subscripts i and s denote the incident and scattered components, respectively. The subscripts l and r denote parallel and perpendicular polarization of the E fields, respectively. The parallel and perpendicular directions are defined with respect to the scattering plane defined by the incident and scattering directions (Figure 16.1A). The function F (discussed earlier), and which defines the *intensity* relationship between the incident and scattered light, can be directly deduced from the relationship between the incident and scattered fields given by the matrix S. For light of arbitrary polarization it is common to rewrite Equation 16.1 as

$$\begin{bmatrix} I_{s} \\ Q_{s} \\ U_{s} \\ V_{s} \end{bmatrix} = \frac{1}{k^{2}r^{2}} \begin{bmatrix} S_{11} S_{12} S_{13} S_{14} \\ S_{21} S_{22} S_{23} S_{24} \\ S_{31} S_{32} S_{33} S_{34} \\ S_{41} S_{42} S_{43} S_{44} \\ V_{s} \end{bmatrix} \begin{bmatrix} I_{i} \\ Q_{i} \\ U_{i} \\ V_{s} \end{bmatrix}$$
(16.2)

I, Q, U, and V are the Stokes parameters, which can be given in terms of the electric field components as

$$I = E_{l}E_{l}^{*} + E_{r}E_{r}^{*},$$

$$Q = E_{l}E_{l}^{*} - E_{r}E_{r}^{*},$$

$$U = E_{l}E_{r}^{*} + E_{r}E_{l}^{*},$$

$$V = i(E_{l}E_{r}^{*} - E_{r}E_{l}^{*}).$$

The asterisk indicates the complex conjugate and the parameter I represents the intensity of the light. In this notation, unpolarized (or natural light) is represented by the Stokes vector (1,0,0,0). The matrix in Equation 16.2 is known as the Mueller matrix. For an explanation of the explicit relationship between the elements of the Mueller scattering matrix and those of the matrix S in Equation 16.1 see Reference 20 (p. 65). Also note that the 16 elements of the scattering Mueller matrix are not all independent. Only seven of them are independent, corresponding to the magnitudes of the S_1 , S_2 , S_3 , and S_4 of Equation 16.1, and the three possible independent phase differences between these S_1 .

16.2.2 Common Approximations to Solve for the Scattered Field of Biological Particles

The matrix S in Equation 16.1 is a general expression that describes light scattering by a single scatterer. To predict the scattered field, the matrix elements of S need to be determined. In general, these are complex numbers with magnitude and phase dependent on Θ and Φ , as well as the dimensions of the particle, the wavelength of light, and the refractive index ratio $m = n_p/n_m$, between the particle (index n_p) and the surrounding medium (index n_m). The elements of S are rarely solved analytically in the general case of a scatterer with arbitrary shape and refractive index. Depending on the biological system at hand, an approximation is usually made to simplify the problem. Commonly used approximations are discussed below.

16.2.2.1 Rayleigh-Gans Theory for Scattering Particles with Refractive Index Ratio Close to 1

Qualitatively, a scattering particle may be viewed as composed of different microscopic regions. An oscillating dipole moment is induced by the applied incident electric field in each of these microscopic regions. In turn, these driven dipoles scatter radiations in all directions. Thus the scattered wave originating from the particle is the sum of all the dipole radiations. The angular intensity dependence of the scattered wave will therefore depend on the phase relationships between the radiated waves and the separations between the particle dipoles relative to the incident wavelength. If the particle is very small compared to the wavelength, it may be approximated by a single dipole, and one can use Rayleigh's theory of scattering. In this case the elements of the matrix S in Equation 16.1 are $S_3 = S_4 = 0$, $S_1 = ik^3\alpha$, and $S_2 = ik^3\alpha\cos\theta$. α is the polarizability of the particle, and k is the wavenumber $2\pi/\lambda$. For a sphere with radius r and refractive index ratio, m, $\alpha = r^3(m^2 - 1)/(m^2 + 2)$, and for a homogeneous particle with refractive index ratio close to 1, $\alpha = (m^2 - 1)(V/4\pi)$, where V is the particle's volume (see Chapter 6 of Reference 19).

To satisfy the Rayleigh approximation, $|m|ka \ll 1$, where a is a lengthscale on the order of the size of the particle. A similar situation arises if the refractive index ratio, m, is close to one, such that $|m-1| \ll 1$, and $2ka|m-1| \ll 1$. These two latter conditions imply that the field inside the particle is close to the incident field, and that the particle may be assumed to be composed of volume elements dV that are subjected to the same incident field. Thus, instead of assuming that the particle is a single dipole, the particle is now composed of independently scattering dipoles corresponding to the different volume elements. These dipoles are therefore driven by the same applied field, and the scattered wave is the sum of the waves scattered by these dipoles. In this case, $S_3 = S_4 = 0$, as for Rayleigh scattering, and:

$$S_{1} = \frac{ik^{3}(m-1)}{2\pi} VR(\theta, \phi)$$

$$S_{2} = \frac{ik^{3}(m-1)}{2\pi} VR(\theta, \phi)\cos\theta$$
with $R(\theta, \phi) = \frac{1}{V} \int e^{i\delta} dV$ (16.3)

The phase δ in Equation 16.3 refers to the phase of the scattered waves with respect to a common origin in the reference coordinate system. After reformulating δ in terms of the problem's geometry, R can then be integrated for a given particle shape. Calculations of R for spheres, ellipsoids, and cylinders are discussed in Reference 19 (Chapter 7) and Reference 20 (Chapter 6). The treatment of scattering resulting in Equation 16.3 is referred to as the Rayleigh-Gans, or Rayleigh-Debye-Gans, theory.

Because the refractive index of biological organelles, such as mitochondria, is typically close to that of the surrounding medium, ^{23,24} various light scattering studies based on Rayleigh-Gans theory can be found in the literature. These include studies of scattering by bacteria, ^{24,25} macromolecules, ^{26,27} or nucleated lymphocytes. ²⁸ Moreover, if the size and refractive index of the scattering particles satisfy the Rayleigh-Gans conditions, light scattering by a three-dimensional scattering object may be approximated as Fraunhofer diffraction by a two-dimensional aperture function. ²⁹ This diffraction-based approach allows the Fourier optical treatment of diffraction and can be used to extract cellular geometric parameters from the diffraction pattern of biological cells. ^{30,31}

16.2.2.2 Mie Theory for Spherical Particles of Arbitrary Size and Index

For a sphere with symmetry around ϕ (Figure 16.1B), S may be re-expressed as a function of θ , x, and m, where θ is the angle of scatter, x is a dimensionless size parameter equal to the ratio of the sphere circumference to the wavelength, $x = 2\pi a/\lambda$, a = particle radius, and $\lambda = \text{wavelength}$; $m = n_p/n_m$ is the ratio of the particle's refractive index, n_p , to the surrounding medium's refractive index, n_m . The analytical solution for spheres was given by Mie in 1908, and can be found in Chapter 9 of Reference 19 or Chapter 4 of Reference 20. For a sphere, S_3 and S_4 are 0 in Equation 16.1, while S_1 and S_2 can be expressed as infinite sums that can be calculated on a computer. Fortran computing routines to solve for the angular scattering function for a homogeneous or coated sphere can be found in Reference 20. Graaff et al. Present a simple numerical approximation of Mie scattering for 5 < x < 50, and 1 < m < 1.1. Combined with a model of light propagation in a microscope with high numerical aperture, Mie theory was also used successfully to predict high-resolution images of spheres.

The existence of an analytical solution for the case of a spherical scatterer has prompted many to approximate biological particles as spheres as a first-order approach to understanding light scatter from cells and tissues. Despite the complicated morphologies of biological particles, studies have been successful in utilizing Mie theory to model the angular scattering response of bulk biological tissue. For example, the angular scattering functions of brain and muscle were successfully predicted by use of Mie theory and assuming that the tissue is composed of spheres with sizes distributed according to a skewed logarithmic function. ³⁴ Similarly, a model based on Mie theory was able to approximate reflectance spectra of colon tissue adequately. ³⁵

16.2.3 Solving the Scattering Problem for a Scatterer of Arbitrary Shape and Index

Although biological particles are close to spherical in some cases, such as when considering the nuclei of certain cells, in general this assumption is not necessarily warranted, especially when considering mitochondria, which appear rather filamentous *in situ*, or when considering neuronal dendritic structures or scattering collagen and elastin fibers in connective tissue. Thus when considering these tissue components individually, light scattering studies should take into account their potential nonspherical and sometime complicated geometries. Moreover, some tissue components, such as lipids, collagen, or melanin, have refractive index ratio m > 1. Mumerical approaches to solving the problem of scattering by particles of arbitrary shape and refractive index have been gradually emerging in applications of light scatter to biological systems. Two popular approaches for the study of nonspherical biological particles are the transition matrix (T-matrix) method originally developed by Waterman, 38,39 and the finite-difference time-domain (FDTD) technique originally proposed by Yee. With recent advances in computer hardware, numerical computations of angular scatter intensities can now be achieved on a personal computer. Details on the T-matrix method with accompanying software can be found in Barber and

Hill.⁴¹ The T-matrix and FDTD methods are also discussed in detail with relevant references in Mishchenko et al.⁴²

In the T-matrix method, the incident and scattered field are expanded into vector spherical wave functions. Due to the linearity of Maxwell's equations, the incident and scattered field can be related by means of a transition matrix (the T-matrix), which depends solely on the particle geometry and refractive index. Solving for the elements of the T-matrix allows prediction of the scattered field. For example, the T-matrix method was used to study light scattering by red blood cells.⁴³ On the other hand, the FDTD technique is based on the discretization of Maxwell's curl equations in time and space. Numerical calculation of the electric field as a function of time near the scattering particle is computed after applying the appropriate boundary conditions at the edges of each grid element in space. The near-field values thus computed are then transformed to yield the scattered far field. At present, the FDTD technique has been used to predict scattering by inhomogeneous cell models composed of a spherical nucleus and of ellipsoidal organelles.^{17,37} By using an incident time-limited pulse instead of an incident monochromatic plane wave, the frequency response of the scattered far-field response can be calculated. The pulsed FDTD approach was implemented to predict the angular scattering response of two-dimensional models of inhomogeneous cells as a function of wavelength.⁴⁴

16.3 Scatter Data Interpretation

Typically, changes in light scatter result from changes in the scattering particle's size, shape, refractive index, and concentration. Changes in these parameters may accompany important biochemical events in organelles, cells, and tissues, and thus serve as diagnostic markers. If the particles that will change have already been identified, it may be feasible to predict the scattering behavior of these particles by utilizing the theoretical approaches described in Section 16.2. Combining the scatter measurements with the expected theoretical predictions will then serve to quantify the cellular or tissue events under study. In this case the light scattering methods can be utilized to optically track known variations in cell or tissue substructure. The light scatter technique can serve to sort the data, for example, or to automate a well understood diagnostic process.

Light scattering can also be used to probe tissue dynamics in which the scattering sources have not yet been identified. Interpreting the scatter data from such measurements can be particularly complicated however, because one must solve the "inverse problem" consisting of extracting hitherto unknown tissue properties from the available scatter data. Typically, biological systems are inhomogeneous, and contain particles of various geometries and optical properties, all of which could potentially result in the observed light scatter changes. As seen in the previous section, the dependence of scatter intensity on angle of scatter is complicated. Thus, in order to extract an absolute optical or morphological parameter, extensive angular scatter data may need to be gathered such that sufficient measurements are available to fully characterize the angular scatter and cross-section properties of the tissue under study.

Such extensive data are rarely available experimentally, and theoretical prediction about the scatterers is often limited by the set of measurements at hand. In most cases, to identify and characterize the possible sources of the tissue scatter, including organelles and other substructures, the biological system must be approximated by a model that can be easily plugged into the theoretical frameworks available. For example, the particles within the biological specimen are often assumed to be spherical or randomly oriented. Although such simplifying assumptions are necessary to begin analyzing a given scatter problem, such assumptions restrict data interpretation. Refining the initial simplifying assumptions will often prove necessary to ensure that the model is adequately taking into account the important variables in a given biological situation. In light of the difficulty of specifically identifying the sources of scatter change in a given tissue, light scattering techniques are best used in conjunction with other methods. For example, light scatter can be used to detect and localize possible morphological changes, while additional biochemical manipulation can be used to modulate scatter changes and help identify the molecules or tissue components leading to the observed change.

16.4 Methods and Applications of Light Scatter Measurements to the Study of Cells, Organelles, and Tissue Slices

As we saw briefly in Section 16.2, the amount of light scattered from a given particle typically depends on its size compared to the incident wavelength, and on the ratio of its refractive index compared to the surrounding medium. In general, the larger the particle and its refractive index ratio are, the larger the amount of scatter it will produce. Moreover, the shape and size of the particle will also affect the angular dependence of the scattered light. Thus, light scattered sideways as a fraction of the total light scattered will be larger for small spheres than for larger ones. Several techniques have been used to track such changes in the light scattering properties of biological samples. These techniques typically consist of measuring the angular scattering properties of a given sample. For example, changes in angular scatter as a function of sample composition or experimental condition can be monitored to deduce the size, shape or index of the scatterers in each case. In some studies, the dependence of light scatter on incident wavelength or polarization is also taken into account.

Scatter intensities at multiple angles could be studied by collecting angular scatter intensity with the aid of a motorized goniometer. On the other hand, the pattern of diffraction by the sample could be analyzed utilizing Fourier optics to infer angular scatter. Quantitative transmission and reflection microscopy have also been used to generate images in which the scatter intensity signals are measured locally in different parts of the specimen. Representative examples of these scatter measurement methods and their applications are discussed in this section.

16.4.1 Light Scattering Spectroscopy of Cells and Organelles in Suspensions 16.4.1.1 Methods to Study Scattering by Particle Suspensions

Particle suspensions are usually probed spectroscopically without optically resolving the individual scatterers. Scatter intensities at multiple angles can be collected with a rotating goniometer and a single photodetector 17,18,45 (Figure 16.2A), or by many detectors positioned at different angles around the specimen 27 (Figure 16.2B). The cell or organelle suspensions are usually contained in a cuvette, or the particles may be flowed in single file through the optical analysis chamber of a flow cytometer (Figure 16.2C). Scatter intensities are plotted vs. angle around the specimen, and could then be compared to theoretical predictions. By varying the polarization of the incident light and analyzing the polarization of the scattered light (if polarizers are used in Figure 16.2A), additional elements of the scattering Mueller matrix (see Section 16.2.1) can be measured. Bohren and Huffman list all the possible relationships between the intensity of the scattered light at the different polarizations and the intensity of the polarized incident beam in terms of the Mueller matrix elements, S_{ij} (Table 13.1 in Reference 20).

16.4.1.2 Applications

16.4.1.2.1 Flow Cytometry

Light scattering spectroscopy has extensively been employed in cell analysis, such as flow cytometry, to probe intracellular morphology. In a flow cytometer, scattering near the forward direction and side scatter near 90° are typically collected. Although data at many angles are necessary to characterize the scatterers in the suspensions fully, limited measurements, such as the amount of near-forward scattered light and side-scattered light, can also provide very useful information. These two measurements of forward- and side-scatter can be used individually, or combined into a ratio to yield discriminating data that allow cell identification.

In clinical flow cytometry, cells flowing in a single file through an optical analysis chamber can be analyzed, sorted, and counted based on the ratio of forward- to side-scatter intensity. These cells may originate from a patient's blood or from a tissue biopsy. By sorting and counting the cells with specific forward-to-side scatter signatures, the status of a patient may be evaluated, and disease may be ruled in or out. For example, utilizing the elastic scattering properties of the different blood cells, human leukocytes may be sorted and counted.⁴⁷ Differentiation of leukocyte can also be improved by measuring

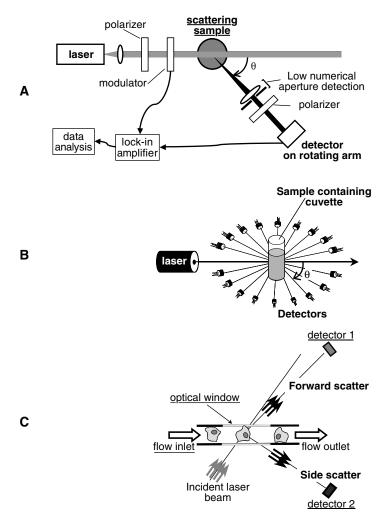

FIGURE 16.2 Schematics illustrating the principle behind experimental setups for collecting angular scatter from particle suspensions. (A) Scanning goniometer. Light scattered by the sample at a given scattering angle, θ , is collected by a low numerical aperture setup. The collection-detection setup is mounted on the arm of a rotating goniometer. The polarizers and modulator are optional. (B) Multidetector setup. Light scattered by the sample is collected as a function of scattering angle, θ , by several detectors placed around the sample. In contrast to the setup in (A), here the angular measurements are made simultaneously. (Adapted from Wyatt, P.J., *Anal. Chim. Acta*, 272, 1, 1993.) (C) Flow cytometry. The diagram shows cells flowing in single file through a flow cytometer channel, while the scattered light is collected through an optical window. Near-forward and near-90° scatter are typically collected.

changes in the amount of depolarization of the side-scattered light.⁴⁸ A discussion of light scattering as it applies to flow cytometry can be found in Salzman et al.² (See also Chapter 25 of this handbook.)

16.4.1.2.2 Angular Scatter Measurements of Isolated Mitochondria

Light scattering spectroscopy has been extensively used to study mitochondrial swelling and changes in mitochondrial matrix conformations. Although change in mitochondrial morphology could be assessed by electron microscopy, dynamic studies of *viable* mitochondria typically utilize light scattering to study this organelle, whose size is close to the optical resolution of microscopes. Light scattering is a simple and convenient method that is sensitive to changes in the size and shape of particles with dimensions on the order of the wavelength. Moreover, as an optical method, light scattering permits rapid detection

commensurate with the rates at which mitochondria are expected to change. The light scattering measurement may be carried out in a spectrophotometer with the mitochondria suspension contained in a regular cuvette or by flow cytometry. Studies on mitochondria isolated from tissue date back to the 1950s. Alterations in mitochondrial morphology measured by light scattering have been associated with mitochondrial metabolic state.^{49–56} Measurements of light transmission or angular light scattering at 90° from a suspension of isolated mitochondria have long been correlated with the morphology of mitochondria in the orthodox and condensed states.^{14,51,52,57} Since these early studies, light scattering has become the technique of choice to detect mitochondrial size change. Light scattering techniques have proved essential in studying the mitochondrial permeability transition.^{14–16,58–62}

The first scattering studies of mitochondria were interpreted by correlating the absorbance or 90° scatter intensity from the mitochondrial suspension with electron micrographs of the tested mitochondria. In most cases, mitochondrial scatter at 90° decreased as the number of mitochondria in the "aggregated" configuration decreased.¹⁴ This aggregated form was typically characterized by a shrunken, electron-dense matrix space with large intercristal space.⁵⁴ In addition, the absorbance and 90° scatter by mitochondrial suspensions were shown to decrease with increased mitochondrial swelling^{63,64} (Figure 16.3). More recently, this relationship between swelling and mitochondrial absorbance and 90° scatter was utilized in the detection of mitochondrial morphology change during apoptosis. These recent studies were conducted utilizing flow cytometry⁶⁵ and by measuring changes either in 90° scatter or absorbance by a suspension of isolated mitochondria in a spectrophotometer cell.⁶⁶⁻⁶⁹

Nonetheless, one should interpret single angle scatter, or absorbance measurements with great care. Under certain conditions the early scattering studies of mitochondrial scatter have provided good correlation between light absorbance, or 90° scatter intensity, and mitochondrial morphology; 14,63,64 however, these methods could present some shortcomings. The general relationship between transmitted light, or light scattered at one single angle, and particle volume is not always monotonic. 70,71 Moreover, changes in refractive index also contribute to the change in light scatter in addition to morphology change, thus confounding data interpretation. A study by Knight et al. 72 shows how changes in light scattered at 90° may not necessarily correlate with mitochondrial volume change and points at the difficulty in interpreting single angle scatter data. Thus, additional validation by means of electron microscopy, for example, will prove necessary to infer the particles' morphologic configurations correctly from absorbance or single angle scatter measurements.

16.4.1.2.3 Angular Scatter Measurements of Cellular Suspensions

With the recent applications of diffuse light scattering techniques to the diagnosis of tissue *in vivo* (see accompanying chapter on elastic scattering and diffuse reflectance), interest in studying the scattering properties of cells, organelles, and subtissue structure has increased. Scattering parameters can be used to define the morphological organization of biological tissue and to better understand the different sources of scatter that contribute to the bulk tissue signal. Scattering from cell suspensions was used to show that cells have a broad distribution of scatterer sizes. Significant cell scatter was shown to originate from particles between 0.2 and 1 µm; the small tissue particles are expected to contribute to wide angle scatter, while larger particles will contribute mainly to forward directed light scatter.¹⁸

Moreover, the nuclei angular scatter spectrum most closely resembled that of the whole cells (Figure 16.4). In this study Mourant et al. assumed that the cells comprise spherical scatterers and used Mie theory to analyze the angular scatter distributions. Further studies by the same group have shown that cell suspensions do not depolarize light significantly.⁷³ Angular scatter measurements of cell suspensions were also utilized as experimental validation in the construction of a cell model based on the FDTD technique¹⁷ (see Section 16.2.3). In contrast to the study by Mourant et al.,¹⁸ the cell model in this case does not assume a distribution of spherical scatters. Instead, the model considers a 15-µm diameter spherical cell containing a nucleus with subnuclear refractive index variations, and ellipsoidal organelles. In particular, such optical cell models were used to explain the effect of adding acetic acid to cells, suggesting that acetic acid increases the frequency of fluctuations in nuclear refractive index; acetic acid was also found to increase the amplitude of these index variations.

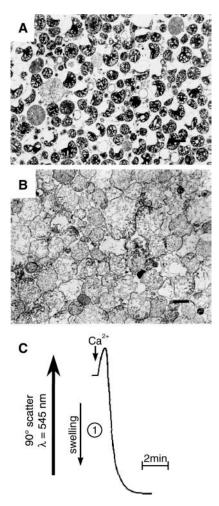

FIGURE 16.3 Electron microcrographs and absorbance measurements from mitochondrial suspensions subjected to calcium overload. (A) Isolated liver mitochondria suspended in calcium-free incubation medium. (B) The medium was supplemented with 150 μ M Ca²⁺. (C) The decrease in the measured 90° light scattering at 545 nm correlates with mitochondrial swelling upon addition of 150 μ M Ca²⁺ to the control medium. Bar = 1 μ m. (From Petronilli, V. et al., *J. Biol. Chem.*, 268, 1939, 1993. With permission.)

Acetic acid addition is very relevant to cancer diagnosis. Topical application of acetic acid to tissue is a very common method used by colposcopists to enhance contrast between normal and diseased regions of the cervical epithelium. Thus, by understanding how different conditions may change the optical scattering properties of the cells under study, cell modeling, together with scattering studies of cell suspensions, represents an important set of data, which will undoubtedly be helpful when optimizing and designing current and future optical diagnostic tools.

16.4.1.2.4 Angular Scatter Measurements of Bacteria, Macromolecules, and Vesicles

Scattering spectroscopy of cells and organelles has direct applications to understanding the scattering properties of biological tissues. It is important to note that the methods described here for collecting angular scatter data from particle suspensions may also have other biologically relevant applications. In particular, angular scatter has been used to identify bacteria.²⁵ The state of polarization of the light scattered by bacteria was also shown to be sensitive to very small changes in bacterial structure.⁴⁶ Angular

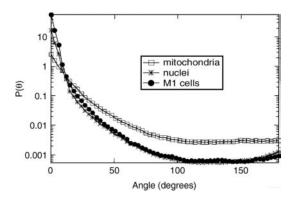

FIGURE 16.4 Normalized angular scatter intensity, $P(\theta)$, of fibroblast cells (M1 cells), isolated fibroblast nuclei, and isolated fibroblast mitochondria. Values below 9 and 168° were extrapolated. (From Mourant, J.R. et al., *Appl. Opt.*, 30, 3586, 1998. With permission.)

scattering was used to characterize the size of macromolecules in suspension.²⁷ In addition, in a system where angular scatter distributions were measured as a function of time, the dynamics of time varying systems were characterized. Thus, time-dependent angular scatter measurement was used to track the polymerization of microtubules as well as dynamic changes in the size of chromaffin granules subjected to osmotic stress.²⁶

16.4.2 Light Scattering Spectroscopy of Cellular Monolayers and Thin Tissue Slices

16.4.2.1 Methods for Collecting Angular Scatter Measurements by Diffraction

Another way to infer angular scatter is by analyzing the sample's diffraction pattern with Fourier optics. The principle behind this method is shown in Figure 16.5. In this setup, the sample is illuminated by a plane wave of light obtained by a collimated laser beam, for example. The light scattered by the sample is collected by a lens, whose numerical aperture will determine the highest angle of scatter that can be collected by the setup. As shown in Figure 16.5, the diffraction pattern of the sample is formed in the back focal plane, *F*, of the collection lens. Because the incident laser beam is collimated, the diffraction pattern is generated from light scattered by the sample. The angles of scatter are mapped onto the plane *F* in increasing order, moving radially away from the optical axis. The laser light that is transmitted without being scattered by the sample will be focused in the center of the plane *F*, and can be subtracted by a beam block at this point. Usually the diffraction pattern in *F* is reimaged by a second lens onto a photodetector array, such as a charge-coupled device (CCD) camera.^{30,31,74} Changes in angular scattering by the sample can be studied by analyzing its diffraction pattern. The cell sample can be plated on a microscope slide in this diffraction-based setup, so this method is particularly useful for analyzing cells in a monolayer, as opposed to in suspension, as was discussed in the previous section.

As for the angular scattering measurements of particle suspensions, the diffraction technique is of spectroscopic nature: the diffraction pattern corresponds to scattering by the entire sample region illuminated by the laser beam. The size of this illuminated region can be a few hundreds of microns in width. To correlate the angular scatter pattern with a specific region of the sample, Valentine et al. 74 used a microscope condenser in the illumination path and were able to set the laser beam diameter to 70-100 μ m, thus selectively analyzing small regions of a porcine skin specimen (Figure 16.6). In that system the optical microscope was also equipped with a beam splitter after the collection lens, such that an image of the sampled 70- to 100- μ m region could be collected simultaneously with an image of its diffraction pattern on two separate cameras.

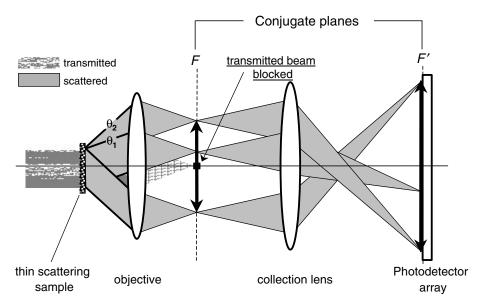

FIGURE 16.5 Experimental setup for imaging the diffraction pattern of cells or tissue slices plated on a microscope slide. F = objective's back focal plane. F and F'are conjugate Fourier planes. The scattered light (gray beam), which forms the diffraction pattern of the sample, is reimaged onto a photodetector array, while the transmitted light (cross-hatched beam) is blocked at the center of the plane F.

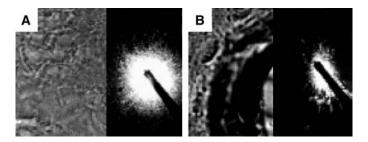

FIGURE 16.6 Images and diffraction patterns of two porcine skin specimens, 20 μ m thin. (A) The tissue region sampled is homogeneous and the diffraction pattern is isotropic. (B) A region in the vicinity of a hair results in an anisotropic scattering pattern. The black rod in the diffraction images corresponds to the transmitted light beam block. The scattering angle, θ , increases in the radial direction. Transmitted light and light scattered at 0° will be focused in the center of the diffraction pattern. (From Valentine, M.T. et al., *Opt. Lett.*, 26, 890, 2001. With permission.)

16.4.2.2 Applications of Diffraction to Cellular Analysis

Analysis of angular scattering by modeling the scatter as a Fraunhofer diffraction field from a two-dimensional flat object was used to measure the diameters of the nucleus and cytoplasm of stained cervical cells. The nucleated cells were modeled as two circular concentric regions having different optical densities, and diameters d_N and d_C corresponding to the nucleus and cytoplasm, respectively. In some cases the effects of offsetting the nucleus from the center of the cell were also considered. The solution of the Fraunhofer diffraction model gives the radial dependence of the light intensity in the diffraction pattern of the sample. By analyzing only one radial scan of the diffraction pattern, nuclear and cytoplasmic diameters were calculated and compared with the actual dimensions of normal, dysplastic and cancerous cells. The results show that the correct nuclear diameter was inferred in more than 80% of the 378 cells tested.

A similar approach was taken by Burger et al.³¹ to extract nuclear and cytoplasmic diameters from the Fraunhofer diffraction pattern of nucleated cell models and nucleated erythrocytes. The cellular dimensions inferred from the light scatter analysis in the diffraction pattern matched the microscopically determined dimensions of the cytoplasm and nucleus very well. An additional radial scan of the diffraction pattern taken at 90° to the first one also helped differentiate diameters of the major and minor axes these elliptical erythrocytes. More recently, modeling of light scattering as a Fraunhofer diffraction pattern was used to monitor the rounding of initially elongated cells in response to follicle-stimulating hormone⁷⁵ and the changes in cell diameter at the onset of apoptosis.⁷⁶

16.4.2.3 Other Techniques to Study Scattering of Cellular Monolayers and Thin Tissue Slices

Angular scatter measurements from thin tissue slices can be made by directly measuring the intensity of the forward scattered light from a tissue slice mounted on a cover slip. Direct measurements of angular light scattering were used to extract information about order and spacing between the collagen fibers in cartilage. In particular, the average scatter angle from 40- μ m thin cartilage slices was shown to decrease as a function of the aggregate compressive modulus (measured separately from the bulk samples prior to slicing). This relationship between angular scatter and modulus could be explained by a theoretical analysis relating average scatter angle, compressive modulus, and a short-range order parameter. From this analytical model, this short-range order parameter, which describes the spatial correlation length between the collagen fibers, was found to be $8.2 \,\mu$ m.

Other scattering spectroscopic techniques of monolayers of cells and thin tissue slices have also been described. By analyzing the refractive index fluctuations of mouse liver tissue obtained by phase-contrast microscopy, Schmitt and Kumar⁷⁸ showed that the power spectrum of refractive index variations follows an inverse power law as a function of spatial frequency suggesting a fractal packing of tissue mass.

Angle-dependent low coherence interferometry was used to measure the backscatter intensity as a function of angle from monolayers of cultured HT29 epithelial cells.⁷⁹ As for optical coherence tomography, this technique offers a depth resolution defined by the coherence length of the light source and allows scattering measurements from a specific point within the penetration depth of the sample. When probing a point close to the sample surface, or thin monolayers of cells, the angular scattering is dominated by single scattering and can be analyzed by Mie theory. Assuming spherical scatterers, the angle-dependent low coherence method was used to extract nuclear diameter and nuclear refractive index. Once the nuclear contribution to the angular scattering is subtracted, the remaining angular scatter spectrum can be analyzed to extract information about subcellular organelles smaller than the nucleus. From this residual angle distribution, a two-point spatial correlation of the optical field was obtained. This spatial correlation followed an inverse power law indicating fractal packing of subcellular structure as previously suggested by Schmitt and Kumar.⁷⁸

16.4.3 Combining Spectrscopy and Imaging

16.4.3.1 Transmission and Reflectance Images of Brain Slices

The techniques described in the two previous subsections probe the angular dependence of light scattering by the specimen under study, but without imaging the sample. The scatter intensities are typically collected from an ensemble of particles, and information about the location of the scatter sources within the specimen is not always saved. Cells often respond differentially to a given treatment; tracking the location of the scatter change within a monolayer of cells or within a tissue slice could provide a better understanding of the basic dynamics of a time dependent biological process. To this end, *imaging* methods based on scattering signals can be used to record relative changes in light scatter within the full field of view. Scattering information can be collected directly from bright-field and dark-field microscopic images collected at a specific wavelength.

The imaging wavelength is typically chosen in the red or near infrared, which penetrate tissue deeper than shorter wavelengths. The intensity distributions within transmission and reflectance microscopy images depend on the way the light is absorbed or scattered by the tissue under study. Changes in the biological composition of the tissue can affect absorbance and transmission through the specimen and can therefore be used to track subtissue dynamics. Transmission and reflectance imaging have been used to map neural activity within brain slices by differentiating the response of the different neuronal layers within the slice in response to a stimulus. Intrinsic optical signals such as transmittance or reflectance are often recorded in conjunction with fluorescent images using voltage-sensitive dyes or mitochondrial potential dyes, for example. These fluorescent images help correlate the optical scatter signal with biochemical and electrophysiological properties of the different tissue regions.

A short review of the application of intrinsic optical imaging techniques to brain slices can be found in Aitken et al. 80 Transmitted and reflected light signals are shown in the CA1 region of the hippocampus as a function of hypotonic stress, 80,81 neural stimulation, 80 or spreading depression. 80 Changes in light transmission were also compared between the CA1 and CA3 regions of the hippocampus as a function of *N*-methyl D-aspartate (NMDA) and kainate mediated excito-toxic injury. 82 Changes in transmitted light and mitochondrial depolarization measured with the fluorescent dye rhodamine 123 were used to track the spatio-temporal dynamics of hypoxia and spreading depression within hippocampal slices. 83 Using a fiber-optic excitation/collection bundle, reflected light was measured *in vivo* from the cat hippocampus and correlated with evoked potentials. 84

Brain slices are advantageous compared to isolated neuronal cultures in that they preserve the physiological relationship between neurons and glia, as well as the connectivity between different neuronal regions. However, to preserve these relationships adequately and maintain an experimentally viable tissue, the slices are often several microns in thickness. As a result, multiple scattering may affect the optical signals detected, and the single particle scattering approaches presented in Section 16.2 may not be applicable. Moreover, because most studies do not record the full angular scatter response from the tissue, the optical signal interpretation becomes limited.

16.4.3.2 Dual Angle Scatter Imaging of Brain Slices

To explore angular scatter by brain slices, Johnson et al. measured light scattered by hippocampal slices after illuminating the tissue at two different angles (Figure 16.7).⁸⁵ These brain slices were still 310 µm thick and multiple scatter may not be negligible. However, by comparing the individual images collected at each of the two illumination angles and their ratio, Johnson et al. were able to differentiate the hippocampal response to hypotonic stress from the response to NMDA-mediated injury (Figure 16.8).⁸⁵ When each illumination angle was considered individually, both hypotonic and NMDA treatments showed a relative decrease in the intensity of the light scattered by the CA1 region. However, when the ratio of the images collected at the two angles was considered, changes could only be measured after the NMDA treatment.

Although several scattering components, such as dendritic processes, axonal varicosities or cellular organelles, can contribute to transmission, reflection, and scattering measurements of brain slices, ⁸⁶ the study by Johnson et al. still shows that intrinsic optical signals can be successfully used to differentiate functional neuronal responses. As such, despite the difficulty in fully interpreting the scattering response of relatively thick tissue slices, transmission and reflectance imaging of brain slices remain very valuable because they provide a simple method to record spatio-temporal dynamics that reflect morphological change and that can be measured simultaneously in the whole preparation, unlike focal electrode recordings.

16.4.3.3 Optical Scatter Imaging of Cellular Monolayers

Recently, Boustany et al. demonstrated an optical scatter imaging (OSI) technique that produces images that directly encode a morphometric parameter within the full field of view of the microscope.⁸⁷ This OSI method combines Fourier filtering with central dark-field microscopy to detect alterations in the size of particles with wavelength-scale dimensions. A "scatter ratio" image is generated by taking the ratio of images collected at high and low numerical aperture in central dark-field microscopy. Such an image spatially encodes the ratio of wide to narrow angle scatter (or optical scatter image ratio, designated here as "OSIR") and hence provides a measure of local particle size.

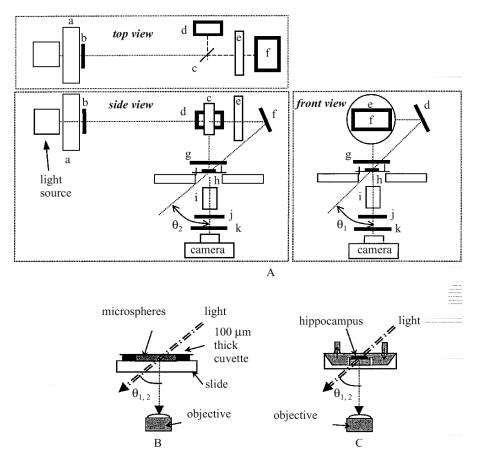

FIGURE 16.7 (A) Setup for dual-angle scattering images of hippocampal slices. a = shutter; b = infrared filter; c = beam splitter; d = mirror; e = shutter; f = mirror; g = polarizer; h = specimen; i = low numerical aperture objective; j = polarizer; k = interference filter. (B) Stage design for experiments on microsphere suspensions. (C): Stage design for brain slice experiment. $\theta_{1,2}$ represent the two scattering angles, 31 and 34°, for which the images were acquired. (From Johnson, L.J., Hanley, D.F., and Thakor, N.V., *J. Neurosci. Methods*, 98, 21, 2000. With permission.)

Figure 16.9 shows the OSI microscopy setup. The specimens are mounted on the stage of an inverted microscope, which can also be fitted with an epi-fluorescence and differential interference contrast (DIC) imaging capabilities. The microscope condenser is adjusted to central Kohler illumination, with a condenser numerical aperture (NA) of 0.03 (condenser front aperture closed). For illumination, light from the microscope's Halogen lamp is filtered to yield an incident red beam, $\lambda = 630 \pm 5$ nm. The images were collected with a 60× oil immersion objective, NA = 1.4, and displayed on a CCD camera. In a Fourier plane conjugate to the back focal plane of the objective, a beam stop was placed in the center of an iris with variable diameter. As the inset in Figure 16.9 shows, the variable iris collects light scattered within a solid angle, bound by $2^{\circ} < \theta < 10^{\circ}$ for low NA, and $2^{\circ} < \theta < 67^{\circ}$ for high NA. Two sequential dark-field images are acquired at high and low NA by manually adjusting the diameter of the variable iris. The scatter ratio image is obtained by dividing the background subtracted high NA image by the background subtracted low NA image.

OSI was validated on sphere suspensions and live cells.⁸⁷ Figure 16.10A shows the mean pixel value and standard deviation of OSI images collected from polystyrene sphere suspensions and plotted against sphere diameter (open circles). The optical scatter images of the suspensions are displayed to the left of the graph. The solid line represents OSIR predictions as calculated from Mie theory for m = 1.2, and shows excellent agreement with experiment. For comparison, the dashed line shows the theoretical

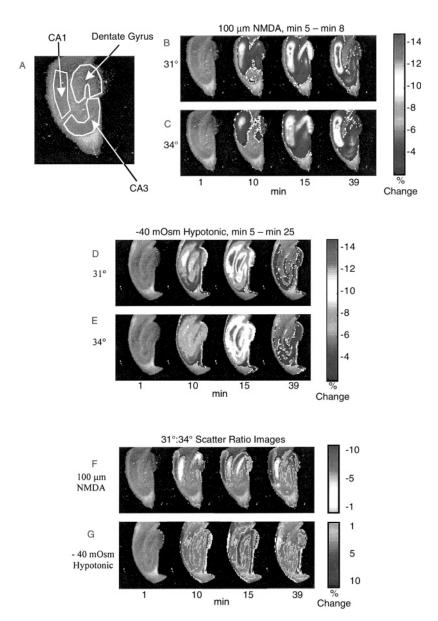

FIGURE 16.8 (Color figure follows p. 28-30.) Single-angle and dual-angle scatter images of hippocampal slices under osmotic stress and subjected to NMDA. In each case, the color bars indicate the percent change in image intensity. In regions of the slice where the change is less than ±2%, the gray scale images of the hippocampus are shown. (A) The scatter image of a hippocampal slice. The three main regions of the hippocampus are CA1, CA3, and the dentate gyrus. Also shown are single-angle scatter images at 31° (B) and 34° (C) of an NMDA-treated slice. In both (B) and (C) there is a large change in the CA1 region. There is also a significant change in the dentate gyrus that fades by minute 39 of the experiment. Single-angle scatter images at 31° (D) and 34° (E) are shown for hypotonic treatment. In both (D) and (E), a large change is indicative of cellular swelling in the CA1 region. There is also a significant change in the dendate gyrus. Dual-angle scatter ratio images are shown for NMDA (F) and hypotonic (G) treatments. The NMDA-treated slices in (F) undergo a relatively larger change in the dual-angle scatter ratio in CA1. In CA1 the scatter ratio change is negative, possibly indicating particle shrinkage. In (G), hypotonic treatment, the magnitude of the change in the scatter ratio is less in CA1. In addition, the overall location of the scatter change is more spread out than for NMDA treatment. In both (F) and (G) the white matter areas reveal a positive change in the scatter ratio. (From Johnson, L.J., Hanley, D.F., and Thakor, N.V., *J. Neurosci. Methods*, 98, 21, 2000. With permission.) Refer to color figure for accurate data rendering.

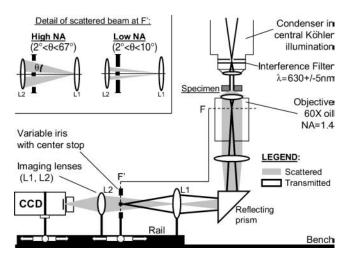

FIGURE 16.9 Apparatus for optical scatter imaging (OSI) of cellular monolayers. A collimated beam, $\lambda = 630$ nm (±5 nm), illuminates a sample mounted on the stage of an inverted microscope. The scattered light is collected by an oil immersion objective, NA = 1.4, and measured on a CCD camera. F = objective's back focal plane. F and F' are conjugate Fourier planes. The scattered light (gray beam) is used to image the specimen on the CCD, while the transmitted light (black ray traces) is blocked at F'. In this setup, two images are acquired sequentially by manually varying the aperture diameter in the plane F'. The inset shows the scattered angles passed at the high and low numerical aperture (NA) settings of the variable diameter iris. (From Boustany, N.N., Kuo, S.C., and Thakor, N.V., Opt. Lett., 26, 1063, 2001. With permission.)

prediction for m = 1.06. The OSIR parameter has the advantage of decreasing monotonically over a large range of sphere diameters from 0.2 to 1.5 μ m. In addition, the OSIR is not significantly sensitive to refractive index changes for spheres in this size range and therefore reflects changes in morphology rather than composition.

The method was applied to cells that naturally contain scatterers of varying size, such as the nucleus, (4 to 15 μ m) and mitochondria (0.5 to 2 μ m). As expected, particle size variation was seen across the cell. Figure 16.10B (top panels) shows DIC and OSI images of a normal endothelial cell. The nucleus region (N) and the cytoplasm (C) containing the mitochondria are clearly differentiated in the OSI image despite a much larger pixel size than the accompanying DIC image. Due to the nonlinear inverse relationship between OSIR and particle diameter, in the OSI image, regions with small particles (C) appear brighter than regions with large particles (N). By monitoring the cells after treatment with 2 μ m staurosporine (STS) (Figure 16.10B, t > 0), the OSI method revealed very early, apoptosis-induced subcellular changes, which were not apparent in conventional differential interference contrast images. The OSI method was also used to quantify calcium-induced changes in mitochondrial shape resulting from the mitochondrial permeability transition.

16.5 Summary and Conclusion

Light scattering techniques present simple and effective methods to detect subtle morphological changes, *in situ*, for particles with wavelength-scale dimensions, such as organelles or connective tissue fibers. The particles being probed need not be individually resolved and measured by traditional morphometric methods, thus avoiding a tedious process of image recognition, particle sizing and counting. Light scattering techniques complement other microscopic methods and, in contrast to electron microscopy, require no potentially damaging cell preparation procedures.

Unlike fluorescence labeling, which results in illuminating specific biochemical markers, methods based on light scattering do not require labeling. As a result, scattering is not biochemically specific,

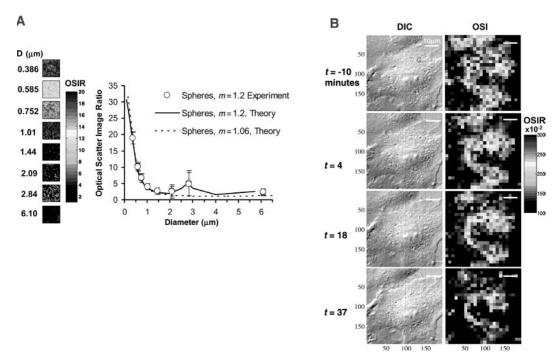

FIGURE 16.10 (Color figure follows p. 28-30.) (A) OSI images and measurement of the OSIR in aqueous suspensions of polystyrene spheres (m = 1.2). The OSIR is a measure of wide to narrow angle scatter. Experimental data (open circles), and theoretical predictions (solid line, m = 1.2; dashed line; m = 1.06) are shown. The experimental data points show the mean pixel value and standard deviation in the scatter images displayed to the left of the graph. (From Boustany, N.N., Kuo, S.C., and Thakor, N.V., *Opt. Lett.*, 26, 1063, 2001. With permission.) (B) Representative cell undergoing apoptosis after treatment with 2 μ M staurosporine (STS). The cell was imaged in DIC (left panels) and OSI (right panels) at different time points. C = cytoplasm, N = nucleus. Images are displayed at times t = -10, 4, 18, and 37 min from STS addition at t = 0. The ratiometric scatter images show a decreasing scatter ratio within the cytoplasm (C). Refer to color figure for accurate data rendering.

and may originate from different tissue and cellular structures, often requiring further biochemical elucidation. Still, light scattering data can have important diagnostic value despite having limited specificity. One of the strengths of light scattering techniques is that they can reveal the presence of cellular and subcellular *morphological* dynamics noninvasively. Morphological information complements biochemical data, and could be particularly valuable if the biochemical events and time sequence underlying a given biological behavior are not yet known to allow specific biochemical manipulation. Moreover, under certain conditions in which only a few parameters are known to vary, scattering data can be used to automate cell differentiation and sorting efficiently during high-throughput cell analysis, as in flow cytometry.

Combining theory and experiment, various researchers have been striving to provide novel approaches to solve the "inverse problem" and infer, from a limited light scattering data set, the morphologic and optical properties of cells and organelles. These studies are invaluable in transforming hitherto phenomenological results into data that could be used to design optical instruments with a high impact on biology and medicine.

17.1 Introduction

The change in local temperature of blood, tissue, and skin in biological systems is determined by the difference in the thermal energies received and lost by conduction transfer and advection, as well as by the thermal energy released by chemical reaction processes such as metabolism. The use of temperature (measured at a convenient location such as the ear, armpit, or mouth), as an indicator of health has been in routine use for a very long time. However, even in such use, it is widely recognized that different healthy individuals can have different temperatures. In fact, the same healthy individual can have different temperatures at different times, based on the local environmental conditions, blood perfusion rates as controlled by the nervous system, and metabolic rates as controlled by a variety of complex factors.

In addition, the single temperature measured at a chosen location does not represent the temperatures of the different parts of the body even on the skin surface. The temperature of a human being typically decreases from the core to the skin by 3 to 5°C to support the heat dissipation to the surroundings. The transport processes involving conduction and advection (blood perfusion) within the body and the thermal boundary conditions at the skin determine the local skin temperature. In addition, the sweat glands in the human skin respond to different stimuli and the surface temperature is affected by the evaporation of water at the surface.

Diagnostic techniques using single-point temperature measurements have long benefited patients. The theoretical possibility exists that temperature at multiple points, if properly interpreted, can provide information about conditions affecting blood circulation, local metabolism, sweat gland malfunction, inflammation and healing, and energy imbalances created by hyperactivity of glands such as the thyroid. Temperatures of internal surfaces such as the colon, lung, and arteries could also be indicators of the state of health. Measuring such internal surface temperatures using endoscopes is a possibility.

Thermal imaging involves measurements of surface temperature using an array of infrared sensors installed in an infrared camera. This imaging allows the simultaneous measurement of temperatures of

multiple points on the skin and is also a reference for surrounding temperature. The reference measurement could be subtracted from local measurements to provide an improved estimate of the temperature. In addition, measurement of differences in temperature between two points or in different regions of the image may be better indicators of the state of health. Motivated by this, thermal imaging using infrared cameras for medical diagnostics was initiated in the early 1970s. Over the subsequent three decades the technique has received mixed reviews and produced mixed results. Although the fundamentals of the thermal imaging process are sound, the relationship to a particular anomaly is not necessarily specific; therefore, the technique has greater promise as an adjunct diagnostic tool. The technique could also become valuable for monitoring the changes in skin temperature pattern over a specified period under highly controlled conditions.

Thermal imaging was considered for early diagnosis of breast cancer based on the theoretical conjecture that a rapidly growing tumor has high metabolism and blood perfusion rates leading to an increase in the local tumor temperature. If the tumor were to be located in a region close to the skin, then the local high temperature would also appear as a high temperature spot on the skin. Pattern recognition techniques, heuristic diagnosis, and left-breast-to-right-breast temperature pattern comparisons were used to interpret analog images visually. The results of the trials were highly inconclusive and controversial.

The controversy continues today with those opposed to the technique still basing their opinions on past failures. They have not changed their opinions even though the trials were in an era before the personal computer and advances in image processing techniques that can increase measurement accuracy and yield better computerized algorithms and objective tests for specific maladies. In addition, they also discount the possible use of thermal imaging as an adjunct functional diagnosis tool, for example, to determine if a positive mammography result could be combined with a high metabolic rate indication to separate malignancies, thereby reducing the number of false biopsies. Tests conducted for use as standalone diagnostics are generally not indicative of the value of a method for adjunct use.

Temperature patterns on the skin are the result of biological heat and mass transfer, metabolic processes in response to specific surrounding conditions, and mental, neurological and hormonal states of the subjects. Therefore, interpretation of single thermal images must not be based on use of arbitrary pattern recognition methods because such a diagnosis can be highly nonspecific and misleading. However, interpretation using proper accounting of the biological processes that determine the skin surface temperature, as well as multiple images taken during annual examinations and of dynamic thermal response to stimuli, can yield useful results, particularly when used as a function indicator technique in conjunction with a structure indication technique such as x-ray or ultrasound imaging. Therefore, we next review the fundamentals of infrared radiation and thermal imaging, followed by abstracts of some recent work in thermal imaging for biology and diagnostics. A table of available infrared cameras is also provided, followed by two examples of the use of the bioheat transfer equation for the interpretation of thermal images.

17.2 Infrared Radiation and Thermal Imaging

Thermal imaging relies on sensing the infrared radiation emitted by all objects above absolute zero temperature. All objects emit photons as a result of transitions from a high-energy to a low-energy state. In solids, such transitions lead to a continuous distribution of energy between different wavelengths according to the Planck distribution. Objects at a relatively high temperature, such as carbon particles in a flame or a hot iron rod, emit visible light, while the emission from objects closer to normal room temperature is at much longer wavelengths. At the normal temperature of the human body, the peak of the Planck function occurs in the mid-infrared region between 9- and 10-µm wavelengths. This radiation is not visible to the human eye but, in sufficient intensity, can be felt by the human skin, one function of which is a low-sensitivity infrared array detector.

The Planck function is exponentially nonlinear in temperature. This means that the lower-temperature objects emit orders of magnitude less energy than do higher-temperature objects. Therefore, detection of infrared energy accurately is a challenging task. In addition, lower-temperature objects and their surroundings

emit comparable amounts of infrared energy, which leads to difficulties in measurements. Often the signal-to-noise ratios (SNRs) are of comparable magnitude, requiring specialized background correction instrumentation, mode-locked signal processing techniques, and careful analysis of the resulting data.

The technology of infrared array detectors, associated electronics, image processing, and noise reduction has significantly improved over the last 10 years. The accuracy with which temperature and temperature changes can be measured has reached 10^{-3} K. This is better by a factor of 100 compared to the techniques used in past studies — a fact missed by many readers of the thermal imaging literature.

The infrared or thermal imaging cameras available commercially are listed in Table 17.1. The most relevant attributes of these cameras are listed in Tables 17.1 through 17.4. The most important parameters for biological applications are the range and accuracy. The array size and the pixel size determine the spatial resolution possible for the measurements. The wavelength sensitivity is important, even in thermal imaging, because the object imaged must have a high enough emissivity in the spectral sensitivity range of the camera. The cameras with highest sensitivity near 9- μ m wavelength are the most popular for biological applications because of the Planck function's peak near this wavelength. Most biological solids also have a significant emissivity in this region, yielding a high SNR.

The cameras must be calibrated routinely using a blackbody standard source; however, the sensitivity of the detectors has long surpassed many blackbody standards used in general purpose laboratories. In addition to the blackbody calibration standard, lenses, mirrors, filters, and prisms made from infrared transmitting materials form the core tool set of a thermal imaging laboratory. Many laboratories work in the visible and the infrared portion of the light spectrum; most visible optics do not transmit infrared but most infrared optics transmit visible. Therefore, care must be taken to separate and label the optical components properly.

TABLE 17.2 IR Camera Models, Spatial Resolution, Spectral Range, and Detector Materials

Camera	Spatial Resolution (mrad)	Spectral Range (µm)	Detector Material	
ThermaCAM E1	2.6	7.5 to 13	FPA uncooled microbolometer

17.3 Applications of Infrared Thermal Imaging

Many applications of infrared thermal imaging have been reported in the literature.¹⁻⁵ The basic measurement involves skin temperature distribution resulting from a variety of internal and external conditions affecting the circulation and metabolic processes. Therefore, there is an existing nonspecificity in the process, which must be recognized and addressed by improving the analytical tools and recognizing that, even with the most improved tools, a fundamentally nonspecific diagnostic technique such as thermal imaging can only be used as a powerful adjunct tool. Such recognition will avoid the controversy and confusion often surrounding this issue. More scientific work is needed to distinguish the differences between enhanced blood flow because of tumor and because of stress of a polygraph test. The present problem is that proponents of thermal imaging claim that the technique can be used as a diagnostic tool in both these scenarios, while opponents of the technique claim that a health parameter as basic as temperature and its distribution on different parts of the body has no diagnostic value. Both positions are extreme because the former ignores the nonspecificity of the technique while the later ignores the fact that, along with pulse and appearance, temperature is a health diagnostic modality proven over thousands of years.

Some of the recent literature involving use of infrared thermal imaging as an experimental tool in biology and health studies is summarized briefly in the next paragraph. This summary points to the broad applications as well as the nonspecificity inherent in this measurement modality.

TABLE 17.3 Infrared Camera Models, Temperature Range, Sensitivity, Framing Rate, and Bits

			Framing Rate	
Camera	Temperature Range	Sensitivity	(Hz)	Bits
ThermaCAM E1	−20 to 250°C	120 mK	60	14
ThermaCAM SC300	−40 to 500°C	100 mK at 30°C	50 to 60	14
ThermaCAM SC3000	−20 to 2000°C	20 mK at 30°C	50 to 60	14
PD300 IR	−10 to 1500°C	100 mK at 30°C	60	12
IR 747	−15 to 45°C	100 mK at 30°C

Barnett et al.⁶ used thermal imaging to conduct a preliminary investigation of the human gingiva and suggested that, with cooling and rewarming, it can be used as an indicator of inflammatory state. Chan et al.⁷ state that thermal imaging is useful for identifying the health status of the thyroid gland. Whole-body thermal images are adequate indicators of ectodermal displasia according to Clark and co-workers,⁸ and Dickey et al.⁹ report that infrared thermography can be used to measure the depth of burns in burn victims. Thermal imaging systems in the management of pain were used by Hasegawa et al.¹⁰ Stein and co-workers¹¹ demonstrated the use of thermal imaging in monitoring surgical tendon repair in veterinary medicine.

One of the oldest, most controversial, but possibly most promising applications of thermal imaging involves breast cancer detection. ¹² The literature in this area is briefly reviewed in Section 17.3.1. Villringer and Dirnagl¹³ used infrared thermal imaging to measure brain activity. Applications of thermal imaging to internal surfaces have begun appearing, with papers on the use of infrared fiber optic catheter for thermal imaging of atherosclerotic plaque by Naghavi-Morteza et al. ¹⁴

Thermal imaging is being used in the two basic fields of biology, zoology and botany. In addition to human health studies, the applications are wide and therefore care is required in claims of specificity like those in health studies. Thermal imaging has been used in population studies of burrowing mammals by Hubbs et al. ¹⁵ Fuller and Wisnewski use thermal imaging to study freezing in plants, and Jones ¹⁷ uses it to measure stomatal conductance of plants.

The most recent claims for thermal imaging involve its use in detecting anxiety by observing changes in facial temperature patterns resulting from neurological responses of the circulatory system. 18,19

Although the publicity value of such claims is high, care must be exercised in the interpretation of results based on the nonspecificity of the primary measure.

The following section describes an example of using temperature measurements in conjunction with a mathematical model. The mathematical model is then used to generate expected thermal images, which show their effectiveness in indicating high blood-perfusion and metabolic rates typically associated with a tumor. Very few studies of this nature aimed at evaluating the scientific basis for thermal imaging as a breast cancer diagnostic have been reported. Based on the results of this study, it is established that computational models of the bioheat transfer process can render thermal imaging a viable adjunct tool.

17.3.1 Calculations of Temperature Profiles in a Female Breast with and without a Tumor

17.3.1.1 Introduction

Breast cancer is one of the leading causes of death from cancer in women in the United States. One out of eight women suffers from breast cancer during her lifetime. The American Cancer Society estimated that in 2001, approximately 192,000 women in the United States would be diagnosed with breast cancer and approximately 40,600 would die as a result of this disease.²⁰ Early detection is considered to be the best defense against breast cancer.

Tumors grow by signaling for and receiving higher arterial blood supply, which supports the higher metabolic rates required for rapid cell division. Many diagnostic and therapeutic technologies based on these fundamentals are being considered. The differences in the energy consumption of normal and cancerous tissue lead to small but detectable local temperature changes.²¹ For breast tumors near the skin surface the local temperature changes at the tumor location can be large enough to cause a local perturbation in temperature on the patient's skin.

Gautherie²² examined 147 patients with malignant breast cancers and measured local temperatures and thermal conductivity using sterile fine-needle thermoelectric probes. He used a model based on electrical analogy to investigate correlations between thermal and geometrical parameters that appeared during heat interactions between the tumor and its surrounding tissue. The tumor metabolic heat generation rate was inferred from the model. The differences in effective thermal conductivity of healthy and cancerous tissues *in vivo* and *in vitro* as postoperative specimens were described as a function of local blood perfusion rate.

Osman et al.²³ developed a mathematical model of the three-dimensional temperature distribution in women's breasts using a finite element method. Based on their literature survey, the blood flow to the tumor was considered to be two- to threefold that of the normal tissue. They correlated the tumor metabolic heat generation rate with the doubling time of tumor volume as measured by Gautherie et al.²⁴ They modeled the tumor as a point heat source with the heat generation equal to the total metabolic heat production of the neoplastic tissue. Surface temperature distributions were plotted for the malignant breasts; however, the temperature distributions inside the breasts were not discussed and compared to the measurements of Gautherie.²²

Infrared images of skin temperature can be used as an adjunct tool for detection combined with mammography in cases in which significant thermal expression of the tumor occurs on the skin surface. Some past studies have shown significant benefits of such a detection scheme, increasing the sensitivity rate from 85 to 95%.²⁵ However, many other studies were inconclusive, primarily because of incorrect measurements and qualitative interpretation. As a result, thermography is currently not used or recommended as an early detection technique. The accuracy of interpretation can be significantly enhanced if solutions of the bioheat equation are used to relate the infrared images obtained with modern high-accuracy cameras to the functional changes inside the breast. Such work is being conducted primarily outside the United States.^{25–29}

17.3.1.2 Bioheat Transfer Equation

The steady-state form of the bioheat transfer equation proposed by Pennes²¹ is

$$\nabla \cdot k \nabla T + \rho_h \cdot c_h \cdot \omega_h \cdot (T_a - T) + \dot{q}_m = 0 \tag{17.1}$$

where k denotes thermal conductivity of tissue, ρ_b , c_b are the density and the specific heat of the blood; ω_b (ml/s/ml) is the blood perfusion rate, \dot{q}_m is the metabolic heat generation rate (W/m³), T_a is the arterial blood temperature (K), and T is the local temperature of the breast tissue. Equation 17.1 gives the quantitative relationship of the heat transfer characteristics in human tissue and includes the effects of blood perfusion (ω_b) and metabolic heat generation (\dot{q}_m). The temperature of the arterial blood is approximated to be the core temperature of the body.

In the bioheat equation proposed by Weinbaum et al.,³⁰ the expression derived for the tensor conductivity of the tissue is a function of the local vascular geometry and flow velocity in thermally significant small vessels. The solution of this equation gives rise to an effective thermal conductivity to account for the enhanced heat transfer due to incomplete countercurrent heat exchange between paired vessels. Structural properties of the breast in terms of size and distribution of blood vessels are necessary, but not available, for the solution of this equation; therefore, Equation 17.1 was used in the present simulations.

17.3.1.3 Mathematical Model

A hemisphere of radius 9 cm was considered to match the patient in Gautherie's study.²² The normal breast was approximated to be composed of a single layer with averaged properties. The breast with tumor included a sphere of radius 1.1 cm with its center located at 2.1 cm beneath the surface. The tumor was assigned a higher blood perfusion and metabolic heat generation rate compared to the

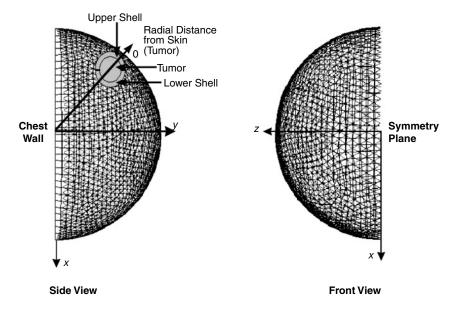

FIGURE 17.1 Numerical grid for bioheat transfer calculations in a breast model for the generation of a computational thermal image.

corresponding quantities for the healthy tissue. Gautherie observed regions of increased metabolic activity around the tumor. Because metabolic heating depends on the supply of metabolites from the blood perfusion, the two quantities change in an interdependent monotonic manner. The region of abnormal metabolic rates around the tumor was modeled as 0.7-cm-thick lower and upper hemispherical shells of different properties around the tumor. The two different shells are used to represent the differences in the upper and lower parts of the breast that surround the tumor.

A convective boundary condition is specified at the skin surface. Natural convection for a sphere (Nusselt number \cong 2) gives a heat transfer coefficient of approximately 5 W/m² K at the surface for ambient air at 21°C. The inner boundary of the breast is the pectorals muscle, which covers the ribs and is considered as adiabatic in the present simulations.

17.3.1.4 Solution

Figure 17.1 illustrates the computational grid created using the computer program GAMBIT 1.3. The volume is discretized into finite elements (tetrahedral and triangular). There are 96,410 cells and 238,324 faces in the grid and it satisfies a mesh independent solution. During meshing, a boundary layer was considered at the surface to account for the high temperature gradient. The grid is exported to the computer program FLUENT5 to solve for the temperature distributions. Blood perfusion and metabolic heat generation terms are added to the computations with a user-defined function written in C++. The function also increases the blood perfusion and metabolic heat generation at the tumor and the surrounding shells.

17.3.1.5 Optimum Results

The metabolic heat generation and the blood perfusion inside the normal breast were varied. Initially, the metabolic heat generation was assumed to be $\dot{q}_m = 420 \text{ W/m}^3.^{31}$ The temperatures were calculated at three different angles, namely, 0, 45, and 90° with respect to the *x*-axis. The maximum difference in temperature for these three angles was about 0.1°C.

Gautherie²² determined the metabolic heat generation of the tumor to be 29,000 W/m³ using the electrical analogy. Thus, for this metabolic heat generation inside the tumor, the blood perfusion rate varied. The thermal effect of higher blood perfusion is to reduce the highest temperature attained inside the tumor.

TABLE 17.5 Blood Perfusion and Metabolic Heat Generation Values Used for an Optimum Fit with the Gautherie Data

	$\dot{q}_m \ (\text{W/m}^3)$	ω_{b} (ml/s/ml of tissue)
Normal	450	0.00018
Tumor	29,000	0.00900
Lower Shell	11,700	0.00360
Upper Shell	4,725	0.00144

Data from Gautherie, M., Ann. N.Y. Acad. Sci., 335, 383, 1980.

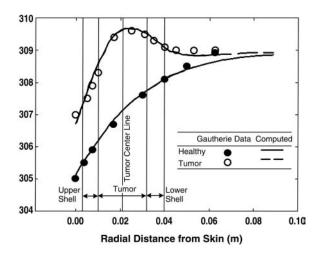

FIGURE 17.2 Verification of the numberical model parameters used in the bioheat transfer simulations.

Table 17.5 gives the blood perfusion and metabolic heat generation rates used to give the best match with Gautherie's²² temperature distributions using the least mean square error method. At the optimum, the root mean square error over the entire profile is 0.112°C for the normal breast and 0.293°C for the malignant breast. The blood perfusion rates for all domains are within the range specified by Vaupel.³² The predicted radial temperature profile is plotted in Figure 17.2.

17.3.1.6 Conclusion, Discussion, and Future Work

The calculated temperature distributions agree very well with the measurements based on the model structure and the parametric values used in the present simulation. This suggests that the tumor has approximately 1.5 to 2 orders of magnitude higher metabolic rate and close to 10 to 20 times blood perfusion rate. As long as the orders of magnitude of the metabolic rate and blood perfusion rate are correct, reasonable temperature profiles can be obtained. A more significant result is that the tumor introduces a local temperature rise on the breast surface that is accurately detectable by modern infrared cameras. Further inverse bioheat transfer calculations may provide a method of locating the tumor using the surface thermograms.

Figure 17.3 shows computational thermograms created using the results of the calculations. These data indicate that, for the tumor measured by Gautherie, the temperature differences apparent on the skin surface would be significant and detectable with thermal imaging. Furthermore, the right-hand panel shows that modern image processing techniques can enhance the thermal imaging signal significantly.

Presently, experimental verification of the combined use of thermal imaging and bioheat transfer computations is in progress in our laboratory. The initial thermal imaging results are shown in Figure 17.4. The

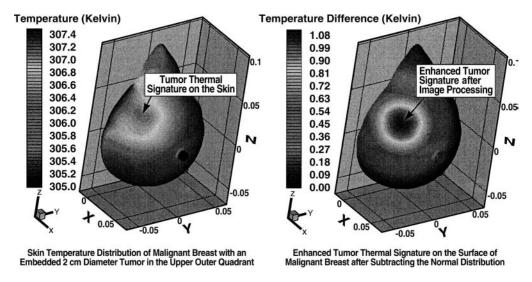

FIGURE 17.3 Numerical thermal images demonstrating the fundamental ability of a thermal image to capture an abnormality and the power of image processing.

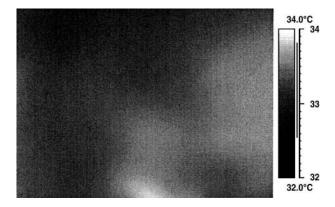

FIGURE 17.4 A sample infrared image demonstrating the high temperature sensitivity of modern IR cameras.

data show that it is feasible to measure the type of temperature changes of interest in biological systems with very high accuracy and precision.

17.4 Summary and Conclusions

Infrared thermal imaging of temperature changes in a biological system is a measurement modality with a fundamental scientific basis. However, fundamental science also clearly points out the non-specific nature of this measurement for monitoring any disease state. Therefore, this technique must be used as an adjunct to other diagnostic techniques and in conjunction with newly emerging analytical and numerical computational tools such as the one demonstrated previously.

The technique is clearly not ready for general purpose clinical applications without the establishment of a fundamental science and technology base aimed at addressing the nonspecificity issue by developing adjunct instrumentation and numerical tools. If such work is completed, thermal imaging can add a powerful measure of function in biological systems because of its fundamental basis in blood perfusion and metabolic activity.

18.1 Introduction

Glucose is one of the most important carbohydrate nutrient sources and is fundamental to almost all biological processes. Quantification of glucose concentration is important in monitoring and analysis of agricultural products, control and regulation of cell culture, and diagnosis and control of human diseases including diabetes. A wide range of parameters, including glucose concentration range, volume of glucose solution available, and required accuracy, exist across these applications. For instance, the sugar concentration in many agricultural products (e.g., fruit juices) is hundreds of grams per liter while the glucose concentration for an on-line cell culture system may be in the milligrams per deciliter range. Additionally, the volume or, more importantly for optical approaches, the available optical path length for on-line process control and agricultural applications can be tens of centimeters while *in vivo* these are typically millimeters to centimeters. Consequently, the required glucose sensitivity *in vivo* needs to be orders of magnitude better than in the agricultural industry. Finally, the environmental challenges associated with *in vivo* monitoring make this problem more difficult than typical industrial applications because of a range of potential confounders that cannot be controlled. These include temperature and pH variations, confounding chemical species, pressure changes, and correlated physiological changes.

For biotechnological processes such as cell culture, measurements of analytes such as glucose are currently obtained using off-line methods that require sample extraction from the process or bioreactor. The off-line measurements may cause cell contamination, can be time consuming, can be expensive, and may not reflect the real-time status of the cells. In order to overcome many of these limitations, nondestructive optical methods have been proposed as a solution. Three of the most common optical approaches for on-line glucose monitoring and process control are described in Section 18.2.

A significant role for physiological glucose monitoring is in the diagnosis and management of diabetes. Diabetes mellitus is a metabolic disease that presents as a complex group of syndromes related in large part to problems with insulin production and/or utilization. Insulin is the primary hormone responsible for glucose regulation in the body; in diabetics, blood glucose levels, which would normally be maintained between 90 and 120 mg/dl, may fluctuate between 40 and 400 mg/dl or more. Over time, elevated glucose levels may damage the kidneys, eyes, nerves, and heart, and severely low glucose levels may cause a patient

to go into shock or even die. Therefore, a goal of diabetes management is tight maintenance of blood glucose levels via insulin injection, modified diet, exercise, or a combination of these. In order to guide this therapy, regular measurement of blood glucose levels (up to five times per day) is required. Because current glucose sensing methods require a painful and inconvenient puncture of the skin to obtain a blood sample for analysis, efforts to develop a noninvasive or implantable glucose meter using optical methods have been strong.

A number of invasive and noninvasive techniques are being investigated for glucose monitoring, including direct transmission through blood vessels, measurement of glucose in interstitial fluid in the dermis, light transmission through blood containing body parts (including the earlobe, the finger, and the forearm), and optical interrogation of the aqueous humor of the eye. The invasive approaches have the advantage of direct contact with the media of interest and thereby enhanced specificity, but they often suffer from biocompatibility issues. The noninvasive approaches do not suffer from the biocompatibility issues but are less specific and must account for the fact that they simultaneously probe multiple volumes including interstitial fluid, blood, and intracellular fluid. The anterior chamber of the eye has been suggested as a noninvasive glucose monitoring site because it is uniquely transmissive to optical radiation. It has been shown that the aqueous humor (AH), the fluid just beneath the cornea, exhibits an age-dependent steady-state value of glucose approximately 70% of that found in blood and that the time lag between AH and blood glucose is on the order of minutes. The lack of significant scattering components and the relative simplicity of AH compared to blood or blood and tissue make it an attractive site for optical measurement techniques. Section 18.3 focuses on the optical approaches currently used and being developed for glucose monitoring.

18.2 On-Line Glucose Monitoring and Process Control

18.2.1 Near-Infrared Spectroscopy

The near-infrared (NIR) region of the optical spectrum extends from 700 to 2500 nm (0.7 to 2.5 μ m) and can be used for quantitative measurement of organic functional groups, especially C–H, O–H, N–H, and C=O. Absorption bands in the NIR are composed primarily of overtone and combination bands of stretching and vibrational modes of organic molecules. These bands tend to be rather broad and overlap considerably, so the NIR region is not particularly well suited for qualitative analysis. However, the significantly reduced intensity of NIR absorption bands does allow for use of reasonable pathlengths in the millimeter to centimeter range; when used with multivariate statistics, suitable quantitative information involving multiple analytes may be obtained.

NIR transmission spectroscopy (NIRS) and diffuse reflectance spectroscopy have been the primary optical approaches investigated for on-line glucose monitoring and process control.^{1–15} NIRS has been developed extensively in the agricultural and food industries for the past 30 years. An advancement that has enabled NIRS as an analytical tool has been the development of sophisticated multivariate data analysis or chemometric techniques. The use of NIRS for glucose monitoring in industrial and agricultural applications has been described in References 16 through 18. In this section we will focus on the application of NIRS to on-line measurement of glucose concentration in bioreactors and cell cultures. These applications represent the most challenging application of NIR glucose measurement because the media involved are more complex and the analyte concentrations involved are significantly lower than those found in current industrial applications.

Cell culture applications require careful maintenance of a number of factors, including pH, temperature and, importantly, glucose concentration. The automated control of glucose concentration via online continuous monitoring could result in improved culture productivity and efficiency. Optical measurement of glucose is complicated by the complex nature of cell culture media, which contain proteins, amino acids, salts, and other small carbohydrates and nutrients including glucose. A typical NIR spectrum of GTSF-2 cell culture medium in the 2- to 2.5-µm range with respect to an air background is shown in

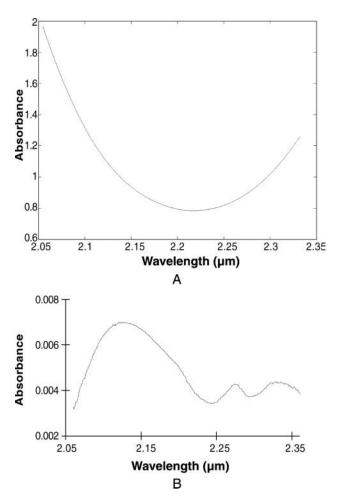

FIGURE 18.1 (A) NIR absorbance spectrum of cell culture media with air as the background. (B) NIR absorbance spectrum for glucose in the 2- to 2.5-μm wavelength range after baseline removal of the other cell culture media components. Note that the glucose signal amplitude is orders of magnitude smaller than the raw absorption, which has strong water and protein bands.

Figure 18.1A. The NIR spectrum for aqueous glucose at a concentration of 500 mg/dl (27.5 mM), with the other cell culture medium background removed, is shown in Figure 18.1B. Of particular importance is the magnitude of the absorbance units on the y-axis. Note that the absorbance by water and proteins is at least three orders of magnitude greater than that of glucose. Thus, the stability and signal-to-noise ratio of an NIR instrument must be very good if it is to be used to distinguish changes in the glucose concentration. Further, the temperature of the sample must also be very tightly controlled because, with even a slight change in temperature, the absorbance of the background water spectrum will shift, severely impacting measurement of the glucose signal.

Figure 18.2 demonstrates the effect of varying temperature on the NIR spectrum of cell culture medium. Fortunately, techniques such as digital filtering combined with high-order multivariate statistics have been able to compensate for and model such variations. Additionally, cell culture applications typically exhibit well-controlled temperature and are amenable to inclusion of a fixed pathlength for optical measurements, thus making on-line NIR glucose monitoring in cell culture promising. Detailed discussion of specific NIR spectroscopic studies of glucose measurement in cell culture media may be found in References 6, 15, and 19.

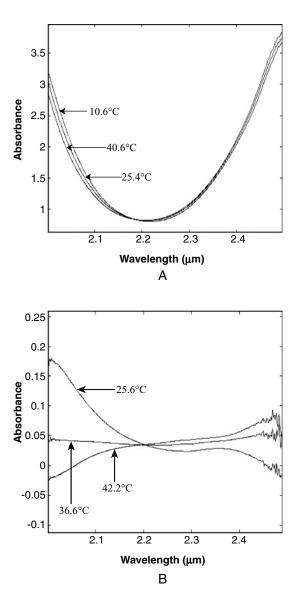

FIGURE 18.2 (A) Water absorbance spectrum, referenced to air, showing the shift in the water peaks with temperature. (B) Glucose (500 mg/dl) absorbance spectrum taken at different temperatures, referenced to a water background taken at one temperature showing the baseline water peak shifts.

18.2.2 Raman Spectroscopy for Biological Glucose Analysis

In addition to NIR, the optical method known as Raman spectroscopy may provide for potentially rapid, precise, and accurate analysis of glucose concentration and biochemical composition. Raman spectroscopy provides information about the inelastic scattering that occurs when vibrational or rotational energy is exchanged with incident probe radiation. When monochromatic radiation is incident upon Raman active media, most of the incident light of frequency v_o is elastically scattered at the same frequency (Rayleigh scattering); however, a very small portion of the light undergoes Raman scattering and exhibits frequency shifts of $\pm v_m$ that are associated with transitions between the rotational and vibrational levels. Prove that are decreases $v_o - v_m$ are referred to as Stokes shifts and energy increases $v_o - v_m$ are referred to as anti-Stokes shifts. Because Stokes shifts are much more prevalent, most studies utilize the

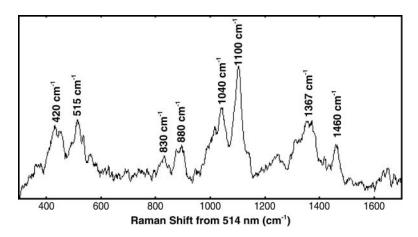

FIGURE 18.3 Baseline corrected Raman spectra of glucose showing the narrow peaks that can be obtained when compared with the NIR spectra of Figure 18.1B.

Stokes type of scattering bands. Therefore, the Raman bands of interest are shifted to longer wavelengths relative to the excitation wavelength.

As with infrared spectroscopic techniques, Raman spectra can be utilized to identify molecules such as glucose because these spectra are characteristic of variations in the molecular polarizability and dipole moments. However, in contrast to infrared and NIRS, Raman spectroscopy has a spectral signature that is less influenced by water. In addition, as shown in Figure 18.3, Raman spectral bands are considerably narrower than those produced in NIR spectral experiments. Raman also has the ability to permit the simultaneous estimation of multiple analytes, requires minimum sample preparation, and would allow for direct sample analysis (i.e., would be on-line). Different bonds scatter different wavelengths of EM radiation, so this method gives quantitative information about the total biochemical composition of a sample, without its destruction.

The fundamental instrumentation required to produce a Raman spectrum includes a monochromatic light source such as a laser, a wavelength separation system such as a dispersive monochromater or nondispersive Fourier transform (FT) spectrometer, and a detection system such as a CCD array for the dispersive case or point detector for the FT Raman case. In either system, it is very important to eliminate the elastically scattered light, which is roughly 10⁵ times greater in intensity and occurs at the same wavelength. Normal optical filters are not adequate to remove enough of this elastically scattered light and therefore holographic notch filters are typically required.

One application of dispersive Raman spectroscopy is the noninvasive, on-line determination of the biotransformation by yeast of glucose to ethanol.²³ Using a diode-laser exciting at 780 nm and a CCD detector along with partial least squares multivariate analysis, glucose and ethanol could be measured to within 5%.

Although Raman scattering can be used in on-line monitoring applications of analytes at the millimolar level, it is a rather weak effect that typically requires a fairly powerful laser and cooled CCD array; it has substantial fluorescence interference from biological samples. However, the Raman effect can be greatly enhanced (by approximately 10⁶- to 10⁸-fold) if the molecules of interest in the monitoring process are attached to, or microscopically close to, a suitably undulating (roughened) surface, usually of the coinage metals Cu, Ag, or Au.²⁴ This method, called surface-enhanced Raman scattering (SERS),^{25,26} has received much attention recently within biomedicine²⁶ and genomics.²⁷ Since the development of reproducible SERS on a silver-coated alumina substrate by Vo-Dinh and colleagues,²⁸ this technology has emerged as a very powerful biochemical detection method. It is noteworthy as well that the fluorescence background typically observed in many on-line samples using dispersive Raman may potentially be reduced by using SERS.

18.2.3 Polarimetric Measurement of Aqueous Glucose

Polarimetry is a sensitive, nondestructive technique for measuring the optical activity exhibited by inorganic and organic compounds. A compound is considered to be chiral if it has at least one center about which no structural symmetry exists. Such molecules are said to be optically active because linearly polarized light is rotated when passing through them. The amount of optical rotation is determined by the molecular structure of the molecule, the concentration of chiral molecules in the substance, and the pathlength the light traverses through the sample. Each optically active substance has its own specific rotation as defined by Biot's law:

$$\left[\alpha\right] = \frac{100\alpha}{LC} \tag{18.1}$$

where L is the layer thickness in decimeters, C is the concentration of solute in grams per 100 ml of solution, and α is the observed rotation in degrees. In the preceding equation the specific rotation $[\alpha]$ of a molecule is dependent on temperature, T, wavelength, λ , and the pH of the solvent.

The polarimetric method is employed in quality control, process control, and research in the pharmaceutical, chemical, essential oil, flavor, and food industries. It is so well established that the United States Pharmacopoeia and the Food and Drug Administration include polarimetric specifications for numerous substances.²⁹ Historically, one of the earliest applications of polarimetry has been the development of bench-top polarimeters, known as saccharimeters, designed solely for the estimation of starch and sugar in foods and beverage manufacturing and in the sugar industry.³⁰ For this agricultural industry application, in which the concentrations and path lengths are high, the commercial bench-top units are adequate. However, for the low glucose concentrations found in cell culture systems and *in vivo*, much more sophisticated polarimetry systems are required to monitor the glucose, as described next.

18.3 Diabetic Monitoring

18.3.1 Commercial Colorimetric Glucose Meters

Many of the home blood glucose monitors currently in use rely on the so-called colorimetric approach to glucose sensing. The colorimetric method consists of three basic steps: (1) the invasive withdrawal of a small blood sample, (2) the application of the blood sample to a specially formulated "test strip," and (3) the automated reading of the test strip results via optical means. In this section we focus on the second and third steps of this process.

Glucose monitor test strips are available from a number of manufacturers and in several varieties. However, all commercially available glucose monitor test strips (electroenzymatic or colorimetric) rely on the quantification of reaction of glucose with the naturally occurring enzyme glucose oxidase (GOX). While a number of red-ox reaction-based methods for determining the concentration of reducing sugars exist, the specificity afforded by GOX makes it the standardly practiced assay. GOX is a protein approximately 160,000 Da in size and is composed of two identical 80-kDa subunits linked by disulfide bonds. Each subunit contains 1 mol of Fe and 1 mol of flavin–adenine–dinucleotide (FAD). During the oxidation of glucose, the FAD groups become temporarily reduced; thus, GOX is one of the family of flavoenzymes. The reaction that is catalyzed by GOX is shown in Figure 18.4. In the presence of oxygen, reduced GOX further reacts to drive the reaction to the right. This reaction, which results in the production of hydrogen peroxide, is shown in Figure 18.5.

Commercially available colorimetric sensors employ a peroxidase enzyme (commonly horseradish peroxidase) and a red-ox-coupled dye pair to generate chromophore concentrations proportional to the amount of hydrogen peroxide produced. One such dye pair is the oxygen acceptor 3-methyl-2-benzothiazolinone hydrazone plus 3-(dimethylamino)benzoic acid (MBTH-DMAB), which has an absorption peak at 635 nm. Production of hydrogen peroxide by oxidation of glucose and reduction of oxygen drives

FIGURE 18.4 Oxidation of glucose to gluconolactone by the flavoenzyme GOX.

$$GOX-FADH_2$$
 + O_2 GOX-FAD + H_2O_2

FIGURE 18.5 Production of hydrogen peroxide by reduced GOX in the presence of oxygen.

the peroxidase catalyzed production of active MBTH-DMAB chormophore and thus results in a measurable increase in absorbance of light at 635 nm. Other oxygen acceptor dyes that can be used include O-dianisidine, benzidine, and 4-aminoantipyrene and chromotropic acid (AAP-CTA), among others.³¹

Optical measurement of the dye product (and hence glucose concentration) is based on the Beer's law increase in absorbance of the dye product. In practice, this increase in absorbance is usually quantified by measuring the attendant decrease in reflectance of the active site on a test strip. The relationship between absorbance and reflectance is described by the Kubelka–Munk equation (see, for example, Reference 16), $K/S = (1 - R)^2/2R$, where K is the concentration-dependent absorbance, S is a constant related to the scattering coefficient, and R is the measured reflectance.

Practical colorimetric measurement systems typically employ a multi- (at least two) wavelength detection scheme to increase accuracy and account for variables like the background absorbance of blood, the oxygenation state of blood, and the hematocrit of the blood under test. For the case of the MBTH-DMAB dye pair, the absorbance peak at 635 nm is fairly sharp and absorbance by the dye at 700 nm is negligible. Therefore, a second reflectance measurement at 700 nm affords a correction factor, which is used to account for background and sample variations. Since the GOX reaction is a progressive one, the timing of measurements is also extremely important. Early measurement systems required that a timer be started when blood was placed on the strip and that a reading be taken after a specific period of time (typically 15 to 60 s). Modern systems overcome this inconvenience by taking continuous reflectance measurements as soon as a new test strip is inserted into the meter. When a drop of blood is placed on the meter, an immediate change in the reflectance signals the start of the reaction; multiple reflectance readings may be taken during the reaction to further increase accuracy or dynamic range of the sensor.

18.3.2 Laser Perforation and Poration Devices for Fluid Extraction

High-powered medical lasers have been used for surgical applications for decades, but over the last few years they have found their way into glucose monitoring. Currently, two laser techniques can penetrate skin tissue: one that perforates deep enough into the skin tissue to provide for the collection of a capillary blood sample, and a second poration technique that only removes the stratum corneum (the dead uppermost layer of the epidermis) of the skin to allow interstitial fluid to be collected. A standard glucose analysis method like the colorimetric one described earlier could be used on the blood sample, while a modified system would be needed for the interstitial fluid sample because it has different chemical confounding components and would have an overall lower glucose concentration level.

The laser perforation systems for collecting capillary blood typically use a pulsed laser such as an erbium yttrium aluminum garnet (Er:YAG) for ablation of the upper layers of skin.^{32,33} This particular laser has a spectral peak of 2.94 µm, which is a primary absorption wavelength band for water. These systems differ from previous surgical laser ablation systems in that they are small and battery operated, provide for a limited cutting depth, and do not heat collateral tissue or cauterize the delicate capillary vessels. The typical opening it provides is on the order of 0.3 to 0.5 mm in diameter. Overall, the

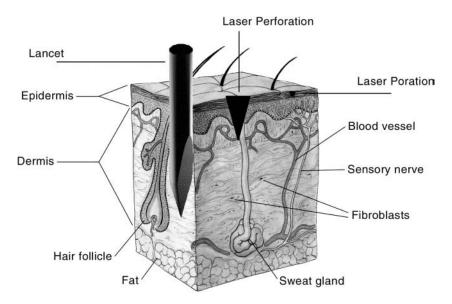

FIGURE 18.6 (Color figure follows p. 28-30.) Cross section of skin comparing the depth of penetration incurred for a standard lancet to that of both the laser perforation and laser poration approaches.

advantages of using laser light, as opposed to a stainless steel lancet tip, are that it reduces the blunt tissue trauma, provides for less bruising and more rapid healing, and eliminates sharps as a potential source of cross contamination.

The laser poration approach has been described in the literature³⁴ and is being commercially pursued by SpectRx, Inc.³⁵ The individuals at SpectRx are developing the laser system as well as the sample handling system, which includes a suction system to remove the fluid and the sensor for measuring glucose. As mentioned, the biggest difference between this approach and the laser perforation system commercially available is that this approach removes only the stratum corneum and thus interstitial fluid (ISF) is obtained instead of capillary blood. This is illustrated in Figure 18.6, which shows a cross section of the skin comparing a standard lancet, laser perforation, and laser poration for drawing blood or ISF. Initially, a very short ultraviolet (UV) laser such as an argon-fluoride excimer was used, which operates at 193 nm. The strong absorption of the UV radiation by the protein of the stratum corneum allows as little as 0.25 µm of tissue to be removed per pulse.³⁴ Firing 80 pulses from the laser would therefore create a pore in the roughly 15-µm-thick stratum corneum. Er:YAG lasers similar to the type used in the laser perforation approach and NIR diode lasers have been investigated as alternatives to excimer because of their strong absorbance by tissue water.³⁴ After poration, an ISF harvesting device that potentially houses the glucose assay must be employed, followed by a vacuum pump to help in fluid withdrawal and an ISF glucose-sensing meter.

18.3.3 Spectroscopic Methods for in Vivo Glucose Diagnostics

18.3.3.1 Fluorescence Spectroscopy

18.3.3.1.1 Glucose Oxidase and O2-Based Fluorescent Sensors

The specificity afforded by the catalytic enzyme GOX has been exploited to create a number of fiber-optic fluorescence-based sensors for glucose. Recall that, in the reaction of Figures 18.4 and 18.5, O_2 and glucose are consumed to produce gluconolactone and H_2O_2 . A simple approach for creating a sensor based on this reaction is to incorporate an oxygen-sensitive dye such as a ruthenium complex. Ruthenium(II) complexes exhibit fluorescence quenching in the presence of oxygen; therefore, a decrease in local oxygen concentration can be detected as an increase in fluorescence of a ruthenium-based dye. Incorporating GOX and a ruthenium dye together results in a sensor whose fluorescence increases with

increased glucose concentration since increased glucose concentration will lead to the consumption of more O₂. One example of such a sensor is described in References 36 and 37. A disadvantage of this simple approach is that a decrease in local oxygen content may not be distinguished from a rise in glucose concentration. Li et al. have solved this problem by creating a dual-channel sensor with a ruthenium–GOX channel and a second ruthenium-only channel.³⁸ Thus, the second O₂-sensitive channel can be used to correct for changes in local oxygen tension. Development of GOX-based fiber-optic sensors continues, and more elaborate sensors have been described.^{39,40}

18.3.3.1.2 Nonoxygen-Based Fluorescent Sensors

One of the first nonoxygen-based fluorescence assays investigated for glucose monitoring *in vivo* used an indwelling fiber optic approach and a semipermeable membrane. In this initial approach a fluorophore was linked to dextran, which was bound on the inner surface of the membrane to a lectin, concanavalin A (Con A) at the tip of the fiber, as shown in Figure 18.7A. Glucose has a higher affinity for the membrane-based lectin and thus displaces the dextran with the fluorophore causing the fluorescent light to be returned through the fiber. The use of concanavalin A (Con A) as the membrane-bound molecule affords the technique fairly good sensitivity because of Con A's strong affinity for glucose. Because the approach only used a single fluorophore, the probe was sensitive to alignment and had to be made to ensure the beam did not shine on the walls of the membrane.

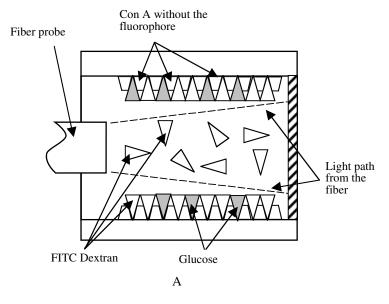

A second approach, which was independent of the beam path into the fiber, was also developed by this group. 43,44 This glucose monitoring approach is based on fluorescent resonance energy transfer (FRET) between two fluorescent molecules — in this case fluorescein isothiocyanate (FITC) bound to dextran and tetramethylrhodamine isothiocyanate (TRITC) bound to Con A, as depicted in Figure 18.7B. When TRITC-Con A binds FITC-dextran, the fluorescent labels are brought to within the required molecular proximity (~50 Å) for FRET-based quenching to occur. 44 In this case, energy from excited FITC is donated to the TRITC acceptor, resulting in quenching of the observed FITC fluorescence peak. Using this approach, glucose concentrations can be measured by a rise in amplitude of the FITC fluorescence peak with increasing glucose concentration as depicted in Figure 18.8. Another potential means of monitoring the change with glucose is based on phase-modulation fluorimetry, a technique that measures fluorescent lifetimes. 45

In either approach, the fluorescence techniques are very specific to glucose and sensitive to glucose concentration, without interference from other constituents frequently found in blood. Other advantages of the fiber-optic chemical sensors, specifically over electrochemical sensors, include miniaturization, geometric flexibility, and the lack of electrical contact between the sensor and sample. However, inherent problems with an indwelling optical fiber-based approach are similar to the problems associated with electrochemical approaches and include membrane fouling, encapsulation, increase in response time, and increased potential for infection. In addition, a fiber is small and thereby yields very low signal-to-noise-ratios.

As an alternative to fiber-optic-based assay sensing, it has been proposed that fully implantable fluorescence-based glucose assays, encapsulated using various membranes or polymers, could be used. 46,47 It has been suggested that small particles containing the FRET-based assay chemistry described previously could be implanted in the superficial dermis and interrogated by external means. In order for this type of implantable device to be useful, it must be biocompatible, must not exhibit acute reagent consumption or degradation, and must provide a means of communicating the sensor output to the physician or patient. Also, once injected, the implant will not be exposed to blood but will rather be exposed to interstitial fluid. The fluorescent assay has the potential problem of limited chemical and photochemical stability over the long term and the construct, such as the hydrogel or dialysis membrane that encases the assay, must be biocompatible.

18.3.3.2 Infrared and Near-Infrared Absorption Spectroscopy

Infrared and NIR absorption spectroscopy techniques have long been mainstays of nondestructive chemometric analysis and therefore hold great potential for the development of noninvasive blood glucose

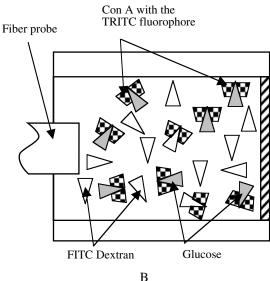

FIGURE 18.7 Characterization of a fiber optic fluorescence assay using (A) a single fluorescent molecule bound to dextran. Note that the light path is critical in this configuration since it is necessary to measure fluorescence only from the free dextran and not from that bound to Con A on the walls of the sensor. (B) A FRET approach that uses two fluorescent molecules (FITC and TRITC), one bound to Con A and the other to dextran. Note that the FITC is quenched when placed in close proximity to the TRITC, as would be the case in the absence of glucose. The beam alignment is no longer critical.

measurement techniques. Optical absorption methods are based on the concentration-dependent absorption of specific wavelengths of light by glucose or other compounds of interest. The methods are attractive because, in theory, a beam of nonionizing radiation may be directed through a blood-containing portion of the body and the exiting light analyzed to determine the content of glucose or other molecules of interest. In the infrared region and, more specifically, the mid-infrared (MIR) region (from about 5 to $50 \mu m$), the so-called "fingerprint" spectrum can be found. Absorption bands in this region are due to fundamental resonances of specific functional groups and bonds contained within the molecule, and

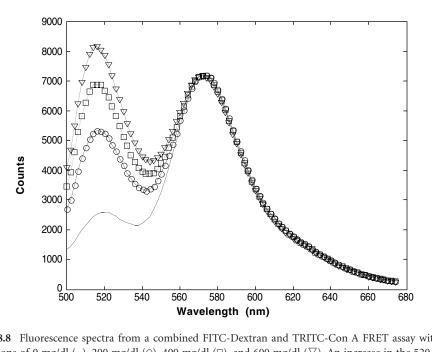

FIGURE 18.8 Fluorescence spectra from a combined FITC-Dextran and TRITC-Con A FRET assay with glucose concentrations of 0 mg/dl (-), 200 mg/dl (\bigcirc), 400 mg/dl (\square), and 600 mg/dl (∇). An increase in the 520-nm FITC fluorescence relative to the 580-nm TRITC fluorescence is observed with increasing glucose concentration.

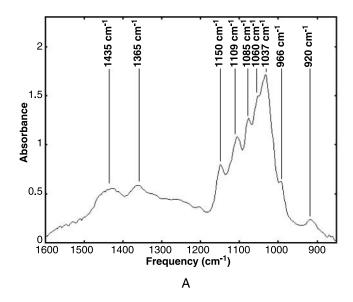

they tend to be rather sharp. The fingerprint spectrum, therefore, offers highly specific information about the molecular makeup of the compound or mixture under study. In contrast, absorption bands in the near infrared are composed of complex overtone or combination bands and tend to be broad, overlapping, and much less specific. Figures 18.9A and 18.9B show, respectively, portions of the MIR and NIR absorption spectra for glucose.

Despite the specificity offered by infrared absorption spectroscopy, its application to quantitative blood glucose measurement is limited. A strong background absorption by water and other components of blood and tissue severely limits the pathlength that may be used for transmission spectroscopy to roughly $100~\mu m$ or less. Further, the magnitude of the absorption peaks and the dynamic range required to record them make quantitation based on these sharp peaks difficult. Nonetheless, attempts have been made to quantify blood glucose using infrared absorption spectroscopy *in vitro* and *in vivo*. $^{48-52}$

In contrast to the infrared and MIR spectrum, the NIR spectrum passes relatively easily through water and body tissues allowing moderate pathlengths to be used for measurements. Further, NIR instrumentation is readily available and relatively easy to use. Thus, a large amount of effort has been devoted to the development of NIR spectroscopy techniques for noninvasive measurement of blood glucose.

Though all optical glucose sensing methodologies require use of a prediction model relating optical measurements to glucose concentration, the broad overlapping peaks and complicated nature of multicomponent, NIR spectra make single or dual wavelength models inadequate. NIR absorption bands may be significantly influenced by factors such as temperature, pH, and the degree of hydrogen bonding present; the unknown influence of background spectra further complicates the problem. For this reason, quantitative NIR spectroscopy has long relied on the development of very high-order multivariate prediction models and empirical calibration techniques. A brief analysis of the signal variation due to glucose in a typical sample should serve to illustrate the problem at hand.

The physiological range of glucose values seen in the normal human body may range from 80 to 120 mg/dl and should ideally remain around 100 mg/dl (5.5 mM). In diabetics, blood sugar may rise as high as 500 mg/dl. The generally accepted figure of merit for required accuracy of a useful glucose meter is 10 mg/dl (0.55 mM). For the most identifiable NIR glucose peak at approximately 2.27 µm, molar

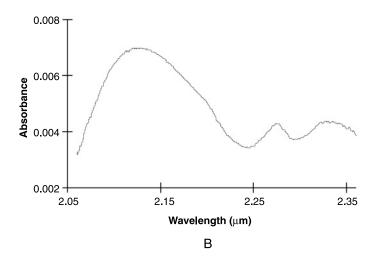

FIGURE 18.9 Optical absorption spectra for glucose. (A) MIR region extending from 1600 to 900 cm⁻¹ or 6.25 to 11 μ m and showing absorption peak assignments. (B) NIR region extending from 2.0 to 2.5 μ m or 5000 to 4000 cm⁻¹. Note that the magnitude of the three absorbance peaks in the NIR region is much smaller.

absorptivity is roughly 0.23 M^{-1} cm⁻¹. The molar absorptivity of water at the same wavelength is 0.41 M^{-1} cm⁻¹ and the concentration of the water in typical body tissues is approximately 39 M. Consider a transmission measurement made through 1 mm of body tissue. The background absorbance due to water will be about 1.6 and that due to glucose will be about $1.26 \cdot 10^{-4}$. To meet the accuracy requirement, we must further be able to discern an absorbance change of about $1.26 \cdot 10^{-5}$ on a background of 1.6, and it is evident that even a change in tissue hydration of 1/1000 of a percent would result in a larger signal change than would a 10 mg/dl change in glucose concentration.

For this reason, high-order multivariate models that incorporate analysis of entire spectra must be used to extract NIR glucose information. A number of excellent and authoritative sources on such methods are available, ^{18,53,54} and these methods are not discussed here other than to introduce some of the terminology associated with their formulation, use, and practice.

Multivariate calibration techniques focus on finding a response matrix suitable to describe spectral observations obtained when analyzing a solution containing particular concentrations of a number of analytes. Once this response matrix has been found, it may then be inverted in order to relate analyte concentrations to observed spectral readings. The most direct method is the classical least squares method in which spectral observations are made of a number of samples with known analyte concentrations. The problem can be written mathematically as A = KC, where A is the matrix containing spectral observations for each sample, K is the response matrix, and C is the concentration matrix containing analyte concentrations for each known sample. In the classical least squares solution, K is computed from A and C as $K = AC^T(CC^T)^{-1}$, and estimates of the concentration of analytes in subsequent samples may be determined from the spectral observations A as $C = (K^TK)^{-1}K^TA$.

This approach assumes that all measurement errors occur in the spectral observations and that the concentration matrix C is known exactly. This is often not the case, however, and alternative formulations for the least squares calibration model solution have been proposed that include inverse least squares and partial least squares (PLS). The latter has become overwhelmingly popular due to its robust ability to model complex data interactions and to formulate powerful prediction models. The PLS technique employs an iterative singular value decomposition of the A matrix to extricate spectral changes most strongly correlated to analyte concentration changes and thereby creates a number of model "factors," which may be linear combinations of many of the observations in A.

In the practical application of PLS, data observations are typically split into two groups: one is used for formulation of the model (calibration) and the other is used for validation of the model (prediction). Two common statistics are the standard error of calibration (SEC), which is the RMS prediction error of the model compared to the calibration data set, and standard error of prediction (SEP), which is the RMS prediction error of the model when applied to the validation set. A problem that can arise in PLS modeling is "overfitting" of the data in which noise or spurious trends evident in the calibration data may actually be factored into the model if chance correlation to analyte concentrations exists. The separation of calibration and validation data sets is one technique used to detect potential overfitting.

For the purposes of discussion of the literature, it is useful to break the NIR region into the very NIR region (from 700 to 1300 nm) and the NIR region (from 2.0 to 5.0 μ m). The attraction to the very NIR region is that optical detectors and sources in this region are particularly easy to come by, transmission through tissue is rather good, and transmissive fiber optics may be employed to facilitate probe design. However, glucose absorption bands are particularly weak in this region, and it may be difficult to acquire signals with substantial signal to noise to allow robust measurement. Examples of very NIR studies of glucose determination include References 55 through 58.

Longer in the NIR spectrum, a relative dip in the water absorbance spectrum opens a unique window in the 2.0 to 2.5 μ m wavelength region. This window, saddled between two large water absorbance peaks, allows pathlengths or penetration depths on the order of millimeters and contains specific glucose peaks at 2.13, 2.27, and 2.34 μ m. So far, this region has offered the most promising results for quantifiable glucose measurement using NIR spectroscopy. The instrumentation required for spectral measurements in this region is somewhat more expensive. Typically, FTIR spectrometers with InSb, HgCdTe, or extended InGaAs are required to obtain spectra with sufficient signal to noise. A further challenge is that fiber-optic materials appropriate for this spectral region are not as readily available. Chalcogenide fibers have typically high refactive indices leading to large Fresnel losses during coupling. They also exhibit sharp bands in transmission that may be bend dependent. Very low –OH glass fibers provide partial transmission out to about 2.3 μ m, but fall off very rapidly in this region. Sapphire fibers and now fluoride are transmissive in this region and offer promise; however, they are quite expensive and typically more brittle and less flexible than glass fibers. Investigations of glucose determination using this spectral region include those recounted in References 59 through 62.

18.3.3.3 Raman Spectroscopy

Early attempts to employ Raman techniques to measure glucose concentration directly in aqueous solutions, serum, and plasma have met with some success *in vitro*.^{63–67} However, efforts to utilize these

techniques *in vivo* for transcutaneous measurement of whole blood glucose levels have met with considerable difficulty.^{67,68} This is partly because whole blood and most tissues are highly absorptive; in addition, most tissues contain many fluorescent and Raman-active confounders.⁶⁸ As a surrogate to blood glucose measurement, several investigators have suggested using Raman spectroscopy to obtain the glucose signal from the aqueous humor of the eye.^{68–70}

The glucose content of the aqueous humor reflects an age-dependent steady-state value of approximately 70% of that found in blood, and the time lag between aqueous humor and blood glucose has been shown to be on the order of minutes. For Raman sensing, the aqueous humor of the eye is relatively nonabsorptive and contains many fewer Raman-active molecules than whole blood. However, even though only four or five Raman-active constituents are present in significant concentrations in the aqueous humor, it is still necessary to use both linear and nonlinear multifactor analytical techniques to obtain accurate estimates of glucose concentrations from the total Raman spectrum.⁷¹ In addition, as with other tissues, when excited in the near-infrared region (700 to 1300 nm) Raman spectra encounter less fluorescence background. However, although the background fluorescence falls off when excitation is moved to the NIR region, the Raman signal also falls off to the fourth power with wavelength. Thus it remains to be seen if the Raman approach could be measured at laser intensities that can be used safely in the eye.

18.3.3.4 Polarimetric Glucose Sensing

As mentioned in the *in vitro* analysis section earlier, molecules such as glucose have the ability to rotate plane polarized light and this rotation is proportional to the concentration of the molecule. For polarimetry to be used as a noninvasive technique for blood glucose monitoring, the polarized light signal must be able to pass from the source, through the body, and to a detector without total depolarization of the beam. Since most tissues, including the skin, possess high scattering coefficients, maintaining polarization information in a beam passing through a thick piece of tissue (i.e., 1 cm), which includes skin, would not be feasible. Even highly scattering tissue thicknesses of less than 4 mm incur 95% depolarization of the light due to scattering from the tissue. In addition, in these highly scattering tissues a large amount of proteins and other chiral substances have a much stronger rotation than that due to glucose, making it very difficult to measure the millidegree rotations required for physiologic glucose concentrations. Similar to the Raman approach, the aqueous humor of the eye as a site for detection of *in vivo* glucose concentrations has been suggested as an alternative to transmitting light through the skin.^{72–77} For the polarimetric approach, the cornea and the aqueous humor provide a low scattering window into the body and, because the aqueous humor is virtually devoid of proteins, the main optically chiral molecule is glucose.

Unlike on line processing systems that measure relatively high sugar concentrations (grams) and allow for longer pathlengths (10 cm), the *in vivo* glucose concentration is smaller and, if the eye is to be used as the sensing site, the pathlength is only 1 cm. Therefore, advances in polarimetric instrumentation have only recently made it possible to measure the small rotations due to glucose at physiological levels. For example, at a wavelength of 670 nm (red), glucose will rotate the linear polarization of a light beam approximately 0.4 millidegrees per 10 mg/dl for a 1-cm sample pathlength. In order to measure such small rotations, a very sensitive and stable polarimeter must be employed. Throughout the past decade many researchers have investigated the development of such sensitive units.^{74–77} The primary approach being investigated today includes a light source (typically a laser), a means of modulating the polarization (photoelastic modulator, faraday rotator, etc.), and a means of detecting the signal, typically by using a lock-in amplifier or some means of heterodyne detection.

The eye as a sensing site for polarimetric glucose monitoring is not without its share of problems that need to be overcome. The cornea is birefringent, which means it can change the polarization vector of the light (i.e., like a quartz crystal); this change is variable in the presence of eye motion, which can confound the polarization signal due to glucose. For polarimetric monitoring, the light must travel across the anterior chamber of the eye but, due to its curvature and change in refractive index, the eye naturally tries to focus all the light impinging on it toward the retina. Therefore, the key issues to be addressed

for this approach to be feasible for monitoring glucose include building an instrument that can accommodate for the large birefringence of the cornea, particularly in the presence of motion artifact, and to develop an instrument that can safely and simply couple the light source across the anterior chamber of the eye.

18.3.3.5 Other Optical Glucose Diagnostic Approaches

18.3.3.5.1 Photoacoustic Spectroscopy

Photoacoustic spectroscopy (PAS) can be used to acquire absorption spectra noninvasively from samples, including biological ones. The photoacoustic signal is obtained by probing the sample with a monochromatic radiation that is modulated or pulsed. Absorption of probe radiation by the sample results in localized short-duration heating. Thermal expansion then gives rise to a pressure wave, which can be detected with a suitable transducer. An absorption spectrum for the sample can be obtained by recording the amplitude of generated pressure waves as a function of probe beam wavelength. Because high signal-to-noise measurements require reasonable penetration of the sample by the probe radiation, the NIR region holds the same attraction as for more conventional NIR spectroscopy approaches. A purported advantage of PAS, however, is that the signal recorded is a direct result of absorption alone, and scatter or dispersion does not play a role in the acquired signal.

PAS techniques in the NIR region face many of the same challenges attendant to other NIR spectroscopic methods, namely, that complicated and empirical calibration models must be created in order to account for the broad overlapping spectral bands associated with the NIR spectrum. Further, the technique requires expensive instrumentation and the measurements are particularly sensitive to variables including temperature, transducer pressure, and sample morphology. Some examples of PAS techniques applied to glucose sensing include those found in References 78 and 79.

18.3.3.5.2. Optical Property Measurements as Indicators of Glucose

The refractive index (RI) of a material is routinely used to determine sugar concentrations in syrups, honey, molasses, tomato products, and jams for which the glucose concentration is very high. The RI of a solution of carbohydrate such as glucose increases with increasing concentration and so can be used to measure the amount of carbohydrate present. The RI of a liquid can easily be determined by optically measuring the angle of refraction at a boundary between the liquid and a solid of known RI. The RI is also temperature and wavelength dependent and so measurements are usually made at a specific temperature (20°C) and wavelength (589.3 nm). This method is quick and easy to carry out and can be performed with simple handheld instruments.

The change in refractive index is also directly related to a change in the elastic scatter of a molecule. Therefore, the measurement of light scatter in the NIR region has been investigated for potentially quantifying glucose noninvasively; both *in vitro* and *in vivo* results have been obtained. 80–82 This is much more challenging than for the agricultural measurement because *in vivo* blood glucose, as opposed to *in vitro* sugars such as that found in syrup, has very small concentrations. In addition, the specificity is potentially problematic because other physiologic effects, unrelated to glucose concentration, could produce similar variations of the reduced scattering coefficient with time. The measurement precision of the reduced scattering coefficient and separation of scatter and absorption changes is another potential problem with this approach. Tissue scattering is caused by a variety of substances and organelles (membranes, mitochondria, nucleus, etc.) and all have different RIs; thus, this approach also needs to take into account the different RIs of tissue. Lastly, there is a need to account for factors that might change the reduced scattering coefficient such as variations in temperature, red blood cell concentration, electrolyte levels, and movements of extracellular and intracellular water.

18.3.3.5.3 Optical Coherence Tomography

Optical coherence tomography (OCT) provides a particularly sensitive means for measuring the optical properties of turbid media including scatter and RI. OCT is an optical ranging technique in which a very short coherence length source is coupled to an interferometer with a sample in one arm and a reference reflector in the other. As the reference reflector is scanned, depth resolved interference fringes are produced

with amplitude dependent on the amplitude of backscattered radiation. Because the scattering coefficient of tissue is dependent on the bulk index of refraction, an increase in RI and a decrease in scatter can be detected as a change in the slope of fall-off of the depth-resolved OCT amplitude. At least one group has explored this detection technique for measurement of glucose *in vivo*.⁸³

19.1 Introduction

Clinical diagnostic tests can be performed *in situ* or on physiological specimens that have been removed from the living organism. These latter tests are referred to as *in vitro* diagnostics. Specimens for *in vitro* diagnostic testing range from tissue and cell samples (or extracts from them) to respired or dissolved gasses and all types of physiological fluids and exudates. Analytes of interest span the gamut from inorganic ions and small organic molecules to cellular entities such as bacteria and viruses. Testing methods and their underlying technologies are almost as diverse as the samples evaluated. Furthermore, these tests are delivered on a variety of platforms ranging from dedicated-function, single-use, noninstrumented devices to high-throughput automated analyzers capable of performing a wide range of tests in a batch or a random access mode.

This chapter surveys optically based detection and transduction modalities frequently encountered in instrumented *in vitro* clinical diagnostic applications. Our approach is to summarize the characteristics of these system components with particular emphasis on the function, precision, and application of the different system components.

Automated *in vitro* diagnostic instruments capable of performing assays for multiple analytes on multiple samples may be dated to the introduction of the Technicon Auto Analyzer in 1957.¹ This innovation, and other early automated optical absorbance-based clinical analyzers, led the transformation of the laboratory measurement paradigm from individual samples analyzed manually to automated high-throughput instrumental analysis. Since the debut of the original Auto Analyzer, numerous signal generation, transduction, and systems have been introduced to expand and enhance the repertoire and performance of *in vitro* clinical laboratory instruments greatly.^{2,3} Today, these instrument systems are being pushed to provide ever higher levels of analytical accuracy and precision — at progressively lower

limits of detection in a rapidly broadening array of assay types and in the face of significant legal and regulatory requirements, reduced laboratory staffing, and severe cost constraints.⁴⁻⁶

From a systems engineering perspective, a clinical diagnostic instrument can be viewed as a sequence of black boxes that transduce a parameter of clinical interest, such as the concentration of an analyte, into a form that can be used by the clinician. In most typical clinical diagnostic tests, the sequence of black boxes required to perform this function include sample acquisition and preparation, signal generation, signal transduction, data reduction, and results reporting. These black boxes, and the details of the operations that they perform, are tied together by the "intended use" of the test. The concept of intended use is particularly important to the developer of *in vitro* diagnostic tests because it often dictates the overall approach to be taken, the methods to be used, and the compromises to be made during the development process. For the purposes of this chapter, the focus is on the "black box" labeled signal transduction. It must, however, be recognized that the other "boxes" play critical roles in the overall system.

19.2 Assay Chemistry

By convention, the sample acquisition, sample preparation, and signal generation functions are usually lumped together under the rubric of "assay chemistry." The key design goals in the development of an assay chemistry are the delivery of an optical signal that is a tightly controlled function of the concentration of the analyte of interest and that exhibits a significant optical contrast between the analyte and its matrix. The actual signal delivered by the assay chemistry defines the type, spectral characteristics, magnitude, dynamic range, and signal-to-noise ratio (SNR) of the signal presented to the signal transduction element, while the intended use of the test defines the required measurement resolution. The assay chemistry also establishes the characteristics of the noise component of the input signal and operational parameters such as timing constraints.⁷

The assay chemistry can generate the necessary optical signal in any of a diverse variety of ways depending on the characteristics of the target analyte and specimen as well as on the intended use of the test. In the simplest cases, the analyte has some intrinsic characteristic that allows it to be directly differentiated from its matrix. In the majority of cases, however, the specimen must be treated with some extrinsic reagent to generate the necessary contrast. Chemical reagents that bind to (stain, label) or react with the analyte to generate an optical contrast are the basis of many traditional clinical chemistry, cytological, and histological tests. Tests based upon these types of reagents can be quite sensitive, but frequently are somewhat limited in specificity.

Increased specificity in signal generation is often obtained by incorporating some type of biological "recognition" moiety such as an enzyme, antibody, or nucleic acid probe into the reagent. Enzymatic reagent(s) are used to convert the target analyte into some other molecular form in a highly specific manner.⁸ Depending on the specifics of the particular analyte–enzyme combination used, the contrast is generated by conversion of the analyte into some product or through ancillary chemical or enzymatic reactions stoicheometrically linked to the primary conversion.^{7,9}

Antibodies, as well as certain other biological molecules such as nucleic acid probes, lectins, and certain nonantibody proteins, have the characteristic of being able to bind to an analyte with a high degree of specificity and tenacity. ^{10,11} In cases such as agglutination tests, this binding is used directly to cross-link multiple instances of the analyte, leading to the formation of a detectable aggregate or precipitate. ^{12,13} In other cases, the specific binding agent is used as a carrier for some indicator moiety such as a chromaphore or fluorophore. ^{12,13} Alternatively, the binding agent may serve as a carrier for an enzyme that, in turn, stoicheometrically causes a detectable transformation in some indicator species.

Generation of contrast is implemented in one of two ways: "end point" or "kinetic." In an end point assay, where the contrast-generating reaction is run to completion, the total amount of contrast produced is directly limited by the amount of analyte present. Kinetic assays, on the other hand, are performed under conditions where the rate of contrast formation is directly related to analyte concentration. End point assays tend to be relatively insensitive to process parameters such as reagent concentrations and reaction temperature, while kinetic assays are by definition sensitive to any and all factors that affect the

rate of the reaction. Kinetic assays, therefore, impose stringent process control requirements that must be met in order to obtain valid results. However, accurate kinetic results can be obtained well before the assay chemistry has proceeded to completion. Thus, a kinetic assay is often the method of choice in an instrument-based system where sample throughput is a critical issue.

The methods that assay developers use to generate and optimize the necessary signal are many, varied, and, in any case, well beyond the scope of this chapter. However, it should be kept in mind that the assay chemistry can be and often is one of the larger contributors to the total system error budget. Some factors that contribute to this, such as accuracy of fluid transfers, rates and thoroughness of mixing, concentrations of reagents, and stability of temperature control, are operational issues. Chemical and biochemical factors, such as the purity and specificity of the assay reagent for the target analyte, can also be significant. The sample is yet another common contributor to the system error budget because it may contain substances that interfere with the detection reaction, signal transduction, or even physical operations such as fluid transfer. During the design process, accounting for and managing errors originating in the assay chemistry are as important as attending to those associated with the instrumentation.^{7,14}

19.3 System Components

The components within the signal transduction black box usually consist of an optical system to deliver the signal produced by the assay to the transducer (detector), a detector that transduces the signal from the optical to the electronic domain, and supporting electronics that condition the detector output and convert it into a form suitable to be supplied to the data reduction black box. With few exceptions such as photomultiplier tubes (PMTs) and avalanche photodiodes used in the photon counting mode, almost all detectors commonly used in clinical diagnostic instruments intrinsically produce an analog output that is a continuous representation of the optical input to the detector. Many modern instruments, however, perform most, if not all, of the necessary signal conditioning and data reduction operations in the digital domain. The location in the signal processing chain at which analog-to-digital (A/D) conversion is performed and the characteristics of the circuitry utilized to perform this conversion are design decisions that can have significant impacts upon the error budget for the signal transduction process. 15–18

In most types of clinical diagnostic instruments, an illumination subsystem is an essential component of the signal transduction optics. The major requirement placed on the sample illumination subsystem is that it illuminate the portion of the specimen to be interrogated in a uniform and stable manner, with light of suitable application specific intensity, spatial distribution, and spectral characteristics. Certain applications such as interferometric or polarization-based techniques require that additional controls be placed on the illuminating wavefront.

Numerous illuminator designs have been developed to meet the needs of different applications. 19,20 Incandescent and arc lamps remain the most popular illumination sources; however, with the advent of high power and "white" light-emitting diodes (LEDs) and relatively low cost diode lasers, solid-state illuminators are appearing in some applications. Most illuminators utilize free space optics, but optical waveguide—based light delivery systems can be useful in some applications.

Almost all clinical laboratory instruments utilize some form of optical arrangement to capture the light passing through or emitted by the sample and to deliver this light to the detector. In addition to light capture and delivery, most such optical systems process the captured light in some manner. Most commonly, this processing involves operations such as reformatting the size or shape of the captured beam of light to match the detector, wavelength selection, and aperturing or masking to control stray light. Again, numerous optical designs have been developed to meet the needs of specific applications.

Most of these designs are of the imaging or pseudo-imaging type, although true nonimaging optics are employed in some specialized applications.

Imaging optics are exemplified by photographic lenses and microscope objectives and are intended to deliver a spatially resolved image of the sample to the detector. The lenses or mirrors used in these applications are typically required to exhibit a uniform transfer function over the field of view and often must incorporate corrections for geometric and chromatic aberrations. The pseudo-imaging optics used

in most photometer designs are intended to deliver an image of the sample to the detector without regard for maintaining spatial resolution. Efficient delivery of optical power from the sample to the detector is a major design consideration in this type of system, and transfer function uniformity and aberration correction are lesser concerns. Nonimaging optics, usually in the form of integrating spheres and compound parabolic or elliptical concentrators, are primarily used in chemiluminescent and similar photon-limited applications in which optical collection and throughput efficiency must be maximized while spatial resolution and the light intensity distribution at the detector are irrelevant.^{21,22}

19.4 Detection Modalities

This section considers the transduction of several of the more widely used types of optical signals from the perspective of the physics of the measurement and the sources and effects of potential measurement errors. As implied earlier, the designs of the signal transduction subsystems of most clinical laboratory instruments are unique reflections of numerous application-specific design decisions and trade-offs made during the course of the instrument development process. Because a detailed mathematical analysis of a measurement system is sensitive to the specifics of the design and multiple designs need to be analyzed in order to represent current practices adequately, space constraints dictate that a number of the topics presented in this section be addressed in broad qualitative generalities rather than through formal derivations. For similar reasons, equations will be presented in this section without derivation or proof. Table 19.1 provides a summary of *in vitro* clinical diagnostic applications of various detection modalities.

19.4.1 Optical Absorbance

Optical absorbance is a contrast parameter widely utilized in instrumental and in visual clinical diagnostic tests. Traditionally, instrument-based absorbance assays are based upon the photometric measurement of optical transmission or reflectance of a sample at one or a small number of the wavelengths in the UV or visible spectral region. A few recently introduced tests, however, extend this spectral range into the near-infrared (NIR) region or utilize data captured at a large number of wavelengths.

Optical absorbance measures the reduction in the intensity of an incident beam by absorptive interaction with the sample. In this case, the governing equation for optical transmittance (T) under monochromatic illumination is

$$T = (I/I_0) = 10^{(-\varepsilon LC)} \tag{19.1}$$

where I_0 is the incident light intensity, I is the measured light intensity after passage through the sample, L is the optical path length through the sample in centimeters, C is the analyte concentration in molar units, and ε is the molar absorptivity (extinction coefficient) of the analyte in units of I/M-cm.

Equation 19.2 is the linearized form of Equation 19.1. This equation, which is known as Beer's law of absorbance, is used far more frequently in clinical diagnostic applications than is Equation 19.1 because absorbance (*A*) is a linear function of analyte concentration.

$$A = \log_{10}(I_0/I) = -\log_{10}T = \varepsilon LC$$
 (19.2)

The measurements of I_0 and I are subject to noncompensating errors from a number of sources. Classical single- and dual-beam optical arrangements, for example, carry the implicit assumption that the sample and reference paths differ only in concentration of the target analyte. Single-beam measurements further assume that the intensity and spectral distribution of the illumination source is stable over the entire period of time required to make the measurements. For these reasons, many clinical photometers use a single-beam arrangement in which I_0 is determined from a sample of the illuminating beam that is "picked off" before it enters the cuvette. These systems treat a "reagent blank" as a separate

TABLE 19.1 In Vitro Clinical Diagnostic Applications of Detection Modalities

Detection	Typical Assay Types	Routine Analytes	Features
Absorbance			
Single wavelength	Chemical, EIA	Clinical chemistries, drugs	
Dual wavelength	Chemical, EIA	Clinical chemistries, drugs	Partially self-compensating
Diffuse Reflectance			
	Lateral flow immunoassays	Drugs, small molecules	Simplified processing
	Transverse flow immunoassays	Drugs, small molecules, large molecules, bacteria, viruses	Simplified processing
Fluorescence			
Intensity	Direct staining, EIA, DNA probe	Drugs, small molecules, large molecules, bacteria, viruses	Sensitive
Polarization	Direct binding immunoassays	Drugs, small molecules	Assay mixture separtion not required
Chemiluminescence	Direct binding immunoassays	Drugs, small molecules, large molecules, bacteria, viruses	Very sensitive
Waveguide Sensors			
Absorbance	Competitive immunoassays	Drugs, small molecules	Simplified processing
Fluorescence	Competitive immunoassays	Drugs, small molecules	Simplified processing
Refractive index	Specific binding	Drugs, small molecules, large molecules, bacteria, viruses	No extrinsic reagents
Imaging Systems			
Classical	Image analysis	Cytology, histology, microbiology, agglutination	Combines chromatic and morphological
Multiplexed	Photometric	Drugs, small molecules, large molecules, bacteria, viruses	Improved throughput
Spectrographic	Hyperspectral	Cellular analysis	Detailed characterization and morphology

sample, the apparent analyte concentration of which is subtracted from those of the corresponding experimental samples. 17,23

Equation 19.2 can be used to estimate the effects of noise on the limits of detection obtainable in absorbance measurements. For example, at low absorbances, a noise level equivalent to $0.001 \times I_0$ corresponds to an uncertainty in A of approximately 4.4×10^{-4} . If the detection limit is taken as three times the noise level, the corresponding lower limit of detection (LOD) is approximately 0.0013A. Applying the same calculation at high absorbances gives an upper LOD of about 3.00A. This noise also limits the resolution with which measurements can be made between the lower and upper LODs.²⁴

Measurement uncertainties also play a role in the accuracy of determination of T or A. At analyte concentrations that correspond to high values of T (low A), I and I_0 are large and of nearly equal magnitude. Under these conditions, measurement resolution limitations and optical and electronic noise in the system degrade the accuracy of the measurements and thus the accuracy of T or A. At the opposite extreme, $I << I_0$, electronic noise and stray light in the system effectively introduce a "floor" under the measurement of I. Due to the large difference between I and I_0 , limitations on the dynamic range and resolution of the measurement device may also affect the accuracy with which T and T are determined. The effects of these factors can be illustrated by differentiating Equation 19.2 to obtain

$$\delta A/A = 0.434 \ dT/(T \log_{10} T) = \delta C/C = RCE$$
 (19.3)

where RCE is the relative concentration error. Qualitatively,

At high T/low A, T approaches 1 and log T approaches 0, so the RCE increases.

At low T/high A, the term T log T approaches 0 and the RCE increases.

At some intermediate value of *A*, the RCE passes through a minimum with a range of low RCE centered about that minimum. ^{15,17}

Deriving Equation 19.3 in a form that includes a suitable noise model for the system allows determination of the value of A at which the RCE will be at a minimum. Assuming a shot-noise limited model in which uncertainties in I_0 are neglected, for example, yields A = 0.869. The range of A over which the RCE remains within preselected limits can also be determined. In this particular example, assuming that the RCE is less than twice its minimum value translates to the lowest measurement errors occurring in the range $0.201 < A < 2.326.^{25-27}$

Both ε and L can be sources of analytical error when T or A is translated into analyte concentration by means of Equation 19.1 or 19.2, respectively. The value of ε is wavelength dependent and thus takes on a range of values over the spectral passband of the instrument. Similarly, the optical path length through a clinical laboratory sample is not necessarily well controlled over the entire region being interrogated, particularly when a disposable cuvette is used for each measurement. In cases such as microscopy specimens, the specimen can be the source of significant path length variability. In the slope of the A vs. C relationship, the assay/instrument combination in question can be experimentally determined and used as an empirical constant that subsumes ε and L as well as fixed errors in these parameters. This empirical constant can be used in place of the εL term in Equations 19.1 and 19.2. To the extent that it cannot be controlled by design or process, variability must be included in the system error budget. The assay chemistry can also contribute to the measurement error and has been found to produce RCE $\sim 1/A$.

Bichromatic absorption photometry can be a useful technique in situations where the effects of interfering factors such as light scattering vary more slowly with wavelength than does the absorbance of the analyte of interest. If the absorbance of the sample is measured at two wavelengths, one at the peak absorbance of the analyte and the other at a (typically longer) wavelength where the analyte has no or minimal absorbance, an approximate correction for the interfering factors can be performed by subtracting the second measurement from the first.²⁹

19.4.2 Reflectance

Lateral and transverse flow assays are performed and "read" on porous surfaces such as chromatographic and depth filtration media. Many of these assays utilize a color-generating indicator reaction and can be read out visually or by means of a photometric instrument. Because the substrates used in lateral and transverse flow assays tend to be highly scattering and opaque, the measurement instrument of choice is almost always a reflectance photometer. Light reflected from a surface consists of specularly reflected and diffusely reflected components. The intensity of the specular component is largely determined by the surface properties of the sample and is generally not of analytical utility. The intensity of the diffuse component, which includes contributions from the absorbance of light by the specimen and the scattering of light by the specimen and substrate, can be used to determine the concentration of the indicator species. In the ideal limiting case where all reflection is diffuse, light scattering is independent of the incident wavelength, the specimen is infinitely thick, and the indicator species is infinitely diluted in a nonabsorbing matrix, the relationship between diffuse reflectance, absorbance, and light scattering is given by the Kubelka–Munk equation³⁰

$$f_{(R)} = (1 - R)^2 / (2R) = K/S$$
 (19.4)

where R is the absolute reflectance, K is the molar absorbance coefficient, and S is the scattering coefficient of the specimen. By convention, quantitative diffuse reflectance measurements are presented in "log 1/R" units that are directly analogous to the absorbance units (log 1/T) described previously. In other words, the magnitude of the diffuse reflectance is linearly proportional to sample absorbance and, therefore, to indicator concentration.³¹

Although Equation 19.4 was derived for an ideal limiting case, it is generally applicable to real-world specimens so long as:

Light scattering and absorbance by the sample matrix are largely independent of wavelength over the wavelength band of interest.

The specimen is of sufficient thickness.

The species of interest is relatively dilute (typically <10% concentration).

The scattering constraint is generally satisfied if the sizes of the scattering centers are substantially greater than the wavelength of the incident light. The other constraints are addressed through the mechanics of the assay implementation and the design of the assay chemistry. Most of the remaining deviations from the ideal can be addressed through careful calibration of the system. It should be noted that the effective optical path length in a diffuse reflectance measurement can be exceptionally long due to the scattering and diffusion of photons in the specimen matrix. This means that the sensitivity of a reflectance measurement is often substantially greater than that of the corresponding measurement made in transmission.

As with the methods discussed earlier, the Kubelka–Monk model for light-sample interaction permits a minimum RCE analysis. Solving the dependence of the reflectance function on absorber concentration C for C and obtaining an expression for $\delta C/C$, which is then minimized, yields a minimum in RCE at R=0.414. The RCE is within 10% of this minimum value for values of R between 0.13 to 0.77.³⁰ This analysis can be combined with models for detector uncertainty, chemical noise, and other system uncertainties for a more complete understanding.³²

19.4.3 Fluorescence

Fluorescence emission is the result of a complex series of events that occur at the molecular level. The net effect is that a fluorescent molecule absorbs light within a molecule-specific absorption band and consequently emits light isotropically at a longer wavelength. The wavelength shift accompanying fluorescent emission and the isotropic nature of these emissions facilitate in discriminating between exciting and emitted light in fluorescence measurements.

One form of the relationship between measured fluorescence intensity and analyte concentration is given in

$$I_{E} = I_{0}KQ(1 - 10^{-\varepsilon LC}) \tag{19.5}$$

where I_F is the measured fluorescence intensity, K is a geometric instrument factor, Q is the quantum efficiency, and the remaining terms have their previous meanings. This equation indicates that, for low analyte concentrations (typically under about 10^{-5} M), fluorescence intensity is linearly proportional to the analyte concentration. At very low analyte concentrations, the RCE for fluorescence measurements is similar to that for absorbance in that measurement noise and stray light predominate and result in values of I_F that are systematically higher than expected. At high analyte concentrations, a variety of intermolecular interactions act to quench fluorescence emissions, thus leading to systematically low values of I_F .³³

Many of the same factors that contribute to errors in absorbance measurements are of concern in fluorescence. Fluorescence emissions are isotropic, so geometry dictates that most practical optical systems can capture only a small fraction of the emitted light. Consequently, signal levels at the detector are low even at high analyte concentrations. Noise control is, therefore, a major consideration in the

design of fluorescence-based instrumentation. A source of errors that is unique to fluorescence measurements is that, for Equation 19.4 to remain valid over any significant range of analyte concentrations, the incident photon flux must be sufficient to "saturate" the fluorophores at the highest analyte concentration of interest. This ensures that the amount of time that a fluorophore spends in its ground state is minimized and that I_F will not be affected by fluctuations in illumination intensity.

The high illumination intensity implied by this consideration directly conflicts with the propensity of many fluorophores used in clinical assays to "photobleach" (i.e., be photochemically degraded) over time. Photobleaching, which leads to systematically low results, is generally addressed by limiting the amount of time that fluorescent samples are exposed to light and by limiting the illumination intensity during the measurement period to the minimum necessary to ensure saturation. In some cases, the assay chemists can select a fluorophore that is resistant to photobleaching, or can add stabilizer (usually a free radical scavenger or antioxidant) to the assay reagents. Many constituents of biological samples, as well as some assay reagents and some materials used in instrument construction, are intrinsically fluorescent. Unless considerable care is taken in the selection of the fluorophore, intrinsic system fluorescence may interfere with analyte quantitation.^{24,34}

Fluorescent emission is time delayed from excitation by the fluorescence lifetime of the fluorophore. This time delay can, in some cases, be used to assist in discrimination of the fluorescence signal of interest from extraneous sources such as emissions from other fluorophores. Because fluorescence lifetimes are typically less than tens of nanoseconds, the instrumentation required to perform this time-based discrimination tends to be relatively sophisticated. Although direct time gating of the source and detector is routinely used in research laboratories, the few clinical laboratory instruments that perform "lifetime" measurements generally measure the phase shift between sinusoidally modulated exciting light and the correspondingly modulated fluorescence emissions.

Some molecules that are occasionally used in clinical assays have fluorescent lifetimes considerably in excess of 100-ns. These molecules are typically described as phosphorescent (typically considered as molecules having lifetimes in the 100-ns to 100-ms range) or luminescent (lifetimes over 100 ms). Fluorescent species are ubiquitous in biological materials and routinely introduce unwanted background fluorescence into clinical assays. Many materials commonly used in instrument construction also exhibit low levels of fluorescence. The use of a phosphorescent or luminescent indicator species in an assay permits the signal of interest to be discriminated from this background fluorescence by time gating, thus improving the SNR and lower LOD of the assay.^{35,36}

19.4.4 Fluorescence Polarization (Fluorescence Anisotropy)

The excitation of a fluorophore can be modeled as excitation of a dipolar oscillator by an incident photon followed, after a time delay, by the emission of a longer wavelength photon by this same dipole. The net effect is that the fluorescent emission will be polarized in the plane defined by the emitting dipole. Furthermore, the fluorophore is not fixed in space, but rather is in a constant state of diffusional motion on several different timescales, with rotational diffusion typically being the fastest. Since the orientation of the emitting dipole is intrinsically linked to the molecular and electronic structure of the fluorophore, the orientation of the plane of polarization of the emitted photon will vary as a function of the excited state lifetime and the rotational rate of the fluorophore. The faster the rotational rate is relative to the excited state lifetime, the greater the change in the orientation of the polarization. This effect is employed in several different forms in clinical assays.³⁷

The most common implementation is the measurement of steady-state fluorescence anisotropy. Typically, an external frame of reference is imposed by illuminating the sample with plane polarized light at the desired excitation wavelength, resulting in the dipole of each excited fluorophore being initially oriented in the same plane. If rotational diffusion rate of the excited state fluorophore is very slow with respect to the excited state lifetime, the emitted fluorescence retains this initial polarization. However, if the rotational rate is comparable to or faster than the excited state lifetime, the plane of polarization will change by some random amount. Taken as an ensemble over all of the fluorophores in a sample, this

latter case results in at least partial depolarization of the fluorescence emissions.³⁸ The amount of this depolarization is usually determined by measuring the intensities of fluorescence emission having polarizations parallel (I_{\parallel}) and perpendicular (I_{\perp}) to that of the exciting light. The resulting polarization (P) is then defined as:

$$P = (I_{\parallel} - I_{\perp})/(I_{\parallel} + I_{\perp}) \tag{19.6}$$

Due to the requirement that the rotational rate and fluorescence lifetime of the fluorophore be roughly comparable, fluorescence polarization assays are largely restricted to small molecule analytes. These assays are most often of the competitive type in which the fluorescent reagent (tracer) is constructed by fluorescently labeling the target small molecule analyte or an analogue thereof. The other primary reagent in these assays is typically an unlabeled antibody directed against the target analyte. When the tracer and antibody are combined with the sample, the tracer competes with any analyte present in the sample for antibody binding sites.³⁹

If several operational constraints are met, the amount of antibody-bound tracer present at the end of the reaction is inversely proportional to the amount of analyte that was initially present in the sample. Because the antibody–tracer complex is much larger and more massive than the free tracer, the polarization (P) of the fluorescent emissions decreases with increasing analyte concentration. A calibration curve is used to determine the analyte concentration from the value of P. For operational reasons, the assay chemistry is usually configured such that $I_{\parallel} > I_{\perp}$, which means that $\Delta P < 0.5$. Measurement resolution is usually in the range of 0.01 to 0.001 P.

19.4.5 Chemiluminescence

All of the previously described modalities rely on the illumination of the sample in order to generate a detectable signal. Stray light and other adverse consequences of this illumination are frequently the controlling factors in determining the detection limit of the assay. Chemiluminescence, in which the detectable light signal is generated chemically, does not require an illuminator and can, therefore, often achieve significantly lower limits of detection than can the previously described methods.⁴² The chemical light generating systems used in this modality typically consist of an acridinium ester or a cyclic hydrazide as the lumiphore and a peroxide as the trigger. Because only one photon is produced per lumiphore, photon counting techniques are generally required in order to quantitate light emission. Both photon emission rate and total integrated emission measurements have been used in clinical assays. Stray light and electronic noise in the detection circuitry are the usual nonchemical limits on detection sensitivity, although photon statistics also play a role.⁴³

19.4.6 Guided Wave Optical Sensors

Guided wave sensors rely on total internal reflection⁴⁴ to confine incident light within a guiding medium (core) that is surrounded by a medium of lower refractive index (cladding).^{45,46} The critical angle in such a device is given by

$$\sin \theta_c = \eta_{\text{clad}}/\eta_{\text{core}}.$$
 (19.7)

Under conditions where the light propagating in the core is fully confined by total internal reflection, propagation of this energy is accompanied by an exponentially decaying field ("evanescent wave"), which extends into the cladding to a depth that is a function of the refractive indices of the core and cladding. ^{45,46} This evanescent wave provides a means of coupling energy between the core and molecules located external to the core, and is the basis of most types of guided wave sensors. ^{47–51} In order to maximize the efficiency of this bidirectional coupling process in sensing applications, the waveguide cladding generally consists of or incorporates some indicator species that produces an optical signal in response to the presence of an analyte. ⁵² The assay chemistries used in these applications are usually similar, if not identical, to those used in absorbance and fluorescence assays read out by conventional means. ^{53,54}

If a waveguide sensor is configured for an absorbance assay, energy is coupled from the core into the indicator species via the evanescent wave.⁵⁵ The measured property in this instance is the reduction in the optical energy propagating in the waveguide core. Fluorescence sensors operate in a similar manner except that the fluorescence signal radiated into the medium surrounding the waveguide or the fluorescence coupled from the fluorophore into the core via the evanescent wave can be measured.^{56,57}

Another implementation of a waveguide-based sensor interposes a thin, (typically) discontinuous layer of metal (usually silver, gold, or aluminum) between the core and the fluorophore. Surface plasmon modes excited at the metal surface by energy coupled from the core can couple to indicator species via the evanescent wave. As the plasmon resonances act to amplify or concentrate the electric field at the surface of the metal, the amount of energy available for coupling to an indicator species is greatly increased over what is available in the absence of the metal. This increases the sensitivity of the sensor when used in either of the two operating modes described previously. In addition, surface plasmon sensors are sensitive to species that are neither absorbing nor fluorescent. Interaction of such a species with the surface plasmon is detectable through the resulting change in the energy distribution between the core and the metal. Left.

In all of these implementations, a major advantage of guided wave sensors over their conventional counterparts is that the "active" volume at the surface of the sensor is controlled and restricted by the penetration depth of the evanescent wave.⁶⁸ This means that guided wave sensors tend to be relatively insensitive to any species not in direct contact with the surface of the waveguide. Thus, because the assay chemistry is designed to concentrate the analyte at the surface of the waveguide, the contribution of interfering substances (which are not in close proximity to the surface) is greatly reduced.

19.4.7 Imaging Systems

For the purposes of this chapter, imaging systems are defined as those that capture specimen data in a spatially resolved manner. This definition includes classical *in vitro* diagnostic imaging applications such as microscopy or the reading of agglutination and microbial culture assays, as well as more recent applications in which imaging techniques are employed to capture data simultaneously from multiple independent samples.

Qualitative and quantitative imaging is used in *in vitro* diagnostic testing. Qualitative images are usually intended for visual evaluation, thus placing a premium on the appearance of the image and on the visual fidelity of the image to the specimen. In most cases, this translates to the operational requirements of using spectrally balanced, broadband illumination, employing a broadband detector, and maximizing spatial resolution at the specimen. Quantitative images are, in effect, spatially resolved arrays of photometric measurements that are mathematically processed in order to extract the information of interest. In this case, the emphasis is on the numerical quality and integrity of the data. In order to minimize the effects of stray light on this quality, illumination and detection are generally performed in one or more narrow spectral bands.

Images captured using an electronic imaging system comprise arrays of individual picture elements or pixels. (A pixel represents the smallest unit of spatial resolution in the captured image.) One approach to electronic imaging, exemplified by flying spot scanners and most forms of confocal microscopes, is to capture each individual pixel in the image sequentially using a single-element detector such as a photomultiplier tube or photodiode. The other common approach to electronic image capture is based on the use of a detector comprising an array of individual detection elements, each element corresponding to a pixel in the captured image.

Array detectors generally permit faster image capture than is possible using a single-point detector because all pixels in the image are captured simultaneously rather than sequentially. Another benefit of array detectors is that the spatial relationships between the individual pixels in the image are fixed during the manufacture of the sensor, rather than being dependent upon the characteristics of some scanning process. For various reasons related to device physics and construction, discrete detectors offer substantially greater useful sensitivity, dynamic range, and photometric resolution than do currently available

array detectors. Array detectors, on the other hand, offer convenience and higher throughput, particularly in the case of high-pixel-count images.

It should be noted that the vast majority of the charge-coupled device (CCD) array detectors currently available for imaging applications have been explicitly designed and are intended for use in consumer applications in which low cost and the generation of a "pretty" picture are of paramount importance. As a consequence, certain operational and performance parameters, such as photometric resolution, that are of importance in quantitative imaging have been compromised. For example, one very widely used class of CCD array detectors is advertised as delivering "8-bit" or 256 level photometric resolution. When evaluated, however, many members of this class actually deliver only 5 to 6 bits (32 to 64 levels) of photometric resolution. The remaining 2 to 3 bits of the output signal are noise. This is generally not a significant issue in qualitative applications because the human eye has difficulty in discriminating between adjacent intensity levels in an image having 32 to 64 levels of photometric resolution, but it is unacceptable in many quantitative imaging applications.

Array detectors for quantitative applications must therefore be carefully selected to deliver the number of "true" bits of photometric resolution required by the application. The SNR of the detector is a useful indicator in this regard. A detector capable of delivering true 8-bit (256) photometric resolution will have an SNR in excess of approximately 50 dB. The SNR requirement increases by 3 dB for each additional bit of photometric resolution required. The poor spectral characteristics of the polymeric filters used in most "1-chip" color CCD sensors can also cause significant problems in quantitative imaging applications.

One of the primary challenges in clinical diagnostic imaging is matching the region of interest at the specimen to the field of view of the detector. In order to maximize the utilization of the detector array while minimizing the effects of optical aberrations, it is usually desirable to size the detector such that it occupies approximately the central 70% of the field of view (FOV) of the image-forming optics. The spatial resolution and depth of focus of the optical system are determined by the NA of the optics, while the spatial resolution of the detector in the specimen plane is determined by detector pixel size divided by the magnification of the optical system. It is usually desirable that system spatial resolution be limited by the optics in qualitative applications and by the detector in quantitative applications. Matching these parameters to each other, the requirements of the applications, and the characteristics of available components often requires design compromises.

A detailed discussion of the analysis of quantitative images is beyond the scope of this chapter. It is, however, generally desirable to perform a "shading correction" on the captured image to minimize the effects of variations in illumination, as well as optical and detector response nonuniformities, before analyzing the data. Chromatic corrections are usually also desirable when analyzing data captured using a "1-chip" array detector. Photometric calculations can be performed on the captured and corrected data using the equations given previously in this chapter and can be combined with morphological analysis in order to extract information as to the spatial distribution of the indicator species.

19.5 Conclusion

Successful clinical laboratory instrument system development is centered around two critical factors: clear and complete definition of what the instrument is intended to accomplish and the characteristics of the assay chemistry to be utilized. Given these prerequisites, selection of appropriate detection technology and design of the instrument can then proceed in a systematic manner. Adhering to the principles and "rules of thumb" presented in this chapter does not guarantee the successful development of a clinical laboratory instrument. However, the guidelines and processes described will usually increase the probability of success by a significant factor.

20.1 Introduction

Human beings, along with other mammals, consciously interact with the surrounding world by means of seven sensing mechanisms. In addition to the five senses, the abilities to detect temperature and variations in elevation are almost as important. One cannot help but be awed by the evolutionary process that brought about the development of such senses and by their integration into a brain capable of information processing and storage.

If a better awareness of our surroundings, food supplies, and predators was the main driver for this evolutionary process, a parallel might be drawn with our own human enterprise of creating sensors that help us understand the world with which we interact. A sensor can be viewed as the "primary element of a measurement chain, which converts the input variable into a signal suitable for measurement." A sensing scheme is usually based on a transduction principle or mechanism; an input variable is transformed into an output variable through a transduction mechanism. Transduction principles are known physical or chemical effects that correlate observations in different domains. For example, the photoelectric effect is used to correlate number of photons with electric current. The piezoelectric effect does the same for stress and electricity, and Biot-Savart's law correlates magnetic field and electric current. In other words, the operating principle of a sensor involves transforming signals between different domains, from a domain we cannot directly access to one we can measure.

A biosensor is a special type of sensor often used in bioanalysis. Humankind has been performing bioanalysis since the dawn of time, using the sensory nerve cells of the nose to detect scents and those of the tongue to taste dissolved substances. As time has progressed, so has our level of understanding about the function of living organisms in detecting trace amounts of biochemicals in complex systems. The abilities of biological organisms to recognize foreign substances are unparalleled and have to some extent been mimicked by researchers in the development of biosensors. Using bioreceptors from biological organisms or receptors patterned after biological systems, scientists have developed a new means of chemical analysis that often has the high selectivity of biological recognition systems. These biorecognition elements, in combination with various transduction methods, have helped to create the rapidly expanding fields of bioanalysis and related technologies known as biosensors and biochemical sensors.

20.2 Biosensors: Definition and Classification

Two fundamental operating principles of a biosensor are biological recognition and sensing. Therefore, a biosensor can be generally defined as a device that consists of two basic components connected in series: (1) a biological recognition system, often called a bioreceptor, and (2) a transducer. The basic principle of a biosensor is to detect this molecular recognition and to transform it into another type of signal using a transducer. The main purpose of the recognition system is to provide the sensor with a high degree of selectivity for the analyte to be measured. The interaction of the analyte with the bioreceptor is designed to produce an effect measured by the transducer, which converts the information into a measurable effect such as an electrical signal. Figure 20.1 illustrates the conceptual principle of the biosensing process.

Biosensors can be classified by bioreceptor or transducer type (Figure 20.2). A bioreceptor is a biological molecular species (e.g., an antibody, an enzyme, a protein, or a nucleic acid) or a living biological system (e.g., cells, tissue, or whole organisms) that utilizes a biochemical mechanism for recognition. The sampling component of a biosensor contains a biosensitive layer that can contain

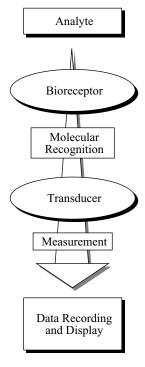

FIGURE 20.1 Conceptual diagram of the biosensing principle.

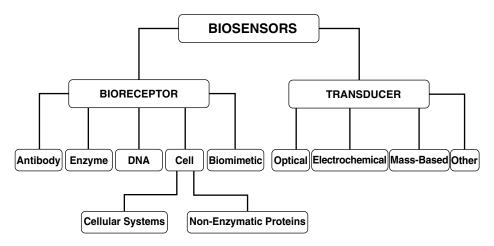

FIGURE 20.2 Biosensor classification schemes.

bioreceptors or be made of bioreceptors covalently attached to the transducer. The most common forms of bioreceptors used in biosensing are based on (1) antibody/antigen interactions, (2) nucleic acid interactions, (3) enzymatic interactions, (4) cellular interactions (i.e., microorganisms, proteins), and (5) interactions using biomimetic materials (i.e., synthetic bioreceptors). For transducer classification, the previously mentioned techniques (optical, electrochemical, and mass-sensitive) are used.

Bioreceptors are the key to specificity for biosensor technologies. They are responsible for binding the analyte of interest to the sensor for the measurement. These bioreceptors can take many forms; the different bioreceptors that have been used are as numerous as the different analytes that have been monitored using biosensors. However, bioreceptors can generally be classified into five different major categories: (1) antibody/antigen, (2) enzymes, (3) nucleic acids/DNA, (4) cellular structures/cells, and (5) biomimetic. Figure 20.3 shows a schematic diagram of two types of bioreceptors: the structure of an immunoglobulin G (IgG) antibody molecule (Figure 20.3A), and DNA and the principle of base pairing in hybridization (Figure 20.3B).

Since the first biosensors were reported in the early 1960s,² growth of research activities in this area has accelerated.^{3–28} Biosensors have seen a wide variety of applications, primarily in three major areas: biological monitoring, biomedical diagnostics and environmental sensing applications.

20.3 Transduction Systems

Biosensors can be classified based on the transduction methods they employ. Transduction can be accomplished through a large variety of methods. Most forms can be categorized in one of three main classes: (1) optical detection methods, (2) electrochemical detection methods, and (3) mass-based detection methods. Other detection methods include voltaic and magnetic methods, and new types of transducers are constantly being developed for use in biosensors. Each of these three main classes contains many different subclasses, creating a large number of possible transduction methods or combination of methods. This section provides a brief overview of the various detection methods used in biosensors. Special emphasis will be placed on the description of optical transducing principles, which is the focus of this chapter.

20.3.1 Optical Detection

Optical detection offers the largest number of possible subcategories of all three of the transducer classes. This is because optical biosensors can be used with many different types of spectroscopies (e.g., absorption, fluorescence, phosphorescence, Raman, surface-enhanced Raman scattering

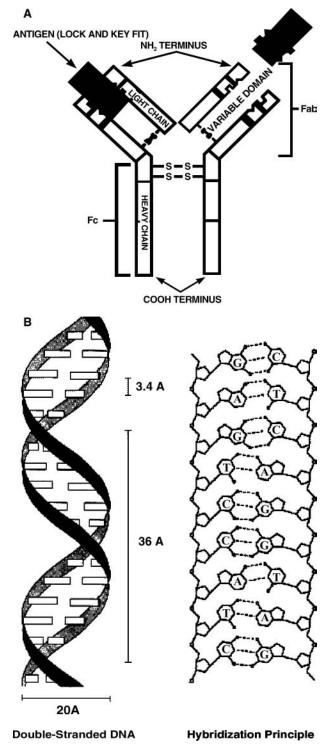

FIGURE 20.3 Schematic diagrams of two types of bioreceptors: (A) IgG antibody; (B) DNA and the hybridization principle. (From Vo-Dinh, T. et al., *Fresenius J. Anal. Chem.*, 366, 540, 2000. With permission.)

(SERS), refraction, dispersion spectrometry) to measure different spectrochemical properties of target species. These properties include amplitude, energy, polarization, decay time, and phase. Amplitude is the most commonly measured parameter of the electromagnetic spectrum because it can generally be correlated with the concentration of the analyte of interest.

The energy of the electromagnetic radiation measured can often provide information about changes in the local environment surrounding the analyte, its molecular vibrations (i.e., Raman or infrared absorption spectroscopies), or the formation of new energy levels. Measurement of the interaction of a free molecule with a fixed surface can often be investigated with polarization measurements. Polarization of emitted light is usually random when emitted from a free molecule in solution; however, when a molecule becomes bound to a fixed surface, the emitted light often remains polarized. The decay time of a specific emission signal (i.e., fluorescence or phosphorescence) can also be used to gain information about molecular interactions because these decay times are highly dependent upon the excited state of the molecules and their local molecular environment. Another property that can be measured is the phase of the emitted radiation. When electromagnetic radiation interacts with a surface, the speed or phase of that radiation is altered, based on the refractive index of the medium (analyte). When the medium changes via binding of an analyte, the refractive index may change, thus changing the phase of the impinging radiation. This property of electromagnetic radiation has been successfully exploited in commercial applications using surface plasmon resonance sensors.

20.3.1.1 Fluorescence

Fluorescence is one of the most sensitive spectroscopic techniques, and its sensitivity makes it uniquely suited for the detection of very low concentrations of bioanalytes. Background information on the photophysical principles of the fluorescence emission process can be found in Chapter 28 of this handbook. When coupled with a high-power light source such as a laser, it can yield very high signal-to-noise (S/N) values. Single-molecule detection using laser-induced fluorescence has been reported in many studies. Because of its inherently high sensitivity, fluorescence has traditionally been the technique of choice for optical detection of trace-level analytes (at the femtomole level or lower). For high-quantum-yield fluorophores, the effective fluorescence cross sections can be as high as 10^{-16} cm²/molecule.

A typical optical setup for a fluorescence biosensor using a laser as the light source is shown in Figure 20.4.²⁹ The instrument consists of an optical fiber with antibodies immobilized at the sensor tip. Excitation light from a laser is sent through a beam splitter onto the incidence end of the optical fiber. The laser beam is transmitted inside the fiber onto the sensor tip, where it excites the analyte molecules bound to the antibodies. The excited antigen fluorescence is collected and retransmitted to

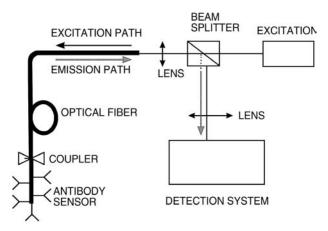

FIGURE 20.4 Schematic diagram of an optical system for an antibody-based biosensor. (From Vo-Dinh, T. et al., *Appl. Spectrosc.*, 41, 735, 1987. With permission.)

the incidence end of the fiber, directed by the beam splitter onto the entrance slit of a monochromator, and recorded by a photomultiplier. This fluoroimmunosensor (FIS) was used to detect the carcinogen benzo[a]pyrene (BaP).²⁹

Fluorescence detection is also suitable for time- or phase-resolved measurements, yielding additional information from the system of interest. Vo-Dinh and co-workers reported the development of a phase-resolved fiberoptic fluoroimmunosensor (PR-FIS) that can differentiate BaP and its metabolite benzopyrene tetrol (BPT) based on the difference in their fluorescence lifetimes.

A diagram for a phase-resolved optical setup is shown in Figure 20.5.³⁰ The excitation laser beam is modulated with an acousto-optic modulation system. A function generator provides the waveforms to drive the modulator. Laser light is delivered to the sample by an optical fiber and the fluorescence is collected by the same fiber. The fluorescence from the sensing probe is collimated by appropriate optics and focused onto the entrance slit of a monochromator equipped with a photomultiplier. A lock-in amplifier synchronized with the function generator is used to measure phase-resolved signals. With this setup, BaP and BPT could be detected simultaneously using phase-resolved fluorescence. Their phase-dependent spectrum is shown in Figure 20.6.³⁰

Figure 20.6A shows the fluorescence of BPT with the use of the optimal phase shift for maximum BPT signal. On the other hand, Figure 20.6B shows the fluorescence of BaP with the use of the optimal phase shift for maximum BaP signal. The results illustrate the capability of the PR-FIS device to reveal the spectrum of 30 femtomoles of BPT in the presence of much higher amounts of interfering BaP.

Femtomolar sensitivities for fluorescently labeled proteins were reported by Herron and coworkers using a channel-etched thin film waveguide fluoroimmunosensor.³¹ A silicon-oxynitride thin optical waveguide film was etched to create a channel for small volumes of analyte. Two different types of assays were performed and compared using this biosensor. The first was a direct assay of a fluorescently tagged protein ligand to a protein receptor that had been immobilized onto the waveguide. The second assay was an indirect sandwich-type assay of a nonfluorescent protein ligand, where the analyte (the protein ligand) binds to a protein bioreceptor immobilized on the waveguide; then a fluorescently tagged secondary receptor was used for measurement purposes. The fluorescent dye used to tag the proteins was Cy-5, a red emitting cyanine dye that reduced the chance of excitation of possible interferents.

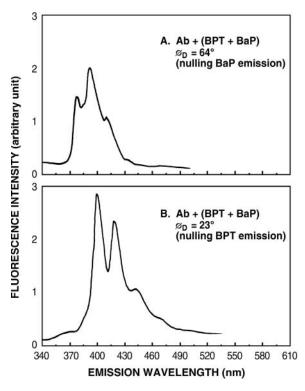

FIGURE 20.6 Phase-resolved fluorescence spectra of BaP and BPT. (From Vo-Dinh, T. et al., *Appl. Spectrosc.*, 44, 128, 1990. With permission.)

An interesting application of fluorescence spectroscopy involves the detection of lipopolysaccharide endotoxin (LPS), which is the most powerful immune stimulant known and a causative agent in the clinical syndrome known as sepsis. Sepsis is responsible for more than 100,000 deaths annually, in large part due to the lack of a rapid, reliable, and sensitive diagnostic technique. LPS has been detected in *Escherichia coli* at concentrations as low as 10 ng/ml in 30 s, using an evanescent wave fiber-optic biosensor. Polymyxin B covalently immobilized onto the surface of the fiber-optic probe selectively bound fluorescently labeled LPS. The competitive assay format worked in buffer and in plasma with similar sensitivities. This method can be used with other LPS capture molecules such as antibodies, lectins, or antibiotics to detect LPS and determine the LPS serotype simultaneously. This LPS assay using the fiber-optic biosensor can be applied in clinical and environmental testing.³²

20.3.1.2 Surface Plasmon Resonance

Since the first application of the surface plasmon resonance (SPR) phenomenon for sensing almost two decades ago, this method has made great strides in terms of instrumentation development and in applications.³³ SPR sensor technology has been commercially available and SPR biosensors have become a useful tool for characterizing and quantifying biomolecular interactions.

SPR makes it possible to monitor the binding process as a function of time by following the increase in refractive index that occurs when one of the interacting partners binds to its ligand immobilized on the surface of a SPR sensor substrate.³⁴ A technique that does not require the reactants to be labeled is a major advantage, simplifying the data collection process. Biosensor binding data are also useful for selecting peptides to be used in diagnostic solid-phase immunoassays. Very small changes in binding affinity can be measured with good precision, which is a prerequisite for analyzing the functional effect and thermodynamic implications of limited structural changes in interacting molecules. For example, the on-rate (k_a) and off-rate (k_d) kinetic constants of the interaction between a protein and an antibody

can be readily measured and the equilibrium affinity constant, K, can be calculated from the ratio $k_a/k_d = K$.

The transduction principle involved in surface plasmon resonance sensors is based on the arrangement of a dielectric/metal/dielectric sandwich so that, when light impinges on a metal surface, a wave is excited within the plasma formed by the conduction electrons of the metal.^{35,36} A surface plasmon is a surface charge density wave occurring at a metal surface. When a plasmon resonance is induced in the surface of a metal conductor by the impact of light of a critical wavelength and angle, the effect is observed as a minimum in the intensity of the light reflected off the metal surface. The critical angle is naturally very sensitive to the dielectric constant of the medium immediately adjacent to the metal and therefore lends itself to exploitation for bioassay. For example, the metal can be deposited as, or on, a grating; upon illumination with a wide band of frequencies, the absence of reflected light at the frequencies at which the resonance matching conditions are met can be observed.

Because of the intrinsic dependence with the index of refraction at the surface, surface plasmon resonance can be used as a sensor transducer to indicate when alterations at the surface happen. The binding event involving antibody–antigen recognition or DNA hybridization at the SPR sensor surface is the most common SPR application. SPR is able to detect small variations of the index of refraction at the metal-coated interface caused by changes in a few monolayers above the surface.

In biosensor devices, the surface plasmon resonance is detected as a very sharp decrease of the light reflectance when the angle of incidence is varied. The resonance angle is very sensitive to variations in the refractive index of the medium just outside the metal film. Because the electric field probes the medium within only a few hundreds of nanometers from the metal surface, the condition for resonance is very sensitive to variations in thin films on this surface. Changes in the refractive index of about 10⁻⁵ are easily detected.

The surface plasmon wave penetrates in both directions normal to the interface; consequently, the incident angle or frequency at which resonance is observed is dependent on the refractive index of dielectric at the interface. Liedberg and co-workers³⁵ have shown that surface plasmon resonance can be used as the basis of a genuine reagentless immunosensor if large analytes are to be monitored. The antibody is immobilized on the metal. When a large antibody binds, it displaces solution (having a refractive index of approximately 1.34) with, for example, protein (having a refractive index of 1.5). The effective refractive index of the dielectric adjacent to the metal is thus changed in proportion to the amount of analyte bound, and the surface plasmon resonance (incident angle or resonance frequency) is shifted accordingly. Flanagan and Pantell³⁶ have shown that the amount of analyte bound can be directly related to the resonance shift even when the resonance curve is distorted by scattering caused by surface roughness, thus relieving one of the constraints of precise control of metalization, which would be unattractive in the mass production of inexpensive sensors.

SPR biosensors can provide qualitative information on macromolecular assembly processes under a variety of conditions. Quantitative information, in the form of affinity constants for complex formation, can be obtained in a manner similar to conventional solid phase assays. The major advantage of SPR biosensors is that the formation and breakdown of complexes can be monitored in real time. This offers the possibility of determining the mechanism and kinetic rate constants associated with a binding event. This information is essential for understanding how biological systems function at the molecular level.

However, accurate interpretation of biosensor data is not always straightforward.³⁷ A few software programs can interpolate SPR data and provide an estimate binding constants. The program CLAMP is software developed to interpret complex interactions recorded on biosensors.³⁷ It combines numerical integration and nonlinear global curve-fitting routines. The BIAcoreTM system is one of the most used among the several commercially available optical biosensors.

For example, the interactions between adenylate kinase (AK) and a monoclonal antibody against AK (McAb3D3) were examined with an optical biosensor, and the sensograms were fitted to four models using numerical integration algorithms.³⁸ The interaction of AK in solution with immobilized McAb3D3 followed a single exponential function and the data fitted well to a pseudo first-order reaction model.

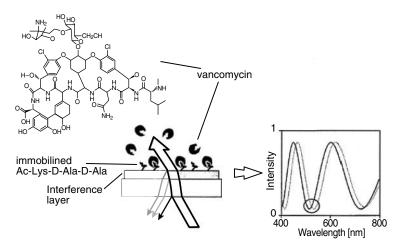

FIGURE 20.7 Principle of reflectometric interference spectrometry. (From Tunnemann, R. et al., *Anal. Chem.*, 73, 4313, 2001. With permission.)

The application of surface plasmon resonance biosensors in life sciences and pharmaceutical research continues to increase. Several reviews providing a comprehensive analysis of the commercial SPR biosensor literature and highlights of emerging applications are available.^{33,39,40} Some general guidelines to help increase confidence in the results reported from biosensor analyses (because of the variability in the quality of published biosensor data) have been compiled as well.³⁹

20.3.1.3 Near-Infrared Absorption

Near-infrared (NIR) spectroscopy utilizes wavelengths above 800 nm to excite vibrational overtones and low-energy electronic levels of chemical species. Use of NIR usually profits from lower fluorescence background and higher specificity for appropriate dyes. Longer wavelengths also offer better penetration of translucent tissue, another major advantage of NIR for biomedical diagnostics.

A biomolecular probe utilizing NIR for the detection of biological molecules (immunochemical samples) with a semiconductor laser diode (780 nm) has been reported.⁴¹ This probe consists of a modified fiber tip binding site, an NIR dye, and a photodiode detector. Preparation of the NIR biosensor involved the immobilization of anti-IgG antibody to the activated binding site of the fiber, followed by coating with IgG for a sandwich-type probe. The antibody was labeled with the commercially available NIR dye IR-144. The low background signal of the detector allowed the detection of 2.72 ng/ml of IgG in a probe coated with 10 ng/ml antibody at 820 nm.⁴¹

20.3.1.4 Reflectometric Interference

Gauglitz and co-workers have developed a unique technique based on reflectometric interference spectroscopy (RifS) for detection in biosensors.⁴²⁻⁴⁴ RifS was used for the detection of biomolecular interactions and applied for small-molecule detection by chemical sensor surfaces. The principle of RifS, which does not require the use of labels, is illustrated in Figure 20.7.⁴² A thin silica layer on a glass substrate is illuminated from the back side using white light. Light beams are reflected at the different layers and superimposed to form a characteristic interference pattern. Changes in the thickness of the transducer surface caused by biomolecular interactions lead to a shift of the interference pattern, which can be analyzed in real time.

20.3.1.5 Raman

The possibility of using Raman or surface-enhanced Raman scattering (SERS) labels as gene probes has been reported.^{45–47} The SERS technique has been recently applied to the detection of DNA fragments of the human immunodeficiency virus (HIV)^{20,45,46} and of the breast cancer gene.⁴⁸ Raman spectroscopy

has also proved to be a very useful tool for chemical analysis because it can identify chemical groups. This technique, however, suffers from poor sensitivity, often requiring powerful and expensive laser excitation sources. However, the discovery of the SERS effect,^{49–51} which results in increased sensitivities of up to 10⁸-fold for some compounds, has renewed interest in this technology for analytical purposes.⁴ The feasibility of using surface-enhanced Raman gene (SERGen) probes, which exhibit an extremely narrow small spectral bandwidth, has been demonstrated.^{45–47} The ability to use labeled primers extends the utility of the SERGen probes for medical diagnostic purposes.

Because SERGen probes rely on chemical identification rather than emission of radioactivity, they have a significant advantage over radioactive probes. SERGen probes are formed with stable chemicals that do not emit potentially dangerous ionizing radiation. Furthermore, the probes offer the excellent specificity inherent in Raman spectroscopy. While isotope labels are few, many chemicals can be used to label DNA for SERS detection. Potentially, dozens to hundreds of different SERGen probes could be constructed and used to probe several DNA sequences of interest (label multiplexing) simultaneously, thus decreasing the time and cost for gene diagnostics and DNA mapping. The multispectral imaging (MSI) system developed in this work, with its rapid wavelength switching of the acoustooptic tunable filter (AOTF) system could allow very rapid scanning and high-throughput data collection.⁴⁵

For biomedical diagnostics, the SERGen probe could have a wide variety of applications in areas where nucleic acid identification is involved. The SERGen probes may also be used in polymerase chain reaction (PCR) applications for medical diagnostic applications, e.g., for HIV detection. In genomics applications as well as in high-throughput analysis, the SERS gene probe technology could lead to the development of detection methods that minimize the time, expense, and variability of preparing samples by combining the BAC mapping approach with SERS "label multiplex" detection. Large numbers of DNA samples can be simultaneously prepared by automated devices. With the SERGen technique, multiple samples can be separated and directly analyzed using multiple SERGen labels simultaneously (label multiplex scheme). The use of the SERS technique for biomedical application is further described in Chapter 64 of this handbook.

20.3.2 Electrochemical Detection

Electrochemical detection is another possible means of transduction that has been extensively used in biosensors.^{52–56} This technique is complementary to optical detection methods such as fluorescence, the most sensitive of the optical techniques. Since many analytes of interest are not strongly fluorescent and tagging a molecule with a fluorescent label is often labor-intensive, electrochemical transduction can be very useful. By combining the sensitivity of electrochemical measurements with the selectivity provided by bioreception, detection limits comparable to those of fluorescence biosensors are often achievable.

Electrochemical detection is usually based on the chemical potential of a particular species in solution (the analyte), as measured by comparison to a reference electrode. Therefore, the electrochemical response is dependent on the activity of the analyte species, not their concentration. However, for dilute solutions of low ionic strength, the thermodynamic parameter activity approaches the physical parameter concentration (in molar terms). In comparison, the signal intensity associated with optical detection is usually directly proportional to the number of a specific chromophore within a certain pathlength and, therefore, directly dependent on the concentration of the chromophore. The linear relationship between signal intensity and concentration of a species is known as Beer–Lambert's law. The cases in which discrepancies from this linear relationship occur are usually caused by secondary effects such as self-absorbance, and equilibrium conditions.

Multiple examples of electrochemical sensors applied to biological systems are known. For example, electrochemical flow-through enzyme-based biosensors for the detection of glucose and lactate have been developed by Cammann and co-workers.⁵⁷ Glucose oxidase and lactate oxidase were immobilized in conducting polymers generated from pyrrole, *N*-methylpyrrole, aniline, and *o*-phenylenediamine on platinum surfaces. These various sensor matrices were compared on basis of amperometric measurements of glucose and lactate, and the *o*-phenylenediamine polymer was found to be the most sensitive.

This polymer matrix was also deposited on a piece of graphite felt and used as an enzyme reactor as well as a working electrode in an electrochemical detection system. Using this system, a linear dynamic range of 500 μ M to 10 mM glucose was determined with a detection limit of <500 μ M. For lactate, the linear dynamic range covered concentrations from 50 μ M to 1 mM with a detection limit of <50 μ M.

A biosensor for protein and amino acid estimation has been reported by Sarkar and Turner.⁵⁸ A screen-printed biosensor based on a rhodinized carbon-paste working electrode was used in the three-electrode configuration for a two-step detection method. Electrolysis of an acidic potassium bromide electrolyte at the working electrode produced bromine, which was consumed by the proteins and amino acids. The bromine production occurred at one potential while monitoring of the bromine consumption was performed using a lower potential. The method proved very sensitive to almost all of the amino acids, as well as some common proteins, and was even capable of measuring L- and D-proline, which gave no response to enzyme-based biosensors. This sensor has been tested by measuring proteins and amino acids in fruit juice, milk, and urine.

Scheller and co-workers have developed an electrochemical biosensor for the indirect detection of L-phenylalanine via NADH.⁵⁹ This sensor is based on a three-step multi-enzymatic/electrochemical reaction. Three enzymes — L-phenylalanine dehydrogenase, salicylate hydroxylase, and tyrosinase — are immobilized in a carbon paste electrode. The principle behind this reaction/detection scheme is as follows. First, the L-phenylalanine dehydrogenase, upon binding and reacting with L-phenylalanine, produces NADH. The second enzyme, salicylate hydroxylase, then converts salicylate to catechol in the presence of oxygen and NADH. The tyrosinase then oxidizes the catechol to *o*-quinone, which is detected electrochemically, and reduced back to catechol with an electrode potential of –50 mV vs. an Ag/AgCl reference electrode.

This reduction step results in an amplification of signal due to the recycling of catechol from o-quinone. Prior to the addition of the L-phenylalanine dehydrogenase to the electrode, it was tested for its sensitivity to NADH, its pH dependence, and its response to possible interferents, urea, and ascorbic acid. From these measurements, it was found that the sensor sensitivity for NADH increased 33-fold by introducing the recycling step over the salicylate hydroxylase system alone. When this sensor was tested for the detection of L-phenylalanine in human serum, the linear dynamic range was found to cover concentrations ranging from 20 to 150 μ M with a detection limit of 5 μ M, which is well within the clinical range of 78 to 206 μ M.

20.3.3 Mass-Sensitive Detection

Another form of transduction has also been used in biosensors to measure small changes in mass.^{60–62} Mass-based detection is the newest of the three classes of transducers and has already been shown to be capable of sensitive measurements. Mass analysis relies on the use of piezoelectric crystals that can be made to vibrate at a specific frequency with the application of an electrical signal of a specific frequency. The frequency of oscillation is dependent on the electrical frequency applied to the crystal as well as the crystal's mass. Therefore, when the mass increases due to binding of chemicals, the oscillation frequency of the crystal changes and the resulting change can be measured electrically and used to determine the mass added to the crystal. In most cases the added mass consists of antibodies or DNA fragments bound to their biospecific counterparts that have been immobilized on the sensor surface.

Guilbault and co-workers developed a quartz crystal microbalance biosensor for the detection of *Listeria monocytogenes*. Several approaches were tested for the immobilization of *Listeria* onto the quartz crystal through a gold film on the surface. Once bound, the microbalance was then placed in a liquid flow-cell, where the antibody and antigen were allowed to form a complex, and measurements were obtained. Calibration of the sensor was accomplished using a displacement assay and was found to have a response range from 2.5×10^5 to 2.5×10^7 cells/crystal. More recently, Guilbault and co-workers have also developed a method for covalently binding antibodies to the surface of piezoelectric crystals via sulfur-based self-assembled monolayers. Prior to antibody binding, the monolayers are activated with 1-ethyl-3-[3-(dimethylamino)propyl] carbodiimide hydrochloride

and N-hydroxysulfosuccinimide. Using this binding technique, a real-time capture assay based on mouse IgG was performed and results were reported.

The first use of a horizontally polarized surface acoustic wave biosensor has been reported by Hunklinger and co-workers.⁶⁵ This sensor has a dual path configuration, with one path acting as an analyte-sensitive path and the other acting as a reference path. A theoretical detection limit of 33 pg was calculated based on these experiments, and a sensitivity of 100 kHz/(ng/mm²) is reported. In addition, a means of inductively coupling a surface acoustic wave biosensor to its radio-frequency generating circuitry has been reported recently.⁶⁶ This technique could greatly reduce problems associated with wire bonding for measurements made in liquids because the electrodes are coated with a layer of SiO₂.

A relatively new type of mass-based detection system uses microcantilevers. Constructed of silicon, these devices are generally shaped like a microsize diving board. Their advantages include their miniature size, high degree of sensitivity, simplicity, low power consumption, low manufacturing cost, and compatibility with array designs.⁶⁷ The extremely low mass of the device allows it to sense perturbing forces because of the adsorbed masses at the picogram level, the viscosity of a gas or liquid over several orders of magnitude, and the acoustic and seismic vibrations. Special coatings on the silicon will adapt the cantilever to sense relative humidity, temperature, mercury, lead, ultraviolet radiation, and infrared (IR) radiation. By using current micromachining technology, multiple arrays could be used to make multielement or multitarget sensor arrays involving hundreds of cantilevers without significantly increasing the size, complexity, or overall package costs.

20.4 Bioreceptors and Biosensor Systems

20.4.1 Antibody

20.4.1.1 Antibody Bioreceptors

The basis for the specificity of immunoassays is the antigen-antibody (Ag-Ab) binding reaction, which is a key mechanism by which the immune system detects and eliminates foreign matter.⁶⁸ The enormous range of potential applications of immunosensors is due, at least in part, to the astonishing diversity possible in one of their key components, antibody molecules. Antibodies are complex biomolecules made up of hundreds of individual amino acids arranged in a highly ordered sequence. The structure of an IgG antibody molecule is schematically illustrated in Figure 20.3A. The antibodies are actually produced by immune system cells (B cells) when such cells are exposed to substances or molecules called antigens. The antibodies called forth following antigen exposure have recognition/binding sites for specific molecular structures (or substructures) of the antigen.

The way in which an antigen and an antigen-specific antibody interact may perhaps be understood as analogous to a lock-and-key fit, in which the specific configurations of a unique key enable it to open a lock. In the same way, an antigen-specific antibody fits its unique antigen in a highly specific manner, so that hollows, protrusions, planes, and ridges on the antigen and the antibody molecules. (in a word, the total three-dimensional structure) are complementary. Further details of how such complementarity is achieved will be discussed later in this chapter. It is sufficient at this point simply to indicate that, due to this three-dimensional shape fitting, and the diversity inherent in individual antibody makeup, it is possible to find an antibody that can recognize and bind to any one of a huge variety of molecular shapes.

This unique property of antibodies is the key to their usefulness in immunosensors; the ability to recognize molecular structures allows one to develop antibodies that bind specifically to chemicals, biomolecules, microorganism components, etc. One can then use such antibodies as specific detectors to identify and find an analyte of interest that is present, even in extremely small amounts, in a myriad of other chemical substances.

The other antibody property of paramount importance to their analytical role in immunosensors is the strength or avidity/affinity of the antigen—antibody interaction. Because of the variety of interactions that can take place as the Ag—Ab surfaces lie in close proximity to each other, the overall strength of the interaction can be considerable, with correspondingly favorable association and equilibrium constants. What this means

in practical terms is that the Ag–Ab interactions can take place very rapidly (for small antigen molecules, almost as rapidly as diffusion processes can bring antigen and antibody together) and that, once formed, the Ag–Ab complex has a reasonable lifetime. Figure 20.10 shows a schematic of how biosensor probes can be prepared from antibody production, isolation, and binding to the sensing surface.

For an immune response to be produced against a particular molecule, a certain molecular size and complexity are necessary: proteins with molecular weights greater then 5000 Da are generally immunogenic. Radioimmunoassay (RIA), which utilizes radioactive labels, has been one of the most widely used immunoassay methods. RIA has been applied to a number of fields, including pharmacology, clinical chemistry, forensic science, environmental monitoring, molecular epidemiology and agricultural science. The usefulness of RIA, however, is limited by several shortcomings, including the cost of instrumentation, the limited shelf life of radioisotopes, and the potential deleterious biological effects inherent to radioactive materials. For these reasons, extensive research efforts are aimed at developing simpler, more practical immunochemical techniques and instrumentation that offer comparable sensitivity and selectivity to RIA. In the 1980s, advances in spectrochemical instrumentation, laser miniaturization, biotechnology, and fiber-optic research provided opportunities for novel approaches to the development of sensors for the detection of chemicals and biological materials of environmental and biomedical interest.

Since the development of a remote fiber-optic immunosensor for *in situ* detection of the chemical carcinogen benzo[a]pyrene,^{7,29} antibodies have become common bioreceptors used in biosensors today.^{8–12,69} The schematics for the optical detection of a bioanalyte are shown in Figure 20.11. In the arrangement shown, a single optical fiber carries the excitation light source to the sample and the fluorescence signal back to a spectrometer.

Due to fiber-to-fiber differences in fiber-optic biosensors, there is often a great difficulty in normalizing the spectral signal obtained with one fiber to another fiber. Ligler and co-workers reported on a method for calibrating antibody-based biosensors using two different fluorescent dyes. To accomplish this, they labeled the capture antibodies bound to the fiber with one fluorescent dye and the antigen with a different dye. Both dyes were excited at the same wavelength and their fluorescence was monitored. The resultant emission spectrum of the fluorescence signal from the capture antibodies was used to normalize the signal from the tagged antigen.

Another example of antibody-based biosensors for bioanalysis is the development of an electrochemical immunoassay for whole blood.⁷¹ This work involved the development of a sandwich type of separationless amperometric immunoassy without any washing steps. The assay is performed on a conducting redox hydrogel on a carbon electrode on which avidin and choline oxidase have been co-immobilized. Biotinylated antibody is then bound to the gel. When the antigen binds to the sensor, another solution of complementary horseradish peroxidase-labeled antibody is bound to the antigen, thus creating an electrical contact between the redox hydrogel and the peroxidase. The hydrogel then acts as an electrocatalyst for the reduction of hydrogen peroxide water.

An important aspect of biosensor fabrication is the binding of the bioreceptor to the sensor solid support or to the transducer. Vogel and co-workers report on a method for the immobilization of histidine-tagged antibodies onto a gold surface for surface plasmon resonance measurements. A synthetic thioalkane chelator is self-assembled on a gold surface. Reversible binding of an anti-lysozyme Fab fragment with a hexahistidine-modified extension on the C terminal end is then performed. Infrared spectroscopy was used to determine that the secondary structure of the protein was unaffected by the immobilization process. Retention of antibody functionality upon immobilization was also demonstrated.

Due to the reversible binding of such a technique, this could prove a valuable method for regeneration of biosensors for various applications.⁷² Enzyme immunoassays can further increase the sensitivity of detection of antigen–antibody interactions by the chemical amplification process, whereby one measures the accumulated products after the enzyme has been allowed to react with excess substrate for a period of time.⁷³

With the use of nanotechnology, submicron fiber-optic antibody-based biosensors have been developed by Vo-Dinh and co-workers for the measurements of biochemicals inside a single cell.^{74–76} Nanometer-scale

fiberoptic biosensors were used for monitoring biomarkers related to human health effects associated with exposure to polycyclic aromatic hydrocarbons (PAHs). These sensors use a monoclonal antibody for benzo[a]pyrene tetrol (BPT), a metabolite of the carcinogen benzo[a]pyrene, as the bioreceptor. Excitation light is launched into the fiber and the resulting evanescent field at the tip of the fiber is used to excite any of the BPT molecules that have bound to the antibody. The fluorescent light is then collected via a microscope. Using these antibody-based nanosensors, absolute detection limits for BPT of approximately 300 zeptomol (10⁻²¹ mol) have been reported.⁷⁴ These nanosensors allow probing of cellular and subcellular environments in single cells.^{19,75,76} The development and applications of optical nanosensors are described in further detail in Chapter 60 of this handbook.

20.4.1.2 Immunoassay Formats

Biomolecular interactions can be classified into two categories according to the test format performed (direct or indirect). In a direct format the immobilized target molecule interacts with a ligand molecule or the immobilized ligand interacts with a target molecule directly. For immunosensors, the simplest situation involves *in situ* incubation followed by direct measurement of a naturally fluorescent analyte.⁷ For nonfluorescent analyte systems, *in situ* incubation is followed by development of a fluorophor-labeled second antibody. The resulting antibody sandwich produces a fluorescence signal directly proportional to the amount of bound antigen. The sensitivity obtained when using these techniques increases with increasing amounts of immobilized receptor. The indirect format involves competition between fluorophor-labeled and unlabeled antigens.⁶⁹ In this case, the unlabeled analyte competes with the labeled analyte for a limited number of receptor binding sites. Assay sensitivity therefore increases with decreasing amounts of immobilized reagent. Figure 20.8 illustrates the principles of (1) a competitive assay, (2) a direct assay, and (3) a sandwich assay.

A sandwich immunoassay using fluorescently labeled tracer antibodies has been developed to detect cholera toxin (CT).⁷⁷ Using this fluorescence-based biosensor, researchers analyzed six samples simultaneously in 20 min. The biochemical assays utilized a ganglioside-capture format: ganglioside GM1, utilized for capture of the analyte, was immobilized in discrete locations on the surface of the optical waveguide. Binding of CT to the immobilized GM1 was demonstrated with direct assays (using fluorescently labeled CT). The limits of detection for CT were 200 ng/ml in direct assays and 40 ng/ml and 1 μ g/ml in sandwichtype assays performed using rabbit and goat tracer antibodies. Binding of CT to other glycolipid capture reagents was also observed. While significant CT binding to loci patterned with GD1b, Gb3, and Gb4 was observed, CT did not bind significantly to immobilized GT1b at the concentrations tested.

A similar planar array, equipped with a charge-coupled device (CCD) as a detector, was used to detect three toxic analytes simultaneously. Wells approximately 2 mm in diameter were formed on glass slides using a photoactivated optical adhesive. Antibodies against staphylococcal enterotoxin B (SEB), ricin, and *Yersinia pestis* were covalently attached to the bottoms of the circular wells to form the sensing surface. Rectangular wells containing chicken immunoglobulin were used as alignment markers and to generate control signals. After the optical adhesive was removed, the slides were mounted over a CCD operating at ambient temperature in inverted (multipin phasing) mode. Cy5-labeled antibodies were used to determine the identity and amount of toxin bound at each location, using quantitative image analysis. Concentrations as low as 25 ng/ml of ricin, 15 ng/ml of pestis F1 antigen, and 5 ng/ml of SEB could be routinely measured.

A similar assay for ricin, using an immobilized anti-ricin IgG on an optical fiber surface, was reported.⁷⁸ Two immobilization methods were tried: in the first, the antibody was directly coated onto the silanized fiber using a cross linker; in the second, avidin-coated fibers were incubated with biotinylated antiricin IgG to immobilize the antibody using an avidin-biotin bridge. The assay using the avidin-biotin-linked antibody demonstrated higher sensitivity and wider linear dynamic range than the assay using antibody directly conjugated to the surface. The limits of detection for ricin in buffer solution and river water are 100 pg/ml and 1 ng/ml, respectively.

The use of protein A, an immunoglobulin-binding protein, for antibody immobilization on the surface of these fiber probes has been investigated as an alternative immobilization method to the

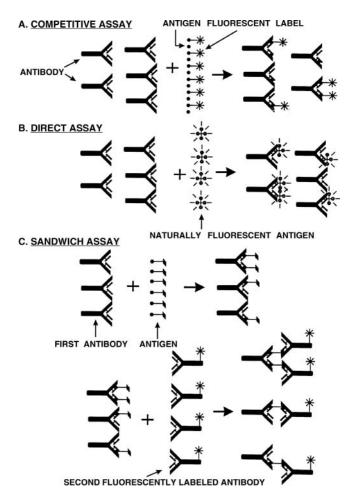

FIGURE 20.8 Immunoassay formats: (A) competitive assay; (B) direct assay; (C) sandwich assay.

classical avidin–biotin and IgG–anti-IgG interactions.¹⁴ No difference was observed in the binding of fluorescently labeled goat IgG by rabbit anti-goat IgG, regardless of whether the capture antibody was bound to the probe surface via protein A or covalently attached. However, in a sandwich immunoassay for the F1 antigen of *Yersinia pestis*, probes with rabbit anti-plague IgG bound to the surface via protein A generated twice the signal generated by the probes with the antibody covalently attached. Assay regeneration was also examined with protein A probes because Ab–Ag complexes have been successfully eluted from protein A under low pH conditions.

The regeneration of antibodies covalently immobilized to an optical fiber surface is also an important parameter that classifies the usefulness of a biosensor. Ideally, the antibody–antigen complex can be dissociated under mild conditions to regenerate the sensor. In a study by Liegler and co-workers, ⁷⁹ three different restoring solutions were tested and compared: (1) 0.1 M glycine hydrochloride in 50% (v/v) ethylene glycol, pH = 1.75; (2) a basic solution 0.05 M tetraethylamine in 50% (v/v) ethylene glycol, pH = 11.0; and (3) 50% (v/v) ethanol in PBS. In this study, optical fibers coated with polyclonal rabbit anti-goat antibody against a large protein retained 70 and 65% of the original signal after five consecutive regenerations with acidic and basic solvent systems, respectively. The fibers coated with monoclonal mouse anti-trinitrobenzene antibody specific for a small organic molecule retained over 90% of the original signal when regenerated with basic and ethanol solutions.

Using a 635-nm laser diode light source, a biosensor based on labeled Cy5 antibodies was used to detect the F1 antigen of *Y. pestis* and the protective antigen of *Bacillus anthracis*. In a blind test

containing F1 antigen spiked into 30 of 173 serum samples, this immunosensor was able to achieve 100% detection success for samples with 100 ng/ml or more of F1 antigen, with a specificity of 88%.¹³

20.4.1.3 Antibody Probe Regeneration

Removal of antigens bound to antibodies covalently attached to optical fiber surfaces is one of the limiting factors in the development of reusable, inexpensive, and reliable optical fiber immunosensors for environmental and clinical analysis. Chemical reagents were supposed to cleave the binding between antibody and antigen, thus regenerating the biosensor⁸⁰ — a chemical procedure that is simple but ineffective after multiple regeneration operations (less than five cycles), due to possible denaturation of the antibody. Another approach in the development of regenerable biosensors involves the design of microcapillary systems capable of delivering and removing reagents and antibody-coated microbeads into the sensing chamber without removing the sensor from the sample.⁸¹ Several investigators have searched for fast dissociation protocols able to regenerate immobilized antibodies while maintaining their stability for use in routine analysis, commercial immunosorbents,⁸² or optical fiber sensors.⁷⁹

Antigen–antibody interactions can be classified in three different groups:⁸³ hydrophobic interactions, electrostatic (or Coulombic) interactions, and interactions due to a combination of both forces. Hydrophobic interactions are due to the propensity of nonpolar groups and chains to aggregate when immersed in water. This type of interaction is maximized between the hydrophobic complementary determining regions (CDR) of the antibody parotopes and the predominantly hydrophilic groups found in the antigen epitope. Electrostatic interactions between antigen and antibody are caused by one or more ionized sites of the epitope and ions of opposite charge on the parotope. After primary binding has occurred through hydrophobic and electrostatic interactions, the epitope and the parotope will be close enough to allow van der Waals and hydrogen bonds to become operative. In order to dissociate the antigen–antibody complexes, the strength of these forces may be reduced by changing the pH, ionic strength, and temperature through the addition of dehydrating agents and/or organics. In this sense, strong acids such as HCl or H₂SO₄, mixtures such as glycine-HCl, or basic solutions of tetraethylamine, for example, have been used when the primary attractive forces in the bond can be considered electrostatic interactions.⁸⁴

Lu et al. pointed out that the use of organic solutions such as ethylene glycol could improve the washing efficiency by reducing the van der Waals and the Coulombic forces maintaining the bond;⁸⁵ Wijesuriya et al. made a similar observation.⁷⁹ Nevertheless, every antigen–antibody pair may differ with respect to the nature of the forces implicated in the binding site. Haga et al. studied the effect of 28-kHz ultrasonic radiation with an intensity of 0.83 W/cm² on the dissociation of antigen–antibody complexes immobilized on CH-Sepharose gels.⁸⁶ They observed that the percent of dissociation increased with irradiation time and input wattage, obtaining a 22% dissociation after 20 min, whereas the immune reactivity decreased 8% without degradation of the dissolved antibody upon exposure to the ultrasound for times of up to 120 min.

Higher-frequency ultrasound (high-kHz to low-MHz range) is used to remove small (micrometer to submicrometer) particles from the surfaces of silicon wafers. This so-called megasonic cleaning process does not damage the surfaces, suggesting that its mode of action does not depend on the strong effects of inertial cavitation that occur with lower frequency (e.g., 20 kHz) ultrasonic horns and baths. The mechanisms of megasonic cleaning likely involve nonlinear effects such as acoustic streaming and radiation pressure as well as the oscillatory linear forces. Stable cavitation (a less intense process than inertial cavitation) may also play an important role, particularly in enhancing streaming effects. The success of the gentle but effective megasonic cleaning process suggests that MHz-range ultrasound may have some utility in regeneration of biosensor surfaces.

Vo-Dinh and co-workers described a novel procedure for regenerating antibodies immobilized on a fiberoptic surface with ultrasonic irradiation using a broadband imaging transducer operating near 5 MHz.²² This type of ultrasound device is commonly used for the detection of flaws in the nondestructive evaluation of engineering materials and measurement of the mechanical properties of various media,⁸⁹ including biological tissues.⁹⁰ The use of ultrasound for the regeneration of optical fiber immunosensors could be an important advance in the application of these devices for *in vivo*

and *in situ* measurements because it would no longer be necessary to supply a regeneration solution to the sensor system that could lead to the denaturation of the immobilized antibody.

20.4.2 Enzyme

Enzymes are often used as bioreceptors because of their specific binding capabilities as well as their catalytic activity. In biocatalytic recognition mechanisms, the detection is amplified by a catalytic reaction. This is the basis for the now commonplace enzyme-linked immunosorbent assay (ELISA) technique.

With the exception of a small group of catalytic ribonucleic acid molecules, all enzymes are proteins. Some enzymes require no chemical groups other than their amino acid residues for activity. Others require an additional component called a cofactor, which may be either one or more inorganic ions, such as Fe²⁺, Mg²⁺, Mn²⁺, or Zn²⁺, or a more complex organic or organometallic molecule called a coenzyme. The catalytic activity provided by enzymes allows for much lower limits of detection than would be obtained with common binding techniques. As expected, the catalytic activity of enzymes depends upon the integrity of their native protein conformation. If an enzyme is denatured, dissociated into its subunits, or broken down into its component amino acids, its catalytic activity is destroyed. Enzyme-coupled receptors can also be used to modify the recognition mechanisms. For instance, the activity of an enzyme can be modulated when a ligand binds at the receptor. This enzymatic activity is often greatly enhanced by an enzyme cascade, which leads to complex reactions in the cell.^{91,92}

Gauglitz and co-workers have immobilized enzymes onto an array of optical fibers for use in the simultaneous detection of penicillin and ampicillin. 93,94 These biosensors provide an interferometric technique for measuring penicillin and ampicillin based on pH changes during their hydrolysis by penicillinase. Immobilized onto the fibers with the penicillinase is a pH indicator, phenol red. As the enzyme hydrolyzes the two substrates, shifts in the reflectance spectrum of the pH indicator are measured. Various types of data analysis of the spectral information were evaluated using a multivariate calibration method for the sensor array, which consisted of different biosensors

Rosenzweig and Kopelman described the development and use of a micrometer-sized fiber-optic biosensor for the detection of glucose.⁹⁵ These biosensors are 100 times smaller than existing glucose optodes and represent the beginning of a new trend in nanosensor technology.⁹⁶ They are based on the enzymatic reaction of glucose oxidase, which catalyses the oxidation of glucose and oxygen into gluconic acid and hydrogen peroxide. To monitor the reaction, an oxygen indicator, tris(1,10-phenanthroline)ruthenium chloride, is immobilized into an acrylamide polymer with the glucose oxidase, and this polymer is attached to the optical fiber via photopolymerization. A comparison of the response of glucose sensors created on different sizes of fibers found that the micrometer-size sensors have response times at least 25 times faster (2 s) than the larger fibers. In addition, these sensors are reported to have absolute detection limits of approximately 10 to 15 mol and an absolute sensitivity five to six orders of magnitude greater than current glucose optodes.⁹⁶

A fiber-optic evanescent wave immunosensor for the detection of lactate dehydrogenase has been developed.⁹⁷ Two different assay methods, a one-step and a two-step process, using the sensor based on polyclonal antibody recognition were described. The response of this evanescent wave immunosensor was then compared to a commercially available SPR-based biosensor for lactate dehydrogenase detection using similar assay techniques, and similar results were obtained. It was also demonstrated that, although the same polyclonal antibody can be used for the one- and the two-step assay techniques, the two-step technique is significantly better when the antigen is large.

20.4.3 Nucleic Acid

20.4.3.1 Nucleic Acid Bioreceptors

Another biorecognition mechanism involves hybridization of DNA or RNA. In the last decade, interest in nucleic acids as bioreceptors for biosensor and biochip technologies has increased. 96,98–102 The complementarity of the pairing of the nucleotides adenine: thymine (A:T) and cytosine: guanine

(C:G) in a DNA ladder (Figure 20.3B) forms the basis for the specificity of biorecognition in DNA biosensors, often referred to as genosensors. If the sequence of bases composing a certain part of the DNA molecule is known, then the complementary sequence, often called a probe, can be synthesized and labeled with an optically detectable compound (e.g., a fluorescent label). By unwinding the double-stranded DNA into single strands, adding the probe, and then annealing the strands, the labeled probe can be made to hybridize to its complementary sequence on the target molecule.

Grabley and co-workers have reported the use of DNA biosensors for monitoring DNA-ligand interactions. On Surface plasmon resonance was the analytical method used to monitor real-time binding of low-molecular-weight ligands to DNA fragments that were irreversibly bound to the sensor surface via Coulombic interactions. The sensor was capable of detecting binding effects between 10 and 400 pg/mm². Binding rates and equilibrium coverages were determined for various ligands by changing the ligand concentration. In addition, affinity constants, association rates, and dissociation rates were also determined for these various ligands.

Sandwich-type biosensors based on liquid-crystalline dispersions formed from DNA-polycation complexes have been described by Yevdokimov and co-workers. 104 These sandwich biosensors have been shown to be useful for detection of compounds and physical factors that affect the ability of specific DNA cross linkers — polycationic molecules — to bind between adjacent DNA molecules. The specific case of dispersions from DNA/protamine complexes was investigated and it was demonstrated that, by using this type of sensor with this complex, the hydrolytic enzyme trypsin could be measured down to concentrations of approximately $10^{-14}\,M$.

Karube and co-workers demonstrated another type of biosensor that uses a peptide nucleic acid as the biorecognition element.⁹⁹ The peptide nucleic acid is an artificial oligo amide capable of binding very strongly to complementary oligonucleotide sequences. By use of a surface plasmon resonance sensor, the direct detection of double stranded DNA that had been amplified by a polymerase chain reaction (PCR) has been demonstrated. This technique was capable of monitoring the target DNA over a concentration range of 40 to 160 nM, corresponding to an absolute detection limit of 7.5 pmol.

Using a unique analytical technique, Vo-Dinh and co-workers have developed a new type of DNA gene probe based on SERS detection.^{20,45–47,105} The SERS probes do not require the use of radioactive labels and have great potential to provide sensitivity and selectivity via label multiplexing due to the intrinsically narrow bandwiths of Raman peaks. The effectiveness of the new detection scheme is demonstrated using the *gag* gene sequence of the human immunodefficiency (HIV) virus.²⁰ A SERS-based DNA assay for the breast cancer susceptibility gene (*BRCA1*) has also been developed. The assay is based on the immobilization of oligonucleotides on a thin silver surface and hybridization with Rhodamine-labeled probes.²¹ The silver surface serves as the hybridization support and the means for Raman signal enhancement. The development of a biosensor for DNA diagnostics using visible and NIR dyes has been reported.²³ The system employed a two-dimensional charge-coupled device and was used to detect the cancer suppressor *p53* gene.

20.4.3.2 DNA Biosensors

DNA sensors are usually based on hybridization assays and may incorporate simultaneous analytical capability to detect a large number of oligonucleotide fragments. A fiber-optic DNA biosensor microarray for the analysis of gene expression has been reported for the simultaneous analysis of multiple DNA sequences using fluorescent probes. 106

Fluorescent intercalating and groove-binding dyes that can associate with double-stranded DNA (dsDNA) are used for detection of hybridization in some sensor and biochip designs. ¹⁰⁷ It is possible that dye–dye interactions at concentrations relevant to biosensor use can lead to unexpected and undesired emission wavelength shifts and fluorescence quenching interactions. To maximize signal to noise, many biosensors utilize dye concentrations in large excess in comparison to the quantity of immobilized DNA. The linearity of fluorescence intensity response of dyes intercalated to dsDNA may vary with different dye:base pair ratios. ¹⁰⁷

A very common alternative to intercalating fluorescent dyes for the detection of dsDNA are covalently bound dyes. Dyes attached to the terminus of a strand of DNA through a short hydrocarbon chain (also known as a tether) are continuously available for hybridization and allow the biosensor to be fully reversible.²⁵

Another important characteristic of the biosensor assay is the choice of the fluorescent dye that acts as the signal transducer. Traditionally, ethidium bromide (EB) has been used extensively to detect hybridization of DNA in applications such as electrophoresis, gene chips, and biosensors. A number of dyes with greater quantum efficiency than EB for detection of hybridization have been reported. Furthermore, other practical spectroscopic advantages can be gained in terms of improved signal-to-noise ratio (SNR) by use of dyes with excitation that is red-shifted relative to EB. Pyrilium iodide has been shown to be an intercalator of high quantum efficiency and long excitation wavelength.²⁵

One type of DNA sensor utilized the direct synthesis of an ssDNA sequence directly onto optical fibers, using the well established solid-phase phosphoramidite methodology. The covalently immobilized oligomers were able to hybridize with available complementary ssDNA, which was introduced into the local environment to form dsDNA. This event was detected by the use of the fluorescent DNA stain ethidium bromide (EB). The sampling configuration utilized total internal reflection of optical radiation within the fiber, resulting in an intrinsic-mode optical sensor. The nonoptimized procedure used standard hybridization assay techniques to provide a detection limit of 86 ng ml⁻¹ cDNA, a sensitivity of 83% fluorescence intensity increase per 100 ng ml⁻¹ of cDNA initially present, with a hybridization analysis time of 46 min. The sensor has been observed to sustain activity after prolonged storage times (3 months) and harsh washing conditions (sonication).²⁶ A similar sensor fabricated using quartz optical fibers as the support provided very similar results.¹⁰⁸

A very interesting biosensor capable of detecting triple-helical DNA formation was also based on the direct synthesis of oligonucleotides on the surface of fused silica optical fibers, using a DNA synthesizer. Two sets of oligonucleotides on different fibers were grown in the 3' to 5' and 5' to 3' directions, respectively. Fluorescence studies of hybridization showed unequivocal hybridization between oligomers immobilized on the fibers and complementary oligonucleotides from the solution phase, as detected by fluorescence from intercalated EB. The complementary origonucleotide, dT(10), which was expected to hybridize when the system was cooled below the duplex melting temperature, provided a fluorescence intensity with a negative temperature coefficient. Upon further cooling, to the point where the pyrimidine motif T*AT triple-helix formation occurred, a fluorescence intensity change with a positive temperature coefficient was observed.²⁷

In another study, the same type of sensor, with directly immobilized ssDNA on optical fibers, was used to monitor variation in the melt temperature of dsDNA. Because of microenvironment conditions, the local ionic strength, the pH, and the dielectric constant at the surface can be substantially different from those in bulk electrolyte solution. The local conditions influence the thermodynamics of hybridization and can be studied by the melt temperature of dsDNA. Fiber-optic biosensors with dT(20) oligonucleotides attached to their surfaces were used to determine the Tm from the dissociation of duplexes of mixtures of fluorescein-labeled and unlabeled dA(20) and d(A(9)GA(10)). Each thermal denaturation of dsDNA at the surface of the optical fibers was accompanied by a two-to threefold reduction in standard enthalpy change relative to values determined for denaturation in bulk solution. The experimental results suggested that the thermodynamic stability of duplexes immobilized on a surface is dependent on the density of immobilized DNA.

Additionally, the deviation in melt temperature, arising as a result of the presence of a centrally located single base-pair mismatch, was significantly larger for thermal denaturation occurring at the surface of the optical fibers ($\Delta T_m = 6$ to 10°C) relative to that observed in bulk solution ($\Delta T_m = 3.8$ to 6.1°C). These results suggest that hybridization at an interface occurs in a significantly different physical environment from hybridization in bulk solution, and that surface density can be tuned to design analytical figures of merit. ¹⁰⁹ Increased immobilization density resulted in significantly higher sensitivity but reduced dynamic range in all hybridization assays conducted. Sensitivity and selectivity

were functions of temperature; however, the selectivity of hybridization assays done using the sensors could not be predicted by consideration of thermal denaturation temperatures alone.²⁸

20.4.4 Cell-Based Systems

Cellular structures and cells comprise a broad category of bioreceptors that have been used in the development of biosensors and biochips. 110–120 These bioreceptors are based on biorecognition by an entire cell or microorganism or by a specific cellular component capable of specific binding to certain species. There are presently three major subclasses of this category: (1) cellular systems, (2) enzymes, and (3) nonenzymatic proteins. Due to the importance and large number of biosensors based on enzymes, these have been given their own classification and were previously discussed in Section 20.4.2. This section deals with cellular systems and nonenzymatic proteins.

20.4.4.1 Cellular Bioreceptors

Microorganisms offer a form of bioreceptor that often allows a whole class of compounds to be monitored. Generally these microorganism biosensors rely on the uptake of certain chemicals into the microorganism for digestion. Often, a class of chemicals is ingested by a microorganism, therefore allowing a class-specific biosensor to be created. Microorganisms such as bacteria and fungi have been used as indicators of toxicity or for the measurement of specific substances. For example, cell metabolism (e.g., growth inhibition, cell viability, substrate uptake), cell respiration, and bacterial bioluminescence have been used to evaluate the effects of toxic heavy metals. Many cell organelles can be isolated and used as bioreceptors. Cell organelles are essentially closed systems, so they can be used over long periods of time. Whole mammalian tissue slices or *in vitro* cultured mammalian cells are used as biosensing elements in bioreceptors. Plant tissues are also used in plant-based biosensors; they are effective catalysts because of the enzymatic pathways they possess.⁹²

Bilitewski and co-workers have developed a microbial biosensor for monitoring short-chain fatty acids in milk. 121 Arthrobacter nicotianae microorganisms were immobilized in a calcium-alginate gel on an electrode surface. To this gel was added 0.5 mM CaCl₂ to help stabilize it. Monitoring the oxygen consumption of the *A. nicotianae* electrochemically allowed its respiratory activity to be monitored, thereby providing an indirect means of monitoring fatty acid consumption. Detection of short-chain fatty acids in milk, ranging from 4 to 12 carbons in length, was accomplished with butyric acid as the major substrate. A linear dynamic range from 9.5 to 165.5 μ M was reported, with a response time of 3 min.

20.4.4.2 Nonenzymatic Proteins

Many proteins found within cells often serve the purpose of bioreception for intracellular reactions that will take place later or in another part of the cell. These proteins could simply be used for transport of a chemical from one place to another, e.g., a carrier protein or channel protein on a cellular surface. In any case, these proteins provide a means of molecular recognition through one or another type of mechanism (i.e., active site or potential sensitive site). By attaching these proteins to various types of transducers, many researchers have constructed biosensors based on nonenzymatic protein biorecognition.

In one recent application, Cusanovich and co-workers developed micro- and nanobiosensors for nitric oxide that are free from most potential interferents. Find These sensors are based on bioreception of nitric oxide by cytochrome c'. Two different techniques of immobilization of the cytochrome c' to fibers were tested: polymerization in an acrylamide gel and reversible binding using a gold colloid-based attachment. The cytochrome used in this work was labeled with a fluorescent dye that is excited via an energy transfer from the hemoprotein. Response times of faster than 1 s were reported along with a detection limit of 20 μ M. Cytochrome c' samples from three different species of bacteria were evaluated.

Vogel and co-workers have reported on the use of lipopeptides as bioreceptors for biosensors.¹²² A lipopeptide containing an antigenic peptide segment of VP1, a capsid protein of the picornavirus that causes foot-and-mouth diseases in cattle, was evaluated as a technique for monitoring antigen–antibody interactions. The protein was characterized via circular dichroism and infrared spectroscopy to verify that upon self-assembly onto a solid surface it retained the same structure as in

its free form. Based on surface plasmon resonance measurements, it was found that the protein was still fully accessible for antibody binding. This technique could provide an effective means of developing biomimetic ligands for binding to cell surfaces.

20.4.5 Biomimetic Receptors

A receptor fabricated and designed to mimic a bioreceptor is often termed a "biomimetic receptor." Several different methods have been developed over the years for the construction of biomimetic receptors. ^{123–128} These methods include genetically engineered molecules, artificial membrane fabrication, and molecular imprinting. The molecular imprinting technique, which has recently received great interest, consists of mixing analyte molecules with monomers and a large number of cross linkers. Following polymerization, the hard polymer is ground into a powder, and the analyte molecules are extracted with organic solvents to remove them from the polymer network. As a result, the polymer has molecular holes or binding sites that are complementary to the selected analyte.

Recombinant techniques, which allow for the synthesis or modification of a wide variety of binding sites using chemical means, have provided powerful tools for designing synthetic bioreceptors with desired properties. Hellinga and co-workers reported the development of a genetically engineered single-chain antibody fragment for monitoring phosphorylcholine.¹²⁹ In this work, protein engineering techniques are used to fuse a peptide sequence that mimics the binding properties of biotin to the carboxyterminus of the phosphorylcholine-binding fragment of IgA. This genetically engineered molecule can be attached to a streptavidin monolayer, and total internal reflection fluorescence was used to monitor the binding of a fluorescently labeled phosphorylcholine analog.

Artificial membranes have been developed for many different bioreception applications. Stevens and co-workers developed one by incorporating gangliosides into a matrix of diacetylenic lipids (5 to 10% of which were derivatized with sialic acid). The lipids were allowed to self-assemble into Langmuir-Blodgett layers and were then photopolymerized via ultraviolet irradiation into polydiacetylene membranes. When cholera toxins bind to the membrane, its natural blue color changes to red; absorption measurements were used to monitor the toxin concentration. Using these polydiacetylenic lipid membranes coupled with absorption measurements, concentrations of cholera toxin as low as 20 µg/ml could be monitored.

Molecular imprinting has been used for the construction of a biosensor based on electrochemical detection of morphine. A molecularly imprinted polymer for the detection of morphine was fabricated on a platinum wire using agarose and a cross-linking process. The resulting imprinted polymer was used to specifically bind morphine to the electrode. Following morphine binding, an electroinactive competitor, codeine, was used to wash the electrode and thus release some of the bound morphine. The freed morphine was then measured by oxidation at the electrode; concentrations ranging from 0.1 to 10 μ g/ml were analyzed, with a reported detection limit of 0.05 μ g/ml. One of the major advantages of the molecular imprinting technique is the rugged nature of a polymer relative to a biological sample. The molecularly imprinted polymer can withstand harsh environments such as those experienced in an autoclave or chemicals that would denature a protein.

20.5 Probe Development: Immobilization of Biomolecules

Many of the methods used in biosensor fabrication involve binding the recognition probe (oligonucleotide strand, antibody, etc.) to a sensor-sensitive surface or to an optically active tag (fluorescent dye, etc.). For enzyme-based sensors, immobilization of an enzyme is a critical step and can be accomplished via simple physical adsorption or through more elaborate covalent binding schemes.

Molecules may be physically immobilized in a solid support through hydrophobic or ionic interactions or covalently immobilized by attachment to activated surface groups.¹³² Noncovalent immobilization is effective for many applications and usually requires easier and faster preparation steps.^{133–135} In addition, the adsorbed molecules usually preserve their original properties (e.g., wavelength of absorption, excitation

or emission, enzymatic activity) because they do not require the structural modification inherent in covalent immobilization to a solid support. However, continuous leaching of the adsorbate from the solid support may reduce the sensor's durability and even render it useless in the worst cases.

Covalent immobilization is often necessary for binding molecules that do not adsorb, adsorb very weakly, or adsorb with improper orientation and conformation to noncovalent surfaces. Covalent immobilization may provide greater stability, reduced nonspecific adsorption, and greater durability. 136,137

Several synthetic techniques are available for the covalent immobilization of biomolecules or labeling of a sensor probe with a fluorescent dye. Most of these techniques use free amine groups in a polypeptide (enzymes, antibodies, antigens, etc.) or in an amino-labeled DNA strand to react with a carboxylic acid moiety to form amide bonds. As a general rule, a more active intermediate (labile ester) is first formed with the carboxylic acid moiety and in a later stage reacted with the free amine, increasing the coupling yield. A few coupling procedures are described below.

Carbodiimide coupling. Surfaces modified with mercaptoalkyldiols can be activated with 1,1'-carbonyldiimidazole (CDI) to form a carbonylimidazole intermediate. A biomolecule with an available amine group displaces the imidazole to form a carbamate linkage to the alkylthiol tethered to the surface¹³⁹

N-hydroxysuccinimide (NHS) and its derivatives. Using a succinimide ester intermediate in acylation reactions of 5'-amino-labeled DNA is also a very efficient protocol. The NHS-activated carboxyl group has a much longer lifetime than the reaction intermediates produced by carbodiimide coupling. 140 NHS can also be used to facilitate amide formation between a carboxylic acid moiety and free amine groups in a polypeptide (enzymes, antibodies, antigens, etc.). NHS reacts almost exclusively with primary amine groups, with the exception of mercaptans. This nucleophilic substitution reaction covalently immobilizes biomolecules via available amine moieties by forming stable amide bonds. Covalent immobilization can be achieved in as little as 30 min. This surface has been shown to immobilize 5' amine-modified oligonucleotides, providing an ideal template for hybridization and amplification. Because the DNA is bound at one end rather than at numerous sites along the molecule, the result is high specificity and low background. Because H₂O competes with -NH₂ in reactions involving these very labile esters, it is important to consider the hydrolysis kinetics of the esters used in this type of coupling. A derivative of NHS, O-(N-succinimidyl)-N,N,N',N'-tetramethyluronium tetrafluoroborate, increases the coupling yield by utilizing a leaving group that is converted to urea during the carboxylic acid activation, hence favorably increasing the negative enthalpy of the reaction. The schematic in Figure 20.9 illustrates this approach.

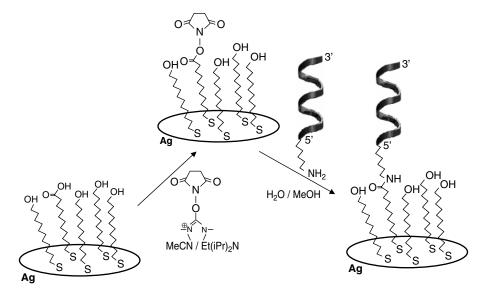

FIGURE 20.9 Binding scheme for biomolecule immobilization.

Maleimide. Maleimide can be used to immobilize biomolecules through available –SH moieties. Coupling schemes with maleimide have been proven useful for the site-specific immobilization of antibodies, Fab fragments, peptides, and SH-modified DNA strands. Sample preparation for the maleimide coupling of a protein involves the simple reduction of disulfide bonds between two cysteine residues with a mild reducing agent, such as dithiothreitol, 2-mercaptoethanol, or tris(2-carboxyethyl)phosphine hydrochloride. However, disulfide reduction will usually lead to the protein losing its natural conformation and might impair enzymatic acitivity or antibody recognition. The modification of primary amine groups with 2-iminothiolane hydrochloride (Traut's reagent) to introduce sulfydryl groups is an alternative for biomolecules lacking them. Free sulfhydryls are immobilized to the maleimide surface by an additional reaction to unsaturated carbon–carbon bonds.

Hydrazide. Hydrazide is used for the covalent coupling of periodate-activated carbohydrates or glycosylated biomolecules. It can be used for the site-specific immobilization of antibodies, carbohydrates, glycolipids, glycoproteins, and many enzymes. Antibodies are immobilized to the hydrazide surface through the carbohydrate moieties on the Fc region, which allows the Fab regions to be properly oriented.

Non-covalent immobilization of biomolecules includes sol-gel or polymer entrapment of enzymes, 141-146 and adsorption of oligonuleotides onto poly-cationic membranes (poly-lysine, polymers with quaternarium ammonium groups, etc). 95,147,148 For sol-gel or polymeric immobilization, solubility of the biomolecules in the polymerization medium is a major constraint for the use of this technique. In the case of surface adsorption, conformation changes of proteins that might diminish antibody recognition or enzyme activity need to be considered.

A sensor for the nitrate ion based on the encapsulation of an enzyme in a sol-gel structure is reported to be effective even after a storage period of up to 6 months. ¹⁴¹ The enzyme of choice was the periplasmic nitrate reductase (Nap), extracted from the denitrifiying bacterium *Thiosphaera pantotropha*, which reacts specifically with the nitrate (NO_3) anion.

Edmiston and co-workers found evidence that the immobilization of proteins by entrapment in a porous silica matrix prepared by sol-gel techniques may significantly change the conformation of the proteins. These researchers examined two model proteins, bovine serum albumin (BSA) and horse heart myoglobin (Mb), entrapped in wet sol-gel glass bulks. They investigated the fluorescence behavior of dissolved and entrapped BSA in the presence of acid, a chemical denaturant, and a collisional quencher. The results show that a large fraction of the BSA added to the sol is entrapped within the gelled glass in a native conformation. However, the reversible conformational transitions that BSA undergoes in solution are sterically restricted in the gel. In contrast, the native properties of Mb are largely lost upon entrapment, as judged by the changes in the visible absorbance spectra of dissolved and entrapped Mb in acidic solutions. Fluorescence studies of dissolved and entrapped apomyoglobin supported this conclusion.¹⁴⁹

20.6 Biomedical Applications

This section presents an overview of various medical applications of biosensors, especially in the diagnosis of diseases. A large body of work was accomplished using SPR commercial instruments and involves the study of protein or DNA interactions relevant for medical applications. Other widely used methods include fluorescence spectroscopy, NIR, and circular dichroism.

2.6.1 Cellular Processes

Staining cellular organelles is a classic laboratory method that utilizes visible or fluorescent dyes that have high affinity for specific organelles. After staining, visible or UV illumination is used for microscopy identification. Newer techniques explore the same principles to obtain more information on cellular processes as well.

For example, G protein-coupled receptors (GPCRs) represent one of the most important drug targets for medical therapy, and information from genome sequencing and genomic databases has substantially accelerated their discovery.¹⁵⁰ The lack of a systematic approach to identify the function

of a new GPCR or to associate it with a cognate ligand has added to the growing number of orphan receptors. A novel approach to this problem using optical detection of a beta-arrestin2/green fluorescent protein conjugate (beta arr2-GFP) has been reported. Confocal microscopy demonstrates the translocation of beta arr2-GFP to more than 15 different ligand-activated GPCRs, providing a real-time and single-cell-based assay to monitor GPCR activation and GPCR-Gr protein-coupled receptor kinase or GPCR-arrestin interactions. The use of beta-arr2-GFP as a biosensor to recognize the activation of pharmacologically distinct GPCRs should accelerate the identification of orphan receptors and permit the optical study of their signal transduction biology, which is intractable to ordinary biochemical methods. ¹⁵⁰

Abscisic acid (ABA) is a plant hormone involved in many developmental and physiological processes, but no ABA receptor has been identified yet.¹⁵¹ In an attempt to demonstrate that the monoclonal antibody JIM19 recognizes carbohydrate epitopes of cell surface glycoproteins, researchers have used flow cytometry of rice protoplasts and immunoblotting of purified plasma membranes (PMs).¹⁵¹ Through use of SPR technology, specific binding of PMs to JIM19 was observed. The interaction was antagonized significantly by ABA but not by the biologically inactive ABA catabolite, phaseic acid. Pretreatment with JIM19 resulted in significant inhibition of ABA-inducible gene expression. Taken together, these data suggest that JIM19 interacts with a functional PM complex involved in ABA signaling.¹⁵¹

Another receptor binding study done with optical biosensor technology investigated the affinity and specificity of the putative proximal tubular scavenging receptor for protein reabsorption and the specificity of AGE-modified protein interactions with primary human mesangial cells. ¹⁵² An SPR biosensor with a carboxy-methyl dextran surface was used for binding competition analysis of five different proteins of the LLCPK cell line (ranging in size and charge). The biosensor data show evidence to support the existence of a single scavenging receptor for all the proteins tested. The proteins competed with each other, differing only in their relative binding affinity for the common receptor. This study has also showed that human mesangial cells can bind to AGE-modified human serum albumin (AGE-HSA) immobilized onto the carboxylate surface and that binding can be inhibited by using increasing concentrations of soluble AGE-HSA. However, increasing concentrations of soluble non-AGE-modified HSA can also inhibit binding to a similar extent, which implies relatively little AGE-receptor expression on cultured primary human mesangial cells. The SPR biosensor is a potential tool to explore cellular interactions with renal cells. ¹⁵²

20.6.2 Viral Agents

The use of biosensors to detect specific viruses in biological samples offers a great diagnostic tool for medical applications. To date, studies have targeted several viruses, including HIV (discussed separately), measles virus, herpes simplex virus, rhinoviruses, and foot-and-mouth disease prions. Some of the techniques used in their detection are outlined below.

Identifying viruses in clinical materials during the acute phase of infections could give necessary information for the treatment of infections by human immunoglobulin (hIg) or interferon (IF). However, because of lack of information, most virus infections are not treated. A real-time detection system for viruses in general has been developed using an optical biosensor and a model virus: herpes simplex virus Type 1 (HSV-1). The HSV-1 virus was found to propagate in Vero cells and, when diluted in minimum essential medium (MEM) with 10% fetal bovine serum (FBS), could be detected with an SPR sensor with high sensitivity and a detection limit of 10 infectious units (50% tissue culture infective dose [TCID50] units). When a crude homemade rabbit antiserum was used against measles virus with host cell debris as a ligand, the SPR sensor performed with lower sensitivity, detecting less than 500 infectious (TCID50) units of virus in a 100-µl solution. This real-time viral detection and titration system has sensitivity high enough for clinical purposes.¹⁵³

The herpes virus was also the object of a study of epitope mapping using an SPR optical biosensor. The human herpes virus entry mediator C (HveC), also known as the poliovirus receptor-related protein 1 (PRR1) and as nectin-1, allows the entry of HSV-1 and HSV-2 into mammalian cells. The interaction of the virus envelope glycoprotein D (gD) with such a receptor is an essential step in

the process leading to membrane fusion.¹⁵⁴ HveC is a member of the immunoglobulin (Ig) superfamily and contains three Ig-like domains in its extracellular portion. The gD binding site is located within the first Ig-like domain (V domain) of HveC. In a careful study using SPR, 11 monoclonal antibodies (MAbs) against the ectodomain of HveC were chosen to detect linear or conformational epitopes within the V domain. Besides the biosensor analysis, the HveC was detected by enzymelinked immunosorbent assay, Western blotting, and directly on the surface of HeLa cells and human neuroblastoma cell lines, as well as simian Vero cells. A few of the 11 monoclonal antibodis blocked HSV entry. Competition assays on an optical biosensor showed that CK6 and CK8 (linear epitopes) inhibited the binding of CK41 and R1.302 (conformational epitopes) to HveC and vice versa.¹⁵⁴

One of the reasons for the traditionally low success for the direct identification of viruses by simple immunological assays is the large variability of their surface epitopes. For example, more than 100 immunologically distinct serotypes of human rhinoviruses (HRV) have been discovered, making detection of surface-exposed capsid antigens impractical. However, the nonstructural protein 3C protease (3Cpro) is essential for viral replication and is relatively highly conserved among serotypes, making it a potential target for diagnostic testing of HRVs. An SPR biosensor with a modified silicon surface with broadly reactive serotype antibodies to 3Cpro has been developed. 155

The *in vitro* sensitivity, specificity and multiserotype cross reactivity of the 3Cpro assay were tested using the SPR sensor in a 28-min, noninstrumented room-temperature test with a visual detection limit of 12 pM of 3Cpro (1000 TCID50 equivalents). Nasal washes from naturally infected individuals were used as test samples. The assay detected 87% (45 of 52) of the HRV serotypes tested but showed no cross reactivity to common respiratory viruses or bacteria. The SPR assay detected 3Cpro in expelled nasal secretions from a symptomatic individual on the first day of illness. In addition, 82% (9 of 11) concentrated nasal wash specimens from HRV-infected children were positive in the 3Cpro test. Thus the assay is suitable as a diagnostic test for a point-of-care setting, where rapid HRV diagnostic test results could contribute to clinical decisions regarding appropriate antibiotic or antiviral therapy.¹⁵⁵

Another SPR system was applied to the quantitative analysis of the binding of HSV-1 to Vero cells. A commercially available sulfonated human immunoglobulin preparation was used as the neutralization antibody titer against this virus.¹⁵⁶

Virus-like particles (VLPs) are multimeric proteins expressed by *Saccharomyces cerevisiae*. These particles are approximately 80 nm in diameter and are used as a framework for a range of biological products, including carriers of viral antigens. An SPR biosensor was developed for rapid monitoring of purified VLPs; this device can be used for real-time bioprocess monitoring of VLPs. Problems of mass transfer of the analyte were overcome through selection of a planar biosensor surface instead of the traditional polymer-coated surface. To prolong the surface activity for interaction analysis, a sandwich assay was developed that involved the use of a secondary capture species. It was shown that VLP concentration in pure solution could be determined within 10 min.¹⁵⁷

An SPR biosensor has been used for screening synthetic peptides mimicking the immunodominant region of C-S8c1 foot-and-mouth disease virus. The main antigenic site (site A) of the foot-and-mouth disease virus (FMDV, strain C-S8c1) may be adequately reproduced by a 15-peptide with the amino acid sequence H-YTASARGDLAHLTTT-NH2 (A15), corresponding to the residues 136 to 150 of the viral protein VPI.¹⁵⁸ The SPR sensor surface was modified with monoclonal antibodies raised against antigenic site A. Although these antigenicities have previously been determined from ELISA methods, the SPR-based technique is superior in that it allows a fast and straightforward screening of antigens while simultaneously providing kinetic data for the Ag–Ab interaction.¹⁵⁸

20.6.3 Human Immunodeficiency Virus (HIV)

The human immunodeficiency virus (HIV) has been the target of intense research in the past two decades. Some of the research efforts involving optical biosensors are outlined below.

The two main proteins on the HIV envelope are glycoproteins gp120 and gp41 (named for their approximate size in kilodaltons). Glycoproteins gp120 and gp41 are associated together noncovalently. Binding of

HIV-1 gp120 to T-cell receptor CD4 initiates conformational changes in the viral envelope that trigger viral entry into the host cells. 159

SPR has been used in a number of HIV studies. This technique was applied to observe the conformational changes in gp120 upon binding to certain ligands, to compare the gp120-activation effects of CD4 mimetics, and to examine for CD4 competition and gp120 activation. SPR optical biosensors provide a means of looking at the interaction between macromolecules as it occurs in real time, providing information about the kinetics of the interaction, in addition to estimating affinity constants.

SPR optical biosensor assays for the screening of low-molecular-weight compounds, using an immobilized protein target, have been developed. HIV-1 proteinase was immobilized on the sensor surface by direct amine coupling. A large number of inhibitors and noninteracting reference drugs were applied to the sensor surface in a continuous flow of buffer to estimate binding constants. The optimized assay could correctly distinguish HIV-1 inhibitors from other compounds in a randomized series, indicate differences in their interaction kinetics, and reveal artifacts due to nonspecific signals, incomplete regeneration, or carryover.¹⁶³

SPR biosensors have also been used to study the interaction between HIV-1 protease and reversible inhibitors. The steady-state binding level and the time course of association and dissociation could be observed by measuring the binding of inhibitors injected in a continuous flow of buffer to the enzyme immobilized on the biosensor surface. Fourteen low-molecular-weight inhibitors (500? to 700 Da), including four clinically used HIV-1 protease inhibitors (indinavir, nelfinavir, ritonavir, and saquinavir) were analyzed. Inhibition constants (Ki) were determined by a separate enzyme inhibition assay. Indinavir had the highest affinity ($B_{50} = 11 \text{ nM}$) and the fastest dissociation ($t_{1/2} = 500 \text{ s}$) among the clinically used inhibitors, while saquinavir had a lower affinity ($B_{50} = 25 \text{ nM}$) and the slowest dissociation rate ($t_{1/2} = 6500 \text{ s}$). Because these two inhibitors have similar affinities, the differences in dissociation rates reveal important characteristics in the interaction that cannot be obtained by the inhibition studies alone. 164,165 Characterization of another set of HIV-1 protease inhibitors using binding kinetics data from an SPR biosensor-based screen has also been reported. 166

Fluorescence polarization, circular dichroism, and SPR optical biosensor binding studies were used to investigate the novel virucidal protein cyanovirin-n (cv-n). Cv-n binds with equally high affinity to soluble forms of either h9 cell-produced or recombinant glycosylated HIV-1 gp120 (sgp120) or gp160 (sgp160). Studies showed that cv-n is also capable of binding to the glycosylated ectodomain of the HIV-envelope protein gp41 (sgp41), albeit with considerably lower affinity than the sgp120/cv-n interaction. These optical techniques shed light on the binding of cv-n with sgp120 and sgp41, providing direct evidence that conformational changes are a consequence of cv-n interactions with both HIV-1 envelope glycoproteins. ¹⁶⁷

20.6.4 Bacterial Pathogens

Several physicochemical instrumental techniques for direct and indirect identification of bacteria such as IR and fluorescence spectroscopy, flow cytometry, chromatography, and chemiluminescence have been reviewed as feasible biosensor technologies.¹⁶⁸

Staphylococcus aureus is a pathogen that commonly causes human infections and intoxication. An evanescent-wave optical sensor was developed for the detection of protein A, a product secreted only by S. aureus. A 488-nm laser was used in conjunction with a plastic optical fiber with adsorbed antibodies for protein. A sandwich immunoassay with fluorescein isothiocyanate conjugated with anti-(protein A) IgG was used to monitor the Ag–Ab reaction. The detection limit was 1 ng/ml of protein A. 169

In a different approach, an optical biosensor based on resonant mirrors was used in the detection of whole cells of *S. aureus* (Cowan-1).¹⁷⁰ The bacterium cells, which express protein-A at their surface, were detected through their binding to human IgG immobilized on an aminosilane-derivatized sensor surface at concentrations in the range 8×10^6 to 8×10^7 cells/ml. A control *S. aureus* strain (Wood-46) that does not express protein-A produced no significant response. The sensitivity of the technique was increased by three orders of magnitude when a human IgG-colloidal gold conjugate

(30 nm) was used in a sandwich assay format. S. aureus (Cowan-1) cells were detected in spiked milk samples at cell concentrations from 4×10^3 to 1.6×10^6 cells/ml using the sandwich assay.¹⁷⁰

The same resonant mirror optical biosensor technology was used to characterize *Helicobacter pylori* strains according to their sialic acid binding. In that work, intact bacteria were used in real-time measurements of competition and displacement assays using different glycoconjugates. The authors found that several, but not all, *H. pylori* strains express sialic acid-binding adhesin specific for alpha-2,3-sialyllactose. The adhesin, removable from the bacterial surface by water extraction, is not related to other reported *H. pylori* cell surface proteins with binding ability to sialylated compounds such as sialylglycoceramides.^{171,172}

A fiber-optic evanescent-wave sensing system that features all-fiber optical design and red semiconductorlaser excitation has been developed and tested. A 650-nm laser was used because biological matrices demonstrate minimal fluorescent background in the red; this helps reduce the background signal of nonessential biomolecules. The fiber directs the fluorescent signal of a sandwich immunoassay to detect *Salmonella* back to a charge-coupled device (CCD) fiber spectrophotometer. The system could detect *Salmonella* with a concentration as low as 10⁴ colony-forming units (CFU) per milliliter.¹⁷³

With a similar biodetection approach utilizing laser-induced fluorescence, an optic biosensor was used to detect the fraction 1 (F1) antigen from *Y. pestis*, the etiologic agent of plague.¹⁵ An argon ion laser (514 nm) was used to launch light into a long-clad fiber, and the fluorescence produced by an immunofluorescent complex formed in the evanescent wave region was measured with a photodiode. Capture antibodies, which bind to F1 antigen, were immobilized on the core surface to form the basis of the sandwich fluoroimmunoassay. The evanescent wave has a limited penetration depth (<1 lambda), which restricts detection of the fluorescent complexes bound to the fiber's surface. The direct correlation between the concentration of the F1 antigen and the signal provided an effective method for sample quantitation; the method was able to detect F1 antigen concentrations from 50 to 400 ng/ml in phosphate-buffered saline, serum, plasma, and whole blood, with a 5-ng/ml detection limit.¹⁵

A very different detection approach for *Salmonella typhimurium* involved immunomagnetic separation and a subsequent enzyme-linked assay with alkaline phosphatase. The magnetic microbeads coated with anti-*Salmonella* were used to separate *Salmonella* from sample solutions at room temperature for 30 min. A sandwich complex with alkaline phosphatase and the *Salmonella* immobilized on the magnetic beads was formed, separated from the solution by a magnetic filtration, and incubated with a p-nitrophenyl phosphate substrate at 37°C for 30 min to produce p-nitrophenol by the enzymatic hydrolysis. *Salmonella* was detected by measuring the absorbance of p-nitrophenol at 404 nm, with a linear response between 2.2×10^4 and 2.2×10^6 CFU/ml.¹⁷⁴

20.6.5 Cancer

Optical biosensors have been utilized as tools to aid in the direct diagnosis of carcinogenesis, the identification of genetic markers associated with it, and the quantification of known carcinogens.

Fluorescent detection has become a technique of choice for oligonucleotide hybridization detection. Pairs of high density oligonucleotide arrays (DNA chips) consisting of more than 96,000 oligonucleotides were designed to screen the entire 5.53-kb coding region of the hereditary breast and ovarian cancer BRCA1 gene for all possible sequence changes in the homozygous and heterozygous states. Fluorescent hybridization signals from targets, containing the 4 natural bases to more than 5592 different, fully complementary 25mer oligonucleotide probes on the chip, varied over two orders of magnitude. To examine the thermodynamic contribution of rU.dA and rA.dT target probe base pairs to this variability, modified uridine [5-methyluridine and 5-(1-propynyl)-uridine)] and modified adenosine (2,6- diaminopurine riboside) 5'-triphosphates were incorporated into *BRCA1* targets. Hybridization specificity was assessed based upon hybridization signals from >33,200 probes containing centrally localized single base pair mismatches relative to target sequence. Targets containing 5-methyluridine displayed promising localized enhancements in the hybridization signal, especially in pyrimidine-rich target tracts,

while maintaining single nucleotide mismatch hybridization specificities comparable with those of unmodified targets.¹⁷⁵

In another study, the breast cancer susceptibility gene *BRCA1* was also detected by a relatively new technique based on SERS. A single 24-mer sequence was used as the capture probe and was immobilized on a silver-coated microarray platform for hybridization.²¹ Breast cancer was also the target of a biosensor design to measure the interaction of S100A4 and potential binding partners.¹⁷⁶ Elevated levels of S100A4 induce a metastatic phenotype in benign mammary tumor cells *in vivo*. In humans, the presence of S100A4 in breast cancer cells correlates strongly with reduced patient survival. There was significant interaction of S100A4 with nonmuscle myosin and p53 but not with actin, tropomyosin, or tubulin.¹⁷⁶

A regenerable immunosensor utilizing an antibody against breast cancer antigen has been described. A 65% removal of the antigens bound to the Mab immobilized on the fiber surface is attained after ultrasound regeneration.²² A multiarray biosensor utilizing DNA probes labeled with visible and NIR dyes has also been developed. The detection system uses a two-dimensional CCD to detect the *p53* cancer gene.²³

Prostate cancer is the cause of death of many thousands of men worldwide. Screening men for elevated prostate-specific antigen (PSA) levels is believed to be an important tool for the diagnosis and management of the disease. An assay for measuring PSA in whole blood using the fluorescence capillary fill device has been developed for use in prostate cancer screening programs.¹⁷⁷

A unique example of the technology being developed is optical nano-biosensors capable of interrogating the contents of a single isolated cell. These submicrometer fiber-optic biosensors have been used to measure carcinogens within single cells. Optical fibers were pulled to a distal-end diameter of 40 nm and coated with antibodies to selectively bind benzo[a]pyrene tetrol (BPT), a metabolite of benzo[a]pyrene, an extremely potent carcinogen. Two different cell lines have been investigated: human mammary carcinoma cells and rat liver epithelial cells. The detection limit of these nanosensors has been determined to be (0.64 \pm 0.17) \times 10⁻¹¹ M for BPT. The development and application of nanosensors are further described in the chapter on nanosensors for single-cell analysis in this handbook.

The carcinogen benzo[a]pyrene (BAP) was the target of an antibody-based fiberoptics biosensor.⁷ In that biosensor, BAP was the analyte and fluorophore because it has a large fluorescence cross section. An antibody with high specificity for BAP was immobilized on the tip of an optical fiber. Upon exposure to contaminated samples, the optical fiber was irradiated with a laser and the resulting fluorescence correlated with the BAP concentration.

20.6.6 Parasites

Detection of antibodies specific for the parasite *L. donovani* in human serum samples has been reported. The method is based on an evanescent wave fluorescence collected by optical fibers that have the purified cell surface protein of *L. donovani* immobilized on their surface. The sensing fibers are incubated with the patient serum for 10 min and then incubated with goat anti-human IgG. Fluorescence was proportional to *L. donovani*—specific antibodies present in the test sera.¹⁷⁹

20.6.7 Toxins

Ricin, a potently toxic protein, has been detected with an evanescent-wave fiber-optic biosensor with a detection limit of 100 pg/ml and 1 ng/ml for buffer solutions and river water, respectively. Athis detection was based on a sandwich immunoassay scheme, using an immobilized anti-ricin IgG on the surface of the optical fiber. Two coupling methods were used. In the first, the antibody was directly coated to the silanized fiber using a cross linker; the second method utilized avidin-coated fibers incubated with biotinylated antiricin IgG to immobilize the antibody using an avidin-biotin bridge. The assay using the avidin-biotin-linked antibody demonstrated higher sensitivity and a wider linear dynamic range than the assay using the antibody directly conjugated to the surface. The linear dynamic range of detection for ricin in buffer using the avidin-biotin chemistry is 100 pg/ml to 250 ng/ml.⁷⁸

The lipopolysaccharide (LPS) endotoxin is the most powerful immune stimulant known and a causative agent in the clinical syndrome known as sepsis. Sepsis is responsible for more than 100,000 deaths annually, in large part due to the lack of a rapid, reliable, and sensitive diagnostic technique. ¹⁸ An evanescent wave fiberoptic biosensor was developed for the detection of LPS from *E. coli* at concentrations as low as 10 ng/ml in 30 s. ¹⁸ Polymyxin B covalently immobilized onto the surface of the fiber-optic probe was able to bind fluorescently labeled LPS selectively. Unlabeled LPS present in the biological samples was detected in a competitive assay format, by displacing the labeled LPS. The competitive assay format worked in buffer and in plasma with similar sensitivities. This method might also be used with other LPS capture molecules, such as antibodies, lectins, or antibiotics, to simultaneously detect LPS and determine the LPS serotype. ¹⁸

An immunoaffinity fluorometric biosensor was developed for the detection of aflatoxins, a family of potent fungi-produced carcinogens commonly found in a variety of agriculture products. Developed into a fully automated instrument based on immunoassays with fluorescent tags, the detection system was able to detect aflatoxins from 0.1 to 50 ppb in 2 min with a 1-ml sample volume.¹⁸⁰

Parathion was detected with a biosensor based on total internal reflection using a competitive-displacement immunoassay. This biosensor utilizes casein–parathion conjugates, immobilized by adsorption on quartz fibers, and selectively adsorbed antiparathion rabbit antibodies raised against bovine serum albumin(BSA)–parathion conjugates from polyclonal immune sera. The presence of free parathion inhibited the binding of the rabbit's anti-(BSA)-parathion. Fluorescein isothiocyanate (FITC) goat antirabbit IgG was used to generate the optical signal. It could detect 0.3 ppb of parathion and had a detection limit 100-fold higher for the detection of its oxygen analog, paraoxon. ¹⁸¹ Other biosensor approaches for the detection of parathion include another competition assay that inhibits the alkaline phosphatase generation of a chemiluminescent substance ¹⁸² and a direct detection method based on another enzymatic sensor. ^{183,184}

A very interesting approach for biosensing toxins involves the integration of multiple transducers with different affinities for a large range of biotoxins. The different transducers are based on membranes made of mixtures of biologically occurring lipids deposited on the sensing surface of an SPR optical biosensor. Eight surfaces were prepared, some of which contained various glycolipids as minor components, and one was supplemented with membrane proteins. The researchers analyzed the binding of six protein toxins (cholera toxin, cholera toxin B subunit, diphtheria toxin, ricin, ricin B subunit, and staphylococcal enterotoxin B) and of bovine serum albumin at pH 7.4 and pH 5.2 to each of the sensor surfaces. Each of the seven proteins produced a distinct binding pattern to the multitransducer sensor. The same concept had been used earlier for the development of "artificial noses," which are sensor arrays able to detect a small collection of distinct analytes.

Cholera toxin (CT) has been also detected with a fluorescence-based biosensor using a waveguide platform. The biochemical assay utilized a ganglioside-capture format, where the ganglioside (GM1) that captures the analyte was immobilized in discrete locations on the surface of an optical waveguide. Binding of CT to immobilized GM1 was demonstrated with direct assays (using fluorescently labeled CT) and with "sandwich" immunoassays (using fluorescently labeled tracer antibodies). The detection limits for CT were 200 ng/mL in direct assays and 40 ng/ml and 1 µg/ml in sandwich-type assays performed using rabbit and goat tracer antibodies.⁷⁷ A slightly different biosensing approach was also used to detect cholera toxin. Instead of direct fluorescence detection, fluorescence quenching was used. The ganglioside GM1 was again used as the recognition unit for CT, and was covalently labeled with fluorophores and then incorporated into a biomimetic membrane surface.¹⁸⁶

In a very nice application of surface plasmon resonance, SPR biosensors have been used to estimate the immunoreactivity of tetanus toxin and *Vipera aspis* venom against new pasteurized preparations of their horse F(ab')(2) antidotes, in order to investigate immunoreactivity–immunoprotection efficacy relationships. The immunoreactivity data were compared with seroneutralization titres. The association–dissociation rate and affinity constants of the current and the new tetanus toxin-specific F(ab')(2) preparations were similar, at about $10^4 \text{ M}^{-1} \text{ s}^{-1}$, 10^{-4} s^{-1} and 10^8 M^{-1} , respectively.¹⁸⁷

20.6.8 Blood Factors

SPR was used to determine absolute heparin concentration in human blood plasma. Protamine and polyethylene-imine (PEI) were used to modify the sensor surface and were evaluated for their affinity to heparin. Heparin adsorption onto protamine in blood plasma was specific with a lowest detection limit of 0.2 U/ml and a linear detection range of 0.2 to 2 U/ml. Although heparin adsorption onto PEI in buffer solution had indicated superior sensitivity to that on protamine, in blood plasma it was not specific for heparin and adsorbed plasma species to a steady-state equilibrium. By reducing the incubation time and diluting the plasma samples with buffer to 50%, the nonspecific adsorption of plasma could be controlled and a PEI pretreated with blood plasma could be used successfully for heparin determination. Heparin adsorption in 50% plasma was linear between 0.05 and 1 U/ml so that heparin plasma levels of 0.1 to 2 U/ml could be determined with a relative error of 11% and an accuracy of 0.05 U/ml. ¹⁸⁸

20.6.9 Congenital Diseases

SPR and biospecific interaction analysis (BIA) have been used to detect the Delta F508 mutation (F508del) of the cystic fibrosis transmembrane regulator (CFTR) gene in homozygous as well as heterozygous human subjects. The detection method involved the immobilization on an SA5 sensor chip of two biotinylated oligonucleotide probes (one normal, N-508, and the other mutant, Delta F508) that are able to hybridize to the CFTR gene region involved in F508del mutation. A hybridization step between the oligonucleotide probes immobilized on the sensor chips and (1) wild-type or mutant oligonucleotides, as well as (2) ssDNA. These nucleic acid samples were obtained using asymmetric polymerase chain reaction (PCR), performed using genomic DNA from normal individuals and from F508del heterozygous and Delta 508del homozygous patients. The different stabilities of DNA/DNA molecular complexes generated after hybridization of normal and Delta F508 probes immobilized on the sensor chips were then evaluated. The results strongly suggest that the SPR technology enables a one-step, nonradioactive protocol for the molecular diagnosis of F508del mutation of the CFTR gene. This approach could be of interest in clinical genetics, because the hybridization step is often required to detect microdeletions present within PCR products. The results of the control of the detect microdeletions present within PCR products.

20.7 Conclusions

The past decade has witnessed the rapid development of a wide variety of biosensors for many different analyses and has even seen them begin to advance to clinical and, in some cases, commercially available technologies, such as SPR biosensors. The increasing interest in the field of optical biosensors has provided a great deal of information about the biochemistry of clinically important ailments and has provided drug discovery research with faster analytical tools to investigate drug—receptor interactions. Optical methods have also been extensively applied to DNA fingerprinting and genotyping, techniques that might find enormous applications in clinical diagnosis in the near future.

As a very positive sign, optical biosensors are coming of age as a bioanalytical tool. A larger number of researchers in different areas now have access to a more user-friendly technology, and are able to develop custom applications specific to their research needs, expanding the range of applications for the technology.

For practical medical diagnostic applications, there is a strong need for a truly integrated biosensor system that can be easily operated by relatively unskilled personnel. Some of the current commercially available technologies have dramatically simplified the data collection operation. Although these systems have demonstrated their usefulness in genomic detection, protein interaction analysis, carcinogen monitoring, etc., they are laboratory oriented and involve relatively expensive equipment and trained, supervised operation.

The outlook is promising for optical biosensor systems; the near future should bring a larger number of multichannel applications for the simultaneous detection of multiple biotargets; improvements in size and performance; and lower production costs due to a more integrated package. Highly integrated systems lead

to reduction in noise and increase in signal due to the improved efficiency of sample collection and the reduction of interfaces. The capability of large-scale production using low-cost integrated circuit (IC) technology is an important advantage that cannot be overlooked. For medical applications, the development of low-cost, disposable biosensor surfaces that can be used for clinical diagnostics at the point of care can be a major driving force for the expansion of optical biosensor technologies.

21.1 Introduction

Many materials are visually opaque because photons traveling within them are predominantly scattered rather than absorbed. Some common examples of these highly scattering media include white paint, foam, mayonnaise, and human tissue. Indeed, anyone who has held a flashlight up to his or her hand will notice some of this light is transmitted, albeit after experiencing many scattering events. Light travels through these materials in a process similar to heat diffusion.

What does it mean to say light transport is diffusive? Consider a simple experiment in which an optical fiber is used to inject light into a highly scattering material such as paint or tissue. Microscopically, the injected photons experience thousands of elastic scattering events in the media. A few of the photons will be absorbed by chromophores and will be lost. The remaining photons travel along pathways that resemble a random walk. These individual trajectories are composed of straight-line segments with sudden interruptions where the photon propagation direction is randomly changed. The average length of the straight-line segments is called the random walk steplength of the traveling photon. By summing all trajectories one can compute the photon concentration or photon fluence rate as a function of time and position within the media.

It is then straightforward to show that the collective migration of photon concentration is described by a diffusion equation. In practice one can carry out a variety of measurements to confirm the diffusive nature of light transport. For example, if a short pulse of light is injected into the medium and a second optical fiber is used to detect transmitted photons, then, when the transport is diffusive, the most probable arrival times for the detected photons will scale with the square of the source-detector separation divided by the random walk steplength.

Diffuse light imaging and spectroscopy aims to investigate tissue physiology millimeters to centimeters below the tissue surface. ^{1–5} The cost of this goal is that we must abandon traditional optical spectroscopies and traditional microscopy because traditional methodologies require optically thin samples. In addition, light penetration must be large in order to reach tissue located centimeters below the surface. Fortunately, a spectral window exists within tissues in the near-infrared from 700 to 900 nm, wherein photon transport is dominated by scattering rather than absorption. The absorption of hemoglobin and water is small in the near-infrared, but elastic scattering from organelles and other microscopic interfaces is large. These are precisely the conditions required for application of the diffusion model. The recognition and widespread acceptance that light transport over long distances in tissues is well approximated as a diffusive process has propelled the field. Using this physical model it is possible to separate tissue scattering from tissue absorption quantitatively, and to incorporate the influence of boundaries, such as the air-tissue interface, into the transport theory accurately. The diffusion approximation also provides a tractable basis for tomographic approaches to image reconstruction using highly scattered light. Tomographic methods were not employed in early transillumination patient studies, and are crucial for recovery of information about tissue optical property heterogeneity.

Even though absorption in the near-infrared is relatively small, the spectra of major tissue chromophores, particularly oxy- and deoxyhemoglobin and water, differ significantly in the near-infrared. As a result, the diffuse optical methods are sensitive to blood dynamics, blood volume, blood oxygen saturation, and water and lipid content of interrogated tissues. In addition, one can induce optical contrast in tissues with exogenous contrast agents, for example, chemical species that occupy vascular and extravascular space and preferentially accumulate in diseased tissue. Together these sensitivities provide experimenters with access to a wide spectrum of biophysical problems. The greater blood supply and metabolism of tumors compared to surrounding tissues provides target heterogeneity for tissue maps based on absorption. Similar maps can be applied for studies of brain bleeding and cerebral oxygen dynamics associated with activation by mental and physical stimulation. And the deep tissue methods include the study of mitochondrial diseases, and of muscle function and physiology, and of photodynamic therapy.

Biomedical applications for diffusing near-infrared light probes parallel the application of nuclear magnetic resonance to tissue study. Generally, the categories of measurement can be termed spectroscopy and imaging. Spectroscopy is useful for measurement of time-dependent variations in the absorption and scattering of large tissue volumes. For example, brain oximetry (hemoglobin spectroscopy) of the frontal, parietal, or occipital regions can reveal reduced brain perfusion caused by head injury. Imaging is important when a localized heterogeneity of tissue is involved, for example, an early breast or brain tumor, a small amount of bleeding in the brain, or an early aneurysm. Images enable one to identify the site of the trauma and differentiate it from background tissue. Imaging is also important because it improves the accuracy of a spectroscopic measurement. Typically, spectroscopic methods employ oversimplified assumptions about the scattering media. Imaging relaxes some of these assumptions, usually at the cost of a more complex experimental instrument and computation, and ultimately improves the fidelity of the gathered optical property information.

The purpose of this chapter is to discuss functional imaging with diffusing photons. Our emphasis will be on imaging rather than spectroscopy, but it will be necessary to briefly review the basics of diffuse optical spectroscopy. This chapter is intended as a tutorial about what can be done with diffuse optical imaging, how to do it, and how to understand it. We intend to give a tutorial snapshot of the field with selected examples, but not a comprehensive review of research in the field. The remainder of this tutorial consists of sections on theory, instrumentation, and imaging examples, and a discussion about limitations and compromises associated with the technique.

21.2.1 Diffusion Approximation

Many researchers (e.g., References 52 through 56 and others) have shown that the photon fluence rate, $\Phi(r, t)$ (photons/[cm² · s]), obeys the following diffusion equation in highly scattering media:

$$\nabla \cdot D(\mathbf{r}) \nabla \Phi(\mathbf{r}, t) - \nu \mu_a(\mathbf{r}) \Phi(\mathbf{r}, t) + \nu S(\mathbf{r}, t) = \frac{\partial \Phi(\mathbf{r}, t)}{\partial t}.$$
 (21.1)

 $\Phi(\mathbf{r},t)$ is proportional to the photon number density $U(\mathbf{r},t)$ (photons/cm³), i.e., $\Phi(\mathbf{r},t) = \mathbf{v}U(\mathbf{r},t)$. The turbid medium is characterized by a speed of light, \mathbf{v} , an absorption coefficient μ_a (i.e., the multiplicative inverse of the photon absorption length), and a photon diffusion coefficient, $D = \mathbf{v}/3(\mu_s' + \mu_a) \cong \mathbf{v}/3(\mu_s')$; the dependence of D on μ_a is a subject of recent debate, 53, 57-68 but the latter relation follows in most tissues wherein $\mu_s' >> \mu_a$. The medium's reduced scattering coefficient is defined as $\mu_s' = (1-g)\mu_s$ and represents the multiplicative inverse of the photon random walk steplength, l^* . Here μ_s is the reciprocal of the photon scattering length, l, and $g = \langle cos\theta \rangle$ is the ensemble-averaged cosine of the scattering angle θ associated with a typical single scattering event in the sample; g accounts for the fact that light is more typically scattered in the forward direction, so that many scattering events are required before the initial photon propagation direction is truly randomized. S(r,t) is an isotropic source term that gives the number of photons emitted at position r and time t per unit volume per unit time.

The right-hand side of Equation 21.1 represents the rate of increase of photons within a sample volume element. This rate equals the number of photons scattered into the volume element per unit time from its surroundings, *minus* the number of photons absorbed per unit time within the volume element, *plus* the number of photons emitted per unit time from any sources in the volume element.

The diffusion equation is based upon the P1 approximation of the linear transport equation.^{69,70} It is valid when the reduced albedo $\alpha' = \mu_s'/(\mu_a + \mu_s')$ is close to unity, i.e., the reduced scattering coefficient is much greater than the absorption coefficient ($\mu_s' >> \mu_a$). The near-infrared (NIR) spectral window (commonly called the "therapeutic" window) of biological tissue lies between the intense visible absorption bands of hemoglobin and the NIR absorption band of water. In this window the reduced scattering coefficient is often 10 to 1000 times greater than the absorption coefficient,⁷¹ for example, $\mu_s' \approx 10$ cm⁻¹ and $\mu_a \approx 0.03$ cm⁻¹ at 800 nm in human breast tissues. Of course tissues are not homogeneous, but they can be accurately divided into domains of piecewise homogeneous turbid media, each obeying Equation 21.1. Measurements are accomplished using sources and detectors arranged on the surfaces of or embedded within the tissue. Strictly speaking, it is also important for the source-detector separation to be of order three photon random walk steps (i.e., $3l^*$) or larger; otherwise the photon scattering angles will not be sufficiently randomized at the point of detection for rigorous application of the diffusion approximation.^{72,73}

21.2.2 Sources of Diffusing Photons

Three types of sources are commonly employed in diffusive light measurements (see Figure 21.1). The simplest and easiest method to use is the continuous-wave (CW) device. In this case the source amplitude is constant, and the transmitted amplitude is measured as a function of source-detector separation or wavelength. The second method is the pulsed-time or time-resolved technique. In this scheme a short, usually subnanosecond light pulse is launched into the medium, and the temporal point spread function of the transmitted pulse is measured. The third method is the intensity modulated or frequency-domain technique. In this case the amplitude of the input source is sinusoidally modulated, producing a diffusive wave within the medium. The amplitude and phase of the transmitted diffuse light wave are then measured. These methods are related; the time-resolved and frequency-domain approaches are Fourier

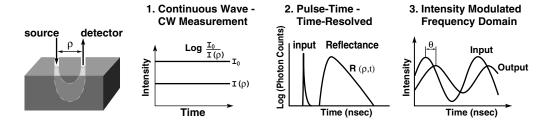

FIGURE 21.1 Three source-detector schemes are generally employed in the photon migration field. On the far left we illustrate a typical remission geometry: (1) continuous-wave, called CW spectroscopy; (2) time-pulsed or time-resolved technique (often called TRS); (3) intensity amplitude modulation, i.e., often referred to as the frequency-domain method.

transformations of one another, and the CW approach is a special case of the frequency-domain approach wherein the modulation frequency is zero. Each of these approaches has strengths and weaknesses.

Briefly, the CW scheme is inexpensive and provides for rapid data collection. However, because it measures amplitude only, it lacks the capability for characterizing simultaneously the absorption and scattering of even a homogeneous medium from a measurement using only a single source-detector pair. The more expensive time-resolved scheme collects the full temporal point spread function, which is equivalent to a frequency domain measurement over a wide range of modulation frequencies. In this case, when the medium is homogeneous, μ_a and μ_s' can be obtained simultaneously from a single source-detector separation. The photon counting, however, can be slow and the technique is often limited by shot noise. The frequency domain technique is a compromise between CW and time-resolved techniques, with respect to cost and speed. It concentrates all the light energy into a single modulation frequency. It measures amplitude and phase, which ideally enable us to obtain μ_a and μ_s' for a homogeneous medium using a single source-detector separation. In practice all of these methods benefit significantly from use of many source-detector pairs and many optical wavelengths. In this chapter we focus on frequency domain sources, but the results can be applied to time-resolved and CW methods.

21.2.3 Diffuse Photon Density Waves in Homogeneous Turbid Media

Consider a light source at the origin with its intensity sinusoidally modulated at a modulation frequency f, e.g., the source term in Equation 21.1 is $S(\mathbf{r},t)=(M_{dc}+M_{ac}e^{-i\omega r})$ $\delta(\mathbf{r})$, where $\omega=2\pi$ f is the angular source modulation frequency, M_{dc} and M_{ac} are the source strengths of the DC and AC source components. The diffusion equation continues to be valid for light derived from these highly modulated sources as long as the modulation frequency ω is significantly smaller than the scattering frequency $\nu\mu'$; that is, photons must experience many scattering events during a single modulation period. Photons leaving the source and traveling along different random walk trajectories within the turbid medium will add incoherently to form a macroscopic scalar wave of photon concentration or fluence rate.

The total fluence rate consists of a DC and an AC component, i.e., $\Phi_{\text{total}}(\mathbf{r},t) = \Phi_{\text{DC}}(\mathbf{r}) + \Phi_{\text{AC}}(\mathbf{r},t)$. We focus on the AC component $\Phi_{\text{AC}}(\mathbf{r},t) = \Phi(\mathbf{r})e^{-i\omega t}$. The photon fluence will oscillate at the source of modulation frequency ω . Plugging the AC source term into Equation 21.1 we obtain the following Helmholtz equation for the oscillating part of the photon fluence:

$$\left(\nabla^2 + k^2\right)\Phi(\mathbf{r}) = -\left(\frac{\nu M_{ac}}{D}\right)\delta(\mathbf{r}). \tag{21.2}$$

We refer to this disturbance as a diffuse photon density wave (DPDW).^{74,75} The DPDW has wavelike properties; for example, refractive,⁷⁶ diffractive,⁷⁷ and dispersive⁷⁸ behaviors of the DPDW have been demonstrated.

The photon density wave has a simple spherical wave solution for an infinite homogeneous highly scattering medium of the form:

$$\Phi_{AC}(\mathbf{r},t) = \left(\frac{vM_{ac}}{4\pi Dr}\right) \exp(ikr) \exp(-i\omega t). \tag{21.3}$$

The diffuse photon density wave wavenumber is complex, $k = k_r + ik_i$, and $k^2 = (-v\mu_a + i\omega)/D$. The real and imaginary parts of the wavenumber are:

$$\begin{split} k_r &= \left(\frac{\nu \mu_a}{2D}\right)^{1/2} \left(\left(1 + \left(\frac{\omega^2}{\nu \mu_a}\right)\right)^{1/2} - 1 \right)^{1/2} \\ k_i &= \left(\frac{\nu \mu_a}{2D}\right)^{1/2} \left(\left(1 + \left(\frac{\omega^2}{\nu \mu_a}\right)\right)^{1/2} + 1 \right)^{1/2} . \end{split} \tag{21.4}$$

In Figure 21.2 the measured wave is demonstrated within a tank of homogeneous highly scattering Intralipid. Constant-phase contours are shown in 20° intervals about the source at the origin. We see that the wave contours are circular and that their radii can be extrapolated back to the source. In the inset we exhibit the phase shift and a simple function of the wave amplitude plotted vs. the source-detector separation. From the slopes of these linear position-dependent measurements, one can deduce the wavelength of the disturbance, as well as the absorption and scattering factors of the homogeneous turbid medium via Equations 21.3 and 21.4.

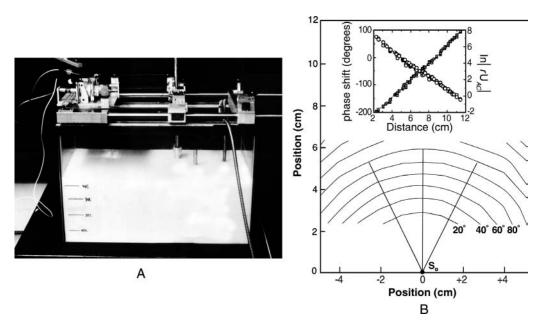

FIGURE 21.2 (A) An aquarium used for model experiments. The aquarium is filled with Intralipid, a polydisperse emulsion whose absorption and scattering coefficients in the NIR region can be adjusted to approximate those of tissue. (B) Constant-phase contours of diffuse photon-density waves in the homogeneous sample of Intralipid. The source for this measurement is a 1-mW laser diode operating at 780 nm and modulated at 200 MHz. Inset: Measured phase-shift and a dimensionless (logarithmic) function of the amplitude as a function of source-detector separation.

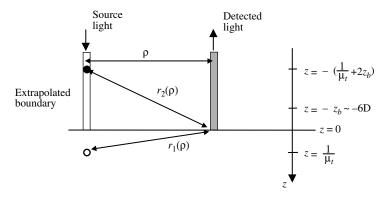

FIGURE 21.3 Schematic of the experimental fiber configuration showing the relative positions of surface boundary (z = 0), extrapolated boundaries, $r_1(\rho)$ and $r_2(\rho)$ as defined in Equations 21.5, 21.6a, and 21.6b.

For homogeneous media in more complex geometries, one can still derive a set of phase and amplitude curves as a function of source-detector separation. The functional relationships may not be linear, but it is still readily possible to derive the average absorption and scattering factors of the underlying media by fitting to this data.

21.2.4 Spectroscopy of Homogeneous Turbid Media

The absorption factor, μ_a , depends on the chromophore concentrations, and their extinction coefficients. The predominant endogenous absorbers in tissues are oxy- and deoxyhemoglobin, and water. The scattering factor, μ'_s , depends on other tissue properties such as organelle (e.g., mitochondria) concentration and the index of refraction of the background fluids. If the medium is sufficiently homogenous, then by measuring the absorption and scattering coefficients as a function of light wavelength, one generates a set of simultaneous equations that can be solved to yield the concentrations of the tissue chromophores.

The simplest and most commonly used physical model for tissue spectroscopy treats the sample as a semi-infinite medium. In this case the sources and detectors are placed on the "air side" of the tissue surface (see, for example, Figure 21.3). Emission and detection take place through optical fibers placed flush with the surface. The quantity measured in practice at position \mathbf{r} , time t, and along the direction n is the radiance integrated over the collection solid angle. Within the diffusion approximation, the radiance consists of an isotropic fluence rate $(\Phi(\mathbf{r},t))$ and a directional photon flux $(J(\mathbf{r},t))$ that is proportional to the gradient of Φ .

Diffusion theory for semi-infinite media predicts the reflectivity $R(\rho; \mu_a, \mu_s')$ as a function of ρ , where ρ is the source-detector separation along the sample surface. $R(\rho; \mu_a, \mu_s')$ is derived from photon flux and fluence rate at the boundary^{79,80}

$$R(\rho; \mu_a, \mu'_s) = C_1 \Phi(\rho) + C_2 J_z(\rho)$$
(21.5)

where

$$\Phi(\rho) = \frac{1}{4\pi D} \left(\frac{\exp(-\mu_{eff} r_1(\rho))}{r_1(\rho)} - \frac{\exp(-\mu_{eff} r_2(\rho))}{r_2(\rho)} \right)$$
(21.6a)

and

$$\begin{split} J_{z}(\rho) &= \frac{1}{4\pi\mu_{t}} \left[\left(\mu_{eff} + \frac{1}{r_{1}(\rho)} \right) \frac{\exp\left(-\mu_{eff}r_{1}(\rho)\right)}{r_{1}^{2}(\rho)} + \left(\frac{1}{\mu_{t}} + 2z_{b} \right) \left(\mu_{eff} + \frac{1}{r_{2}(\rho)} \right) \frac{\exp\left(-\mu_{eff}r_{2}(\rho)\right)}{r_{2}^{2}(\rho)} \right] \end{split} . \tag{21.6b}$$

Here, $\mu_t = \mu_a + \mu_s'$, and $\mu_{eff} = [3\mu_a(\mu_a + \mu_s')]^{1/2}$. C_1 and C_2 are constants that depend on the relative refractive index mismatch between the tissue and the detector fiber, and the numerical aperture of the detection fibers. The parameters $r_i(\rho)$ are defined in Figure 21.2. Briefly, $r_l(\rho)$ is the distance from the point of contact of the detector fiber on the tissue surface to the effective source position in the tissue located $1/\mu_t'$ directly beneath the source fiber; $r_2(\rho)$ is the distance between the point of contact of the detector fiber and a point located $1/\mu_t + 2z_b$ directly above the source; z_b is the extrapolated boundary length above the surface of the medium. Here the z-direction has been taken normal to the tissue surface (located at z = 0), so that J_z is the directional flux normal to the surface.

The tissue optical properties at a fixed wavelength are derived from the measured reflectance by fitting with Equation 21.5. Many schemes have been developed to search for the optimal parameters;^{80–82} their relative success depends on the measurement signal-to-noise ratio and the accuracy of the physical model. When everything works, one obtains a best estimate of the absorption factor and scattering factor at one or more optical wavelengths. We then decompose the absorption coefficient into contributions from different tissue chromophores, i.e.,

$$\mu_a(\lambda) = \sum_i \varepsilon_i(\lambda) c_i. \tag{21.7}$$

Here the sum is over the different tissue chromophores; $\varepsilon_i(\lambda)$ is the extinction coefficient as a function of wavelength for the *i*th chromophore and c_i is the concentration of the *i*th chromophore. The c_i are unknowns to be reconstructed from the wavelength-dependent absorption factors. Three unknowns require measurements at a minimum of three optical wavelengths (generally more, because tissue scattering is also an unknown).

Oxy- and deoxyhemoglobin concentrations (e.g., c_{HbO_2} , c_{Hb} , respectively) along with water concentration are the most significant tissue absorbers in the NIR. They can be combined to obtain blood volume (which is proportional to total hemoglobin concentration ($[c_{\text{Hb}} + c_{\text{HbO}_2}]$) and blood oxygen saturation (i.e., $[c_{\text{HbO}_2}/(c_{\text{Hb}} + c_{\text{HbO}_2})] \times 100$), which in turn provide useful physiological information. The same schemes are often extended to derive information about exogenous agents such as photodynamic therapy (PDT) drugs, indocyanine green (ICG), etc.; in such cases the effect of these other chromophores is accounted for by adding their contribution to the sum in Equation 21.7.

21.2.5 Imaging in Heterogeneous Media

21.2.5.1 Brief History

Tissue is often quite heterogeneous, so it is natural to contemplate making images with the diffusive waves. While high spatial resolution is desirable (e.g., a few millimeters), resolutions of about 1 cm are useful for many problems. A simple example of the utility of imaging is the early localization of a head injury that causes brain bleeding or hematomas. Tumors are another type of structural anomaly that one wants to detect, localize, and classify. The diffuse optical methods probe a variety of properties associated with tumor growth: larger blood volume resulting from a larger number density and volume fraction of blood vessels residing within the tumor; blood deoxygenation arising from relatively high metabolic activity within the tumor; increased concentration of the intracellular organelles necessary for the energy production associated with rapid growth; and the accumulation of highly scattering calcium precipitates.

Some of these properties may prove helpful in classifying tumors as benign or malignant. In the long term it should be possible to design contrast agents that respond to specific tumor properties. Other types of tissue of interest for functional imaging include the neonatal brain and a variety of animal models. For example, physiological studies of hemodynamics in relation to the oxygen demand probe important changes in the functional brain, especially during mental activity. In Section 21.4 we describe current research that investigates many of the clinical issues just outlined.

Optical characterization of the heterogeneous tissues has been attempted since 1929⁸³ when the term *diaphanography* was applied to shadowgraphs of breast tissue. This class of transillumination measurement was renewed in the early 1980s.^{84–95} Even in the region of low tissue absorption, however, the high degree of tissue scattering distorted spectroscopic information and blurred optical images as a result of the large distribution of photon pathways through the tissue. Widebeam transillumination proved largely inadequate for clinical use because the two-dimensional "photographic" data were poorly suited for image reconstruction. The mathematical modeling of light transport in tissues was not developed sufficiently for optical tomography to be readily employed.

The diffusion approximation now provides a tractable basis for tomographic approaches to image reconstruction using highly scattered light. Tomographic methods crucial for recovery of information about breast heterogeneities were not employed in the early transillumination patient studies. Several approaches have been developed for diffuse optical tomography; these include: backprojection methods, 96,97 diffraction tomography in *k*-space, 98-101 perturbation approaches, 102-107 the Taylor series expansion approach, 108-113 gradient-based iterative techniques, 114 elliptic systems method (ESM), 115,116 and Bayesian conditioning. 117 Backprojection methods, borrowed from CT, produce images quickly and use few computational resources. However, they lack quantitative information and rely on simple geometries. Perturbation approaches based on Born or Rytov approximations can use analytic forms or iterative techniques based on numerical solutions. The analytic forms are relatively fast, but require the use of simple boundary conditions and geometries, and generally underestimate the properties of the perturbations. The numerical solutions are relatively slow and computationally intensive; however, in principle, realistic boundaries present no significant limitations for these methods.

21.2.5.2 Formulation of the Imaging Problem

In this section we formulate the imaging problem in the frequency domain. The starting point of this analysis is the time-independent form of the diffusion equation (Equation 21.1), where we have divided out all of the $e^{i\omega t}$ dependencies:

$$\nabla \cdot D(\mathbf{r}) \nabla \Phi(\mathbf{r}) - (\nu \mu_a(\mathbf{r}) - i\omega) \Phi(\mathbf{r}) = -\nu S(\mathbf{r}, \omega). \tag{21.8}$$

The problem is difficult because the diffusion coefficient and the absorption coefficient vary with spatial position. We write $D(\mathbf{r}) = D_o + \delta D(\mathbf{r})$, and $\mu_a(\mathbf{r}) = \mu_{ao} + \delta \mu_a(\mathbf{r})$; here D_o and μ_{ao} are constant, "background" optical properties. The source can have any form, but typically we assume point sources of the form $A\delta(\mathbf{r} - \mathbf{r}_s)$.

The goal of diffuse optical imaging is to derive $D(\mathbf{r})$ and $\mu_a(\mathbf{r})$ from measurements of $\Phi(\mathbf{r})$ on the sample surface. Two common forms are used for $\Phi(\mathbf{r})$ in the formulation of the inversion problem. The Born-type approach writes $\Phi(\mathbf{r}) = \Phi_o(\mathbf{r}) + \Phi_{sc}(\mathbf{r})$; traditionally one can view $\Phi_o(\mathbf{r})$ as the incident wave and $\Phi_{sc}(\mathbf{r})$ as the wave produced by the scattering of this incident wave off the absorptive and diffusive heterogeneities. The Rytov approach writes $\Phi(\mathbf{r}) = \Phi_o(\mathbf{r}) \exp[\Phi_{sc}(\mathbf{r})]$. We will focus on the Born approximation for our analysis, and indicate when possible the corresponding Rytov results.

We next substitute $D(\mathbf{r})$, $\mu_a(\mathbf{r})$, and $\Phi(\mathbf{r}) = \Phi_o(\mathbf{r}) + \Phi_{sc}(\mathbf{r})$ into Equation 21.8 to obtain a differential equation for $\Phi_{sc}(\mathbf{r})$ with general solution:

$$\Phi_{sc}(\mathbf{r}_{d},\mathbf{r}_{s}) = \int \left(\frac{-\nu\delta\mu_{a}(\mathbf{r})}{D_{o}}\right) G(\mathbf{r}_{d},\mathbf{r}) \Phi(\mathbf{r},\mathbf{r}_{s}) d\mathbf{r} + \int \left(\frac{\delta D(\mathbf{r})}{D_{o}}\right) \nabla G(\mathbf{r}_{d},\mathbf{r}) \cdot \nabla \Phi(\mathbf{r},\mathbf{r}_{s}) d\mathbf{r} . \tag{21.9}$$

Here \mathbf{r}_s is the source position, \mathbf{r}_d is the detector position, \mathbf{r} is a position within the sample. The integration is over the entire sample volume. $G(\mathbf{r},\mathbf{r}')$ is the Green's function associated with Equation 21.8. Examination of Equation 21.9 reveals some of the intrinsic challenges of the inverse problem. In a typical experiment one measures Φ on the sample surface and then extracts Φ_s on the surface by subtracting Φ_s from Φ . The problem of deriving $\delta \mu_a(\mathbf{r})$ and $\delta D(\mathbf{r})$ from Φ is intrinsically nonlinear because Φ and G are nonlinear functions of $\delta u_a(\mathbf{r})$ and $\delta D(\mathbf{r})$.

The Linearized Problem

The simplest and most direct route to inverting Equation 21.9 starts by replacing Φ by Φ_o and G by G_o . Here Φ_o and G_o are solutions of the homogeneous version of Equation 21.8 with $D(\mathbf{r}) = D_o$, and $\mu_a(\mathbf{r}) = \mu_{ao}$. This approximation is good when $\Phi_o \ll \Phi$, and when the perturbations are very small compared to the background. It is also important that we have accurate estimates of D_o and μ_{ao} . In this case, Equation 21.9 is readily discretized in Cartesian coordinates and written in the following form:

$$\Phi_{sc}(\mathbf{r}_d, \mathbf{r}_s) = \sum_{j=1}^{NV} \left(W_{a,j} \delta \mu_a(\mathbf{r}_j) + W_{s,j} \delta D(\mathbf{r}_j) \right). \tag{21.10}$$

The sum is taken over NV volume elements (i.e., voxels) within the sample; the absorption and scattering weights are, respectively, $W_{a,j} = G_o(\mathbf{r}_d, \mathbf{r}_j) \Phi_o(\mathbf{r}_j, \mathbf{r}_s)$ ($-\nu \Delta x \Delta y \Delta z/D_o$), and $W_{s,j} = \nabla G_o(\mathbf{r}_d, \mathbf{r}_j) \cdot \nabla \Phi_o(\mathbf{r}_j, \mathbf{r}_s)$ ($\Delta x \Delta y \Delta z/D_o$). In any practical situation there will be NS sources and ND detectors, and so there will be up to $NM = NS \times ND$ measurements of Φ on the sample surface. For the multisource-detector problem one naturally transforms Equation 21.10 into a matrix equation, i.e.,

$$\left[\mathbf{W}_{a,jt}, \mathbf{W}_{s,ij}\right] \left\{ \delta \mu_a \left(\mathbf{r}_j\right), \delta D \left(\mathbf{r}_j\right) \right\}^T = \left\{ \Phi_{sc} \left(\mathbf{r}_d, \mathbf{r}_s\right)_i \right\}. \tag{21.11}$$

Here, the index i refers to source-detector pair, and the index j refers to position within the sample. The perturbation vector $\{\delta \mu_a(\mathbf{r}_j), \delta D(\mathbf{r}_j)\}^T$ is 2NV in length, the measurement vector $\{\Phi_{sc}(\mathbf{r}_d,\mathbf{r}_s)_i\}$ is NM in length, and the matrix [W] has dimensions $NM \times (2NV)$. In the Rytov scheme, the formulation in the weak perturbation limit is almost exactly the same, except that $W_{a,j} = G_o(\mathbf{r}_d,\mathbf{r}_j) \Phi_o(\mathbf{r}_p,\mathbf{r}_s)(-\nu\Delta x \Delta y \Delta z/\Phi_o(\mathbf{r}_d,\mathbf{r}_s) D_o)$, $W_{s,j} = \nabla G_o(\mathbf{r}_d,\mathbf{r}_j) \cdot \nabla \Phi_o(\mathbf{r}_p,\mathbf{r}_s)$ ($\Delta x \Delta y \Delta z/\Phi_o(\mathbf{r}_d,\mathbf{r}_s) D_o$), and the vector $\{\Phi_{sc}(\mathbf{r}_d,\mathbf{r}_s)_i\}$ is set equal to $\{\ln[\Phi(\mathbf{r}_d,\mathbf{r}_s)/\Phi_o(\mathbf{r}_d,\mathbf{r}_s)]_i\}$ rather than $\{[\Phi(\mathbf{r}_d,\mathbf{r}_s)-\Phi_o(\mathbf{r}_d,\mathbf{r}_s)]_i\}$. The Rytov scheme has some experimental advantages because it is intrinsically normalized (the Born scheme, however, can be modified so that it is normalized in essentially the same way); the major approximations of the Rytov scheme are associated with the gradients of Φ , in particular that $(\nabla \Phi_{sc})^2$ is small relative to the perturbation terms in Equation 21.9. Thus both Born and Rytov approaches give rise to an inverse problem of the form [W] $\{x\} = \{b\}$; the unknown vector $\{x\}$ can be determined from this set of linear equations by a number of standard mathematical techniques. The numerical elements in [W] are often assigned in simple geometries using analytic forms of G_o and Φ_o (e.g., Equation 21.3 and variants), or more generally by numerically solving Equation 21.8 and its Green's function analog for Φ_o and G_o .

The Nonlinear Problem

The linear formulation described above works well when perturbations are small and isolated, and when the background media are relatively uniform. However, Equation 21.9 is intrinsically nonlinear because Φ and G are also functions of the variables we are trying to determine by inversion. The most broadly useful image reconstruction schemes are iterative. These approaches follow similar algorithms: (1) the optical properties (μ_a and D) are initialized; (2) the forward problem is solved; (3) a chi-squared is calculated and convergence is checked; (4) the inverse problem is set up; (5) the inverse problem is solved; (6) the optical properties are updated and a return to step 1 occurs.

The forward problem is defined as calculating the diffuse photon density, $\Phi_C(\mathbf{r}, \mathbf{r}_s)$, for each source position \mathbf{r}_s and is typically found using finite elements or finite difference methods using Equation 21.8. The boundary conditions are defined as:

$$\frac{\partial \Phi_C}{\partial \hat{n}} = -\alpha \Phi_C, \quad \alpha = \frac{\left(1 - R_{eff}\right)}{\left(1 + R_{eff}\right)} \frac{3\mu_s'}{2}.$$
 (21.12)

 R_{eff} is the effective reflection coefficient and can be approximated by: $R_{eff} = -1.440n^{-2} + 0.710n^{-1} + 0.668 + 0.0636n$, $n = n_{in}/n_{out}$ the relative index of refraction.⁵⁵ The chi-squared (χ^2) is generally defined as:

$$\chi^{2} = \sum_{NM} \left(\frac{\Phi_{M}(r_{d}^{i}) - \Phi_{C}(r_{d}^{i})}{\sigma^{i}} \right)^{2}. \tag{21.13}$$

Here NM = number of measurements, M = measured, C = calculated, \mathbf{r}_d^i is the ith detector position, and σ^i is the ith measurement error. By comparing χ^2 to some defined ε , a convergence criterion is defined and checked.

We then need a way of updating the optical properties from their previous values. A standard Taylor method expands Φ_C about its assumed optical property distribution, which is a perturbation away from another distribution presumed closer to the true value. In particular we set the measured photon density wave for each source-detector pair equal to the calculated photon density wave at the corresponding source-detector pair plus the first-order Taylor series perturbation expansion terms in μ_a and D, i.e., $\Phi_M = \Phi_C + (\partial \Phi_C/\partial \mu_a)\Delta \mu_a + (\partial \Phi_C/\partial D)\Delta D$.

The inverse problem is defined from this relationship:

$$[\mathbf{J}] \{ \Delta \mu_a, \Delta D \}^T = -\{ \Phi_M(\mathbf{r}_d) - \Phi_C(\mathbf{r}_d) \}. \tag{21.14}$$

Here $[J] = [\partial \Phi_C/\partial \mu_a, \partial \Phi_C/\partial D]$ is called the Jacobian. The Jacobian matrix will have the following entries:

$$\left[\frac{\partial \Phi_C}{\partial \mu_a}\right]_{ij} = \frac{-\nu \Delta x \Delta y \Delta z}{D_o} G(\mathbf{r}_{di}, \mathbf{r}_j) \Phi_C(\mathbf{r}_j, \mathbf{r}_{si})$$
(21.15a)

$$\left[\frac{\partial \Phi_{C}}{\partial D}\right]_{ii} = \frac{\Delta x \Delta y \Delta z}{D_{o}} \nabla G(\mathbf{r}_{di}, \mathbf{r}_{j}) \cdot \nabla \Phi_{C}(\mathbf{r}_{j}, \mathbf{r}_{si}). \tag{21.15b}$$

It is illuminating at this point to compare Equation 21.14 with Equation 21.11. The two expressions are essentially the same if we associate Φ_M with Φ , Φ_C with Φ_o , $\Delta\mu_a$ with $\delta\mu_a$, ΔD with δD , and if we use the true Green's function G rather than G_o . The same set of substitutions in the Rytov formulation gives a Rytov version of the nonlinear inversion scheme. Thus the iterative formulation of the inverse problem is based on the same underlying integral relationship (Equation 21.9), and one readily sees that each step of the "nonlinear" iteration process is a linear inverse problem of the form [J] $\{x\} = \{b\}$.

21.2.5.3 Methods for Solving the Inverse Problem

The inverse problem may be solved using a wide range of methods (an excellent review of these methods was given by Arridge¹¹⁸). The solution method chosen depends in part on the determination of the *implicit* or *explicit* Jacobian. For the explicit Jacobian two methods are commonly employed: the Newton-Raphson and the conjugate gradient techniques. It is also possible to combine these methods with Bayesian conditioning or regularization to improve reconstruction. For the implicit Jacobian, the methods of choice are the gradient-based iterative technique and ART (algebraic reconstruction technique).

There are essentially two ways to construct the Jacobian, [J] explicitly: direct and adjoint. The direct approach explicitly takes the derivative of the forward problem (Equation 21.8) with respect to the optical properties to determine the Jacobian. For example, suppose [A] { Φ_C } = {S} is the forward problem; here [A] is the operator on the left side of Equation 21.8 and {S} is the source on the right side of Equation 21.8.

Then the equation $[A]\{\partial \Phi_C/\partial \mu_a\} = \{\partial S/\partial \mu_a\} [\partial A/\partial \mu_a]\{\Phi_C\}$ enables one to compute $\partial \Phi_C/\partial \mu_a$ (and a similar forward problem enables the computation of $\partial \Phi_C/\partial D$). This approach is optimal with finite elements; because the numerical formulation lends itself easily to taking the derivative of [A]. Φ_C [A] and $[A]^{-1}$ are updated on each iteration. The *adjoint* approach solves the forward problem $[A]\{\Phi_C\} = \{S\}$ to determine Φ_C and an adjoint problem $[A^*]\{G\} = \{S'\}$ to determine Green's function $G(\mathbf{r}_d,\mathbf{r})$ due to a unit source at the detector position. $^{1,102-105,107,119,120}$ G and Φ_C then fix the elements of [J] according to Equation 21.15. Both Φ_C and G are updated at each iteration. The impact of the two different approaches on convergence and accuracy is not well understood. However, from the computational perspective, for each iteration the direct approach requires S solves per iteration, while the adjoint Born or Rytov approach requires S plus S solves per iteration.

The inverse problem, [J] $\{\Delta\mu_a, \Delta D\}^T = \{\Phi_M - \Phi_C\}$, which is also a matrix equation, is significantly more costly than these other subproblems because the Jacobian is a full nonsquare matrix $\{NM \times 2NV\}$. However, the inverse problem only needs to be solved once per iteration cycle. The Jacobian is ill-conditioned and is thus singular or close to singular, which makes it difficult to invert directly. Generally, the approach to address these issues is twofold. First, the matrix is made square by multiplying the inverse problem by the transpose of the Jacobian, i.e.,

$$[\mathbf{J}]^{T} [\mathbf{J}] \{ \Delta \mu_{a}, \Delta D \}^{T} = [\mathbf{J}]^{T} \{ \Phi_{M} - \Phi_{C} \}.$$
 (21.16)

Unfortunately, by squaring the Jacobian the equation becomes even more ill conditioned. This problem is solved by regularization^{121,122} so that the equation becomes

$$\left(\begin{bmatrix} \mathbf{J} \end{bmatrix}^T \begin{bmatrix} \mathbf{J} \end{bmatrix} + \lambda \begin{bmatrix} \mathbf{C} \end{bmatrix}^T \begin{bmatrix} \mathbf{C} \end{bmatrix} \right) \left\{ \Delta \mu_a, \Delta D \right\}^T = \begin{bmatrix} \mathbf{J} \end{bmatrix}^T \left\{ \mathbf{\Phi}_M - \mathbf{\Phi}_C \right\}. \tag{21.17}$$

Here λ is called the regularization parameter and [C] is the regularizing operator, which is sometimes taken to be the identity matrix. The regularization parameter generally is related to the measurement signal-to-noise. It is a theoretical "knob" that can be adjusted and it will affect image quality by introducing a trade-off between spatial resolution and contrast. Nevertheless, its use converts the inverse problem into a readily solvable problem. $\{\Delta\mu_a, \Delta D\}^T$ can now be determined using Equation 21.17 and any number of mathematical techniques that solve systems of linear equations. A particularly useful and common solution scheme is the conjugate gradient method.

A qualitatively different scheme due to Arridge involves the implicit determination of the Jacobian. Briefly, this technique utilizes the Born or Rytov approximation for the inverse problem, and has at least two known solution methods: gradient-based iterative technique and ART (algebraic reconstruction technique). The Jacobian is not calculated; instead an objective function (e.g., a chi-square function) is defined whose gradient, for example, can be used to derive subsequent search directions (see the original papers, References 114 and 118, for details.) Note that the implicit formulation is particularly attractive for experimental systems that rely on many detectors rather than many sources.

21.2.5.4 Challenges for Implementation

The main barrier for full three-dimensional reconstruction is the significant memory and processing time it requires. There are three costly steps of the algorithms: (1) solving the forward problem for each source position, (2) determining the Jacobian, and (3) solving the inverse problem. The forward problem requires the solution of a matrix equation banded in finite difference or sparse in finite elements. The solvers in three-dimensional reconstruction are necessarily iterative because direct solvers require very large storage space for full matrices. Subsequently, multiple source positions demand multiple forward solves. Determination of the Jacobian requires additional matrix equation solutions. For explicit determination, the Green's function for each detector position is needed or the vectors $\partial \Phi_C / \partial \mu_a$ and $\partial \Phi_C / \partial D$ are needed.

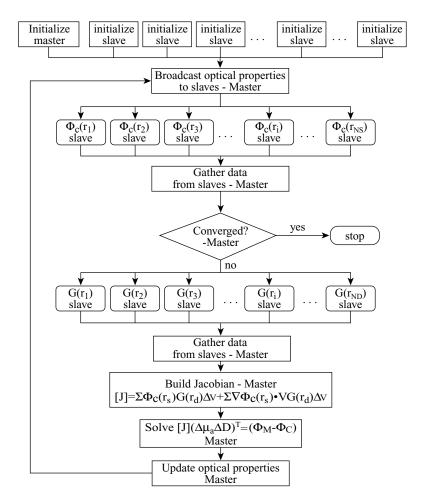

FIGURE 21.4 Schematic of the University of Pennsylvania algorithm for image reconstruction using parallel computing. In the first step each node has its own set of arrays and variables that are initialized. The master must initialize the Jacobian array, the forward solution vector array, and the Green's function vector array. In the second step the master sends out the optical properties, which (in the first iteration) are just the background values. In the third step, the slaves calculate the solutions to the forward problem; NS slaves are used in this step. The solution vectors are then returned to the master and at this point the master checks for convergence. If convergence has not been achieved then the slaves calculate the solutions to the Green's function; ND slaves are used in this step. The solution vectors are returned to the master and the Jacobian is determined. Next the master solves the inverse problem, in this case by using a spatially variant regularized conjugate gradient optimization method. Finally, the optical properties are updated on the master and the algorithm repeats until convergence has been achieved.

Consider a system with one frequency — NS sources and ND detectors; assume further that all the detectors are used for each source. The number of measurements is $NM = NS \times ND$. For each iteration we require NS forward solves and, depending on the Jacobian determination, either ND Green's function or 2NS solves for the vectors $\partial \Phi_C/\partial \mu_a$ and $\partial \Phi_C/\partial D$ (implicit would require NS solves). The final costly step of the algorithm is the solution of the inverse problem. However, the inverse problem only needs to be solved once per iteration cycle. For many practical problems the calculations take a long time, and limited memory is available to store the Jacobian explicitly. An important solution to this large-scale computational problem is parallel computing — the execution of many computations at one time using many processors. It has been used successfully in areas of medical imaging, such as positron emission tomography (PET), 124–128 single photon emission computed tomography (SPECT), 129,130 computed tomography (CT), 131–133 electrical impedance tomography (EIT), 134 and optical sectioning microscopy

(OSM).¹³⁵ It is just beginning to catch on in the diffuse optical tomography (DOT) community.^{136,137} In Figure 21.4, we illustrate how the problem is parallelized at the University of Pennsylvania.

21.2.6 Diffusion of Light Correlations: Blood Flow

Thus far our discussion has centered around the determination of tissue absorption and scattering properties. Among other things, these measurements provide access to concentrations of oxygenated and deoxygenated hemoglobin. Even more information, however, is impressed upon these diffusing light fields. Speckle fluctuations of the scattered light are sensitive to the motions of scatterers such as red blood cells.

The means for using light fluctuations and light frequency shifts to study motions have appeared with numerous names over the years. ^{138–158} In most of these experiments the quantity of interest is the electric field temporal autocorrelation function $G_1(\mathbf{r},\tau) = \langle E(\mathbf{r},t) E^*(\mathbf{r},t+\tau) \rangle$ or its Fourier transform. Here the angle brackets $\langle \cdot \rangle$ denote ensemble averages or averages over time for most systems of practical interest. τ is called the correlation time. The field correlation function is explicitly related to the motions of scatterers within the samples that we study.

The study of these motions in deep tissues is possible because the electric field temporal autocorrelation function for light traveling in highly scattering media also obeys a diffusion equation. In steady-state (i.e., $\omega = 0$) and in homogeneous media, this correlation diffusion equation is quite simple:

$$\left(D\nabla^2 - \nu \mu_a - \alpha k_o^2 \mu_s \left\langle \Delta \mathbf{r}^2(\tau) \right\rangle / 3\right) G_1(\mathbf{r}, \tau) = -\nu S(\mathbf{r}). \tag{21.18}$$

Here k_o is the wavevector of the photons in the medium and $\langle \Delta \mathbf{r}^2(\tau) \rangle$ is the mean-square displacement in time τ of the scattering particles (e.g., blood cells); it can have different forms depending on the nature of the particle motion and can also vary with position. $S(\mathbf{r})$ is the source light distribution, and α represents the fraction of photon scattering events in the tissue that occur from moving cells or particles.

Notice that, for $\tau \to 0$, $\langle \Delta \mathbf{r}^2(\tau) \rangle \to 0$, and Equation 21.18 reduces to the steady-state diffusion equation for diffuse photon fluence rate (i.e., Equation 21.8 with $\omega = 0$). Notice also that the homogenous version of Equation 21.18 can be recast as a Helmholtz-like equation for the temporal field autocorrelation function, $G_1(\mathbf{r},\tau)$, i.e.,

$$\left(\nabla^2 + K^2(\tau)\right)G_1(\mathbf{r},\tau) = -S(\mathbf{r})/D, \qquad (21.19a)$$

$$K^{2}(\tau) = \left(-\nu/D\right)\left(\mu_{a} + \alpha k_{o}^{2}\mu_{s}'\left\langle\Delta\mathbf{r}^{2}(\tau)\right\rangle/3\right). \tag{21.19b}$$

For an infinite homogenous medium with a point source at the origin, this equation will also have the well known spherical-wave solution, i.e., $\sim [\exp\{-K(\tau)\mathbf{r}\}/D4\pi\mathbf{r}]$.

The mean-square displacement $\langle \Delta \mathbf{r}^2(\tau) \rangle = 6D_B \tau$ for organelles or cells undergoing Brownian motion with "particle" diffusion coefficient D_B . For the important case of random flow that can arise in the tissue vasculature, $\langle \Delta \mathbf{r}^2(\tau) \rangle = \langle V^2 \rangle \tau^2$, where $\langle V^2 \rangle$ is the second moment of the cell speed distribution. In the latter case the correlation function will decay exponentially as τ .

Multidistance measurements of $G_1(\mathbf{r}, \mathbf{\tau})$ provide dynamical information about the motions within the sample in exactly the same way that diffusive waves provide information about scattering and absorption properties. The layout of the sources and detectors is similar to the diffusive wave schemes, but the correlation measurements are a little more complex. For the measurements, one needs a special piece of equipment called an autocorrelator, which takes the detector output and uses the photon arrival times to compute $G_1(\mathbf{r}, \mathbf{\tau})$ or (more precisely) its light *intensity* analog.

The entire set of formalisms for imaging outlined in Sections 21.2.5.2 and 21.2.5.3 is applicable to diffuse light temporal correlations. The technique is attractive because it enables us to measure the blood

flow (i.e., $\langle \Delta \mathbf{r}^2(\tau) \rangle$) within deep tissues. The ability to measure relative changes concurrently in blood flow, hemoglobin concentration, and hemoglobin oxygenation within a single instrument makes possible a range of cerebral studies in animal models and in infants and neonates (see References 159 through 161).

21.2.7 Contrast Agents

The use of contrast agents in DOT and spectroscopy for disease diagnostics and for probing tissue functionality follows established clinical imaging modalities such as magnetic resonance imaging (MRI), 162-164 ultrasound, 164-166 and x-ray computed tomography (CT). 164,167,168 Contrast agent administration provides for accurate difference images of the same heterogenous tissue volume under nearly identical experimental conditions; this approach often yields superior diagnostic information. Although contrast agents most commonly induce changes in absorption, recently fluorescent/phosphorescent agents have also been considered as means to increase specificity and sensitivity for tumor detection and imaging. 77,169-184 In addition to concentration changes, fluorophore lifetime is sensitive to physiological environment, for example, through oxygen quenching or pH. Most contrast agent schemes rely on the fact that the exogenous macromolecular structures accumulate preferentially in abnormal tissues.

21.2.7.1 Fluorescent Contrast Agents

A chapter in this handbook already reviews contrast agents in photon migration, so we will be very brief. (Our discussion follows from References 185 through 187.) Suppose a heterogeneous turbid medium with fluorophore distribution $N(\mathbf{r})$ is excited by an excitation diffusive wave, $\Phi(\mathbf{r},\mathbf{r}_s)$, emitted from \mathbf{r}_s and whose optical wavelength is in the absorption band of the fluorophore. A fluorescent diffuse photon density wave, $\Phi_{fl}(\mathbf{r},\mathbf{r}_s)$, is produced in the medium, and

$$\Phi_{fl}(\mathbf{r}, \mathbf{r}_s) = \int G_{fl}(\mathbf{r}, \mathbf{r}') T(\mathbf{r}') \Phi(\mathbf{r}', \mathbf{r}_s) d\mathbf{r}$$
 (21.20a)

where

$$T(\mathbf{r}') = \varepsilon \frac{\tau}{\tau_o} \frac{\eta N(r)}{1 - \omega \tau}$$
 (21.20b)

The integration is over the sample volume. Here $T(\mathbf{r})$ is a fluorescence transfer function, which depends on the fluorophore radiative and total lifetimes, τ_o and τ respectively, the source modulation frequency ω , the fluorophore extinction coefficient ε , the fluorescence quantum yield η , and the fluorophore distribution $N(\mathbf{r})$. In principle, τ_o and τ (and even ε and η) can also depend on position. The Green's function $G_{fl}(\mathbf{r}, \mathbf{r}')$ is derived with a diffusion equation (Equation 21.8) for the fluorescent diffuse photon density wave at the emission wavelength, i.e., the absorption and scattering coefficients in this diffusion equation are defined at the fluorescent emission wavelength. Equation 21.20 is very similar to the equations we inverted in Sections 21.2.5.2 and 21.2.5.3. However, it is deceptively simple because heterogeneity information is embedded in Φ and G_{fl} , in addition to N and τ . Nevertheless, it can be inverted numerically using similar techniques.

21.2.7.2 Differential Absorption

In these measurements optical data are typically obtained before and after administration of the absorbing optical contrast agent (e.g., the intraveneous administration of ICG. In principle, DOT images taken before and after administration may be reconstructed and subtracted; however, in practice a more robust approach derives images of the differential changes due to the extrinsic perturbtion. In the latter case experimental measurements use the exact same geometry within a short time of one another, thereby minimizing positional and movement errors and instrumental drift. Furthermore, the use of differential

measurements eliminates systematic errors associated with the different medium often required to calibrate operational parameters of the instrument or to provide a baseline measurement for independent reconstructions. Finally, the effect of surface absorbers such as hair- or skin-color variation is also minimized.

The main analytical difficulties of the differential approach arise because the media are inhomogeneous. Thus the total diffuse light field in the contrast agent perturbation problem does not separate into a homogeneous background field and a scattered field in a straightforward way. Furthermore, the average background optical properties, particularly the absorption, can change as a result of contrast agent administration.

In the typical experiment, relative absorption changes are much larger than scattering changes and one can ignore the relative changes in scattering. Under these circumstances the differential signal $\Delta\Phi$, can be related to the differential absorption $\Delta\mu_a$ via the integral relation:¹⁸⁸

$$\Delta\Phi(\mathbf{r},\mathbf{r}_s) = \int W_a'(\mathbf{r},\mathbf{r}',\mathbf{r}_s)\Delta\mu_a(\mathbf{r}')d\mathbf{r} + C. \qquad (21.21)$$

Here W_a' is a weight function very similar to the functions discussed in Section 21.2.5.2. C is a correction; it is an integral that depends on source-detector geometry and on the weight function before and after administration of the contrast agent. For many geometries (e.g., the transmission geometry) C is small and can be ignored. In those cases we can directly invert Equation 21.21 according to the ideas described in Sections 21.2.5.2 and 21.2.5.3, and thus obtain the differential absorption changes directly from difference measurements.

21.3 Instrumentation

The basic imaging geometry for diffuse optical tomography consists of a set of distinguishable point-like sources and a set of photodetectors, each covering a small area of $<10 \text{ mm}^2$ on the surface of the medium. In general some type of source encoding strategy must be used so that the origin of the detected signals can be traced to specific sources. In this way, measurements with differing spatial sensitivities are obtained, and an image can be reconstructed.

There are three common measurement geometries: (1) planar transillumination measurements, (2) cylindrical measurements, and (3) reflectance measurements. All three are used for breast imaging (transillumination, 10-13,189 cylindrical, 15,190-192 and reflectance. 119,137,193). The cylindrical and reflectance geometries are used for imaging animals, human baby heads, 28,194-197 and limbs on the human body (e.g., arm or leg). The reflectance geometry is used for imaging human adult heads. 159,198-200

In Section 21.2.2 we identified three diffuse light excitation schemes: (1) illumination by subnanosecond pulses of light, (2) CW illumination, and (3) radio-frequency (RF) amplitude-modulated illumination. Short-pulse systems^{201–205} detect the temporal distribution of photons as they leave the tissue. The shape of the distribution provides information about tissue optical parameters. Although these systems provide the most information per source-detector pair for characterizing optical properties, their relatively poor signal-to-noise ratio (SNR) leads to longer image acquisition times (typically a few minutes in systems used today).

CW systems^{195,206–208} emit light of constant intensity or amplitude. (Sometimes the emitted intensity is amplitude modulated at frequencies less than a few tens of kilohertz.) Detectors measure the amplitude of the light transmitted through the tissue. These systems are simple to build and provide fast image rates (presently up to 100 Hz), but their lack of temporal information makes quantitation of tissue absorption and scattering more difficult. In RF systems^{209–211} the light source intensity is amplitude modulated at frequencies of tens to hundreds of megahertz. Information about the absorption and scattering properties of tissue is obtained by recording amplitude decay and phase shift (delay) of the detected signal with respect to the incident wave.^{211,212} These systems offer the fast image acquisition rate of CW systems and contain information sufficient for quantitative characterization of absorption and

TABLE 21.1 Comparison of Relative Advantages and Disadvantages of Time-Domain, Frequency-Domain, and Continuous-Wave Instrumentation

Instrumentation	Advantages	Disadvantages
Time-Domain	Full temporal impulse response	Difficult to maintain
	Quantitative	Expensive optoelectronics
Frequency-Domain	Diffusive wave phase and amplitude Faster than time-domain	Difficult RF electronics
	Lower cost than time-domain	
Continuous-Wave	Lowest cost	Diffuse light amplitude only
	Easy electronics Fastest Accurate for differential measurements of optical properties	Less accurate for extimates of absolute optical properties

scattering optical properties. The advantages and disadvantages of the three systems are outlined in Table 21.1.

In DOT it is desirable to make a large number of measurements for image reconstruction in a short period of time so that the data are not confounded by physiological or movement artifacts. The balance between number of measurements and image acquisition time is dictated by application. CW systems are popular for imaging spatial variations of absorption changes on timescales of seconds to minutes, for example, imaging muscle^{213,214} and brain activation.^{195,196,198} CW systems usually have the best SNR and lend themselves well to several encoding strategies enabling massively parallel measurements. Furthermore, although CW systems are poor at quantifying static absorption and scattering properties uniquely, they excel at quantifying spectroscopic changes in absorption and scattering, particularly when a priori knowledge of the spectroscopic features is available. On the other hand, RF and time-domain systems are popular for imaging static optical properties when quantitative accuracy is required and when data acquisition times of one to several minutes are acceptable.

21.3.1 Source Encoding Strategies

If cost is not an issue, then increasing the number of parallel detectors or detection systems is a straightforward approach to increasing the number of measurements per unit time. Often, however, measurements with multiple source wavelengths and source positions are desired. In this case an encoding strategy enabling the separation of source wavelengths and positions must be employed. The encoding strategies currently used in CW systems and applicable to RF systems are switched-source time-division multiplexing (SS-TDM), phase-division multiplexing (PDM), pulse-modulated time-division multiplexing (PM-TDM), frequency-division multiplexing (FDM), and wavelength-division multiplexing (WDM). SS-TDM and WDM are applicable to time-domain imaging systems as well.

For SS-TDM, sources are modulated at the same frequency and cycled through consecutively; the detectors synchronously obtain the source signal through their own demodulators. This is the easiest system to design and build. Because at any given time only a single source illuminates the sample, interchannel crosstalk is low, and simple circuit construction techniques (point-to-point wiring, Protoboards, etc.) can be used successfully.

For PDM, two sources are modulated with a square-wave at the same frequency, but in phase quadrature (i.e., at a 90° phase difference). Each of the detectors synchronously detects each source through two separate demodulators and low-pass filters, each of which is "tuned" to the in-phase source. Source pairs can then be cycled through consecutively. This is an easy system to design and build, but component layout affects performance, particularly interchannel crosstalk.

For PM-TDM, M sources are cycled on and off in sequence, but at a rapid (~kHz) rate. For N detectors, each source is synchronously detected through individual demodulators, each of which is time-gated to

one source. This approach has all the benefits of SS-TDM, but with no temporal skew. The system can be difficult to design and construct due to the complex interdigitation and fast switching speeds. Because only one source operates at any one time, the background level is very low.

For FDM, each of the sources is modulated at one of a number of anharmonically related frequencies (to minimize the effects of intermodulation distortion). For each of the detectors, the sources are demodulated coherently (synchronous detection) or incoherently (envelope detection). This is the most complex system to design and build due to the high potential for interchannel crosstalk. The high background flux arising because all sources are on simultaneously raises the shot noise floor and can saturate photo-detectors. However, because each source is "on" all the time, the scheme is more parallel than the sequential approaches described previously.

WDM simply uses bandpass optical filters in front of the photodetectors to distinguish different wavelength sources. This method can be used in combination with any of the encoding strategies described earier to distinguish light from different spatial locations.

21.3.1.1 Continuous-Wave Imaging System

As an example of the CW imaging system, we consider one used at the Massachusetts General Hospital-Nuclear Magnetic Resonance (MGH-NMR) Center. This system employs the FDM scheme to detect 32 lasers with 32 detectors (see Figure 21.5). At present, the 32 lasers are divided into 16 lasers at 690 nm and 16 at 830 nm. These 16 laser pairs are fiber coupled and deliver light to 16 positions on the medium to be imaged. The detectors are avalanche photodiodes (APDs, Hamamatsu C5460-01). A master clock generates the 32 distinct frequencies between 6.4 and 12.6 kHz in approximately 200-Hz steps. These frequencies are then used to drive the individual lasers with current stabilized square-wave modulation. Following each APD module is a bandpass filter, cut-on frequency of ~500 Hz to reduce 1/f noise and the 60-Hz room light signal, and a cut-off frequency of ~16 kHz to reduce the third harmonics of the square-wave signals. After the bandpass filter is a programmable gain stage to match the signal levels with the acquisition level on the analog-to-digital converter within the computer. Each detector is digitized at ~45 kHz and the individual source signals are then obtained by use of a digital bandpass filter — for example, a discrete Fourier transform or an infinite-impulse-response filter.

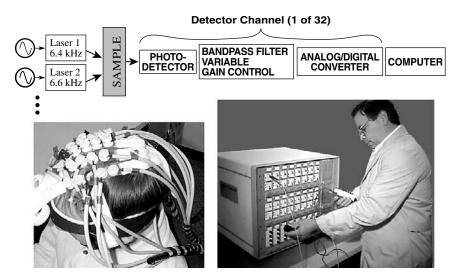

FIGURE 21.5 The MGH-NMR Center CW imaging system with 32 lasers and 32 detectors along with a block diagram indicating the frequency encoded sources and electronic processing steps from the photodetector to the computer memory.

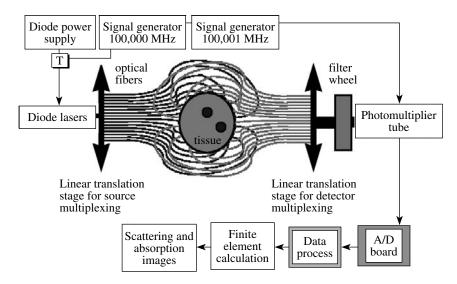

FIGURE 21.6 Schematic of the frequency-domain imaging system developed at Dartmouth College. (From Pogue, B.W. et al., *Opt. Express*, 1, 391, 1997. With permission.)

21.3.1.2 Frequency-Domain Imaging System

A typical frequency-domain imaging system is illustrated in Figure 21.6. Developed at Dartmouth College,²¹⁵ this system modulates the intensity of a laser diode at 100.000 MHz and couples the light sequentially into different fiber optics (the SS-TDM encoding scheme). Diffusely remitted light is captured by detector fibers that are coupled into a single photomultiplier tube (PMT). The PMT is time-shared between the individual detector fibers, so the instrument employs a TDM encoding scheme. A filter wheel is positioned before the PMT to prevent saturation of the detector by stronger optical signals coming from closer to the source. The photo-electric signal within the PMT is modulated at 100.001 MHz to heterodyne the signal down to 1 kHz. The 1-kHz signal is acquired by an analog-to-digital converter, from which a computer calculates the relative amplitude and phase of the detected 100-MHz diffuse photon density wave.

21.3.1.3 Time-Domain Imaging System

Figure 21.7 shows a diagram of the time-domain image system developed at University College London. ²¹⁶ The light source is a subpicosecond pulsed Ti:Sapphire laser with wavelength tunable from approximately 750 to 850 nm. Laser pulses are fiber coupled and fiber-optically multiplexed between 32 fibers that deliver source light to 32 independent positions. Photons exiting the sample are received by 32 large diameter detector fibers that relay the light to 32 individual time-correlated single photon counting channels. Computer controlled variable optical attenuators ensure that the detected light intensity does not saturate the photodetectors. The arrival time of detected photons is histogrammed by a picosecond time analyzer, which simultaneously produces histograms of the measured TPSF for all 32 detector channels. The full set of TPSFs for all source-detector pairs represents the raw data used for reconstructing images.

21.4 Experimental Diffuse Optical Tomography: Functional Breast and Brain Imaging

The imaging systems described previously and others like them have been used in phantom, animal, and human subject studies. In this section we provide a coherent snapshot of these activities. We begin with

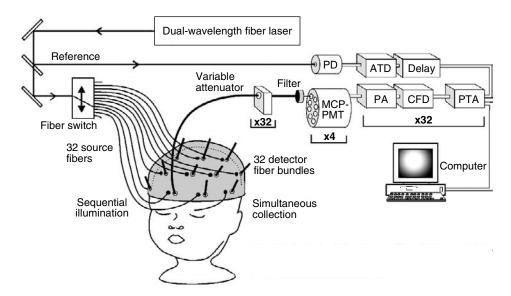

FIGURE 21.7 Schematic diagram of the time-domain imaging system. For clarity, only one detector fiber bundle is shown. PD = photo diode; PA = pre-amplifier; ATD = amplitude timing discriminator; CFD = constant fraction discriminator; PTA = picosecond time analyzer.

a tissue phantom experiment in order to illustrate image reconstruction on a controlled sample; the DOT reconstructions produce acceptable images by striking a balance between image noise, contrast, and resolution. Next we review the application to breast imaging, with recent clinical results. We describe measurements of normal breast optical properties, of tumors based on endogenous contrast, and of tumors using exogenous contrast agents to enhance tumor absorption characteristics preferentially.

Finally, we review the application to functional brain imaging. In this case we show images of blood flow, blood volume, and oxygen saturation changes in a rat stroke model. Then we show images that reveal localized variations in cerebral hemodynamics due to a sensory stimulation of a rat. Finally, we provide an example of functional brain imaging in adult humans with motor-sensory stimuli. The experiments presented are not exhaustive and do not represent the full range of results from the community. Nevertheless, the selected experiments indicate the promise of DOT for *in vivo* functional imaging.

21.4.1 Multiple Absorbers in a Slab Phantom

In this subsection we show how DOT is able to resolve multiple perturbations in the optical properties of a highly scattering medium. We also illustrate the trade-off between image resolution and the contrast-to-noise ratio. This type of experiment is important because it validates DOT techniques in well controlled samples.

The experimental data were collected using a hybrid CW and RF system developed at the University of Pennsylvania^{217,218} (see Figure 21.8). Laser light is multiplexed to 45 positions (a 9×5 array) on one side of the slab phantom (i.e., parallel planes, see Figure 21.8). Nine detector fibers are interspersed within the 9×5 array to receive a 70 MHz frequency-domain signal, simultaneously, from which the amplitude and phase is determined by an IQ-homodyne demodulation.²¹⁹ This frequency-domain information was used to determine the background optical properties of the medium. A 16-bit CCD camera (Roper Scientific, NTE1340) was positioned to image the CW light transmitted through the phantom. The CCD camera had 800×1120 pixels, which were binned 24×24 . The measurements were cropped to within a radius of 6 cm of the maximum transmitted signal producing approximately 250 independent measurements (i.e., a 21×13 detector array) per source position.

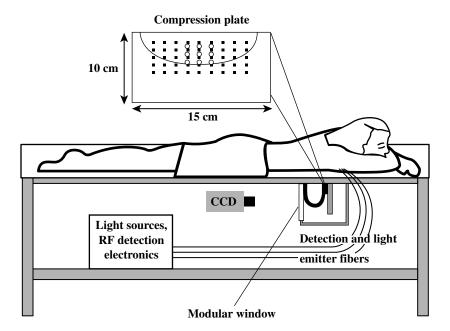

FIGURE 21.8 Phantom geometry for the transillumination measurements. The array of 9×5 light sources is indicated in the compression plate by the black squares. The 3×3 array of frequency-domain photodetectors intermingled with the source fibers is indicated by the open circles. A CCD camera images the transmission of the CW light from each source position individually. A slightly modified version of this experimental system was used for the clinical measurements described in Section 21.4.1, with the CCD camera replaced by a scanning frequency-domain photodetector.

For the phantom experiment, the breast tank was filled with an Intralipid/ink solution (see Figure $21.8)^{220,221}$ with $\mu_s' = 8 \text{ cm}^{-1}$ and $\mu_a = 0.05 \text{ cm}^{-1}$. In one experiment, two highly absorbing spheres ($\mu_a = 2 \text{ cm}^{-1}$ and $\mu_s' = 8 \text{ cm}^{-1}$) were suspended in the Intralipid solution with a 5-cm separation; in another experiment many more spheres were suspended in the Intralipid solution. The image reconstruction algorithm was formulated using the Rytov approximation to the integral solution of the diffusion equation (see Section 21.2.5.2). A finite difference scheme was used to solve the forward problem in the rectangular geometry, and a conjugate gradient method was used to solve the inverse problem. Regularization was used for the inverse problem (see Section 21.2.5.3), and the entire scheme was iterative. Convergence was consistently obtained after 15 iterations.

An image of the two spheres was reconstructed with optimal regularization (see Figure 21.9). The three-dimensional image shows that two absorbers are easily resolved. The optimal regularization parameter was determined by examining the dependence of the regularization parameter on image norm, image variance, full-width at half-maximum (FWHM) of the imaged absorber, and measurement residual (see Figure 21.10). When the numerical value of the regularization parameter was increased, the image norm and image variance decreased, but at the expense of decreased image resolution (i.e., an increase in FWHM of the spheres) and increased measurement residual. A plot of the image contrast-to-noise ratio vs. the regularization parameter indicates that contrast-to-noise ratio is optimized with a regularization parameter that balances image noise and resolution (see arrows in Figure 21.10).²¹⁷ Similar trade-offs between image noise and resolution can be expected when imaging animals and human subjects. Culver et al.²¹⁷ also demonstrated images of many (i.e., >10) spheres in the same sample volume, thus indicating the potential of DOT for reconstructing multiple heterogeneities (as opposed to isolated heterogeneities in a homogenous background).

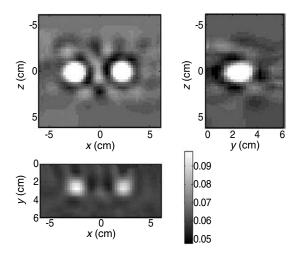

FIGURE 21.9 Three slices of the three-dimensional absorption image reconstructed from the phantom data are shown. The x-z plane is parallel to the measurement planes of the phantom. The scale bar indicates the range of values for the absorption coefficient.

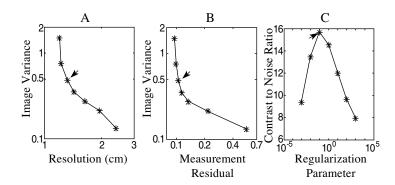

FIGURE 21.10 The dependence of objective measures of image quality on the regularization parameter is shown. (A) Increasing the regularization parameter controls the trade-off between image noise and resolution. (B) Increasing the regularization parameter also increases the residual of the fit to the experimental data. (C) The optimal regularization parameter as determined by the maximum image contrast to noise ratio corresponds to the points in (A) and (B) that balance image noise and resolution/measurement residual (indicated by the arrows in each figure).

21.4.2 Breast Imaging

The use of light to detect tumors in the breast was first proposed by Cutler in 1929,⁸³ who hoped to be able to distinguish between solid tumors and cysts in the breast by illuminating the breast and shadowing the tumors. However, he found it difficult to produce the necessary light intensity without exposing the patient's skin to extreme heat, while the low resolution of the technique severely limited its clinical applications. With the advent of more modern optical sources and detectors, optical transillumination breast imaging was tried again in the 1970s and 1980s, but was abandoned because of lack of sensitivity and specificity.^{93,222,223} The burst of activity in the 1990s can be traced to widespread acceptance of the diffusion approximation, which provides a tractable basis for tomographic approaches to image reconstruction using highly scattered light. Tomographic methods are crucial for recovery of information about heterogeneous breast tissues.

Functional, tomography-based diffuse optical breast imaging has been demonstrated, but further understanding and improvements are needed in order for it to become clinically useful. Current research is focusing on the construction of imaging systems with higher resolution and increased quantitative accuracy, as well as on the improvement of the algorithms used in image reconstruction. Thus far three general patient positions have been used: (1) the patient lies prone on a cot with a breast (or breasts) in a pendant position for imaging; ^{15,190–192} (2) the patient sits or stands with a breast held in compression similar to x-ray mammography; ^{10–13} and (3) the patient lies supine and is imaged with a hand-held probe that is moved to different positions on the breast. ^{119,193} The advantages of one approach over another for extraction of optical properties have not been fully explored.

Current research is also focusing more closely on the physiological information available to the technique. For example, quantitative hemoglobin images of the female breast showed localized increases in hemoglobin concentration that corresponded with biopsy-confirmed pathological abnormalities, suggesting that NIRS is capable of characterizing tumors as small as 0.8 ± 0.1 cm. ¹⁵ Other investigators have focused on the intrinsic sensitivity of the optical method to blood, water, and adipose — the principal components of the breast. Many of these researchers are studying the changes in breast optical properties associated with age, exogenous hormone levels, and menopausal status as well as, to a lesser extent, fluctuations in menstrual cycles. ^{14,224} Still other researchers are exploring the use of contrast agents ^{13,225,226} and the combination of DOT with other imaging techniques such as MRI and ultrasound.

In this section we briefly review some recent advances in the application of DOT to breast imaging. Our first example establishes the baseline optical properties of the normal breast; such information provides a useful benchmark about the requirements for detection of tumors based on endogenous (and exogenous) contrast. Then we describe experiments that image the endogeneous properties of the breast, revealing tumor signals, and we describe experiments that utilize contrast agents to create images with improved tumor sensitivity.

21.4.2.1 Endogenous Properties of Normal Breast

Our group at the University of Pennsylvania has collected optical breast data with the subject in a prone position, using essentially the same system discussed in Reference 218 (see Figure 21.8). The goal of these measurements was to establish *in-vivo* the baseline optical and physiological properties of the normal breast. The experimental system employed diode lasers at three wavelengths (750, 786, and 830 nm), each modulated at 140 MHz. The source light was delivered to the moveable breast-stabilization plate through an optical fiber. For detection, the CCD camera in Figure 21.8 was not used; instead a fiber-coupled PMT was scanned to multiple positions on the breast with the source fiber fixed at the center of the tissue and scan region. Prior to collecting data, the tank surrounding the breast is filled with a scattering liquid whose optical properties closely approximated the breast tissue. The amplitude and phase of the transmitted DPDW was measured using a homodyne IQ demodulation scheme.²¹⁹ In 15 min, 153 measurements (17×9) are obtained over an area of 10 cm \times 7 cm (x,y).

Measurements were collected on 52 healthy volunteers. The analysis had one new innovative feature: the data were fit simultaneously at all three wavelengths and "reconstructed" using spectral responses of oxy- and deoxyhemoglobin, and a Mie-based model for the wavelength dependence of the scattering coefficient. This spectroscopically self-consistent approach reduced crosstalk between scattering and absorption, overcoming some of the limitations of the homogeneous tissue model often used for characterization. The average absorption and scattering coefficients of the normal breast tissue were found to be 0.041 ± 0.025 cm⁻¹ and 8.5 ± 2.1 cm⁻¹, respectively, at 786 nm. The mean blood volume and blood oxygen saturation were found to be $34 \pm 9 \mu M$ and $68 \pm 8\%$, respectively.

A scatter plot of the blood volume and blood saturation results is shown in Figure 21.11. We see from this plot that the optical method will be sensitive to tumors with large blood volume and low blood saturation (outside the dashed lines); this condition might prevail in many tumors. A weak correlation of total hemoglobin concentration and scattering with body mass index (BMI) was found (i.e., decreasing with increasing BMI), but no statistically significant correlation with age was observed (20 to 65 years). This information provides insight into the types of intrinsic contrast available to optical breast imaging

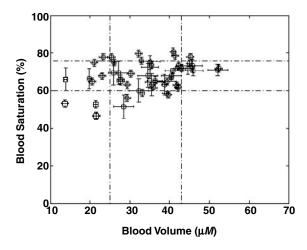

FIGURE 21.11 Hemoglobin saturation vs. total hemoglobin concentration; the dashed lines indicate the ranges for normal tissue from the mean and standard deviation of the healthy breast tissue.

FIGURE 21.12 (A) Patient bed for the optical breast imaging system developed at Dartmouth. (B) The fiber optic array for coupling light to and from the patient. The larger black cables are the detector fibers. The fibers are mounted on posts that translate radially for making contact with the tissue.

and, importantly, indicates the range of values that malignant tumors must have to be clearly distinguishable from the typical variation of normal breast tissue.

21.4.2.2 Clinical Optical Images of Breast Lesions

The optical breast imaging system developed by the group at Dartmouth is shown in Figure 21.12. 15,191 It is a pendant system, similar in many respects to the one at the University of Pennsylvania, but it obtains a coronal image of one breast at a time with a ring of interspersed 16 source and 16 detector fibers. The fiber ring is vertically positioned by a translation stage to image different planes of interest. The laser diodes emit light at 761, 785, 808, and 826 nm, are modulated at 100 MHz, and are optically combined before being serially multiplexed to each of the 16 source fibers. The lasers are driven sequentially so that the signal at each of the 16 photodetectors distinguishes different wavelengths and positions by time-division multiplexing. At each of the 4 wavelengths, 256 independent measurements are obtained and then processed by a finite element program to reconstruct absorption and scattering images (as described in Pogue et al. 15 and McBride et al. 191).

Figure 21.13 shows optical images for a 73-year-old female volunteer who had undergone routine mammography that demonstrated a 2.5-cm focal density with a larger ~6-cm-diameter area of associated architectural distortion. The imaged lesion corresponded to a palpable mass; needle biopsy subsequently diagnosed the mass as an invasive ductal carcinoma. The optical image was acquired 2 weeks after the biopsy and was aligned such that the coronal imaging plane was centered on the palpable lump. From

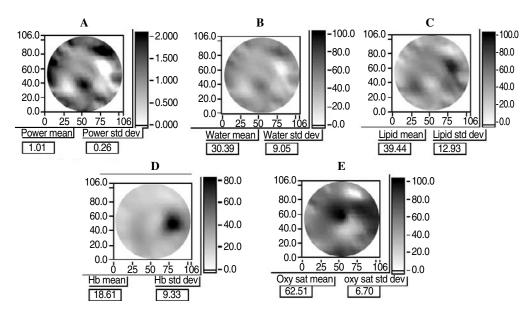

FIGURE 21.13 Clinical breast images are shown of (A) scattering power, (B) water (%), (C) lipids (%), (D) total hemoglobin concentration (μ M), and (E) hemoglobin oxygen saturation (%). (From McBride, T.O. et al., *J. Biomed. Opt.*, 7, 72, 2002. With permission.)

the scattering and absorption information, images were derived of the scatter power, ^{191,227} water concentration, lipid concentration, total hemoglobin concentration, and oxygen saturation. A lesion is clearly visible in the total hemoglobin image, which shows a threefold contrast-to-background ratio. In comparison to the variation of total hemoglobin concentration observed in normal tissue (Figure 21.11), the tumor has significantly greater total hemoglobin concentration. Structures in the other physiological images do not correspond well to the hemoglobin image; however, sensitivity to water and lipid percentages is expected to be weak because of the chosen wavelengths. The similarity between the scattering power, water, and lipid images suggests that water and lipid images are susceptible to crosstalk from the scattering power image.

21.4.2.3 Contrast Agents to Enhance Breast Lesion Detection

Another experiment at the University of Pennsylvania employed a time-domain imaging system in transmission mode to acquire *contrast enhanced* breast images while simultaneously obtaining magnetic resonance images. The time-domain optical imager has been described in detail in References 13 and 228. The instrument uses time-correlated single photon counting to measure the TPSF of photons diffusing through the breast tissue. The TPSF is then Fourier transformed to produce data at multiple modulation frequencies, which are then used to reconstruct differential absorption images¹⁸⁸ of the contrast agent ICG. The 830-nm pulsed laser source is coupled to 24 source fibers through a fiber optic switch. The detection collects light from eight positions simultaneously. Thus images are obtained using 24×8 measurements times the number of modulation frequencies. All source fibers are mounted on one plate forming a 3×8 array of fibers spaced by intervals of 1.25 cm. The detector fibers are mounted on the other plate to form a 2×4 array with a 2.5-cm separation. These two plates stabilize the breast and also contain the RF coils for the MRI. The MR studies were performed with a 1.5 T Signa, GE Medical Systems imager.

Figure 21.14 shows the results from a 70-year-old patient with an infiltrating ductal carcinoma about 1 cm in diameter. The pre-gadolinium (Gd) enhanced sagittal MR image slice passing through the carcinoma is shown in Figure 21.14A in gray scale, while the relative signal increase due to the Gd is

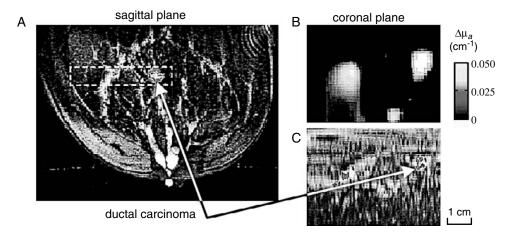

FIGURE 21.14 (Color figure follows p. 28-30.) A dynamic MRI and contrast-enhanced DOT image of a ductal carcinoma. (A) A dynamic sagittal MR image after Gd contrast enhancement passing through the center of the malignant lesion. (B) The coronal DOT image, perpendicular to the plane of the MRI image in (A), but in the volume of interest indicated in (A) by the dashed-line box. (C) The dynamic MR coronal image resliced from the same volume of interest and same dimensions as (B).

shown in color. A rectangle surrounding the carcinoma indicates the sagittal cut of the region of interest that was reconstructed in the optical image (shown in Figure 21.14B) in the coronal plane, and the corresponding MR coronal slice shown in Figure 21.14C. A strong optical contrast-induced absorption increase is seen in the upper right of the optical image, congruent with the position of the carcinoma revealed in the coronal MR image. Another lesion is revealed in the left of the optical image, congruent with the Gd enhancement observed in the MR image, but with a different size and shape. The differences in size and shape can be explained by the low spatial resolution of this implementation of DOT and the chosen threshold level for displaying the images. Similar results were seen in other patients with malignant and benign lesions. A summary of tissue ICG absorption enhancement seen in a group of patients is shown in Figure 21.15. This summary suggests that malignant lesions enhance absorption more than benign lesions by a factor of two, and more than normal tissue by a factor of three to four.

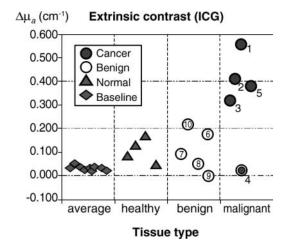

FIGURE 21.15 The ICG-induced absorption enhancement in healthy tissue and benign and malignant lesions compared with the nonenhanced absorption coefficient of normal healthy tissue.

21.4.3 Diffuse Optical Imaging of Brain Function

DOT of the brain affords continuous, *in vivo* deep tissue^{161,229} measurements of cerebral oxyhemoglobin (HbO), deoxyhemoglobin (Hb), total hemoglobin (HbT = HbO + Hb), and even blood flow.^{197,230–232} It is therefore a potentially new and important noninvasive technique for bedside monitoring. For example, optical spectroscopy can provide crucial information about cerebral hemodynamics and oxygenation during acute and chronic brain conditions, and optical imaging enables the detection of brain ischemia, necrosis, and hemorrhage.^{233,234} Knowledge of the most appropriate optical parameters to use clinically, and how they reflect the pathophysiology of such conditions, is still evolving. It is unlikely that DOT will achieve the anatomical resolution of CT or MRI, but its noninvasive nature, low cost, and capability to obtain continuous, real-time information on cerebral hemodynamics and oxygenation under various physiological and pathophysiological conditions constitute a major advantage over other techniques.

Knowledge about how optical parameters reflect tissue pathophysiology is still evolving, but it is clear that application areas for DOT are associated with stroke, brain trauma, and the basic science of brain activation. We elaborate briefly on each of these target areas next.

Diffuse optical tomography offers an attractive alternative for diagnosing and monitoring internal bleeding and ischemic stroke when CT and MRI are not available. There are several possible optical signal indications of stroke. Using a bolus of intravascular contrast agent, it is possible to monitor mean cortical transit times; transit time changes there can reveal flow variations associated with ischemic stroke. Quantitative differential spectroscopy can indicate alterations in hemoglobin saturation in affected tissue due to reduced perfusion or modulated metabolic demand. Bleeding stroke can also be detected spectroscopically, in this case via a large blood volume increase. Scattering contrasts are also possible. Edema and swelling may provide heterogeneities in images of tissue scattering.

The feasibility of near-infrared spectroscopy (NIRS) to detect brain hemorrhage in patients with head trauma has been demonstrated.²⁷ Studies that compare primitive diffuse optical measurements of brain hematomas with CT images clearly demonstrate a correlation between the optical signal and hematoma location.^{26,27,235} These correlation studies have shown that subcortical hemorrhages as deep as 3 cm beneath the cortical surface and as small as 5 mm in diameter can be detected. Furthermore, the different classes of hemorrhages give characteristically different signals. These pilot NIRS results are promising, but they are based on simple relative NIRS measures. Quantitative images of hemoglobin saturation and fast hemodynamics will provide great improvement in available diagnostic information over the data involved in these pilot studies. A means to detect early hemorrhage in at-risk patients — i.e., those treated with thrombolysis or anticoagulants — would have tremendous value. In addition, swelling and edema may be detectable through alterations in the scattering coefficient of the tissue.

Beyond the clinical uses described previously, DOT is experiencing widespread application in functional brain imaging. Since the first demonstrations of noninvasive optical measures of brain function, ^{29–31} studies have been performed on adult humans using visual, ³² auditory, ³³ and somatosensory stimuli. ³⁴ In addition, a number of studies have investigated the motor system. ^{35–37} Other areas of scientific investigation have included language, ³⁸ higher cognitive function, and functional studies of patient populations. ^{39–41} Following in the footsteps of functional MRI, ^{236,237} DOT is likely to play an important role in increasing our knowledge of brain activity associated with various stimulation paradigms, as well as our understanding of cerebral physiology, particularly the coupling between neuronal activity and the associated metabolic and vascular response. Interestingly, optical imaging is potentially the only neuroimaging modality that can measure the hemodynamic (see references above) and metabolic response^{238–244} associated with neuronal activity, and measure neuronal activity directly. ^{245–247}

In the remainder of this section we describe three recent experiments. The first experiments measure flow, hemoglobin saturation, and hemoglobin concentration in a rat during stroke; this combination of parameters ultimately makes possible the assignment of oxygen metabolism changes to specific tissue volumes. The second and third sets of experiments image functional activation in the rat and in humans, with high spatial and temporal resolution.

21.4.3.1 Flow and Blood Oxygen Saturation Images of Rat Stroke

Experimenters at the University of Pennsylvania have used DOT to examine the spatial–temporal evolution of focal ischemia in a rat model.²⁴⁸ Their measurements probe through the *intact* rat skull and combine "static" diffuse photon density wave measurements of Hb and HbO concentrations with "dynamic" diffuse correlation flowmetry (see Section 21.2.6). Their results are the first application of DOT correlation flowmetry to experimental stroke models.

Figure 21.16A shows the TTC stain of the infarct region of a focal ischemia induced in the rats by intraluminal suture occlusion of the middle cerebral artery. After 60 min of occlusion the suture was retracted for reperfusion. The animals recovered and, at 24 h after occlusion, were sacrificed for TTC staining. Differential images of the concentrations were reconstructed in a slice at a depth of 2 mm below the skull surface, extending 5 mm either side of midline and from 2 mm anterior of bregma to 8 mm posterior of bregma. The hemoglobin and flow images were obtained using the linear Rytov approach described in Sections 21.2.5.2 and 21.2.5.3.

Figure 21.16B shows image slices of total hemoglobin concentration ([HbT]), blood oxygen saturation StO_2 , and relative changes in cerebral blood flow (rCBF) reconstructed with DOT. Note that the measurements cover the predominantly penumbral tissue and an equivalent tissue volume on the contralateral side. Image stacks were reconstructed from measurements averaged over five animals. Images are shown for time points representing baseline (–8 min), occlusion (+30 min), and reperfusion (+80 min). Regions of interest (ROIs) were defined for the contralateral and ipsilateral sides, consisting of 4×8 mm areas centered in the respective half of each image; the time traces for [Hb], StO_2 , and (rCBF) in these regions are plotted in Figure 21.16C. Occlusion and saturation decreased by about 40% from baseline in the affected hemisphere. The numbers for flow are in reasonable agreement with near-surface laser Doppler measurements of penumbral tissues. The cerebral blood volume, on the other hand, showed much smaller percentage changes during occlusion.

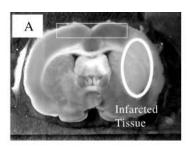

These images demonstrate the feasibility of continuously imaging an integrated set of hemodynamic parameters through the time course of ischemia and reperfusion in experimental focal ischemia models. The combined measurements also offer the possibility to make quantitative maps of differential oxygen metabolism. A simplified model for oxygen metabolism relates two of the measurements made. If we assume that the product of the blood perfusion rate with the difference in oxyhemoglobin concentration between the artery perfusing the tissue and the vein draining the tissue equals the oxygen consumption rate, then the measured changes enable us to construct a map of local variations in cerebral oxygen metabolism in deep tissues.¹⁹⁷ This exciting prospect further enhances the attractiveness of the diffuse optical method.

21.4.3.2 Activation Imaging of Brain Function in a Rat Model

In this section we describe applications to functional activation of the rat brain. By using classical functional stimulation paradigms, these studies provide an opportunity to evaluate the imaging capabilities of diffuse optical tomography through comparisons with exposed cortex and fMRI studies.

These studies employed the CW system developed at the MGH-NMR center (see Section 21.3.1.1). The dual wavelength sources were positioned on a 3 × 3 grid interspersed within the 4 × 4 grid of detectors. In accordance with standard procedures used in exposed cortex studies of functional activation, the baseline hemoglobin concentrations were assumed — i.e., [Hb] = [HbO] = $50 \mu M$. Absorption coefficients were calculated using published spectra. The scattering coefficient was assumed to be equal to 10.0 cm^{-1} .

The experiments were performed on adult male Sprague-Dawley rats weighing 300 to 325 g. The rats were fasted overnight before measurements. The animals were anesthetized (Halothane 1 to 1.5%, N_2O 70%, O_2 30%) and catheters were placed into a femoral artery to monitor the arterial blood pressure and into a femoral vein for drug delivery. The animals were tracheotomized, mechanically ventilated, and fixed on a stereotaxic frame. The probe was then placed symmetrically about midline. It covered a region from 2 mm anterior to 6 mm posterior of the rhinal fissure. After the surgical procedures,

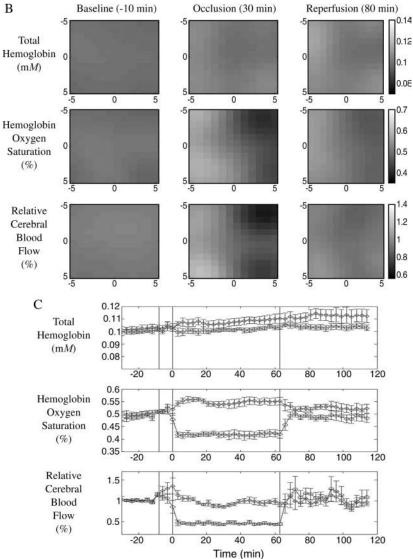

FIGURE 21.16 (A) TTC staining of infarct area; rectangle indicates slice position of DOT image reconstruction. (B–C) Diffuse optical tomography images of total hemoglobin concentrations, tissue averaged hemoglobin saturation, and relative cerebral blood flow (rCBF). A middle cerebral artery occlusion was performed during the time from t = -5 min to t = 0. The suture was retracted at t = 60 min resulting in reperfusion. (B) Images at baseline, during occlusion (+30 min) and +80 min. The spatial dimensions are given in millimeters. The scale bars indicate the concentration of hemoglobin, the percent oxygen saturation, and the relative blood flow change where 1 is no change and 1.4 is a 40% change. (C) The time traces for ipsilateral and contralateral ROIs.

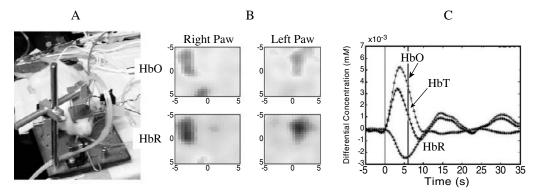

FIGURE 21.17 (A) Photograph of the DOT fibers on the rat scalp. (B) DOT images of oxy- and deoxyhemoglobin concentrations during functional activation of the somatosensory cortex. The oxyhemoglobin (HbO) images exhibit a concentration increase. The deoxyhemoglobin (HbR) images exhibit a concentration decrease. Images are shown for left- and right-forepaw stimulation, the activation showing up on the contralateral side. (C) Time-course of the hemoglobin concentration changes in the region of interest defined by the significant focal concentration change seen in (B).

Halothane was discontinued, and anesthesia was maintained with a 50 mg/kg intravenous bolus of α -chloralose followed by continuous intravenous infusion at 40 mg/kg/hr.

Electrical forepaw stimulation was performed using two subdermal needle electrodes inserted into the dorsal forepaw. The stimulus pattern was relayed to an isolated, pulsed current supply to provide 300 μ_s constant current pulses at programmed times. The current was maintained at 1.0 mA. A 3 Hz, 6-s stimulus was provided with 54-s interstimulus interval. The measurements were then averaged over 42 stimulus intervals. The final averaged temporal data stack was reconstructed frame by frame using the methods described in Sections 21.2.5.2 and 21.2.5.3. Each slice was reconstructed at a depth of 2 mm from the skull surface extending 5 mm either side of midline, and from 2 mm anterior of bregma to 8 mm posterior of bregma. The absorption image stacks were then converted to oxy- and deoxyhemoglobin image stacks.

The series of DOT [Hb] and [HbO] images show focal activation contralateral to the stimulated forepaw. The images are frames taken every 5 s. The time traces were extracted for a 3×3 mm area centered at maximal activation (see Figure 21.17). The oscillations seen after stimulus are similar to vasomotion signals seen by optical studies in exposed cortex.²⁵⁰

21.4.3.3 Images of Brain Function in Humans

The same MGH CW imaging system described in Section 21.3.2.1 was used to study 15 subjects during finger tapping, finger tactile stimulation, and median nerve electrical stimulation. The finger tapping and finger tactile protocols consisted of series of 10 stimulation/rest sequences for each hand (i.e., 20-s stimulation and 20-s rest), wherein the stimulation occurs at a frequency of ~4 to 5 Hz (the stimulus frequency of each subject was adjusted so as to be anharmonic with the heart rate). The median nerve electrical stimulation protocol consisted of a series of 18 stimulation/rest sequences (i.e., 10-s stimulation and 20-s rest) with stimulus intensity slightly above the motor threshold (i.e., using rectangular electrical pulses, current peak: <10 mA, duration: 0.2 ms, repetition rate: 4 to 5 Hz). Motion sensors were used on the fingers of the subjects to synchronize the stimuli with the optical signals recorded on the head.

The optical data were band-pass filtered between 0.02 to 0.50 Hz to correct for slow drifts and to reduce the ~1-Hz arterial pulsation amplitude. Finally, the multiple stimulation sequences were block averaged to achieve better statistics. This resulted in a time series of the measured signal intensity for each source-detector pair. Source-detector pairs near a region of brain activation showed changes similar to those seen in a rat as shown in Figure 21.18, while the other source-detector pairs showed little signal variation. Absorption images at the different wavelengths were converted into images of changes in oxyand deoxyhemoglobin concentrations.

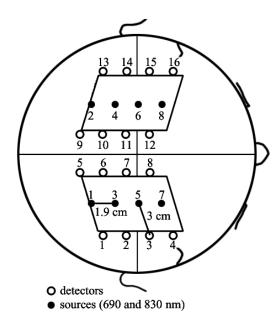

FIGURE 21.18 Geometrical arrangement of source and detector fibers on the head.

The hemodynamic response to stimulation was always visible in the optical data. During the finger tapping experiment, the oxy- and deoxyhemoglobin concentration variations were not sharply localized. This is probably because of a systemic elevation in blood volume, presumably resulting from a corresponding heart rate increase. During finger tactile stimulation, oxyhemoglobin increases were two to three times smaller than during finger tapping; also, oxy- and deoxyhemoglobin were sharply localized. During electrical stimulation, the hemoglobin changes were sharply localized and had a magnitude comparable with finger tactile stimulation. In the latter experiments a peculiar feature of ipsilateral decrease in blood volume was observed during the stimulation period (see Figure 21.19). By contrast, magnetoencephaolography (MEG) and functional magnetic resonance imaging (fMRI) studies during median nerve stimulation have shown an activation of only the contralateral primary sensory-motor cortex. ^{251,252} A deactivation of the ipsilateral primary sensory-motor cortex has been observed in previous fMRI experiments during finger tapping; ²⁵³ these optical results suggest that a similar decrease in blood flow occurs in the ipsilateral cortex during electrical somatosensory stimulation.

In summary, DOT offers an exciting new method for studying human brain function, and should play an important role in the brain sciences when other imaging modalities (e.g., fMRI, EEG, MEG) are not attractive because of cost, sensitivity to motion artifacts, or confinement of the research subject.

21.5 Fundamental and Practical Issues: Problems and Solutions

In this final section we touch on some of the fundamental and practical difficulties associated with DOT. In particular, we discuss the fundamental limits of detection, characterization, and resolution, we discuss practical problems of source-detector calibration, and we briefly outline some of the ways researchers are overcoming these barriers.

21.5.1 Detection, Localization, Characterization, and Resolution Limits

The detection limits of DOT are set by the smallest signal perturbation that can be detected above the noise level. The spatial localization limit is generally the same as the detection limit because the maximum signal perturbation often occurs when an object is located directly between a source and detector. Full characterization of object optical properties, shape, size, and position is more difficult than detection and

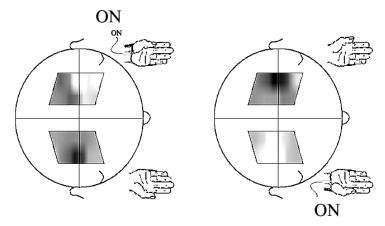

FIGURE 21.19 Block average hemoglobin maps at the end of the electrical stimulation period. Top panels: deoxyhemoglobin changes; bottom panels: oxyhemoglobin changes. Left panels: left wrist median nerve stimulation; right panels: right wrist median nerve stimulation.

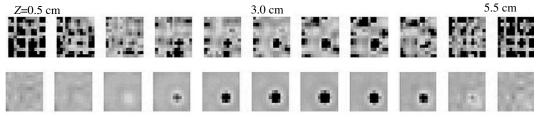

localization. For example, a fixed signal perturbation can be caused by a small, strongly absorbing object or a large, weakly absorbing object. The distinction between the large and small object must be derived from relative spatial differences in the perturbation of the measured fluence.

These limits have been extensively explored²⁵⁴ for a transmission geometry applicable to breast imaging. In this work, a best-case scenario noise model assumed shot noise and small positional uncertainties gave rise to a random noise on the order of 0.1% of the signal intensity. Measurements were simulated in the transmission geometry with a single modulation frequency. With these assumptions about the noise, it was possible to detect 3-mm-diameter-absorbing objects that possessed a threefold greater absorption than the background. A similar analysis of the characterization limits indicated that simultaneous determination of object diameter and absorption coefficient required that object diameters were a minimum of 8 to 10 mm (for a 100% contrast); see Reference 254 for details. Another investigation, focusing on resolution (defined as the FWHM of the fluence point-spread function caused by a localized perturbation, found that, if proper deconvolution of the measured data is performed, then resolutions of order 5 to 7 mm are possible with DOT.

There are potentially many ways to overcome some of these barriers, and many researchers are exploring the following possibilities, as well as other ideas. The brute force approach is to increase the number of measurements or decrease the measurement noise. This can be done, by increasing numbers of source-detector pairs, modulation frequencies, or optical wavelengths. The use of many optical wavelengths is beneficial because relatively few significant chromophores are in tissue and their spectra are well known. The use of prior spatial information, for example, the assignment of particular tissue types to specific volume elements of the image, 106,137,258 enables one to reduce the number of unknowns in the inverse problem and thus can effectively improve images. Optical techniques can also be combined with other imaging modalities (e.g., ultrasound 119,137,259 or MRI^{13,260,261}) to constrain the DOT problem. Singular-value analysis of the tomographic weight matrix associated with specific data types, geometries, and optode arrangements has been developed recently 123 and should provide experimenters with quantitative tools to optimize for the spatial sampling interval, field-of-view parameters, resolution trade-offs, and, ultimately, physiology. Finally, it is now possible to reduce the systematic errors associated with source-detector amplitudes by directly incorporating these unknowns into the image reconstruction problem. This is the subject of the last section of this chapter.

21.5.2 Calibration of Source and Detector Amplitudes

The modeling of the DOT forward problem requires accurate knowledge of source and detector amplitudes and their positions. Systematic errors in the calibration of these parameters will result in absorption

SD Variance = 80%

FIGURE 21.20 A three-dimensional absorption image without (top row) and with (bottom row) modeling the unknown source and detector amplitudes. The images span *X* and *Y* from –3 to 3 cm; *Z*-slices are indicated from 0.5 to 5.5 cm. The absorbing object is observable in the image with modeling of the 80% source and detector variance; however, its contrast is obscured by the large amplitude variation near the boundaries. Modeling for the unknown variance provides an image with significantly improved image quality.

and scattering image artifacts, e.g., image spikes near the positions of the sources and detectors. This type of artifact has been observed by a number of groups. ²⁶² Some schemes to minimize these artifacts include median filtering ²⁶³ and spatial regularization; the latter approach penalizes the reconstruction near sources and detectors with a weight that varies exponentially from the sample surfaces. ^{113,262,264} The result is an image with suppressed variations near the sources and detectors, but with improved image quality further from the boundaries. However, the scheme has the undesirable effect of biasing the reconstruction away from the boundaries of the medium.

A recent and relatively simple solution to this problem models the uncertainties of source and detector amplitude and includes them in the inverse problem.²⁶⁵ Within the linear Rytov approximation, the unknown source and detector amplitudes can be solved simultaneously with the unknown optical properties of the medium. We briefly outline this procedure next, assuming for simplicity a sample with absorption heterogeneities, but without scattering heterogeneities.

Recall the linear approximation for calculating fluence perturbations from spatial variation in the absorption and scattering coefficients, discussed in Section 21.2.5.2. The problem was written in the form $[W]\{x\} = \{b\}$ where [W] represented the weight matrix, $\{x\}$ represented the unknown optical properties, and $\{b\}$ represented the difference between experiment and calculation (or the scattered wave). If we include the unknown source and detector amplitudes into the model, then the matrix equation can be reformulated as $[B]\{\xi\} = \{b\}$ where [B] = [W' S D] and

$$\left\{\xi\right\} = \left\{\frac{\delta\mu_{a,1}}{\mu_{ao}} \cdots \frac{\delta\mu_{a,NV}}{\mu_{ao}} \ln s_1 \cdots \ln s_{NS} \ln d_1 \cdots \ln d_{ND}\right\}. \tag{21.22}$$

Here s_i and d_i represent the amplitude of the *i*th source and detector, respectively, NV is the number of voxels, NS is the number of sources, and ND is the number of detectors. Scaling $\delta \mu_{a,j}$ by μ_{ao} makes the elements dimensionless and of the same order as $\ln s$ and $\ln d$. $\mathbf{W}' = \mu_{ao} \mathbf{W}$ is the rescaling of the standard weight matrix. \mathbf{S} and \mathbf{D} are simple, well-defined matrices with block diagonal form that have 1 or 0 in the elements corresponding to particular sources and detectors.

Simulation results have demonstrated that incorporation of the unknown source and detector amplitudes into the inverse problem maintains image quality despite amplitude uncertainties greater than 50%. This is illustrated in Figure 21.20; a simulation of transmission through a 6-cm slab was considered with background optical properties of $\mu_{so}' = 10 \text{ cm}^{-1}$ and $\mu_{ao} = 0.05 \text{ cm}^{-1}$ and a 1.6-cm diameter absorbing sphere with $\mu_a = 0.15 \text{ cm}^{-1}$, centered at (x,y,z) = (1,1,3) cm. Measurements were made with 16 sources and 16 detectors equally spaced from -3 to 3 cm, and continuous-wave measurements were simulated. There was no additive measurement noise (i.e., shot or detector electronic noise) in the simulated data, only the multiplicative model error associated with the source and detector amplitudes.

Acknowledgments

We have benefited from discussions with many colleagues and collaborators and many of their observations are found in this chapter. In particular, we thank Joe Culver, Maria Angela Franceschini, and Gary Boas for significant assistance in the preparation of this chapter. We also thank Turgut Durduran, Jeremy Hebden, Vasilis Ntziachristos, and Brian Pogue for discussion and for providing figures for the chapter. For other useful discussions over many years we thank Simon Arridge, Britton Chance, Regine Choe, Alper Corlu, Anders Dale, Joel Greenberg, Monica Holboke, Xingde Li, Eric Miller, Bruce Tromberg, Guoqiang Yu, and Tim Zhu.

D.A.B. acknowledges funding from Advanced Research Technologies, from National Institutes of Health grants R29-NS38842 and P41-RR14075, from the Center for Innovative Minimally Invasive Therapies, and from the U.S. Army under Cooperative Agreement DAMD17-99-2-9001. The material presented does not necessarily reflect the position or the policy of the government, and no official endorsement should be inferred. 22.1 Photon Migration Spectroscopy

22.1.1 What Is Photon Migration Spectroscopy?

Photon migration spectroscopy (PMS) is a technique that combines experimental measurements and model-based data analysis to measure the bulk absorption and scattering properties of highly scattering media. PMS typically uses red and near-infrared (NIR) light, especially from 600 to 1000 nm, where light propagation in tissue is heavily dominated by scattering. PMS measurements of tissue optical properties (i.e., absorption and scattering) are assumed to contain information about tissue structure and function. The term "photon migration" refers to photons that propagate diffusively throughout the tissue (i.e., in a random direction). PMS utilizes the photons that conventional optical techniques discard; instead of collimated or coherent photons, PMS measures incoherent, multiply scattered photons that are spread

out over space and time. Diffusive photons probe a large sample volume, providing macroscopically averaged absorption and scattering properties at depths up to a few centimeters in tissues.

In the red and NIR spectral regions, the dominant molecular absorbers in tissue are oxygenated (Hb-O₂) and reduced hemoglobin (Hb-R), water, and lipids.^{2,3} Myoglobin (which is indistinguishable from hemoglobin in the NIR), cytochrome aa_3 , and other hemoglobin states also absorb in the NIR but are found in small concentrations. (Note that the validity of this statement depends upon tissue site and physiological condition.)

The frequency-domain PMS techniques featured in this article measure absorption independently from scattering; not all NIR diffusive measurements do this. Such distinction is important because NIR photon attenuation is chiefly due to scattering. Traditional absorption spectroscopy assumes negligible scattering. With the help of PMS techniques, one can recover undistorted absorption spectra from within tissues and, ultimately, quantify absorber concentrations. Scattering spectra also can provide useful information about tissue structure and composition.

22.1.2 Historical Development

The dramatic growth of clinical laser applications during the 1990s has stimulated intense research into the fundamental nature of light–tissue interactions. Although studies in highly scattering biological materials were performed in the 1930s,⁴ significant advances in the quantitative characterization of tissue optical properties *in vivo* were not made until the early 1990s. Bonner et al. introduced "photon migration" in tissue by proposing a random-walk theory to infer bulk tissue scattering, absorption, and photon pathlengths.⁵ Delpy⁶ and Chance⁷ employed time-resolved spectroscopy to measure photon pathlengths and thereby determine hemoglobin concentration in tissue. Transport theory models had been developed earlier,⁸ but did not become widely accepted for modeling in tissue optics until the late 1980s.^{9,10} Patterson et al. measured absorption independently from scattering using analytic time- and frequency-domain models.^{11,12}

Fishkin and Gratton first applied frequency-domain methods to turbid media and described the propagation of intensity-modulated light in terms of photon density waves (PDW).¹³ Svaasand and Tromberg characterized the frequency-dependence of photon density waves and employed measurements of PDW dispersion to quantify absorption and scattering in turbid media.¹⁴ Rapid and inexpensive means for measuring absorption and scattering in turbid media soon followed.¹⁵ There are several advantages to the frequency-domain method in terms of information content, measurement speed, and cost.¹⁶

Tissue physiology can be inferred from reliable measurements of tissue absorption.² PMS systems typically feature two wavelengths, the bare minimum needed to recover [Hb-O₂] and [Hb-R]. (Brackets [] will be used to denote concentration.) Restricting systems to only two or three wavelengths can lead to significant errors, even for relative parameters such as the hemoglobin saturation, S_tO_2 .¹⁷ (Hemoglobin saturation is defined as $S_tO_2 = [Hb-O_2]/THC$, with $THC = [Hb-R] + [Hb-O_2]$.) Increased spectral bandwidth adds more information content and improves accuracy.¹⁸

Recent reviews of diffuse tissue optics suggest that photon migration methods can provide unique information and will play an important role in medicine. $^{19-21}$ As of this writing, several commercial devices are based upon the technology described in this chapter. Although many possibilities exist, the most important general application of PMS lies in quantifying thick tissue hemodynamics. Because the PMS signal represents a volume average of tissue, the diffusively-measured S_tO_2 is primarily representative of the tissue microvasculature. 22 This exquisite sensitivity to microvasculature suggests many broad applications in medicine (see Section 22.5 for examples).

22.2 Working in the Frequency Domain

22.2.1 The Basics of the Frequency-Domain Method

The time- and frequency-domain methods are general tools used to study light propagation in tissues. Time-domain spectroscopy measures the temporal broadening of an initial narrow pulse of light as it

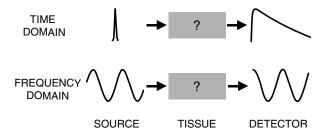

FIGURE 22.1 Time-domain spectroscopy measures the temporal broadening in an incident pulse. Frequency-domain spectroscopy measures changes in wave characteristics relative to the incident wave.

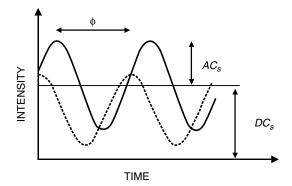

FIGURE 22.2 The measured frequency-domain parameters are a phase shift (ϕ) and a modulation decrease (i.e., ratio of AC to DC components) of the detected wave with respect to the source. Source and detected waves oscillate at the same frequency f.

interacts with a sample (Figure 22.1). Typical mechanisms behind these propagation delays include photon scattering and fluorescence lifetimes. The broadened pulse shape contains quantitative information about the decay mechanisms involved.

Frequency-domain spectroscopy measures the propagation of harmonic signals (Figure 22.2). We start with an intensity-modulated light source, characterized by an average intensity (DC), an oscillating intensity (AC), and a phase (ϕ), which has the form:

$$I_{s} = DC_{s} + AC_{s}\cos(\phi - \omega t). \qquad (22.1)$$

In the preceding expression, I is the total intensity, ω is the angular frequency (such that $\omega = 2\pi f$, where f is the modulation frequency), and the subscript s denotes the source. The modulation frequency is the on–off rate of the source and is not related to the photon energy. The source need not be modulated at a single frequency; any waveform may be described as a sum of the terms of Equation 22.1. The detected wave and source wave repeat at the same frequency.

Figure 22.2 demonstrates the measured frequency-domain parameters. The detected response (dotted wave) is shifted in phase (ϕ) and reduced in modulation (M) with respect to the source (solid wave). The term "modulation" or "modulation depth" refers to AC_s/DC_s at f and ideally is equal to unity. In frequency-domain spectroscopy, there is no carrier wave; we do not modulate the frequency (frequency modulation, or FM), the AC amplitude (amplitude modulation, or AM), or the phase (phase modulation, or PM) of the optical wave.

An important point is that ϕ and M denote relative quantities that describe absolute values. Such relative measurements are insensitive to artifacts that can complicate absolute intensity measurements. Modulated signals can be discriminated against background signals at different frequencies (such as unwanted room light). Measurements in time and frequency domains are equivalent, being related by a

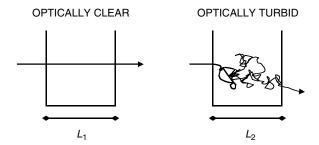

FIGURE 22.3 Multiple scattering increases the photon path length. Although the sample thicknesses are the same, $L_2 >> L_1$ due to intense multiple scattering. The absorber concentration cannot be determined unless L is known.

temporal Fourier transform. Because it is possible to obtain enough information for PMS using a single frequency, frequency-domain measurements can be very rapid and cost effective.¹⁵

22.2.2 The Need for the Frequency Domain

Richer frequency-domain information content (or equivalent time-domain content) is usually needed to perform quantitative absorption and scattering spectroscopy in thick tissues. The intensity of light transmitted through a purely absorbing medium (i.e., negligible scattering) is related to the incident intensity I_0 via the Beer-Lambert law:

$$AB = \log(I_0/I) = \varepsilon [C]L, \qquad (22.2)$$

where AB is the absorbance, L is the photon path length (cm), [C] is the absorber concentration, and ε (based upon a base-10 logarithm scale) is the molar extinction coefficient (moles/liter cm⁻¹ or cm²/mole). In terms of μ_a , the Beer-Lambert law is $I = I_0 \exp(-\mu_a L)$, so that μ_a is proportional to the absorber concentration:

$$\mu_a \approx 2.303 \,\varepsilon[C] \,. \tag{22.3}$$

In purely absorbing media, it is relatively simple to measure μ_a (or [C] if ε is known) because L is equal to the width of the sample. However, in the case of multiple scattering, L is not known a priori. Scattering increases the photon pathlength beyond the geometrical path of the light (Figure 22.3); L must be known in order to determine [C] accurately. Frequency-domain spectroscopy provides a method that effectively measures L so that [C] may be determined.

There is another way to view this dilemma. In the infinite medium geometry, diffusion theory predicts that DC intensity at a detector placed a distance r from the source has the form:

$$DC_d \propto \frac{1}{r} \exp\left[-r\sqrt{\mu_a \mu_s'}\right],\tag{22.4}$$

where the subscript d refers to the detected intensity. It is not possible to separate analytically the effects of μ_a from μ_s' using a single measurement because of the product between μ_a and μ_s' . Under certain conditions, it is possible to separate μ_a from μ_s' while performing steady-state, multiple-distance measurements on a tissue surface (i.e., spatially resolved reflectance), although the method involves source-detector separations too small for characterizing tissue optical properties at depths beyond several millimeters.¹⁷

22.3 Frequency-Domain Solution to the Diffusion Equation

22.3.1 General Transport of Light in Turbid Media

Transport theory is a statistical bookkeeping scheme that treats photons as noninteracting point-particles undergoing elastic interactions. The quantity of interest is the photon density (photons mm⁻³). Note that some texts use radiance as the fundamental quantity, which is the power per unit area per solid angle. The magnitude of this vector, averaged over the solid angle, divided by the photon energy, gives the photon density. The transport equation is easy to assemble, but difficult to solve analytically, even in simple cases.²³ PMS can use numerical solutions, but important physical insight has come from simple analytic models. The general P_n approximation allows tractable analytic solutions. The P_1 approximation keeps only first-order spherical harmonic expansion terms of the transport equation.²³ Forcing the photon density to discard its true angular dependence introduces limitations that must be carefully understood. The P_1 approximation is sometimes referred to as the diffusion approximation, but there are some important differences between these approximations.²⁴ Excellent reviews exist on this topic.^{25,26}

22.3.2 The P₁ Approximation: Infinite Medium Solution

22.3.2.1 Formal Theory

Assuming an isotropic point source, keeping terms to first order reveals the P_1 equation, which expresses the photon density, $U(\mathbf{r},t)$, in terms of the optical properties of the tissue:^{24,27}

$$\nu D \left[\frac{3}{\nu^2} \frac{\partial^2 U(\mathbf{r}, t)}{\partial t^2} - \nabla^2 U(\mathbf{r}, t) \right] + (1 + 3\mu_a D) \frac{\partial U(\mathbf{r}, t)}{\partial t} + \nu \mu_a U(\mathbf{r}, t) = Q(\mathbf{r}, t) + \frac{3D}{\nu} \frac{\partial Q(\mathbf{r}, t)}{\partial t}, \qquad (22.5)$$

where ν is the speed of light inside the medium, $Q(\mathbf{r},t)$ is the photon density per unit time injected by the source, and $\nu D \equiv \nu(3\mu_s' + 3\mu_a)^{-1} \equiv \nu(3\mu_{tr})^{-1}$ is the optical diffusion coefficient (mm² s⁻¹). (Note that μ_s' represents a scattering length where the direction of the photon has been randomized. Actual scattering events occur on a much smaller length scale.) The variables $|\mathbf{r}|$, and t represent distance from the source and time, respectively. Three important assumptions make this expansion possible: (1) the medium is assumed to be macroscopically homogeneous, (2) we must be far from sources and boundaries (i.e., more than one transport mean-free-path, mfp), and (3) the medium must be strongly scattering (i.e., $\mu_s >> \mu_a$). These limitations stem from restricting the angular dependence of U; thus Equation 22.5 is only valid in regions where anisotropy is low.

The P_1 equation is simple to solve in the frequency domain. Noting that $i^2 = -1$, a frequency-domain point source has the form:

$$Q(\mathbf{r}, \omega, t) = S(\omega) \exp\left[-i\left(\omega t - \phi_0(\omega)\right)\right] \delta(\mathbf{r}). \tag{22.6}$$

We have not broken the source into AC and DC components as in Equation 22.1 because the DC component results from setting $\omega = 0$. The terms $S(\omega)$ and $\phi_0(\omega)$ are frequency-dependent instrumental factors, called the source strength (photons mm⁻³ s⁻¹) and source phase (degrees), respectively. The delta function represents a point source centered at $\mathbf{r} = 0$. In the frequency domain, all time-dependent factors become $\exp(-i\omega t)$, as in Equation 22.6. If we substitute $U(\mathbf{r},\omega)\exp(-i\omega t)$ for $U(\mathbf{r},t)$ and so on, we arrive at the following expression for Equation 22.5:

$$\left[\nabla^2 - k^2(\omega)\right] U(\mathbf{r}, \omega) = -\frac{S(\omega)}{vD} \exp\left[-i\phi_o(\omega)\right] \delta(\mathbf{r})$$
 (22.7)

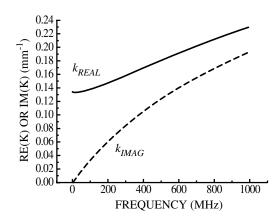

FIGURE 22.4 PDW characteristics are determined by the real (solid line) and imaginary (dashed line) parts of the wave vector, k. The plot uses $\mu_a = 0.006 \text{ mm}^{-1}$ and $\mu_s' = 1.0 \text{ mm}^{-1}$. The sensitivity of k to μ_a and μ_s' depends upon f (i.e., wave dispersion).

$$k^{2}(\omega) \equiv \frac{\mu_{a}}{D} \left[1 - i \frac{\omega}{\nu \mu_{a}} (1 + 3\mu_{a}D) \right]. \tag{22.8}$$

Equation 22.7 is a Helmholtz equation, whose solutions are known to be waves. Within this framework, ik is a wave vector (mm⁻¹). It is critical to note that k depends upon μ_a , μ_s' , and ω . Using infinite-medium boundary conditions (i.e., $U(r,\omega) \to 0$ as $r \to \infty$), we can write a one-dimensional solution to Equation 22.7:

$$U(r,\omega) = \frac{S(\omega)\exp[-i\phi_0(\omega)]}{4\pi\nu D} \frac{1}{r} \exp[-k(\omega)r]. \tag{22.9}$$

The frequency-domain solution emerges as a damped-spherical PDW. These PDWs exhibit classical wave phenomena such as diffraction, reflection, and refraction. The phase and amplitude of the PDW described by Equation 22.7 are:

$$\Theta_{inf}(r,\omega) = k_{imag}(\omega) r + \phi_0 \qquad A_{inf}(r,\omega) = \frac{S(\omega)}{4\pi\nu D r} \exp\left[-k_{real}(\omega) r\right]. \tag{22.10}$$

The subscript *inf* reminds us these equations are valid in infinite media. The real and imaginary parts of k are represented by k_{real} and k_{imag} , respectively. We have written Equation 22.10 as functions of r and ω because measurements of μ_a and μ_s' depend upon changing r and/or ω .

22.3.2.2 Frequency Dependence

Figure 22.4 demonstrates the dispersion of the components of k for a medium with optical properties of $\mu_a = 0.006 \text{ mm}^{-1}$ and $\mu_s' = 1.0 \text{ mm}^{-1}$. Wave attenuation is representatived by k_{real} ; higher frequency components have higher k_{real} and higher attenuation. The sensitivity of k to the optical properties changes with f. Intuitively, we may rewrite absorption and transport coefficients (μ_{tr}) as relaxation frequencies: $f_a \equiv \nu \mu_a$ and $f_{tr} \equiv \nu \mu_{tr} = \nu (\mu_a + \mu_s')$, respectively, or as relaxation times: $\tau_a = 1/f_a$ and $\tau_{tr} = 1/f_{tr}$. In the DC case ($\omega = 0$), the wave vector values become:

$$k_{real}(0) = \sqrt{3\mu_a \mu_s'}$$
 and $k_{imag}(0) = 0$. (22.11)

In the DC regime, the product $\mu_a \mu_s'$ determines the attenuation and there is no phase information. k_{real} is very sensitive to changes in μ_a and μ_s' , but changes in μ_a cannot be distinguished from changes in μ_s' . If we increase f with a low-frequency expansion (i.e., $\omega << \nu \mu_a$) of Equation 22.8:

$$k_{real}(\omega) \approx \sqrt{3\mu_a \mu_s'} \left\{ 1 + \frac{1}{8} \left(\omega \tau_a \right)^2 \right\} \qquad k_{imag}(\omega) \approx \sqrt{3\mu_a \mu_s'} \frac{\omega \tau_a}{2}$$
 (22.12)

where we have made the assumption $\mu_a \ll \mu_s'$ for diffusive media. The term "low-frequency" implies frequencies well below f_a , where most frequency-domain measurements have been performed. In most tissues μ_a ranges from 0.002 to 0.02 mm⁻¹, and thus f_a ranges from 60 to 680 MHz. Within this low-frequency approximation, ϕ is linear in f (see Equation 22.10).

As f increases above f_a , the character of the k changes considerably. A higher-frequency expansion of the real and imaginary parts of Equation 22.8 reveals ($\omega >> f_a$, but $\omega^2 << f_a f_{tr}$):²⁹

$$k_{real}(\omega) = k_{imag}(\omega) = \sqrt{\frac{3}{2}} \frac{\omega}{\nu} \mu_s'.$$
 (22.13)

In this limit, the wave vector loses dependence upon μ_a . Eventually this behavior changes; in the limit where $\omega^2 >> f_a f_{tr}$, transport theory breaks down, leaving us with:

$$k_{real}(\omega \to \infty) = 0$$
 and $k_{imag}(\omega \to \infty) = 3\frac{\omega}{\nu}$. (22.14)

Photons described by this behavior are ballistic in nature and are not scattered. These expressions also describe the leading edge of the time-domain pulse.²⁴

22.3.2.3 Diffusion Wavelength

The diffusion wavelength, or $\lambda_{\text{PDW}} \equiv 2\pi/k_{imag}(\omega)$, has nothing to do with the photon energy. λ_{PDW} depends upon the optical properties of the medium. Given a modulation frequency of 200 MHz, $\mu_a = 0.006 \text{ mm}^{-1}$, and $\mu_s' = 1.0 \text{ mm}^{-1} \ \lambda_{\text{PDW}}$ is about 105 mm. The wave front speed is given by $\nu_{\text{PDW}} = \lambda_{\text{PDW}} f$, setting $\nu_{\text{PDW}} \sim 2.1 \times 10^{10} \text{ mm s}^{-1}$. The diffusive wave front speed proceeds at approximately one order of magnitude slower than the speed of an individual photon. λ_{PDW} is typically much greater than our typical sampling distances of a few centimeters so that, in general, we record PDW phase and amplitude as "near-field" region. Higher modulation frequencies reduce λ_{PDW} , signifying greater attenuation and lower penetration.

22.3.3 The P₁ Approximation: Semi-Infinite Medium Solution

22.3.3.1 Changes in the Theory

Two types of discontinuities impose important boundaries for light propagation in tissues: index of refraction and optical property. For example, the abrupt index of refraction mismatch at the air–tissue interface can lead to total internal reflection. Encounters with this boundary will alter the spatial distribution of the PDW. In order to quantify average tissue optical properties accurately, it is essential to modify the light transport model to account for this interface. In practical terms, this permits the use of measurement geometries that place the source and detector outside the tissue (i.e., in a nonscattering medium). Our approach uses the method of images to place an image source at the same point above the boundary as the actual source below the boundary. This configuration forces U to vanish along a single plane perpendicular to the surface normal. Moving the condition of U = 0 to a plane external to the medium forces a sort of quasi-isotropic condition at the boundary by using the reflected flux at the boundary. The location of the extrapolated boundary, z_{to} is given by:

$$z_b = \frac{2}{3} \frac{1 + R_{eff}}{1 - R_{eff}} l_{tr}, \qquad (22.15)$$

where R_{eff} represents an effective Fresnel coefficient for the tissue–outside medium interface. Typical values for z_b are about 2 mm beyond the physical boundary. Groenhuis et al. have provided an empirical expression for R_{eff} , whereas Haskell et al. have calculated this coefficient to be 0.493 and 0.431 when the air–tissue interfaces are n = 1.4 and 1.33, respectively.^{30,31}

Using the subscript si to denote semi-infinite, solutions to the extrapolated boundary problem take the form of $U_{SI}(r,\omega,t) = U_{INF}(r_a,\omega,t) - U_{INF}(r_b,\omega,t)$. Solving this equation with a modified extrapolated boundary condition yields the phase shift and amplitude of a photon density wave in a semi-infinite medium,³¹ where is the distance between source and detector on the medium surface:

$$\Theta_{si}(\rho, \omega) = k_{imag}(\omega) r_a - \arctan\left(\frac{\eta}{\xi}\right) + \phi_0(\omega)$$
 (22.16)

$$A_{si}(\rho,\omega) = \frac{S(\omega)}{4\pi\nu D} \sqrt{\xi^2 + \eta^2}$$
 (22.17)

where

$$\xi = \frac{1}{r_a} \exp\left[-k_{real}(\omega)r_a\right] - \cos\left[k_{imag}(\omega)(r_i - r_a)\right] \frac{1}{r_i} \exp\left[-k_{real}(\omega)r_i\right]$$

$$\eta = \sin\left[k_{imag}(\omega)(r_i - r_a)\right] \frac{1}{r_i} \exp\left[-k_{real}(\omega)r_i\right]$$
(22.18)

and

$$r_a = \sqrt{\rho^2 + (l_{tr})^2}$$
 $r_i = \sqrt{\rho^2 + (2z_b l_{tr})^2}$ (22.19)

22.3.3.2 Sensitivity to the Optical Properties

Figures 22.5 and 22.6 present the photon density as functions of the experimental variables r and f, respectively. For the sake of comparison each line style represents the same set of optical coefficients: solid line ($\mu_a = 0.01 \text{ mm}^{-1}$, $\mu_s' = 1 \text{ mm}^{-1}$), dashed line ($\mu_a = 0.01 \text{ mm}^{-1}$, $\mu_s' = 0.5 \text{ mm}^{-1}$), and dotted line ($\mu_a = 0.002 \text{ mm}^{-1}$, $\mu_s' = 1 \text{ mm}^{-1}$). In each graph, Equations 22.16 and 22.17 provided the AC intensity and the phase. In Figure 22.5, intensities and phases have been normalized to the r = 10 mm value.

Changes in μ_s' and in μ_a have different effects upon A and Θ . For example, assume μ_s' increases while keeping μ_a constant (dashed line vs. solid line). Increasing μ_s' results in greater attenuation (i.e., lower A). This same increased μ_s' allows longer pathlength photons to be detected (i.e., higher Θ); these increase the overall phase of the detected signal. However, if we increase μ_a and keep μ_s' constant (dotted line vs. solid line), the attenuation increases as before, but the longer pathlength photons will be deleted and hence decrease the phase. Thus, A and Θ have different sensitivities to μ_a and μ_s' , allowing them to be measured independently from each other.

22.3.4 The Standard Diffusion Equation

In the standard diffusion equation (SDE), a few more approximations simplify the mathematics: (1) the scattering mfp must be much smaller than the absorption mfp, or $\mu_s' >> \mu_a$, and (2) $3\omega Dv^{-1} << 1$. The physical meaning of the term $3\omega Dv^{-1}$ is an isotropic collision period $(\tau_{coll} = 1/(\nu \mu_s'))$. The source has its own period too: $\tau_{mod} = 1/f = 2\pi/\omega$. The condition $3\omega Dv^{-1} << 1$ is another way of saying that there must

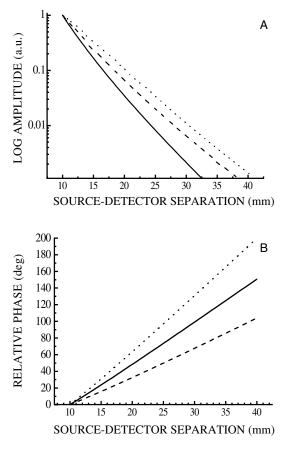

FIGURE 22.5 Calculated changes in PDW amplitude (A) and phase (B) as a function of r for three sets of optical properties: solid line ($\mu_a = 0.01 \text{ mm}^{-1}$, $\mu_s' = 1 \text{ mm}^{-1}$), dashed line ($\mu_a = 0.01 \text{ mm}^{-1}$, $\mu_s' = 0.5 \text{ mm}^{-1}$), and dotted line ($\mu_a = 0.002 \text{ mm}^{-1}$, $\mu_s' = 1 \text{ mm}^{-1}$). Intensities and phases have been normalized to the r = 10 mm value. Note the linearity of the phase and log (amplitude).

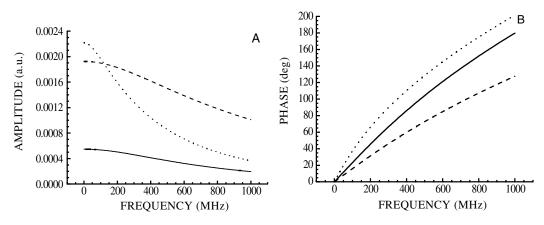

FIGURE 22.6 Calculated changes in PDW amplitude (A) and phase (B) as a function of f. See Figure 22.5 for line definitions. Note that curvature changes vary with changes in μ_a and μ_s' .

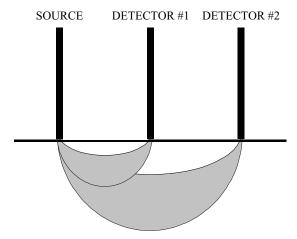

FIGURE 22.7 Different source-detector separations sample different depths of tissue. The shaded areas represent the average volume probed by the light for a given source-detector separation. Differences in probed volume can cause problems in some layered (such as in the brain) or inhomogeneous (such as in a tumor) media. Note that changes in modulation frequency also change the probing depth, but to a lesser extent.

be many collisions within a single modulation period.²⁴ Tissues on average possess $\mu_s' \sim 1 \text{ mm}^{-1}$, so that τ_{coll} is typically about 5 ps, limiting f < 1 GHz. It has been shown conclusively that the diffusion approximation breaks down at higher frequencies.²⁴

The preceding approximations simply change the layout of our previous Helmholtz equation. The solutions (infinite and semi-infinite) remain the same, but the wave vector simplifies to:

$$k^{2}(\omega) \equiv \frac{\mu_{a}}{D} \left(1 - i \frac{\omega}{\nu \,\mu_{a}} \right). \tag{22.20}$$

In many cases there is little difference between the P_1 and diffusion approximations. The slight edge in frequency response and allowed range of μ_s make P_1 the more rigorous choice.

22.3.5 Measurements of PDW

Changing r and f has different effects upon the PDW intensity and phase (Figures 22.5 and 22.6). In each case it is possible to infer the optical properties of the medium by monitoring the response of the intensity and phase to changes in r and/or f.

Tromberg et al. measured the optical properties of turbid media by changing the modulation frequency. Sweeping f assures the sampling of regions where A and Θ are sensitive to μ_a and μ_s . For example, measurements of Θ vs. f can recover μ_a and μ_s , but only when a sufficient frequency range that samples photon density wave dispersion is considered. Fitting A and Θ simultaneously produces the best results. Frequency-swept methods also allow measurements at a single r, limiting depth-sampling errors (Figure 22.7). However, instrumentation artifacts S and ϕ_0 must be removed by a calibration measurement performed on a phantom of known optical properties. Simultaneous fitting of A and Θ must be performed with multiple initial guesses to ensure that nonlinear global fits converge upon a true global minimum.

Fantini et al. demonstrated that the diffusion equation in infinite¹⁵ and semi-infinite geometries³² possesses a linear relationship between Θ and r (Figure 22.5). In addition, $\ln(A \ r)$ is linear in r in the infinite medium geometry; a function related to $\ln(A \ r^2)$ is linear with r in the semi-infinite geometry. The optical properties are related to the slopes of the measured frequency-domain parameters vs. r. All source term information (i.e., S and ϕ) is constrained to the intercepts. Thus, simple linear fits of the intensity and phase slopes yield a direct calculation of μ_a and μ_s' . Measurements can be performed at a

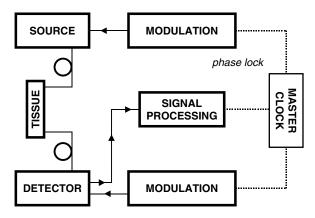

FIGURE 22.8 Simple schematic for a frequency-domain instrument. The key element is that the modulation of source and detector must be synchronized (i.e., phase locked).

single modulation frequency, greatly simplifying the instrumentation. However, one must be careful not to use f in a region of low sensitivity to μ_a or μ_s' .²⁹ If multiple light sources are used for each r, then the intensities and phases of each must be calibrated, again on a phantom of known optical properties. Changing r probes different tissue volumes (Figure 22.7), while changing f over frequencies around f_a changes the probed volume to a lesser extent.

22.4 Frequency-Domain Instrumentation

22.4.1 The Frequency-Domain Instrument

Figure 22.8 shows the essential elements of a frequency-domain instrument. There have been several detailed descriptions of frequency-domain photon migration (FDPM) devices. $^{16,33-35}$ An intensity-modulated light source (at frequency f) excites a sample. Diffusely reflected light is collected from the sample at frequency f and guided to an optical detector. Typically, the detector is modulated at $f + \Delta f$ to process the high-frequency signal. The detected signal is then digitized and processed. Special considerations are required because some components must respond to f > 100 MHz. We will use the designation RF (radio frequencies) to describe the MHz regime.

In order to detect modulated optical signals, source and detector clocks must be phase-locked together. A phase shift between two unsynchronized waves is random, obscuring any physical meaning of the phase; locking together the clocks of these waves synchronizes them. Most frequency-domain systems use a 10-MHz master clock signal as a phase lock. One notable exception is the system developed by Tromberg, which uses a commercial network analyzer as RF source and RF detector, eliminating the need for external phase locking.³³ Typically, the light source is referenced to account for drifts in the source phase and intensity. When it is not possible or practical to employ this optical reference, an electronic reference may be used instead.

22.4.2 The Frequency-Domain Source

22.4.2.1 Internal Modulation

Light sources can be modulated internally by directly modulating their supply power. The modulation of the supply current of laser diodes (LD) and light-emitting diodes (LED) alters the optical output. Conventional lamps can also be modulated internally, but at frequencies far too low for use in PMS. Some lasers are modulated internally by mode locking, or coordinating the phases between different longitudinal modes within the laser cavity. A typical titanium-sapphire laser, such as the Coherent Mira system, is mode locked with 150-fs pulses firing at approximately 80 MHz.

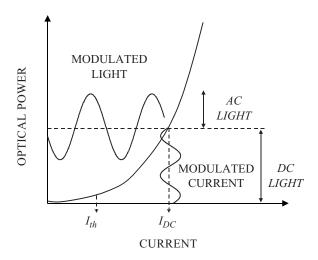

FIGURE 22.9 Modulation of solid-state devices consists of exceeding the threshold current with a modulated current. For a given amount of RF power, the modulation depth decreases as the optical power increases; thus a balance must be made between modulation depth and total output power. Note that this same general diagram principle applies to modulating a solid-state detector such as an APD.

Semiconductor technology has substantially advanced biomedical optics by providing inexpensive and portable light sources. A DC bias current turns on the LD by marginally exceeding the threshold current $I_{\rm th}$. A small RF current on top of the DC bias current drives the diode above and below $I_{\rm th}$, switching the diode on and off (Figure 22.9). This condition yields the maximum modulation depth of the source (100%). One may trade modulation depth for increased optical power. Increasing the DC bias and RF currents results in more optical power, but to maintain the same modulation depth, more RF current is needed. Solid-state devices can only handle so much RF current, and will typically fail if the current drives negative. In general, NIR LEDs can be modulated in the 100-MHz range and LDs up to and beyond 1 GHz.

22.4.2.2 External Modulation

External modulation occurs outside the light source. Mechanical choppers can achieve modulation, but not at frequencies high enough to be useful in PMS. External devices, such as the acousto-optic modulator (AOM) and the Pockels cell, may be used on laser beams or lamps, although modulation efficiency is highly sensitive to input beam quality.

By inducing birefringence in a crystal from the application of an oscillating applied voltage, the Pockels cell is essentially a fast-switching polarizer. Required voltages range from 0.1 to over 1 KV, depending upon the cell material and configuration. Pockels cells made from ammonium dihydrogen phosphase (ADP), for example, modulate light in the 0.3 to 1.2 μ M spectral range up to about 500 MHz. Higher index materials such as lithium niobate can modulate light well above 1 GHz. The ability of the power source to produce voltages of adequate amplitude and frequency also limits the bandwidth of the Pockels cell. High-frequency modulation is achievable only with collimated light.

The AOM uses an applied voltage to induce ultrasonic standing waves inside a crystal to diffract light. The diffracted spots are modulated, whereas the center beam is unmodulated.³⁷ Two AOMs in series can be used to beat signals together, thereby increasing the frequency range.³⁸ Materials such as gallium phosphide can achieve bandwidth up to 1 GHz in the NIR, although a rather large supply voltage is required. Tellurium dioxide AOMs offer lower bandwidths of 300 MHz over a broader spectral region and with a considerable reduction in supply power. Compared to Pockels cells, AOMs have lower overall bandwidth and more modest voltage requirements.³⁶ The AOM working distance is large because the diffraction angles are small.

22.4.3 The Frequency-Domain Detector

22.4.3.1 Signal Detection

Accurately sampling a 100-MHz wave requires a clock running well into the GHz range. One method that allows accurate phase and amplitude measurements of 100-MHz signals is known as heterodyning, which is the same process used by AM radio receivers. Consider two signals, a source wave $A_1\sin(\omega t + \phi_1)$ and a detected wave $A_2\sin([\omega + \Delta\omega]t + \phi_2)$. In mixing these waves together (i.e., multiplying them), the product becomes:

$$\frac{1}{2}A_1A_2\left(\cos(\Delta\omega t + \Delta\phi) - \cos(2\omega t + \Delta\omega t + \phi_1 + \phi_2)\right),\tag{22.21}$$

where $\Delta \phi \equiv \phi_2 - \phi_1$. Equation 22.21 expresses the sum and difference of the frequencies of two waves (i.e., a beat). Typically, f is 100 MHz or greater, and Δf is in the range of 1 KHz. Under these conditions, the first term of Equation 22.21 can be easily filtered from the second term. The usefulness of heterodyning is that the $\Delta \omega$ term is proportional to A_2 and depends upon $\Delta \phi$. Heterodyning translates a high frequency signal into a low frequency signal, while retaining the amplitude and phase information of the detected wave. This low-frequency signal may now be easily processed by standard electronic digitization methods.

Two additional configurations require comment. In the configuration devised by Tromberg, a network analyzer performs all heterodyning operations internally.³³ One can use any detector without concern for additional RF electronics. Secondly, lock-in detection can be used in principle, but in practice can be difficult because (1) both reference and detected signals must be carefully matched in power and (2) most lock-ins are not meant to work in the 100-MHz regime.

22.4.3.2 Photoemissive Detectors

Photo-multiplier tubes (PMT) have been the most commonly used detector in PMS. PMTs are highly inefficient in the NIR, resulting in quantum efficiencies well below 10% out to 800 nm. (See, for example, the PMT catalog of Hamamatsu, Japan). A commonly used PMT is the Hamamatsu R928, which has an effective NIR spectral range of 600 to 840 nm. Advantages of this PMT are its high gain of 10^7 and low dark current (3 nA, with typical signal currents in the 30- μ A range). The R928 also has a rise time of 2.2 ns, allowing in principle the detection of signals up to 400 MHz for well-focused light. Additional concerns for using any PMT are their high voltage considerations (the R928 requires about 1200 V).

Shutting off a dynode early in the chain and stopping the avalanche of electrons from reaching the anode modulates a PMT. Applying a sinusoidal voltage at frequency f to the first dynode will turn the PMT on and off at the frequency f.³⁹ Microchannel plate (MCP) detectors have also been used in PMS.²⁴ The MCP offers immensely increased bandwidth, often exceeding several GHz. However, the dramatically lower signal currents require high-precision microwave electronics, making MCP use cumbersome.

22.4.3.3 Solid-State Detectors

The most useful solid-state detector for FDPM is the avalanche photodiode (APD). Photodiodes in general have excellent NIR sensitivity (Si and InGaAs), reaching quantum efficiencies near 100% at 800 nm. Conventional photodiodes have no gain mechanism, while the APD has internal gains that can reach 10^2 to 10^3 with a low noise figure. Photodiodes in general are very good frequency-domain detectors capable of processing optical signals in excess of 1 GHz. An APD can be modulated via its supply voltage, as with the PMT (see Figure 22.9). APDs used in PMS are usually reverse-biased, with bias voltages below 300 V. One major drawback of the APD is the small active area. An active area of 1 mm² translates into about a 600-MHz bandwidth for the Hamamatsu model S2383 APD; higher active areas generally decrease the frequency response. The APD has adequate sensitivity over the entire NIR range.

22.5 Current Clinical Examples

Next we provide a sample of frequency-domain PMS applied to medical problems. This list is not exhaustive, but only representative of frequency-domain PMS in tissues. Space does not permit mention of important works by other authors. Of course, frequency-domain PMS has not been the only method to investigate the examples we describe. The common thread in these emerging applications is that all measurements are quantitative and noninvasive, and reveal important aspects of tissue function not observed by other methods.

22.5.1 Breast Spectroscopy

22.5.1.1 Past Efforts

Optical transillumination was applied to breast in 1929 as a tool to visualize the shadows cast by breast lesions. Attempts at spectroscopy started in the early 1980s by dividing images into red and NIR bands. Throughout the 1980s many clinical trials compared transillumination with mammography as a screening tool; a potpourri of conflicting clinical conclusions was the result. By 1990, transillumination sensitivity and specificity were found inferior to mammography.¹⁸

Classical transillumination (sometimes called diaphanography) made no attempt to distinguish between absorption and scattering and could not provide measures of tissue chromophore concentrations. Although direct visualization of lesion anatomy is difficult, if not impossible with visible and NIR optics, spectroscopic visualization of tissue function is an entirely different matter. Early studies have shown that red and NIR light absorption in breast is highly sensitive to hemoglobin. However, the presence of blood alone is not sufficient criteria for the diagnosis of cancer — a weakness that probably contributed to the high-false positive rate of transillumination. Neglecting scattering diminishes contrast even further. Additional information about water and lipid content may help improve sensitivity and specificity.

22.5.1.2 New Contributions

Frequency-domain PMS measurements of breast tumors have shown increased absorption by hemoglobin and water, as well as lower S_tO₂ compared to normal tissue.⁴⁰ The sources of NIR contrast in healthy breast tissue have been quantified; studies have demonstrated that NIR-derived breast tissue composition and metabolism correlate with known histological changes that occur from long- and short-term hormonal use.^{41,42} These measurements demonstrate clearly that PMS has the sensitivity to detect small functional changes in breast that may prove useful in detecting cancer and monitoring the effectiveness of cancer therapies. The use of endogenous contrast (i.e., hemoglobin) alleviates concerns for any unknown dynamics and undesirable toxicity of exogenous contrast agents.

Pogue et al. have constructed a frequency-domain imager that combines spectral information from 650 to 850 nm.³⁴ Pilot study results have shown that tumor hemoglobin concentrations correlate with tumor vascularity.⁴³ This finding indicates that PMS techniques could be used to monitor the progression of anti-angiogenesis drugs in the breast. It is important to note that this work uses model-based reconstructions of tissue optical properties and does not rely upon nonspectroscopic images of shadows. Wideband tissue spectroscopy coupled with this fast image capability may provide an important new approach for imaging tumor angiogenesis.

22.5.2 Functional Brain Monitoring

Rapid frequency-domain techniques have proved useful in probing human brain function. There have been numerous attempts to measure changes in brain hemoglobin concentrations using NIR spectroscopy (see Chapter 28 for more details about NIR functional imaging). Activation events, or the so-called "slow" brain signals, are hemodynamic in nature, occurring on a 2- to 10-s timescale. Relatively simple optical instruments can monitor these hemodynamic changes via absorption. However, it has been observed that changes in brain optical properties are also due to changes in scattering, the so-called "fast" events

(50 to 500 ms). Classic NIR methods that cannot separate absorption from scattering will not quantify these events.

E. Gratton, an early pioneer in the application of frequency-domain methods, used frequency-domain PMS to measure absorption and scattering changes in brain *in vivo*.⁴⁴ Gratton and colleagues have reported fast (i.e., <1 s) brain optical signal changes that are apparently the result of scattering fluctuations occurring during localized neural tissue activation. Using a commercial two-wavelength, multidistance device with a measurement time of 160 ms (ISS, Urbana, IL), Gratton et al. measured fast and slow changes in brain optical properties that correlate with brain activity in response to periodic stimuli. In addition, they have shown that these optical changes correlate with electrical changes in the brain. Further work by Cheung and co-workers has centered around measuring correlations in phase and amplitude as a means of quantifying brain optical property changes.⁴⁵

22.5.3 Measurements of Tissue Physiology

22.5.3.1 Deep-Tissue Arterial and Venous Oximetry

Pulse oximetry provides the hemoglobin saturation in arterial blood (S_aO_2) by monitoring pulsitile changes in NIR attenuation (see Chapter 26 for greater detail). The technique is generally limited to thin sections of tissue, such as the finger tip or ear lobe. Frequency-domain PMS provides the S_tO_2 , which is more representative of the tissue capillary bed (i.e., mixed arterial and venous). Franchescini and coworkers have used a multidistance, frequency-domain technique to measure arterial⁴⁶ and venous saturations (S_vO_2)⁴⁷ in thick tissues independently. The frequency-domain technique is required to provide the photon path length, which standard NIR techniques cannot do. The discrimination between S_vO_2 and S_aO_2 is accomplished by locking onto the harmonic content of changes in μ_a which, at the heartbeat frequency correspond to arterial signals; changes in μ_a at the respiratory frequency correspond to venous signals. This technique could be important in brain and in muscle physiology because no way to measure S_vO_2 noninvasively exists. This technique can be performed in real time.

22.5.3.2 Monitoring Photodynamic Therapy Response

Photodynamic therapy (PDT) drugs provide new treatment options in the management of cancer (see Chapters 40 and 41). A photosensitizing drug in the presence of oxygen will cause tissue necrosis after absorbing an appropriate amount of optical radiation. Without knowledge of the optical properties of the tissue, the exact amount of light dosage required for treatment remains an unknown variable, limiting the effectiveness of the treatment.

Pham et al. used a frequency-domain, multifrequency approach to measure changes in tumor physiology in response to a photosensitizer in a rat ovarian cancer model.⁴⁸ PMS revealed significant decreases in THC and S_tO₂ after the application and subsequent optical activation of the photosensitizer. Histologic inspection of the tumors revealed that the long-term efficacy of the treatment highly correlated with the measured changes in THC and S_tO₂. As PDT use increases in clinical practice, PMS could provide rapid feedback about the effectiveness of the delivered photosensitizer dose.

Acknowledgments

We wish to thank many people who have worked with us in contributing to the basic development of PMS: Tuan Pham, Joshua Fishkin, Olivier Coqouz, Eric Anderson, Steen Madsen, and Lars Svaasand. The authors would also like to thank many organizations for their generous support during the development of the ideas in this chapter: National Institutes of Health (NIH) Laser Microbeam and Medical Program (RR-01192), NIH (R29-GM50958), Department of Energy (DOE DE-FG03–91ER61227), Air Force Office of Scientific Research (F49620-00-1-0371), and the Beckman, Whitaker, and Hewitt Foundations. A.E.C. cheerfully acknowledges support from the U.S. Army Medical Research and Material Command (DAMD17-98-1-8186).

23.1 Atomic Spectrometry: Introduction

Within biological systems, elements may be classified as those essential to the well-being of the organism and those that have no known or demonstrable function and are therefore regarded as nonessential.^{1,2} On the basis of the usual concentrations within tissues and body fluids they may also be classified as major or trace elements, trace elements being defined as those that individually contribute no more than 0.01% of the dry body mass.³ All the major elements and a limited number of trace elements are essential (Table 23.1); all others that may be detected are nonessential. Essential elements are required for various biological functions, e.g.,

- · Enzyme structure and function
- · Hormone structure and function
- Vitamin structure and function (e.g., B₁₂)
- · Transport of oxygen
- · Structure of macromolecules

When any are present in less than optimal concentrations, symptoms of morbidity will be evident — indeed, the severity of deficiency may be such that death is the eventual outcome (Figure 23.1). At the same time, all elements, whether essential or nonessential, are toxic if they accumulate in tissues to sufficiently large concentrations.³

Therefore, it is important that accurate measurements in biological and clinical specimens may be obtained for fundamental research involving mechanistic aspects of trace element biology and so that deficiencies or excess may be detected in various situations.^{1,4} In addition to these concepts of essentiality

TABLE 23.1 Major Elements and Essential Trace Elements in Clinical and Biological Samples

	Minerals	Nonminerals
Major elements	Calcium, iron, magnesium, potassium, sodium	Carbon, chlorine, hydrogen, nitrogen, oxygen, phosphorus, sulfur
Essential elements (not all proven to have essential roles in man)	Chromium, cobalt, copper, iron, manganese, molybdenum, nickel, selenium, silicon, vanadium, zinc	Fluorine, iodine

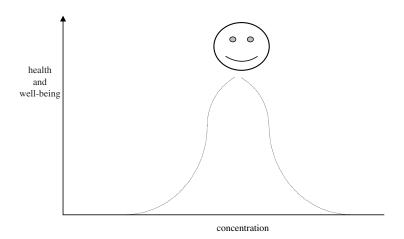

FIGURE 23.1 Representation of the relationship between essential elements and well-being.

and nonessentiality and deficiency and toxicity, elements are also used therapeutically and concentrations in body fluids may be required to monitor the effectiveness and safety of the treatment.³

The analytical techniques used must afford the sensitivity necessary to measure concentrations below 1 ppm, often low ppb levels, in specimens of just a few microliters or milligrams with almost total specificity and relatively few interferences. These demands are met by the atomic spectrometry techniques described in this chapter.^{5,6}

Put very simply, spectroscopy is concerned with the study of interactions between electromagnetic radiation and matter, while spectrometry is the exploitation of these interactions to gain analytical (quantitative or qualitative) information. As indicated by the terminology, the interactions studied in atomic spectrometry involve atoms (rather than molecules) and the purpose is to determine the concentration or, more rarely, simply the presence of an element within a sample. The appropriate energy required to interact with atoms is that derived from the UV-visible section, and by high-energy particles, of the electromagnetic spectrum. In practice, atomic spectrometry involves the emission, absorption, or fluorescence of such energy. Thus this chapter describes atomic emission spectrometry (AES), atomic absorption spectrometry (AAS), atomic fluorescence spectrometry (XF), and x-ray fluorescence spectrometry (XRF). Although these procedures are used extensively, elements may also be determined by a number of other techniques; of particular relevance to biological and clinical specimens are those involving inorganic mass spectrometry, activation analysis, and anodic stripping voltametry. Recognizing the importance of these techniques, brief reference will be included, particularly where features overlap with the more conventional atomic spectrometry.

23.2 Atomic Spectrometry: Principles

Analytical AES, AAS, and AFS are quantitative techniques that exploit interactions between UV-visible light and the outer shell electrons of free, gaseous, uncharged atoms. In XRF and related techniques,

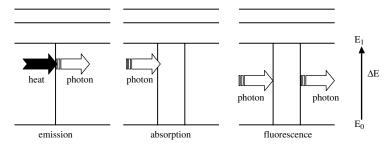

FIGURE 23.2 Energy transitions associated with atomic emission, absorption, and fluorescence.

high-energy particles interact with inner shell electrons to initiate further electron transitions within the atom. Each element has a characteristic atomic structure with a positively charged nucleus surrounded by electrons in orbital shells to provide neutrality. These electrons occupy discrete energy levels, but it is possible for an electron to be moved from one level to another within the atom by the introduction of energy (Figure 23.2). This energy may be supplied by collisions with other atoms, i.e., heating (for AES), as photons of light (for AAS and AFS), or as high-energy particles (for XRF). Such transitions occur only if the available energy is equal to the difference between two levels (Δ E). Uncharged atoms may exist at the lowest energy level or ground state (E₀), or at any one of a series of excited states (E_n) depending on how certain electrons have been moved to higher energy levels, although it is usual to consider just the first transition. Energy levels and the Δ Es associated with electron transitions are unique for each element.

The ΔE for movements of outer shell electrons in most elements correspond to the energy equivalent to UV-visible radiation and these transitions are used for AES, AAS, and AFS. The energy of a photon (E) is characterized by

$$E = hv (23.1)$$

where h = Planck's constant and $\upsilon = the$ frequency of the waveform corresponding to that photon. Furthermore, frequency and wavelength are related as

$$v = c/\lambda \tag{23.2}$$

where c = the velocity of light and $\lambda =$ the wavelength. Therefore,

$$E = hc/\lambda \tag{23.3}$$

and it follows that a specific transition, ΔE, is associated with a unique wavelength.⁶

Under appropriate conditions, outer shell electrons of vaporized atoms may be excited by thermal energy (i.e., collisions with other atoms). As these electrons return to the more stable ground state, energy is lost. As Figure 23.2 shows, some of this energy will be in the form of emitted light, which can be measured with a detector; this is AES. When light (radiant energy) of a characteristic wavelength enters an analytical system, outer shell electrons of the corresponding atoms will be excited as energy is absorbed. Consequently, the amount of light transmitted from the system to the detector will be attenuated; this is understood as AAS. Finally, some of the radiant energy absorbed by ground state atoms can be emitted as light as the atom returns to the ground state, i.e., AFS.

When high-energy photons, electrons or protons strike a solid sample, an electron from the inner shells (K, L, or M) of a constituent atom may be displaced. The resulting orbital vacancy is filled by an outer shell electron, with an accompanying emission of an x-ray photon; its energy is equal to the difference between the energy levels involved. This emission is known as x-ray fluorescence (XRF). The energy of the emission, i.e., the wavelength, is characteristic of the atom (element) from which it originated, while the intensity of the emission is related to the concentration of the atoms in the sample.

Depending on the principle of the spectrometer employed to measure the emission, XRF is divided into wavelength dispersive XRF (WDXRF) or energy dispersive XRF (EDXRF). Total reflection XRF (TXRF) is usually described as a separate technique although it may be seen as a modification of EDXRF. Highenergy hydrogen or helium ions may also be used as incident radiation to displace an electron from a K or L shell with an emission of characteristic x-rays. This is known as particle-induced x-ray emission (PIXE). In addition to being an independent analytical technique, PIXE can be used with electron microscopy to provide elemental analysis of visualized specimens.

Analogous to XRF and PIXE, when an atom is bombarded with charged particles a radioactive nuclide may be formed. Gamma radiation then emitted is characteristic of the nuclide and the intensity of the emission is proportional to the analyte concentration. Neutrons are most often used for excitation and the technique is then called neutron activation analysis. This multielement technique requires specialized facilities and is not widely available.

The high-temperature inductively coupled plasma (see below) is an effective ion source for a mass spectrometer; the technique of inductively coupled plasma-mass spectrometry (ICP-MS) is extensively used for measurements of trace elements in clinical and biological materials. It affords very sensitive multielement analysis and also provides for the determination of stable isotopes.^{7,8}

Anodic stripping voltametry is an electrochemical procedure that offers exceptional sensitivity for some applications. It is ideally suited for large sample volumes such as water specimens, but it is widely applied to the measurement of lead in blood, particularly in North America.

It follows from Equations 23.1 to 23.3 that the wavelengths of the absorbed and emitted energies are unique to a given element. It is this that makes atomic spectrometric techniques specific, so that one element can be determined even in the presence of an enormous excess of a chemically similar element.⁶

23.3 Atomic Spectrometry: Instrumentation

Formation of the atomic vapor, i.e., atomization, is central to emission, absorption, and fluorescence by atoms. Atomizers and the devices for sample introduction are the heart of the instrumentation, with an associated spectrometer for wavelength separation and detection of light. Atomization involves the following steps: removal of solvent (drying), separation from anion or other components of the matrix, and reduction of ions to the ground state atom. Energy necessary to accomplish these steps is supplied as heat. The proportion of an atom population within the vapor, as the excited or the ground state atoms, is influenced by the temperature and the atomic structure of the element. At the temperatures of flame and electrothermal atomizers, around 2 to 3000 K, the ratio is at least 10⁻⁶:1 for most elements and AAS affords superior sensitivity to AES. With the much higher temperatures provided by an inductively coupled plasma atomizer, the proportion changes and AES may be favored.

23.3.1 Flame Atomizers

The flame provides for simple, rapid measurements with few interferences and is preferred wherever the analyte concentration is suitable. The typical pneumatic nebulizer for sample introduction is inefficient and although elements such as Na and K may be measured in biological specimens by flame AES, flame atomization is more usually suited to AAS and AFS. With AAS, measurements are possible with specimens where concentrations are around 1 μ g/ml or more. Devices have been developed that overcome the limitations of the pneumatic nebulizer by by-passing the nebulizer so that 100% of the sample is atomized; they also introduce the sample as a single, rapid pulse rather than by continuous flow. These approaches are also features of electrothermal atomization and vapor generation procedures (see below). Lower detection limits are obtained with AFS but various constraints restrict this technique, with a few exceptions, to the hydride-forming elements (see below).

23.3.2 Electrothermal Atomizers

Most systems use an electrically heated graphite tube, a technique often called graphite furnace atomization, although other materials are sometimes employed. ^{9,10} With a programmed temperature sequence, the test solution (10 to 50 μ l) is dried, organic material destroyed, and the analyte ions dissociated from anions for reduction to ground state atoms. The temperatures achieved by this technique can be up to 3000 K so that refractory elements such as aluminium and chromium will form an atomic vapor. Because all of the sample is atomized and retained within the small volume of the furnace, a dense atom population is produced. The technique is, therefore, very sensitive and allows measurement of μ g/l concentrations. Although the technique is widely used for AAS, electrothermal atomization is suitable for AES and for sample introduction into an inductively coupled plasma. ^{9,11}

23.3.3 Inductively Coupled Plasmas

As stated previously, high-temperature atomizers are required to provide useful numbers of excited atoms for AES. Historical sources include arcs and sparks but modern instruments use argon, or some other inert gas, in the form of a plasma. The plasma is formed when gas atoms are ionized, $Ar + e^- < = > Ar^+ + 2e^-$ — a process generated by seeding from a high-voltage spark — and is sustained with energy from an induction coil connected to a radio-frequency generator. This is known as an inductively coupled plasma (ICP). Plasmas exist at temperatures of up to 10,000 K and in the instrument have the appearance of a torch. Samples can be introduced via a nebulizer, by vapor generation procedures, by vaporization from a graphite atomizer or by laser ablation of solid specimens.

The main feature of AES is that it permits multielement analysis. Optical systems direct the emitted light via a monochromator to a single detector or to an array of monochromators and detectors positioned around the plasma. With the first arrangement, a sequential series of readings are made with the monochromator driven to give each of the wavelengths of interest in turn. Simultaneous readings can be made with the second arrangement. For most elements the analytical sensitivity for ICP-AES is similar to that obtained with flame AAS at the part per million level.

23.3.4 X-Ray Fluorescence

XRF requires that specimens be irradiated by high-energy photons. In most instruments the source is the polychromatic primary beam from x-ray tubes. Of interest to biological applications, however, is the use of radioactive isotopes as sources. Isotopes such as ²⁴⁴Cm, ²⁴¹Am, ⁵⁵Fe, and ¹⁰⁹Cd are used. ^{13,14} The latter is particularly important as the source in portable instruments developed for *in vivo* XRF (see below). A growing number of publications refer to the use of synchrotron radiation that acts as a high-resolution highly energetic source. ¹³

Because sample matrix contributes considerably to signal intensity, calibration can be difficult, usually requiring the use of different reference materials and internal standardization. Fewer problems are encountered with samples prepared as very thin films and in TXRF. Together with the effect of the matrix, sensitivity is also influenced by wavelength, such that lighter elements present a difficult analytical challenge.

In WDXRF, high-intensity x-rays (e.g., from a 3-kW x-ray tube) are used to induce the fluorescence emission, which is dispersed into individual spectral lines by reflection at an analyzer crystal. The diffracted beams are collimated and directed onto a photon detector. As with ICP-AES, spectrometers may operate sequentially, with a number of interchangeable crystals, to permit the measurement of the full range of elements, or in a multichannel (simultaneous) mode usually preset for specific analytes. Detection limits for light elements are 10 to 100 times lower than with EDXRF. Resolution is good, although less so at shorter wavelengths. Sequential instruments require long analysis times to measure several elements compared with the more expensive simultaneous instruments or EDXRF technology.

For EDXRF, x-rays emitted from the sample are directed together into a crystal detector. A pulse of current is generated with a height proportional to the energy of the x-ray photon. The different energies

TABLE 23.2 Approaches to Sample Preparation

Procedure	Remarks	
Dilution, protein precipitation	Using simple off-line arrangements or flow-injection manifold	
Dry ashing	Using a muffle furnace or a low-temperature asher	
Acid digestion	(1) In open vessels with convection or microwave heating	
	(2) In sealed vessels to increase the reaction pressure	
Base dissolution	Using quaternary ammonium hydroxides	
Chelation and solvent extraction	For analyte enhancement and removal of interferences	
Trapping onto solid phase media	For analyte enhancement and removal of interferences	

associated with the various atoms (elements) in the sample are sorted electronically. Lower energy sources (a low-power x-ray tube or an isotopic source) are used. The detector must be maintained at a very low temperature and in a clean vacuum. Analysis times are 10 to 30 times longer than with WDXRF but, as a truly multielement technique, the total time is not necessarily any greater.

When a collimated beam of x-rays is directed against an optically flat surface at an angle of around 5', total reflection will occur. This is the principle of TXRF in which the sample is exposed to primary and total reflected beams and is excited to fluoresce. Emitted radiation is resolved and measured as an ED spectrum. There is effectively no absorption by the matrix, so measurement and calibration are much simpler and sensitivities are greater than with other x-ray techniques.

23.4 Atomic Spectrometry: Sample Preparation

The objectives for preparation of biomedical specimens are to remove interfering components from the matrix and to adjust the concentration of analyte to facilitate the actual measurement. These objectives may be realized by a number of approaches (Table 23.2).

Methods for destruction of the organic matrix by simple heating or by acid digestion have been used extensively and are thoroughly validated. Microwave heating is now well established for this purpose, with specifically constructed apparatus to avoid dangers of excessive pressure within reaction vessels. Although the number of specimens that can be processed is not large, microwave heating affords rapid digestion and low reagent blanks. More recent developments include continuous flow systems for automated digestion linked directly to the instrument for measurement of the analytes.

Preconcentration by liquid-liquid partitioning is a widely used procedure. Analyte atoms in a large volume of aqueous specimen are complexed with an appropriate agent and then extracted into a smaller volume of organic solvent. This leads to enhancement of concentration and also removes the analyte from potential or real interferences in the original matrix. It is used to measure lead in blood, metals in urine and for other applications. Although preconcentration by trapping onto solid phase media represents the area where much of the recent interest in FAAS has been focused, it is relevant to all sample preparation work. 14,15 The original work involved adsorption onto material such as charcoal or alumina but newer phases include ion-exchange resins and novel support systems to which functional groups are added to confer increased selectivity and capacity. 16 Trapping of analyte from dilute sample and elution into a small volume of release solution may be accomplished off-line; however, developments in flowinjection analysis provide for the assembly of simple on-line manifolds so that complete measurements may be carried through automatically. 14,17 Developments in these applications involving a wide range of biological and clinical sample types and elements are regularly published.

Vapor generation procedures were referred to in earlier sections. These permit the rapid introduction of 100% of the sample into the atomizer and are used for AAS, AFS, ICP-AES, and ICP-MS. 9,18 Certain elements such as arsenic, selenium and bismuth readily form gaseous hydrides, e.g., arsine (AsH₃), that are transferred by a flow of inert gas to a heated silica tube positioned in the light path. The tube is heated by the air-acetylene flame or by an electric current and the temperature is sufficient to cause dissociation of the hydride and atomization of the analyte. Thus, there is no loss of specimen, all the

atoms enter the light path within a few seconds and they are trapped within the silica tube, which retards their dispersion. Hydride generation AAS allows the detection of a few nanograms of analyte from whatever sample volume is placed into the reaction flask. Mercury forms a vapor at ambient temperatures and this property is the basis for cold vapor generation. A reducing agent is added to the sample solution to convert Hg²⁺ to the elemental mercury. Agitation or bubbling of gas through the solution causes rapid vaporization of the atomic mercury, which is then transferred to a flow-through cell placed in the light path. As with hydride generation, the detection limit is a few nanograms and common instrumentation to accomplish both procedures has been developed by some manufacturers.

Appreciation of the importance of determining not just the total concentration of an element in a specimen, but also something of its distribution, is now well established. This concept of speciation is applied to associations with different molecules such as proteins, to different organo-metallic compounds, and to different valence states. A number of preparative procedures are available to separate or speciate the analyte, but much innovation is directed to chromatographic and electrophoretic techniques that are coupled directly to the atomic spectrometric equipment to form an integrated analytical arrangement. Examples are presented in the following section.

23.5 Atomic Spectrometry: Recent Developments and Applications

Measurements of major and trace elements in biological and clinical specimens are required in many situations:

- Work to determine mechanisms of action within biological systems at cellular and biochemical levels, of essentiality and of toxicity, involves knowing concentrations within the experimental systems.
- Determining trace element and mineral physiology, routes of absorption, tissue distribution and concentrations in normal subjects and in patients with inborn errors involves these processes, e.g., copper and Wilson's disease.
- Nutritional studies investigate possible deficiencies of essential elements, e.g., in subjects with poor
 diets or patients receiving long-term total parenteral feeding (where protocols for regular monitoring are generally recommended).¹ In addition to measuring trace elements in blood and urine,
 such work may include analysis of foods and special investigations to assess intestinal absorption.
- Investigation of undue exposure to elements: Increased exposure to minerals and trace elements can cause morbidity and some are carcinogenic. While the function of many organs may be perturbed by accumulation of metals, the kidney, liver, nervous, intestinal, and hemopoietec systems are more likely to be involved. Accidental, (or even deliberate suicidal or homicidal) exposures to trace elements feature in the differential diagnosis when considering signs and symptoms involving these sites. Increased exposure may be consequent on sources within the environment or in the home, associated with hobbies or from unusual cosmetics and remedies. In an occupational setting, biological monitoring is important in the implementation of health and safety regulations.²¹
- In other situations iatrogenic poisoning can occur. Profound toxicity has been observed for many elements including aluminium, bismuth, and manganese.⁴

23.5.1 Atomic Emission Spectrometry

Sodium, potassium and lithium are usually measured by flame AES or with ion-selective electrodes although they can also be determined by flame AAS. At the temperature of the flame there is no useful emission of other biologically important elements. However, with the greater energy of the ICP, much lower detection limits, typically around 1 μ g/ml, are obtained and many elements may be determined simultaneously in solutions prepared from biological tissues. Furthermore, a few elements, such as boron, phosphorus, and sulfur, cannot be measured by AAS but are determined by ICP-AES.

Recent developments with the optical systems and array detectors have led to improvements in sensitivity and data collection. In consequence, elements such as copper, zinc, and aluminium may be measured in blood plasma,^{22–24} while the expanded information caught by detectors is making it possible for powerful chemometric manipulation of individual signals to be undertaken. ICP-AES now has an established role for monitoring patients with possible compromised nutritional status²² and those who receive hemodialysis to treat chronic renal failure and are at risk of developing aluminum toxicity.²³ With the multielement feature of the technique, ICP-AES is widely used for analysis of foodstuffs and tissues samples.¹⁴ The convenience of this approach has, however, encouraged the dubious "diagnostic practice" of hair analysis among some laboratories.²⁵ Vapor generation techniques for sample introduction (see below) are possible.

23.5.2 Atomic Absorption Spectrometry

Measurement of calcium in serum was the first analysis to which AAS was applied and is an obvious example of how the technique is useful for biomedical analysis. Elements present in biological fluids at a sufficiently high concentration to be measured by flame AAS are lithium and gold, when used to treat depression and rheumatoid arthritis, respectively, and calcium, magnesium, iron, copper, and zinc. Flame AAS is used by the large majority of laboratories needing to measure these elements. It fulfills an important role in the investigation of patients with possible nutritional problems, genetic disorders, or other relevant clinical challenges. Other elements are present in fluids at too low a concentration to be measured by conventional FAAS with pneumatic nebulization. With more exotic fluids, e.g., seminal plasma or cerebrospinal fluid, analysis may just be possible for a very few elements.

The concentrations of many metals in plant, animal, or human tissues are usually much higher than in biological fluids and very often the weight of an available specimen is such that a relatively large mass of analyte is recovered into a small volume of solution, thus enhancing the concentration still further. For the analysis of tissues (including specimens such as hair and the cellular fractions of blood) following sample dissolution steps, FAAS is suitable for measurement of many of the biologically important elements.¹⁴

Atom traps, such as the slotted quartz tube, increase the sensitivity associated with FAAS for more volatile elements;²⁶ sporadic reports appear of their use in simplified methods for analysis of biological fluids. However, if concentrations are low it is more usual to take advantage of the lower limits of detection provided by electrothermal AAS.

Virtually all the trace elements of biological interest may be determined by electrothermal AAS. Although it is relatively slow, a single-element technique, and subject to various interferences, it is extensively used throughout the world for clinical investigations and for monitoring occupational exposures, as well as in the other settings mentioned earlier. The design and construction of furnaces are subject to continuous development to improve detection limits and to reduce interferences. Povices to measure nonatomic absorption, e.g., Zeeman-effect background correction, are essential. Commercial furnaces are made from electrographite, electrographite with a pyrolytic coating or total pyrolytic graphite, although publications showing the advantages of other materials as coatings or for the furnace itself, regularly appear. Typically these refer to analysis of elements that form extremely refractory carbides in graphite furnaces, e.g., molybdenum.

Design developments are introduced with the objective of separating the appearance of the atomic vapor from components that cause an interference with the atomization signal. These innovations include graphite platforms and probes but, as with automobiles, there are continuous refinements to the overall shape and dimensions to effect improvements in performance. An authoritative review of materials suitable for use in furnace construction and of recent developments in design has been prepared by Frech.¹⁰ Several research groups have designed very novel atomizers with the purpose of separating the analyte from interfering species, to permit simple atomic absorption.^{27–29} Although some appear to be effective, none are commercially available.

TABLE 23.3 Chemical Modifiers Used in the Analysis of Biomedical Specimens by ETAAS

Modifier	Purpose
Triton X-100	To promote drying of protein-rich specimens, avoid a dried crust around a liquid core
Gaseous oxygen	To promote destruction of organic matrix, reduce smoke formation and particulates which give nonatomic absorption
Ni, Cu, Pd	To stabilize volatile elements, e.g., Se, As, during the dry and ash phases
Potassium dichromate	Stabilizes Hg up to a temperature of 200°C
HNO ₃ or NH ₄ NO ₃	To stabilize analyte atoms by removal of halides as HCl or NH ₄ Cl during the ash phase
$Mg(NO_3)_2$	Becomes reduced to MgO, which traps the metals to reduce volatilization losses, delays atomization and separates the analyte signal from the background absorption
NH ₃ H ₂ PO ₄ or (NH ₃) ₂ HPO ₄	Usually used with $Mg(NO_3)_{29}$ reduces volatilization losses and delays atomization to separate the analyte signal from the background absorption

It was shown some years ago that a 150-W tungsten filament from a light bulb could be used as an electrothermal atomizer. More recently, this concept has been used to develop very small portable instruments for on-site measurement of lead in blood.^{30–32} Excellent results have been reported but a commercial model is still awaited.

In addition, effective analysis of most biological samples requires the addition of reagents that modify the behavior of the specimen during the heating program so as to reduce interferences. ¹⁴ The chemical modifiers most commonly employed with biological specimens are given in Table 23.3. Triton X-100 is used at a concentration of around 0.1% w/v and is included with the sample diluent. Gaseous oxygen or air is an effective ashing aid, but will cause rapid deterioration of the graphite furnace unless a desorption step is included before the temperature is increased for atomization. Other modifier solutions can be included with the sample diluent or separately added by the autosampler to the specimen inside the furnace. The choice of modifier often depends on the availability of a source material that is free from contamination.

23.5.3 Atomic Fluorescence Spectrometry

Recent innovations in AFS follow almost entirely from the development of commercial instruments specifically designed for use with hydride generation; the particular applications of interest will be considered in the next section. For various reasons earlier attempts to exploit the inherent sensitivity of AFS using flame systems were never fully realized. However, with improvements in light source technology and other instrumentation, this niche area has progressed rapidly in recent years.^{9,14}

23.5.4 Vapor Generation Procedures

Depending on the nature of the exposure — inorganic salts, organomercury compounds, the metal or its vapor — it may be necessary to analyze specimens of urine, blood or tissues, and foods. Mercury is used extensively in industry and occupational monitoring continues to be relevant. There is now considerable interest in two particular environmental sources of exposure, i.e., from dental amalgam and from the diet, especially fish. Although no good evidence exists for mercury leaching from amalgam fillings in amounts that can cause toxicity, many members of the public believe that their health is affected and seek to have the mercury removed, even after analysis of blood or urine has failed to show increased concentrations of the metal.³³ Concern has been raised that undue exposure to methylmercury may occur from eating large amounts of seafoods. Those at risk are young children *in utero* and during early childhood. Long-term studies are in progress within communities where basic foods contain mercury and maternal hair concentrations of it are high. Mercury intakes and neurological development are being monitored within the target groups.³⁴

Considerable interest in methods to measure arsenic and other hydride-forming elements has been evident in recent years. The basic procedure involves careful digestion of the specimens to convert all the

different species to a single valency form, reduction with BH_4^- and vaporization to the hydride, which is then transferred by a stream of inert gas to a quartz tube heated in an air-acetylene flame or with electrical thermal wire. Atomization is then achieved by the high temperature. Some work has been reported in which the hydride is transferred into a cold graphite furnace where it is trapped onto the surface. Atomization takes place as the furnace is rapidly heated and, as with conventional electrothermal AAS, improved sensitivity is observed due to the high atom density within the small volume of the furnace.

Trapping is more efficient when the graphite is coated with a metal salt, e.g., Ag, Pd, Ir.^{35,36} The chemical hydride reaction is impaired by other hydride-forming elements and by transition metals so that careful calibration is essential. An emerging development involves an electrolytic process in which nascent hydrogen is produced as an alternative to chemical hydride generation. With this arrangement the interferences are much less and the reagents employed introduce less contamination.^{37–39}

The biological and clinical importance of selenium receives much current interest; more attention is focused on measurement of this element than on any other. The stimuli to this flurry of activity are (1) the association between selenium status and cardiovascular disease coupled to the demonstration that dietary intakes are low in some regions and are declining in others,⁴⁰ and (2) epidemiological data suggesting a relationship between selenium status and the incidence of certain carcinomas.⁴¹ Measurements of selenium in foods, biological fluids and tissues, using vapor generation techniques, electrothermal AAS, or ICP-MS, are integral to many large-scale studies now in progress or recently completed.

There is also much interest in the determination of arsenic. This element is important within the microelectronics industry and in other occupations, but extensive environmental exposure is also associated with naturally high concentrations in drinking water. Arsenic in drinking water is a problem in several areas of the world; however, the situation that now exists in Bangladesh and West Bengal, India, is extraordinary, with millions of people consuming highly toxic and carcinogenic water. ⁴² Measurement of total arsenic is not always entirely helpful. Fish contain large amounts of organoarsenic species that are absorbed and excreted without further metabolism and with no adverse health effects. These species will be included in a total arsenic determination and can mask attempts to measure toxic As³⁺ and metabolites. Thus, methods to measure the individual species or related groups of compounds in urine or other samples provide more meaningful results. These methods include separation by chromatography or solvent extraction and pretreatment steps that transform only the species of interest into the reducible form.

As this speciation work has become more refined additional arsenic-containing compounds have been demonstrated and, very recently, some of these have been identified as methylated As species containing As^{III}. It is well known that methylated species with As^V are found in blood and urine following exposure to inorganic arsenic and believed to represent steps in the detoxification pathway. Methylarsenic^{III} species are potent enzyme inhibitors and cytotoxins and their formation may be involved in the mechanism of arsenic toxicity. In one recent study,⁴³ biliary and urinary arsenic species were determined in rats exposed to As^{III} and As.^V MonomethylAs^{III}arsonate (MMA^{III}) was present in bile but not in urine; the authors hypothesized that MMA^{III} was subsequently oxidized to MMA^V and excreted in urine. In a separate investigation, arsenic species were measured in water, urine and cultured cells and methylarsenic^{III} species were identified in the urine of individuals who had consumed water contaminated with inorganic As.⁴⁴

Other elements that form gaseous hydrides, such as antimony, bismuth, tellurium, etc., are also relevant to investigations in clinical and biological specimens.

23.5.5 X-Ray Fluorescence Spectrometry

XRF and other x-ray techniques offer no particular advantage over the many other procedures for simple quantitative measurement of minerals and trace elements in clinical and biochemical specimens. Alternative methods are widely available, well established, and relatively simple. Nevertheless, a few interesting applications have been reported with recent examples of gold and palladium in urine by TXRF, with detection limits around 2.5 ng/l, and the analysis of breast milk by PIXE.^{45,46} In certain applications

involving clinical and biochemical specimens, however, XRF does have a specific role. These include elemental mapping and *in vivo* analyses.

By virtue of the very narrow x-ray beam (100 μ m or less) it is possible to take repeat measurements over a very small surface and develop a map of the distribution of elements within a structure. This approach is regularly applied to solid materials including hairs, teeth, and other calcareous materials. Results have also been reported in which single cells have been investigated, e.g., in a study to compare iron and other elements within neuromelanin aggregates in neuronal cells of patients with Parkinson's disease and their controls.⁴⁷

Developments involving *in vivo* XRF have flourished in the last few years although the majority of the many publications originate from just a few centers. Most of the work is concerned with measurement of lead in bone by ¹⁰⁹Cd-based XRF. Analytically, recent improvements refer to detection systems to reduce detection limits to low part per million levels, and to the methods for calibration. Phantoms (often plaster of Paris) containing known amounts of Pb are generally used. Recent alternative materials that are reported to behave more like bone are a synthetic apatite matrix⁴⁸ and a material with polyure-thane and CaCO₃.⁴⁹ It has been shown that the measurement location, i.e., proximal-distal sites, influences the measured XRF intensity and its uncertainty. Considerable differences in mean bone Pb concentrations between the left and right legs of the same individual (0.8 and 2.0 μg/g bone mineral) have also been demonstrated.⁵⁰ Using this technique, cumulative exposures to lead at work have been assessed and results compared with other markers such as blood and urine lead concentrations.⁵¹ Blood and bone lead concentrations were determined and related to the development of hypertension. A positive association was found between the baseline bone Pb level and the incidence of hypertension but no association was found with blood Pb level.⁵² Bone lead has also been shown to be released into the circulation during pregnancy, with an implied risk to the fetus if the mother has a history of previous lead absorption.

There are reports of the determination of other elements by *in vivo* XRF. Skin iron concentrations correlated strongly with iron in the internal organs of rats injected with iron-dextran and it was concluded that this technique had great potential in the diagnosis and treatment of hereditary hemochromatosis and β -thalassemia.⁵³ A method for measuring platinum in kidneys of patients receiving Pt-based chemotherapy drugs has been developed.⁵⁴ These few examples illustrate that the potential for *in vivo* elemental analysis is hugely exciting.

23.6 Atomic Spectrometry: Quality Assurance

Apart from the actual analysis, adventitious contamination, which can occur during collection and storage of specimens, the preparative procedure, and the spectrometric measurement, has the greatest impact on the quality of results. Data from proficiency testing schemes indicate that specialist trace element centers tend to maintain the highest standards of analytical performance. This observation reflects the continuing application of practices that minimize contamination and the expertise and experience to ensure optimal functioning of equipment. Because of the stability of inorganic analytes and the purity with which standard materials can be prepared, there are reasonable numbers of reference materials available for use to validate methods and for internal and external quality control.⁵⁵ Proficiency testing schemes relating to occupational and environmental laboratory medicine are organized in most countries and all laboratories involved in this work should have access to an appropriate scheme to demonstrate the reliability of their analytical data.⁵⁶

24.1 Overview

Capillary electrophoresis (CE) is a microscale analytical separation technique that has matured rapidly over the past 20 years since the groundbreaking publications of James W. Jorgenson and co-workers. ^{1,2} Biomedical applications of CE are a leading factor driving the development of what has now evolved into a broad family of related separation techniques. Certainly the most prominent biomedical application of CE is the sequencing of the human genome. ³ The accelerated achievement of this goal depended on CE separations. ^{3–5} From 1981 through the writing of this text, more than 14,000 papers were published that included CE and related techniques. A survey of this literature over the past 12 months indicates that more than 70% of these reports include bioanalytical applications of CE.

Clearly, a comprehensive review of biomedical applications of CE is well beyond the scope of a single book chapter. This chapter first reviews basic CE separations; readers are directed to review articles for in-depth coverage of related CE separation methods. Next, the role of photonics in CE, primarily for detection purposes, is discussed. Finally, the chapter reviews specific examples of biomedical applications of CE that feature photonics, to provide the reader with a view of the possibilities of this approach for biomedical analysis.

Capillary electrophoresis typically is performed in 25- to 75-µm internal diameter (ID), fused-silica capillaries (15 to 100 cm in length) filled with aqueous, buffered solutions. Each end of the capillary is immersed in a buffer reservoir, and a potential of 10 to 30 kV is applied across the capillary using Pt electrodes in each reservoir. In its simplest form, capillary zone electrophoresis (CZE), different charged

compounds in an injected sample zone are separated based on their relative electrophoretic migration rates. For newcomers to this technique, an intuitive feel for this separation method can perhaps best be developed by comparing and contrasting CE with two more familiar and related separation techniques: high pressure liquid chromatography (HPLC) and slab gel electrophoresis.

Like HPLC, CE is a column-based separation technique. Sample plugs are injected into the CE column. Compounds separate as they pass through the column, and separated compound zones are detected as they elute past a fixed point. One obvious difference between the two separation techniques is scale. Typical internal diameters for CE are 25 to 75 μ m compared to 1 to 5 mm for HPLC. A 50- μ m ID CE column 1 m in length has a total column volume of only 2 μ l. Typical CE injection volumes are only a few nanoliters; column flow rates are ordinarily a few hundred nanoliters per minute, although linear flow velocities are generally greater than in HPLC. One consequence of the scale of CE is that it is well suited for analysis of small-volume samples such as single cells. In addition, insignificant volumes of solvent waste are generated compared to HPLC. Due to its small scale, CE is primarily an analytical technique, and is not as practical as HPLC for preparative work. Analyte detection is also more challenging at smaller scales, as discussed later in this chapter.

Capillary electrophoretic separations typically exhibit higher separation efficiencies (narrower peaks) and are rapid compared to HPLC. Typically, a CE separation will generate 10 to 100 times more theoretical plates than an HPLC separation for the same compounds and separation time. High separation efficiencies are primarily due to the plug-shaped electroosmotic flow profile and the electrophoretic separation mechanism of CZE. Peaks for HPLC are typically broader due to the parabolic flow profile of pressure-driven flow, effects of the particles used to pack stationary phases for HPLC, and resistance to mass transfer between the mobile phase and separation phase in HPLC. This last source of peak broadening for HPLC underscores the primary difference between the two techniques, which is separation mechanism. HPLC is a chromatographic technique where separation depends on the relative partitioning of different compounds between a mobile phase and a stationary phase. Separation in CZE is based on electrophoretic migration rates in free solution. Related CE techniques that include partitioning as part of the separation also have been developed and will be discussed later in this chapter.

The most common forms of slab gel electrophoresis, SDS-PAGE for proteins and PAGE for DNA analysis, separate molecules based on sieving behavior through a polymer gel while the separation mechanism for CZE is electrophoretic migration in free solution. Gel-free electrophoretic separations are possible with CE due to the small scale of the technique compared to slab gel electrophoresis. The reduced scale of CE results in lower electrophoretic currents and higher surface-to-volume ratios. The small electrophoretic current in CE generates relatively low joule heating, and the heat that is produced is dissipated more effectively. Capillary separations are much more rapid than slab gel separations, in part because much higher potential fields can be applied (hundreds of volts per centimeter) due to reduced electrophoretic currents and increased heat dissipation.

For slab gel electrophoresis, the gel is required to dissipate heat and reduce zone broadening due to convective flow in addition to providing a sieving medium. Like HPLC, slab gel electrophoresis is superior to CE for preparative work. Capillary electrophoresis, however, is better suited to volume-limited samples. In addition, slab gels are ideally suited for parallel separations and two-dimensional separations. Capillary array electrophoresis has been developed for parallel separations,^{4,5} and CE has been used for two-dimensional separations,⁸ but in both cases sophisticated instrumentation had to be developed to realize the advantages of these separation strategies with CE.

24.2 Capillary Electrophoresis Basics

24.2.1 Capillary Zone Electrophoresis

24.2.1.1 Fundamentals

Capillary zone electrophoresis separations are based on differences in electrophoretic migration of ionic species in solution. For practical reasons, which will be explained later, a positive potential is normally

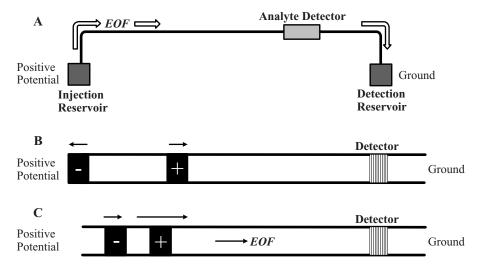

FIGURE 24.1 (A) Capillary electrophoresis instrument. A potential is applied through Pt electrodes (not shown) in the injection and detection reservoirs. (B) Migration of anions and cations in the absence of EOF (fluid flow). (C) Migration of anions and cations in the presence of strong EOF.

applied at the injection end of the capillary, and the opposite end of the capillary is held at a relatively negative potential. Figure 24.1 illustrates a basic CZE instrument and separations with and without fluid flow.

Consider a sample zone at the injection end of a capillary column containing a mixture of cationic, anionic, and neutral compounds when a separation potential is applied (Figure 24.1B). In the absence of fluid flow, cationic compounds will migrate down the column toward the detector. Anionic compounds will immediately exit the column at the injection end. Neutral compounds (not shown) will be unaffected by the separation potential. The following relation describes electrophoretic migration of ionic species in free solution:

$$v_{ep} = u_{ep}E \tag{24.1}$$

where v_{ep} is the electrophoretic velocity of a charged compound, u_{ep} is the electrophoretic mobility, and E is the applied field strength (V/cm). The electrophoretic mobility, u_{ep} is defined as:

$$u_{ep} = \frac{q}{6\pi\eta r} \tag{24.2}$$

where q is the charge of the compound, η is the viscosity of the solution, and r is the compound's hydrodynamic radius. In the absence of fluid flow, only cationic species can be separated with the experimental setup illustrated in Figure 24.1A. Anionic species could be separated by reversing the polarity of the applied potential.

In practice, CZE experiments typically include bulk fluid flow in the capillary due to electroosmosis. Electroosmotic flow (EOF) is generated at the capillary surface in the presence of an applied potential by electrophoretic migration of solvated ions near the capillary surface. If the capillary surface includes charged functional groups (e.g., Si-O⁻ for fused silica), a double-layer structure is formed in solution at the surface (typically nanometer in scale), which contains an excess of ions opposite in charge to the bound surface charge on the capillary inner wall. In the presence of an applied potential, these solvated counter ions in the diffuse part of the double layer will migrate toward one electrode, generating a bulk fluid flow. In effect, the entire capillary inner surface acts as a fluid pump for CE. For the experimental arrangement shown in Figure 24.1 with a fused-silica capillary filled with an aqueous solution near neutral

pH, EOF is in the direction from the injection end of the capillary (positive polarity) to the detection end of the capillary (negative polarity) and is proportional to the applied potential:

$$v_{eof} = u_{eof}E \tag{24.3}$$

where v_{eof} is the EOF velocity, u_{eof} is the electroosmotic mobility, and E is the applied field strength. The electroosmotic mobility is described by:

$$u_{eof} = \frac{\varepsilon \zeta}{4\pi \eta} \tag{24.4}$$

The structure of the double layer defines the zeta potential, ζ , and ε is the dielectric constant of the buffer filling the capillary. Electroosmosis is typically greater in magnitude than electrophoretic migration of charged species so cationic and anionic compounds will have a net migration toward the detection end of the capillary (Figure 24.1C). This is a critical point because strong EOF allows the simultaneous separation of cationic and anionic species. Neutral molecules (not shown) migrate at the EOF rate and are not separated from each other by CZE. Other CE techniques for separations of neutrals will be discussed later in this chapter. The net electrophoretic migration of ionic species in the presence of EOF is described by:

$$v_{net} = u_{net}E = (u_{ep} + u_{eof})E$$
 (24.5)

where v_{net} is the net velocity of a compound due to electrophoresis and EOF, and u_{net} is the net electrophoretic mobility.

The resolving ability of CE is the primary reason for the technique's rapid development and widespread application. The resolution, *R*, for two compounds (1 and 2) by CE is:

$$R = \frac{0.177(u_{ep,1} - u_{ep,2})V^{1/2}}{\sqrt{(u_{avg} + u_{eof})D}}$$
(24.6)

Here u_{avg} is the average electrophoretic mobility of the two compounds, D is the diffusion coefficient of the compounds, and V is the applied potential (volts). High separation efficiency is the primary reason that CE provides good resolution compared to other separation techniques. The number of theoretical plates for a CZE separation is given by:

$$N = \frac{(u_{ep} + u_{eof})V}{2D}$$
 (24.7)

This equation shows that, ideally, CZE peaks are only broadened by axial diffusion. There is no stationary phase in a CZE separation, and, therefore, no mass transfer terms or particle packing terms are in Equation 24.7. Furthermore, EOF has a very flat, plug-shaped flow profile, so resistance to mass transfer in the mobile phase (running buffer) does not contribute to peak broadening. Separations with 10⁵ theoretical plates are common and plate counts over 10⁶ have been reported. Other factors can degrade separations for CE, however. Unwanted adsorption to the capillary surface is frequently encountered. Temperature changes due to excessive joule heating can cause peak broadening. Sample injection and detection can degrade separation efficiencies in some cases. Zone broadening for CE has been reviewed. ^{10,11}

24.2.1.2 Practical Considerations

Basic CE instruments are straightforward to construct in the laboratory, and much of the research in this field has relied on laboratory-constructed instrumentation. Commercial instrumentation for CE is widely available, however, and these instruments offer many advantages for new users of CE and experienced

researchers who also use laboratory-constructed instruments. The most common instrument is a single-capillary device with a UV/VIS absorbance detector. Laser-induced fluorescence (LIF) detectors, electrochemical detectors, and instruments designed to interface with mass spectrometers are also available. Most complete CE systems include autoinjectors (pressure and electrokinetic) and capillary thermostats. Capillary array instruments are also available for applications requiring high throughput.

Most CE experiments are performed in bare fused-silica capillaries filled with buffered, aqueous solutions (running buffer) near neutral pH. Applied potentials typically range from 10 to 30 kV, and Pt electrodes are commonly used in the two buffer reservoirs for this purpose. One of the main advantages of CE is that selectivity can be changed substantially by simply altering the separation buffer. The simplest and most effective means to control selectivity is to change the running buffer pH to alter the net charge of analytes. The running buffer pH also influences EOF; as seen in Equation 24.6, this can have subtle to dramatic effects on resolution. Altering the buffer composition and ionic strength can also affect separation selectivity and EOF, but the effects of these changes are subtle and not as easy to predict as with a pH change. As described in following sections, compounds can be added to the buffer to alter the separation mechanism. Water-miscible organic solvents are often added to CE buffers, and nonaqueous CE has been studied extensively.¹²

Sample injections typically are performed by placing the injection end of the capillary into the sample container and applying pressure or an electrical potential. Both methods can be automated, and the precision for pressure injection can be as much as a factor of two better than for electrokinetic injection. ^{13,14} Electrokinetic injection suffers from injection bias for charged species due to differences in electrophoretic mobilities between sample components. Theoretical descriptions of these injection techniques, which include equations for calculating injection volumes, are available in the literature. ¹⁴ Sample stacking describes a family of related methods used to preconcentrate samples electrophoretically in the capillary column at the start of a CE separation. A number of variations of this technique have been developed to achieve sample preconcentration factors ranging from 10 to 1000 for charged analytes, and related methods have been developed to preconcentrate neutral analytes. ^{15,16} Preconcentration methods using solid phase supports also have been developed for CE. ¹⁶ Preconcentration is particularly important for CE methods due to the difficulty in detecting analytes at low concentrations with this separation method.

A typical CE capillary is 15 to 100 cm in length and has an ID from 25 to 75 μ m. Capillaries made from materials other than fused silica are rarely used. One reason for this is the superior properties of fused-silica capillaries for on-column optical detection. The inner surface of the capillary is commonly modified, however. One goal of capillary surface modification is to reduce band broadening and sample loss due to adsorption of analytes to the capillary surface, which can be especially problematic for protein analysis. A second goal is to suppress EOF. Because EOF is sensitive to the solution composition and the surface chemistry at the capillary surface, it can be irreproducible or unstable, leading to poor analytical reproducibility. Coating the capillary surface can reduce these problems. Covalently bound coatings, adsorbed coatings, and separation buffer additives are used to modify the capillary surface. $^{17-20}$

24.2.2 Biomedically Significant Variations on the Capillary Electrophoresis Theme

The facile addition of a wide variety of reagents to the CE running buffer to influence migration behavior and enhance separations is a major advantage of the technique. Among the additives that have been used are chelating agents such as crown ethers, surfactants above and below the critical micelle concentration (CMC), macrocyclic reagents such as cyclodextrins, antibiotics, and calixarenes, and sieving media such as soluble polymers. ^{17,21,22} In some cases, these reagents have served sufficiently unique and valuable purposes that specialized variants of the CE have been dubbed. We will cover the basic principles of a few of those variations on the CE theme.

A disadvantage of the conventional CZE technique is that neutral species migrate with EOF and coelute at or very near the void time of the system. Given the preponderance of neutral compounds of biological and medical significance, this limitation is significant. Neutral compounds can be separated, however, if they acquire different effective electrophoretic mobilities due to differential association with charged running buffer additives. The most commonly used approach involves the addition of surfactant at concentrations above its CMC to form charged aggregates of surfactant molecules (micelles).

This technique, micellar electrokinetic capillary chromatography (MEKC), was first introduced by Terabe and co-workers.²³ Instrumental and operational aspects of MEKC are virtually indistinguishable from CZE; however, MEKC also shares many of the features of HPLC. The running buffer assumes the role of the mobile phase and is transported at the EOF rate, while the micellar phase constitutes a secondary (albeit not stationary) phase that migrates at a different velocity (usually slower than EOF as negatively charged micelles attempt to migrate in opposition to EOF). The technique differs from HPLC in that movement of the secondary phase creates a distinct elution window, bound by the void time of the capillary (t_0) and the effective migration time of a micelle (t_{mic}), within which neutral species elute. In a typical experiment the ratio of t_0 to t_{mic} might take a value of 0.3. Efficiencies are generally not as high as in CZE because resistance to mass transfer between the running buffer and micellar phases is involved.^{23,24} Efficiencies are much higher in MEKC than in HPLC, however. As with HPLC, resolution in MEKC depends on efficiency, selectivity, and system retention as seen in Equation 24.8:

$$R = \frac{\sqrt{N}}{4} \cdot \frac{\alpha - 1}{\alpha} \cdot \frac{k_2'}{1 + k_2'} \cdot \frac{1 - (t_0/t_{mic})}{1 + (t_0/t_{mic})k_1'}$$
(24.8)

Here, k_1' and k_2' are the capacity factors of the two analytes, and α is the selectivity factor defined as k_2'/k_1' . A unique aspect of having micelles present in the running buffer is that biomedical samples containing charged and neutral species can be efficiently separated. Figure 24.2 is a separation of vitamin B6 (pyridoxine) and several of its metabolites using MEKC (sodium dodecyl sulfate as the surfactant) with LIF detection.²⁵ This group of metabolites contains both acidic and basic functionalities, and, as such, charged and neutral species are present at any pH.

There are two significant limitations of the MEKC technique. First, hydrophobic solutes associate very strongly with the micellar phase and tend to bunch up near t_{mic} . A ramification of the elution window is that R (see Equation 24.8) tends to show an optimum at k' values <5.23 The use of mixed aqueous-organic running buffers expands the elution window and reduces the capacity factors of hydrophobic solutes.26 Unfortunately, organic solvents at greater than about 25% v/v seriously inhibit micelle formation. A second limitation of MEKC is that control over selectivity is rather limited. A good number of surfactants are available, but many are not applicable to the MEKC technique, and when combining different types of surfactants, mixed micelles are formed with unpredictable selectivity effects.

These limitations have led to the use of other running buffer additives to address the separation of neutral solutes. The cyclodextrins (CD) are particularly useful reagents for this purpose. Native CDs are neutral, cylindrically shaped macrocyclic sugar molecules that possess a hydrophobic cavity and a hydrophilic exterior.²⁷ The size of the cavity depends on the number of sugar units in the structure ($\alpha = 6$, $\beta = 7$, and $\gamma = 8$ are most common). Inclusion complex formation between a solute and the cavity of the CD is very selective, and, given that native CDs can be derivatized with a wide variety of neutral and ionizable functional groups, the possibilities to tune selectivity are extensive.

CD-modified MEKC has been shown to be useful for separating hydrophobic compounds.²⁸ Alternately, systems comprising strictly CDs can be created with a technique referred to as cyclodextrin distribution capillary electrochromatography (CDCE).^{29,30} With CDCE, running buffer-CD "cocktails" containing combinations of charged and neutral CDs are created that exhibit the correct selectivity for a given application. Figure 24.3 shows the process of a solute distributing between CD phases and a typical CDCE separation showing high efficiency and selectivity.

Cyclodextrins are also used as a secondary phase to carry out chiral CE separations. Because cyclodextrins are enantiomeric molecules, they can differentially bind pairs of small-molecule enantiomers such as amino acids or small molecules of pharmaceutical importance. This approach for chiral separations has been reviewed extensively.^{21,31} A broad range of additional chiral molecules have been used to

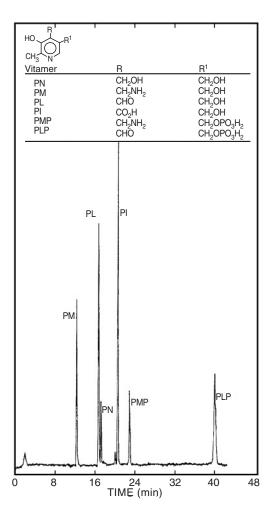

FIGURE 24.2 Separation of vitamin B6 and its metabolites by MEKC using a running buffer containing 0.05 *M* sodium dodecyl sulfate.

form secondary phases for chiral CE separations. These include proteins, crown ethers, linear polysaccharides, macrocyclic antibiotics, and chiral surfactants.^{21,31}

Analytical methodologies involving DNA and proteins are widely used in the life sciences, and a comparison of slab gel electrophoresis and CE approaches to DNA analysis was made earlier in this chapter. DNA fragments possess a charge and, hence, an electrophoretic mobility. Unfortunately, differences in migration rates for differently sized fragments are extremely small because they possess similar charge-to-mass ratios.^{32,33} In order to separate DNA fragments, discrimination must be based on differences in size and is accomplished using sieving media.

One approach is to add a soluble polymer such as methylcellulose to the running buffer at concentrations above the entanglement threshold of the polymer. This creates a dynamic mesh in the capillary with a characteristic mesh size that can be varied by adjusting polymer concentration or molecular weight.³⁴ In practice, the size-selective capillary electrophoresis (SSCE) technique usually employs a surface-modified capillary that does not have appreciable EOF. Detection of the negatively charged DNA fragments, in order of increasing base pair number, is accomplished at the anodic side of the capillary. Because SSCE separations involve large biopolymers migrating through very dense media, axial diffusion is extremely slow and efficiencies numbering millions of theoretical plates are routinely achieved.³⁴ Figure 24.4A illustrates high efficiency in a temporal study of the digestion of a DNA sample,³⁵ and

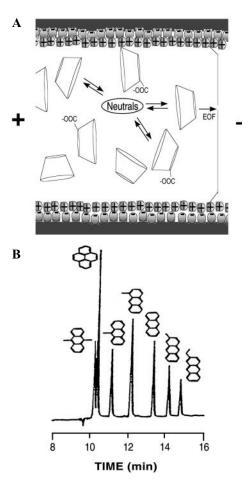

FIGURE 24.3 (A) Depiction of the CDCE process. The neutral CDs migrate with EOF and the negative CDs migrate more slowly toward the cathode. Neutral compounds migrate at an intermediate rate that depends on their distribution between the CDs. (B) Separation of alkyl anthracene compounds using a running buffer with β-CD and carboxymethyl-β-CD.

Figure 24.4B illustrates the ability to study biomedically significant protein–DNA interactions using this technique.³⁶ In both instances, fluorescence labeling protocols and photonics-based detection played a critical role (see below). Moreover, the development of SSCE separations with polymer solutions paved the way for the practical development of large capillary array electrophoresis instruments and their application to sequencing the human genome.^{3–5,22}

24.2.3 Additional Capillary Electrophoresis Separation Modes

During the active development of CE in the 1980s, most separations were based on CZE or on MEKC. Over the next decade, a number of additional separation modes were developed, and several of these have found widespread application (e.g., see preceding discussion). All of the CE-based separation methods currently being developed and applied cannot be discussed adequately in a single chapter; the reader is directed to detailed reviews of these CE-based separation methods. Isotachophoresis and isoelectric focusing have been used with CE technology. ^{37,38} Capillary electrochromatography is similar to reverse-phase HPLC, except that electrophoretic migration and EOF are used to propel analytes through a packed capillary chromatographic column. ^{39,40}

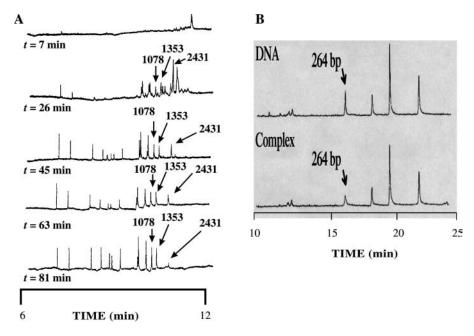

FIGURE 24.4 (A) The use of SSCE for a temporal study of the digestion of ϕ X-174 DNA with *HaeIII* restriction enzyme. The intermediate fragment at 2431 base pairs is digesting to the 1078 and 1353 fragments. On-column labeling with EB is employed. (B) The interaction of digested pBKH26 plasmid DNA with *trp* repressor protein. LIF detection is employed: top, prior to exposure of the digested plasmid to *trp* repressor protein and, bottom, after post-column EB labeling within a sheath flow cell.

24.3 Applications of Photonics to Capillary Electrophoresis

The most prominent role played by photonics in CE is detection of separated analytes. Many of the advantages offered by CE as a separation technique are a result of its small scale, which is a significant limitation for detection of analyte bands. The most common detection method used for liquid-phase separation methods is UV/VIS absorption, and it best illustrates the detection challenges for CE. Beer's law describes absorbance detection, $A = \varepsilon bc$. Here A is the absorbance, ε is the molar absorptivity, b is the detection cell pathlength, and c is the analyte concentration.

The pathlength for a standard cuvette used for absorption measurements is 1 cm. Optical detection for CE is most often carried out on-column using the fused-silica capillary as an optical cell. The pathlength for a 50- μ m ID capillary is, therefore, only about 50 μ m. An absorbance measurement of a compound in a capillary will produce an absorbance that is only 5×10^{-3} that of the absorbance measured in a 1-cm cuvette. A 5-mm pathlength cell for an HPLC detection system will provide an absorbance reading $100\times$ that for a typical CE capillary. Due to the short pathlength provided by a typical CE column and extremely small sample volumes, concentration detection limits are a critical issue when considering detection methods for CE.

24.3.1 Detection of Native Analytes

Ideally, all separated components in a CE separation would be detected sensitively and selectively in their native chemical form by a single detector. Of course, this ideal has not been realized in practice, and a wide range of detection strategies are used for CE separations. Although many of these detection methods require chemical modification of an analyte in order to detect it sensitively, a number of detection methods are able to detect compounds in their native state. Detection of an analyte in its native form is preferred if sufficient sensitivity and selectivity for the application at hand can be achieved. Native detection

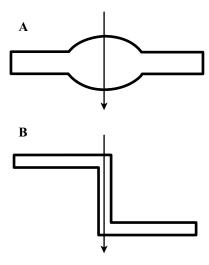

FIGURE 24.5 (A) Bubble capillary to increase the optical pathlength through the capillary column (only the capillary bore is shown). (B) Z cell to increase the detection pathlength through the capillary. The arrows indicate the light path from the source.

simplifies the overall analytical method and typically results in better measurement precision and accuracy by reducing the total number of steps required for analysis.

24.3.1.1 UV/VIS Absorbance

Despite the aforementioned sensitivity limitations due to short optical pathlengths, the most common detection method used for commercial and laboratory-constructed CE instruments is UV/VIS absorbance. The primary reasons for the popularity of UV/VIS absorbance detection are that it is a relatively general detection technique and can be used to detect a broad range of molecules in their native state with moderate sensitivity and selectivity. Single-wavelength UV/VIS absorbance detectors and diodearray based instruments capable of collecting spectra are commercially available. It is possible to use detection wavelengths near 200 nm when using aqueous solution with inorganic buffers, which do not absorb at these wavelengths. Peptides and proteins can be detected at these wavelengths regardless of sequence. Detection selectivity can be obtained by adjusting the detection wavelength using a variable, single- or dual-wavelength absorbance detector. Absorbance spectra can be used to help confirm peak identity or purity if a diode array-based detector is used.

A number of approaches have been used in an attempt to overcome the pathlength limitation of UV/VIS absorbance detection for CE. Most of these methods are based on increasing the optical pathlength by changing the capillary geometry in the region where on-column detection is performed. Figure 24.5 illustrates two common approaches: the Z cell and the bubble cell. These methods have been used to reduce detection limits for CE; however, there is a limit to the usefulness of this approach. As the pathlength is increased using either of the approaches shown in Figure 24.5, eventually a point will be reached where separation efficiency will be compromised due to the increased volume in the detection zone. Other interesting approaches for reducing detection limits for UV/VIS absorbance detection have been reported, such as on-column signal averaging using diode array detectors and thermal lens methods. These approaches, however, are not commercially available and have not been widely used.

24.3.1.2 Native Fluorescence

Laser-induced fluorescence is clearly the most sensitive detection method available for CE.⁴⁴ Single molecule detection has been demonstrated for CE.^{45–47} Unfortunately, most molecules are not highly fluorescent in their native state. In cases where a molecule can be detected by native fluorescence and by UV/VIS absorbance, native fluorescence typically provides detection limits that are orders of magnitude

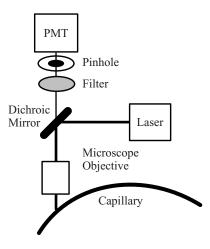

FIGURE 24.6 Schematic of an LIF detector for CE. The same microscope objective is used to focus the laser beam on the capillary and to collect emitted fluorescence for detection at the PMT (photomultiplier tube).

lower.^{48,49} Most proteins and some small peptides can be detected in their native state due to the fluorescence of tryptophan, tyrosine, and phenylalanine. Proteins have been detected after CE separation at low pM concentrations by native fluorescence.⁵⁰ Some nucleotides are also natively fluorescent, as well as catecholamine neurotransmitters.^{51,52} NADH and NADPH are fluorescent; this property has been exploited to follow on-column enzyme reactions by CE.⁵³ These examples of native fluorescence all require excitation at UV wavelengths. Although NADH and NADPH can be excited effectively with a modestly priced He-Cd laser at 325 nm, native fluorescence of peptides, catecholamines, and nucleotides requires excitation at wavelengths below 300 nm. At these wavelengths, special UV optics are necessary and lasers are relatively expensive. Although these technological barriers will be overcome eventually, at present they still limit the widespread use of native fluorescence of peptides, proteins, and nucleotides with CE. Some compounds of biological interest, such as green fluorescent protein and porphyrins, are fluorescent at visible wavelengths, but this is relatively rare.^{54,55}

Concentration detection limits for LIF are less affected by the short optical pathlength of CE because the fluorescence signal can be increased by increasing the laser power until substantial photobleaching begins to dominate. With a small CE capillary, this typically requires a beam of only a few mW focused to the dimensions of the capillary bore. Figure 24.6 shows a common design for LIF detection with a 180° geometry. This optical design is essentially the same as a fluorescence microscope. Detection at 90° with separate objective lenses for focusing the laser beam and collecting fluorescence is also common. Although LIF detection is commercially available, it is less common than absorbance detection, and LIF detectors are substantially more expensive. In addition, it is often necessary to use different lasers for different applications. Most LIF detectors for CE are simple filter fluorometers. Laser-induced fluorescence detectors with CCD detection, which can rapidly collect emission spectra, have been developed, and have been applied to native fluorescence detection. F7,58 Recently, LIF detection with multiphoton excitation has been developed for CE and applied to study natively fluorescent species. F9

24.3.1.3 Additional Detection Methods

Refractive index (RI) detection is common for HPLC but has rarely been used with CE. This technique has the advantage of being universal. Unfortunately, RI detection is less selective and less sensitive than UV/VIS absorbance detection. Furthermore, miniaturizing RI detection for CE has proven to be challenging. Recently, Bornhop and co-workers have reported a simple but effective method for performing RI detection for CE.^{60,61} This technique uses interference fringes from light backscattered through the capillary bore to detect RI changes. Instrumentally simple and inexpensive, it produces detection limits close to those obtained by UV/VIS absorbance for CE. One challenge is that it is necessary to thermostat

the CE capillary carefully to obtain low detection limits because the RI detector response is extremely sensitive to temperature.

Electrochemical techniques are important for detection of native analytes separated by CE. These detection methods are not optical, however, and will not be discussed in detail in this chapter. Amperometry, voltammetry, potentiometry, and conductivity detection have all been used with CE, and detailed reviews about electrochemical detection are available in the literature.^{62,63}

24.3.2 Detection Involving Reactions and Indirect Methods

In many instances the photonic responses of the analytes of interest are weak or nonexistent. However, such responses can be elicited via chemical reactions between the analyte and carefully tailored chromophoric reagents. Alternately, the analytes can be made to modulate a running buffer additive's photonic response in order to measure the analyte indirectly.

24.3.2.1 Derivatization (Fluorescence Labeling) in LIF

The low detection limits and selectivity that can be obtained with LIF provide strong motivation to extend the use of this detection method beyond the relatively few compounds that exhibit modest to high fluorescence quantum efficiencies (QE). This can be accomplished by derivatizing the analytes with suitable reagents. The derivatization can involve the formation of covalent bonds between the analyte and reagent or noncovalent association between these species. The reagent may be a natural fluorophore or it may fluoresce strongly only when associated with the analyte. The timing of the derivatization process relative to the CE separation is a critical factor; preseparation, on-column, or post-separation derivatization all have positive and negative characteristics.⁶⁴ These characteristics are much the same as in HPLC but are sometimes exacerbated by the small volumes and high efficiencies inherent to CE.

In some cases, preseparation derivatization does not involve specific reagents but, rather, a transformation of the analytes to fluorescent products. For example, the antibiotic ampicillin can be degraded preseparation to a fluorescent species.⁶⁵ In most cases, however, covalent interactions between functional groups on the analyte and on the derivatization reagent are involved. Examples of reagents commonly used for CE include *o*-phthalaldehyde (OPA), dansyl-Cl, and fluorescein isothiocyanate (FITC).⁶⁴ All of these reagents react to form fluorescent products with many amines, including those found in free amino acids, proteins, and many drugs. A recent review indicates that most covalent derivatization reagents used with CE react with amine groups, although a few reports include derivatization of thiols, carboxylic acids, carbonyls, hydroxyls, and the reducing end of saccharides.⁶⁴ A general review citing reagents that are specific for carboxylic acids has been published.⁶⁶ Guttman reported the use of 8-aminopyrene-3,6,8-trisulfonate to label sugar moieties and produce low femtomole quantification levels in CE–LIF.⁶⁷

Relatively few compounds are natively fluorescent in the near-infrared (NIR) and, therefore, derivatization to produce molecules that fluoresce in the NIR offers high sensitivity with reduced interference from other compounds in a sample. McWhorter and Soper recently reviewed the use of NIR detection in CE–LIF.⁶⁸ Using a variety of newly developed derivatization dyes many measurements of biological samples have been performed. For example, subattomole limits of detection were achieved for amino acids derivatized preseparation with pyronin succinimidyl ester.⁶⁹ Another significant advantage of the NIR–LIF approach is that inexpensive diode lasers can be used for excitation.

Certain reagents form sufficiently strong noncovalent associations with analytes such that preseparation labeling can be performed and the separation and LIF detection can be conducted without dissociation of the label–analyte complex. For example, the cationic dye DTTCI was used to label proteins prior to CE separation⁷⁰ and certain cyanine intercalation dyes are used in this manner for DNA analysis.⁷¹ Noncovalent labeling of proteins for CE–LIF has been reviewed by Colyer.⁷²

The literature is replete with other examples of preseparation labeling.⁶⁴ Nevertheless, the preseparation derivatization technique is not always the approach of choice — it can be time consuming and often produces chemical by-products that complicate the sample. It is also possible to form multiple derivatization products when more than one functional group is available for reaction on the analyte. Swaile

and Sepaniak compared native fluorescence and preseparation FITC labeling of proteins in terms of detection and of separation performance.⁷³ The 514-nm output of an Ar+ laser was used for excitation in the FITC case, and native fluorescence of the protein was excited via frequency doubling of the Ar+ laser output. In the case of conalbumin, which has over 100 side chain amine groups, the native fluorescence approach was less sensitive but produced a single high-efficiency peak, while the FITC labeling approach produced multiple unresolved peaks resulting from the creation of multiple products (differing labeling ratios) that spanned a range of electrophoretic mobilities.

Ultrahigh CE–LIF sensitivity is possible for analytes derivatized with strongly fluorescing reagents. For example, Dovichi and coworkers demonstrated single molecule detection for a highly fluorescent macromolecule, β -phycoerythin. 46 β -Phycoerythin has been used as a preseparation label. 74 It is important to note that derivatization is prohibitively slow in ultra-dilute solutions, and often the reported ultrahigh sensitivity involves dilution of samples that are derivatized at much higher concentrations. Nevertheless, it is still possible for derivatization at high concentration, when coupled with ultrahigh sensitivity, to provide unique analytical capabilities. For instance, Yeung and co-workers performed "single-molecule electrophoresis" to measure antibody bound and unbound β -phycoerythrin-digoxigenin. 74 The unique single-molecule electrophoresis technique is a direct product of advances in photonic detection. This technique truly takes advantage of the ability to detect single molecules for an analysis application. A relatively large number of migrating molecules are imaged individually and their mobilities measured simultaneously. Differences in the mobilities of the bound and unbound single molecules facilitated determination of the ratio of these species in the digoxigenin assay. 74

On-column derivatization is a dynamic labeling process wherein a reagent is added to the running buffer that associates reversibly with analyte migrating in the capillary. Because the mobilities of the labeled and unlabeled analyte will usually differ, fast association—dissociation exchange is required to maintain efficiency. Thus, association constants generally are relatively modest in magnitude. It is essential that the spectral properties of the running buffer reagents be altered upon association. Swaile and Sepaniak investigated this mode of CE—LIF to measure metals in blood serum.⁷⁵ The reagent employed at low mM concentrations, 8-hydroxy-quinoline-5-sulfonic acid, is a nonfluorescent, bidentate ligand that forms fluorescent complexes with many metals.⁷⁶ Excitation of the complexes is conveniently supplied with the 325-nm output of an He-Cd laser. The same authors demonstrated the on-column dynamic labeling of proteins using hydrophobic probes such as 1-anilinonaohthalene-8-sulfonate.⁷³ This compound intercalates into the hydrophobic regions of proteins with association constants in the 10⁻⁴ to 10⁻⁶ range and experiences a considerable increase in fluorescence QE upon binding. Limits of detection using He-Cd (325 nm) excitation were not as low as with the preseparation labeling approach using FITC, partly because of an appreciable fluorescence background; however, the aforementioned multiple-labeling problem was not encountered.

The most significant use of on-column labeling involves the intercalation of dyes such as ethidium bromide (EB) or newer classes of monomeric and dimeric cyanine dyes into the structure of double-stranded DNA. Ti,77-79 The combination of SSCE and on-column labeling provides a powerful tool for DNA analysis. The cyanine dyes generally outperform the more traditionally used EB in terms of sensitivity. However, EB is extremely reliable and always yields high separation efficiency. Upon intercalation, EB experiences roughly a 20-fold increase in fluorescence QE (less than is observed with the cyanine dyes) and also a bathochromic shift in the lowest energy absorption band convenient for excitation using the 543-nm output of an He-Ne "greenie" laser. Using low μ M concentrations of EB in the running buffer, it is relatively easy to achieve subattomole limits of detection for injections of modest-sized DNA fragments. The separation shown in Figure 24.4A was obtained using SSCE–LIF with a running buffer containing 2.5 μ M EB.

Several types of reactors have been used for post-separation derivatization in CE–LIF; one of the most successful approaches involves sheath flow cells. ^{36,81,82} In this approach, a sheathing capillary or tube surrounds the end of the separation capillary and a coaxial flow is maintained. The sheathing flow serves to focus the effluent from the capillary hydrodynamically to minimize post-capillary band dispersion. It also has photonics-related advantages, such as reduced background due to Rayleigh scattering from the

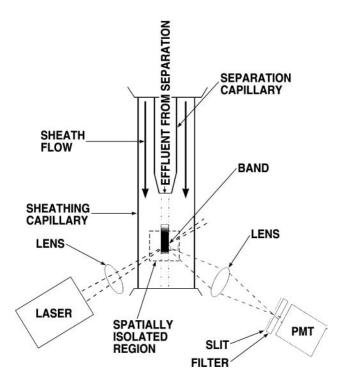

FIGURE 24.7 Depiction of the sheath flow cell used for the experiment shown in Figure 24.4B. The sheathing fluid contained 2.5 μ M EB.

capillary (as compared to on-column detection). When used as a post-separation derivatization reactor, the reagents involved in the reaction are added to the sheathing fluid. To minimize post-separation band dispersion and maximize signal levels, it is critical that the derivatization reaction is rapid. The experiment shown in Figure 24.4B was performed using a sheath flow cell such as that depicted in Figure 24.7.³⁶

Discerning the specifics of protein–DNA interactions is very important in genomic–proteomic studies. Unfortunately, preseparation labeling is problematic when dealing with biopolymers (see above). Similarly, on-column labeling with an intercalator can interfere with interactions between the biopolymers. *Try* repressor protein is responsible for the regulation of L-trytophan in *Escherichia coli*. When the amino acid concentration is low, *trp* operon is expressed. The separation in Figure 24.4B demonstrates that the correct (operand-containing) DNA fragment in a digested plasmid can be identified via SSCE–LIF. In this case EB in the sheathing fluid is used to label the separated DNA fragments as they exit the capillary. When EB is used in the normal manner (on-column labeling) in the running buffer, the protein–DNA interaction is suppressed (not shown).

24.3.2.2 Indirect Detection

Indirect detection involves the addition of a background electrolyte (BE) to the running buffer to create a relatively large optical background. The technique relies on the displacement of the BE from analyte bands by various mechanisms; the most efficient mechanism being charge displacement. A vacancy zone of BE within the analyte band results in a negative response peak as the band passes the point of detection. An obvious advantage of this technique is that detected analytes need not exhibit the measured optical property. A broad range of analytes have been detected using indirect absorbance and fluorescence, and many of these are of biological significance.⁸³ Typical BEs include creatine and chromate for indirect absorbance detection, and salicylate and quinine sulfate for indirect LIF.

Unfortunately, several problems are associated with indirect detection. The large BE background signal can be noisy, and baseline disturbances due to nonanalyte displacement of the BE can occur. The addition

of a fairly large concentration of BE can also result in distorted (fronted or tailed) peaks due to field inhomogeneity in the analyte band.⁸⁴ This problem is exacerbated when the mobilities of the BE and analyte differ greatly. The linear dynamic range (dynamic reserve) for indirect detection is determined by the ratio of the background signal to the noise in that signal and can be small.

The inherent instability of laser sources translates into background fluctuations and results in far less sensitivity than with direct LIF. In early work in this area, Yeung and Kuhr achieved 10⁻⁷ M limits of detection for amino acids, but this required them to go to some length to reduce noise from the laser source. ⁸⁵ More generally, the limits of detection for indirect LIF detection are in the 10⁻⁵ to 10⁻⁶ M range. This is about the same as for indirect absorbance detection where conventional light sources are employed. These sources exhibit better stability than laser sources. ⁸³ Newer diode lasers have been reported to provide detection limits similar to those reported previously by Kuhr and Yeung due to their improved stability. ⁸⁶ A technique that is somewhat similar to indirect fluorescence involves quenching the background emission of a phosphorescent running buffer system by analytes. ⁸⁷ Limits of detection in the 10⁻⁷ to 10⁻⁸ M range were achieved with this technique.

24.3.2.3 Chemiluminescence Detection

Chemiluminescence (CL) is an increasingly common detection method for CE and has been reviewed by several authors.^{88–90} Chemiluminescence involves the excitation of an emitting species via a chemical reaction and can be classified as a direct or as a sensitized detection technique. In the direct case the reaction leaves the emitting analyte species in an excited state. In sensitized CL the reaction generates an excited state species that transfers its energy to a fluorescent analyte. An example of the latter is the peroxyoxalate system.^{88–90} The obvious advantage of CL is that a light source is not needed, and the background is extremely low. However, a major challenge in implementing CL detection is executing the necessary reactions without degrading the separation. The efficiency of CL depends on the local chemical environment; hence, running buffer conditions such as pH are important.

A few basic configurations are used to implement CL detection in CE at the exit of the separation capillary. In many cases a coaxial design is used in which the separation capillary is slipped through a tee and also through a reaction capillary with an ID greater than the OD of the separation capillary.^{82,88–90} The CL reagents flow in the reaction capillary and convectively mix with the effluent at the end of the CE capillary. Convectional mixing reduces problems with slow mixing kinetics but tends to degrade separation efficiency to values of 10⁴ theoretical plates or less. In one example, Ruberto and Grayeski employed a system wherein acridinium ester is oxidized by hydrogen peroxide to an excited state derivative of acridine.⁹¹ This system is amenable to analytes tagged with an acridinium moiety or those that affect peroxide concentration.

A very simple approach employed by Zare and co-workers for CL detection that involves placing the reagents in a relatively large reservoir at the end of the CE capillary has been used with luminol CL and firefly luciferase bioluminescence systems. 92 Limits of detection were 2×10^{-8} M for luminol, but separation efficiencies were still limited to less than 2×10^4 theoretical plates with this approach. This approach would be problematic with sensitized CL because the background level would increase over time as fluorescent species collect in the reservoir.

Dovichi and coworkers utilized a coaxial approach in a sheath flow cell to mix CL reagents contained in the sheathing fluid with CE effluent. 93 Since mixing is based on diffusion, sensitivity can be reduced due to slow mixing kinetics. The authors demonstrated that signals increased moving away from the end of the capillary up to a distance of about 4 mm and then diminished sharply. Absolute limits of detection in the subfemtomole level were quoted for the isoluminol thiocarbamyl derivative of valine. More importantly, the reported separation efficiencies were approximately 105 theoretical plates.

24.3.3 Information-Rich Photonic Detection

Despite the qualitative analysis advantages afforded by the excellent resolving power of CE, keen interest in mating electrophoretic separations with information-rich (sometimes referred to as "hyphenated")

detection techniques remains. Information-rich techniques provide unambiguous analyte identification, structural elucidation, and high selectivity for those cases where adequate resolution is not achieved. In addition, problems associated with poor EOF reproducibility that have inhibited widespread acceptance of CE by the research community are mitigated, to a degree, when one can track eluted analytes with certainty based on distinctive spectra. Nuclear magnetic resonance (NMR) spectrometry provides unmatched structural information and has been employed for detection in capillaries and in CE using microcoils directly surrounding the measurement capillary. Unfortunately, the inherent insensitivity of the technique makes its implementation in CE detection very challenging.

Conversely, significant progress has been made in hyphenating mass spectrometry (MS) with CE. 95,96 Mass spectrometry has been interfaced with CE primarily using electrospray ionization (ESI). Interfacing CE to ESI–MS also poses some challenges. A compromise must be made between a buffer solution ideal for the CE separation and one optimal for ESI. The electrical interface between the CE capillary and the ESI capillary has proven to be a significant challenge. The coupling of CE to MS has been successful in that amol mass detection limits have been obtained for many analytes, and mass spectrometry can provide unambiguous identification of an analyte peak.

Although MS has been used with CE rather extensively, the expense and complications associated with CE–MS provide motivation to develop complementary photonic approaches to performing information-rich detection in CE. Fourier transform infrared (FTIR) spectrometry has been employed in conjunction with separations. However, complications arise from short optical pathlengths and the absorption of IR radiation by running buffers and capillaries when FTIR is employed with CE. One fluorescence-based technique used in CE is fluorescence line narrowing spectrometry (FLNS). FLNS is a very low-temperature spectral technique that does not exhibit inhomogeneous broadening contributions to vibronic bands. Thus, distinctive, sharp line spectra are obtained. FLNS detection has been employed on-line in CE, an approach that involves jacketing a portion of the CE capillary near its outlet to permit submersion in liquid helium. In operation, the CE flow is stopped and the capillary and its contents rapidly frozen prior to acquiring spectra. The obvious limitations of this approach are the stop flow aspect and the fact that it is limited to natural fluorophores.

The advantages of Raman spectroscopy, relative to FTIR, in accommodating glass sample cells and aqueous solvents are realized when the technique is applied to CE. Raman vibrational bands are distinctive and can be used to determine chemical structure and provide selectivity. Lasers operating in the visible to NIR spectral regions are generally used for excitation. Normal Raman spectroscopy suffers from poor sensitivity. Raman scattering cross sections are often ten orders of magnitude smaller than for more efficient photonic processes such as absorbance or fluorescence. Batchelder and co-workers recently reported an efficient hyperhemispherical detector configuration that provided mid- to low-millimolar detectability in CE.⁹⁹ Michael Morris and colleagues have made effective and impressive use of CE preconcentration (sample stacking) and zone-sharpening effects of capillary isotachophoresis to perform normal Raman detection.^{100–102} In this approach, sub- to low-micromolar concentrations of analytes such as ribonucleotides, herbicides, and oxyanions are concentrated to detectable levels; distinctive spectra have been obtained, as shown in Figure 24.8.

The inherent inefficiency of normal Raman scattering has been overcome with remarkable success using resonance- and surface-enhanced techniques. Surface-enhanced Raman scattering (SERS) occurs when analytes are adsorbed onto or very near the nanofeatured surfaces of certain metals. DERS active media range from simple silver colloidal solutions and silver island films on glass to sophisticated nanolithographically prepared planar substrates. DES In some instances, extreme sensitivity reaching the single molecule level with enhancement factors greater than 10¹² has been achieved by resonance-enhanced SERS.

There have been a few reports of SERS detection in CE. ^{107–109} Sepaniak and co-workers have employed on-column and postseparation approaches. The on-column approach is simple and involves adding silver colloidal solution to the CE running buffer. ¹⁰⁹ Spectra are acquired on the fly by positioning the microscope objective of a commercial Raman spectrometer directly above the CE capillary in a confocal optical arrangement. Figure 24.9 shows very good CE–SERS sensitivity with this

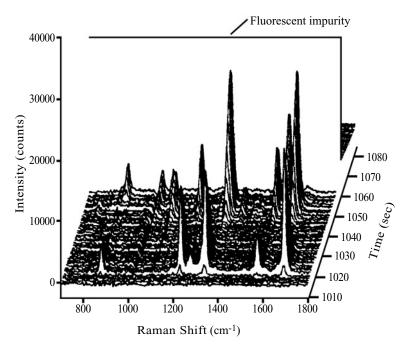

FIGURE 24.8 On-column normal Raman spectra of 1.5×10^{-5} *M* paraquat and diquat acquired in conjunction with a capillary isotachophoresis separation. (From Walker, P.A., III, Shaver, J.M., and Morris, M.D., *Appl. Spectrosc.*, 51, 1394, 1997. With permission.)

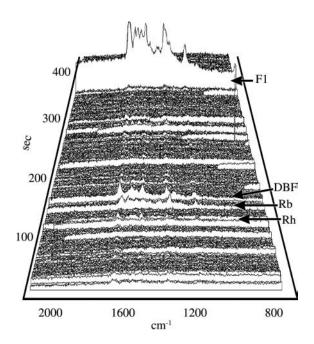

FIGURE 24.9 SERS spectra obtained for the CE separation of rhodamine 6G (Rh), riboflavin (Rb), dibenzofluorescein (DBF) and fluorescein (Fl). The running buffer contained \sim 0.5% by weight Ag nanoparticles. Excitation was provided by an Ar⁺ laser (515 nm, 5 mW). The weak Rh spectrum corresponds to the injection of 10^{-8} M.

approach, although a strong-to-modest resonance enhancement is also occurring with these analytes. Unfortunately, in many cases the running buffer conditions needed for detection, e.g., silver colloid and electrolytes, degrade separation performance and shorten capillary life. However, the postseparation approach allows independent control over separation and detection conditions.
